- I conducted a *cultural competency assessment* with James. I attended, in particular, to the domains of awareness of self and others. The result of this assessment was that James had significant blind spots and frequently operated on stereotypic beliefs about women and

certain ethnic minority groups. I integrated this work into the executive coaching frame. Again the work was delicate in that James was, at first, unwilling to admit to weaknesses in this area. Eventually I was able to effect a referral to a series of cultural competency trainings for managers being conducted in the area. I advised Paula to pay for some percentage of the tuition but not all so that James was more likely to take some responsibility for his own professional growth around diversity issues.

- I convinced James that our executive coaching work would be enhanced and accelerated if we could access more information about his strengths and areas for improvement from his employees. This was a big step for James to take. The coaching alliance we had formed and his growing trust in me supported this step. I *conducted 360° evaluations* with 25 hotel employees using interviews, not surveys or focus groups. Paula, James, and I collaborated on identifying employees who would be representative of the entire hotel staff. I designed interview questions which would elicit both strengths and positives about his style and performance as well as concerns. I also asked questions about the degree to which any changes in James' style were evident, since I had begun coaching him.

- I also conducted a limited *program evaluation* and made two *program development* recommendations to James and Paula. The first involved creating a new position for a human relations specialist. Throughout the hotel's history, the function was never formalized and Paula was the usual point person when HR-type issues arose. My rationale for this proposal was that the roles and responsibilities of employees (including job descriptions) required more individuation and clarity. Paula's "family" culture had advantages but also resulted in a kind of enmeshment in which employees would bring employment concerns to individuals who did not have the authority or "rule book" to take action. The second was the creation and development of an executive committee. This group of managers would serve in an advisory capacity to James and meet once a week. James had an "ad hoc" style of meeting with his managers. He met with some on a regular but not scheduled basis. Other managers (ones he perceived to not support him) he only met when there was a critical incident which he needed to sort out with that manager. Also, when he did meet with his managers, it was typically "on the run" or he would summon them to his office. In these meetings, James would talk and they would listen. With some of the feedback I obtained in the 360° evaluations, I realized that a weekly staff meeting would be an important shift for James. He would have the opportunity to interact with all of his managers once a week and could demonstrate a willingness to listen more and talk less.

- Setting up an executive committee is relatively easy; making it work is another matter. Again James was nervous and hesitant about the creation of a formal committee like this. He was concerned about losing power and authority and about losing control of the meeting if his managers "ganged up on him." The expert competencies I employed at this stage were *group leadership training* and *management team development*. Before the first executive committee meeting, I coached James about how to lead this group and how to facilitate a meeting which would foster input while demonstrating and modeling that he was still the boss. Then I attended the first three meetings as an "advisor to the team's development." Being in the room allowed me to monitor James as he attempted to shift his style to be more open to input and more empathetic to the challenges voiced by his managers. I also supported the entire group as they got more accustomed to this new method of communicating and seeing James in a different light.

20.9.3 Final Comments on Expert Competencies

Every consultation process is different. The basic competencies listed and illustrated earlier in this chapter will be required in almost every consulting project a psychologist undertakes. Some consultation projects are, however, more complex than others and call out for more advanced and expert skills. Case study #2 was such a project. There is no set number of expert competencies. Particularly at the intervention stage, a wide variety of competencies are necessary for the psychologist/consultant to practice effectively. Similar to clinical work, the key is for psychologists to know and practice within the limits of their current competency level.

20.9.4 Acquisition of Expert Competencies

Basic consultation competencies are learned through a combination of classroom work and supervised field placement. Acquisition of expert consultation competencies occurs over the course of many years through continuing education (workshops, extended trainings, and post-doctoral fellowships), mentorship and supervision, and through hours and hours of experience with a wide variety of organizational contact.

One path taken by many clinical psychologists who engage in consultation work with organizations is to become an expert in a particular type of intervention, for example multicultural OD or team building. The advantage of this approach is the ability to sharpen your skill set in a particular kind of intervention. The downside is that the field of potential clients may be narrowed by the consultant's move to be more a specialist than a generalist. On this path, psychologists may be functioning more in a training role than a consultant role unless they were involved in the earlier phases of the process to identify the concerns that the interventions are designed to address.

The more traveled route to gaining competency in consultation is first learning the basics of the entire consulting process from initial contact to evaluation and termination. Almost all the basic competencies blossom into expert ones with time, experience, and good supervision.

20.10 Summary

The field of clinical psychology is in the midst of a quiet revolution. Psychologists, both in practice and training, are expanding their roles to provide a wider array of services including consultation to organizations. The profession is also moving toward a competence model.

In this chapter, I have outlined the basic competencies and some of the expert competencies required for psychologists who provide consultation services to organizations. I made the case that psychologists are uniquely positioned to offer these services because of our understanding of human behavior, interpersonal relationships, group dynamics, and because we operate with existing codes of ethics and multicultural guidelines. Psychologists can transpose relatively easily from the key of clinical to the key of consulting because of the similarity in the stages of both kinds of work and the overlap of many of the competencies required to be a good clinician and a good consultant.

Although as a field we are moving briskly toward a competency-based model of training, the identification, definition, and measurement of consulting competencies is a work in progress. The SCP, APA's Division 13, has made significant progress in this regard with its recent publication of principles for education and training. None the less there is a substantial amount of work ahead to come to anywhere near a consensus on questions such as "What are the basic competencies?", "How do we train psychologists to attain basic competency?", and "How do we measure consultation competency?"

Through the use of two case examples, I identified and defined a set of basic and expert consultation competencies using a stage model to illustrate when these competencies would come into play in a consulting project. I stated that although there are a few competencies that could be seen as basic or expert, most consultation skills are learned and mastered first at a basic level and later refined and enhanced to be more advanced through hours of work experience, continuing education, and supervision and mentoring. There are particular competencies like relationship and diversity skills which permeate every stage of a consulting process. There are other more esoteric competencies which would require a psychologist to seek specialized training and supervision to master.

Traditionally psychologists have focused on providing clinical services to individuals. These individuals on average spend almost one third of their time in work organizations. It is only natural that clinical psychologists would consider bringing their ample knowledge and competence to those individuals in those organizations.

21 Teaching

Bethany C. Johnson · David DiLillo · Calvin P. Garbin

Abstract: Teaching is an important component of most academic clinicians' responsibilities, but it often receives the least attention during graduate training. This chapter describes basic and expert competencies underlying teaching at the both the undergraduate and graduate levels. The underlying premise of the chapter is that teaching competence is comprised of fundamental and advanced skills that can be learned, practiced, and mastered. The majority of the work that goes into teaching happens outside of the classroom, and starts with careful course planning. The skills and behaviors necessary for competent teaching—from classroom management to lesson planning and assessment—should be based on explicit educational objectives and goals. Expert teachers not only integrate pedagogy and content knowledge to implement strategies that are more sophisticated than those used by teachers with basic competence, they also incorporate more complex innovations and interventions into their teaching. Instructors at all levels of competence should include systematic reflection and assessment of the efficacy of their teaching in their normal repertoire of skills. As they gain experience and skill, teachers can take a more experimental approach to improving their instructional approach. By applying a scholarly approach to teaching, academic clinicians can more efficiently improve the quality of instruction based on the empirical evidence of learning outcomes. This chapter can be used as a reference for new teachers just beginning their careers, or by experienced teachers looking to improve their methods.

21.1   Overview

Academic clinical psychologists have multiple roles to play professionally. They must produce meaningful research, engage in service, and, in many cases, teach. Each component of this set of responsibilities does not always get equal attention during training for many newly minted clinicians. However, all four areas of proficiency are integral to the well-rounded professional clinician's arsenal. This handbook addresses the gamut of professional competencies necessary for modern clinical psychologists; our chapter will address the particular standards and strategies needed to become a competent teacher of psychology.

   Competency, in the context of teaching, is an amorphous concept. Some authors claim that a good teacher is one who has a lasting, positive, and significant effect on students' thoughts, behaviors, and values (Bain, 2004). Others argue that a good teacher is one whose unique configuration of personality characteristics and intellectual ability best lends itself to instruction (Lucas & Murray, 2002). Is a competent teacher a good teacher? To make such an assumption, one must equate *good* with *competent*, which falsely likens a subjective evaluation to a quantifiable set of skills and outcomes. Experienced teachers may employ widely divergent teaching methods and strategies, and each may vehemently assert that his or her way is the best and most effective. Nonetheless, there is a difference between the philosophical underpinnings of a methodological approach, and the quantitative merits of solid pedagogy. There is no single best way to teach well; there is, however, a solid foundation of

theoretical principles and empirical evidence, the understanding of which is necessary for every teacher to develop, in his or her own way, into a competent teacher (Lucas & Murray; McKeachie, 2002).

This chapter distinguishes between basic and expert competencies. Basic does not mean simple or easy to achieve; instead, basic competency is comprised of the fundamental skills every teacher should master as a matter of course. These skills and strategies are those necessary to begin on the developmental trajectory toward expert teaching competency. These pedagogical building blocks are necessary regardless of the subject matter being taught, and are applicable to many personal teaching styles. The standards of basic competency for psychology teachers described in this chapter are based on research and theory from the scholarship of teaching and learning. Teachers who have basic competencies should systematically reflect on their teaching; they should be purposeful in their use of specific methods, monitor learning outcomes, and adjust their approach to meet their particular objectives.

Expert competency is directly dependent on basic competency. Expert teachers integrate and generalize basic methods more fully to maximize their efficiency and effectiveness. An advanced technique is one that utilizes more sophisticated tools, or is applied to more complex situations. An expert teacher is committed to gaining a better understanding and integration of both his/her subject matter and the principles of teaching and learning. Expert teachers engage in more sophisticated analysis of their students' learning, and incorporate experimental interventions or teaching innovations into their courses.

The intended audience for this chapter is academic clinical psychologists or students who will be teaching at both the graduate and undergraduate levels. In addition to their standard clinical training and supervision duties, faculty are often called upon to teach core clinical classes at the graduate level (e.g., psychopathology) as well as courses within their particular areas of specialty. It is also common for clinical faculty to teach courses at the undergraduate level, ranging from introduction to psychology to abnormal psychology to statistics. For this reason, the information contained herein will emphasize aspects of teaching and learning that are equally relevant to any course level. Throughout the chapter, we will highlight the topics and applications that are more specifically applicable to one level over another.

In today's academe, there is a growing diversity in course styles and formats. In order to accommodate the needs of modern students, online courses, distance education, and hybrid styles are increasingly common. However, an in-depth examination of those variants is beyond the scope of this chapter (Duffy & Kirkley, 2004). Though we will address course style and format where appropriate, the primary focus of this chapter is on issues related to traditional "brick and mortar" classroom teaching. The skills and strategies that comprise the foundation of good pedagogy are applicable to any kind of course in most cases; nonetheless, the most parsimonious presentation of this information is as it pertains to the "default" classroom.

We trust that readers will use this chapter as a tool to aid in their own teaching. Accordingly, the chapter is organized to facilitate quick reference. Thus, within the broadest headings of basic and expert competencies, we have further divided the information into three discrete subsections. The bulk of the work required to teach happens before the instructor ever steps foot in the classroom; therefore, the first section details *preparation that takes place outside of the classroom*. The second section of both competency categories pertains to *skills and strategies for use in the classroom*. Finally, we present the *tools and methods for teaching assessment and professional development* last in both categories. This section addresses the necessity of reflective and systematic analysis of teaching and learning, and presents the ways teachers incorporate

teaching into their personal career paths. Within these subsections, we provide theoretical background for the principles, followed by empirical research to illustrate its utility in teaching. Where applicable, examples of practical applications for each principle are presented. We intend for this structure to reinforce our commitment to making this chapter useful and convenient as a reference for professional psychologists.

21.2 Basic Competencies

Many graduate programs give short shrift to the teaching aspect of the graduates' overall training as academic psychologists (Boice, 1992; Gibson, 1992; Lucas & Murray, 2002; Vesilind, 2000). For this reason, some doctoral-level clinicians begin their academic careers with little else than a rudimentary understanding of what to do once they find themselves in a teaching role. As a result, new instructors quite often default to replicating the way they were taught, and equate good content with good teaching (Boice; Lucas & Murray). This produces a cyclical pattern of the reiteration of unintentional teaching methods, to the point that those methods become tradition. There is a sense that teaching, as part of the triumvirate of academic roles including research and service, is a self-directed and often burdensome endeavor, which derives more from art than science (Boice; Lucas & Murray). However, this perspective is changing in academia, as a new generation of researchers begins to apply the same kind of effort and empiricism toward their teaching as has been given to their specialties. The result of this shift is the increasingly widespread attitude that teaching can be done in accordance with the principles governing human behavior, cognition, and emotions that psychologists have been investigating for a century. It is in that spirit that this chapter synthesizes theory with research and practical applications of teaching principles. In the following sections, we suggest the fundamental skills that teachers in psychology need to master to achieve basic competency. We will present this information in the recommended order of operation, starting with the first steps in course planning.

21.2.1 Outside the Classroom

The majority of the work required for teaching happens outside of the classroom. Before an instructor ever meets a student, he or she must have put careful thought and purpose into planning and designing the course. Course planning begins by considering the big picture. Some of the essential decisions involved in course planning may appear to be self-evident. However, because they are so obvious, inexperienced teachers sometimes overlook key elements required to put together a course (e.g., visiting the classroom early to account for specific physical and technological logistics) (Lucas & Murray, 2002). The first portion of this section describes the first steps a teacher must take when beginning a new course. The course planning process should begin about 3 months before the class begins (McKeachie, 2002).

21.2.1.1 Course Planning

Academic clinicians are often called upon to teach both graduate and undergraduate courses. These courses are sometimes established parts of a department's curriculum, while at other

times, they may be new. The first order of business when planning a new course is to determine about what the course will be. This is one of those decisions that seems patently obvious; however, neglecting this step can derail many aspects of the rest of the planning. By explicating the precise subject matter of the course, the instructor focuses his or her attention on what is important and necessary to include. For example, a research methods course may or may not incorporate instruction about the use and interpretation of inferential statistics. If the course is an existing part of a department's curriculum, the new instructor should collect syllabi and course materials from those who previously taught the course (Lucas & Murray, 2002).

Such information is not prescriptive; however, in most cases, the teacher is not bound to replicate the course exactly. Nevertheless, it behooves the new teacher of an existing course to be aware of the role the course plays in the department and the school's overarching objectives (Lucas & Murray, 2002).

Once the specific topic of the course has been identified, the instructor should elucidate his or her general instructional goals and learning objectives for the course. Instructional goals are broad, global statements of the purpose of the course, from the teacher's perspective (Lucas & Murray, 2002). These objectives summarize what the teacher hopes to accomplish with the course. For example, an instructional goal for an undergraduate course may be for students to gain an expansive and general understanding of the variety of areas of research and theory included in social psychology, or, at the graduate level, for students to learn the range of treatments available for different types of anxiety in children. General instructional goals pertain to content knowledge, whereas learning objectives are more specific, action-oriented skills (Lucas & Murray; McKeachie, 2002). Examples of learning objectives include improving critical thinking, increasing synthesis of disparate ideas, and enhancing analytical writing skills related to the course topic. These objectives are conceptualized from the students' perspective as a statement of what they should be able to do once they complete the course. These outcomes are sometimes referred to as performance- or competency-based learning (Lucas & Murray; McKeachie). Learning objectives should be relevant to students' development outside of the specific content area covered by a single course. Vesilind (2000) suggests categorizing desired outcomes into concepts, skills, processes, or attitudes when planning learning objectives.

Instructors should conceptualize learning objectives in terms of achieving different levels of knowledge (Lucas & Murray, 2002). Taxonomies of learning describe different types of knowledge and understanding toward which teachers can strive, which then inform decisions about how to approach instruction. Bloom, Engelhart, Furst, Hill, & Krathwohl's (1956) taxonomy of educational objectives is the seminal classification system used by educators. Over the years, other scholars have revised and updated Bloom et al.'s original taxonomy, and many new frameworks have been proposed (Anderson & Krathwohl, 2001; Marzano & Kendall, 2007); however, the basic premise remains unchanged. The taxonomy classifies and hierarchically arranges different levels of learning. At the lowest levels are the simplest, most superficial types of learning (e.g., memorization of jargon and facts). Higher levels build upon the lower ones and involve more complex and sophisticated types of learning (e.g., procedural knowledge and applications).

Anderson and Krathwohl (2001) have updated Bloom et al.'s (1956) classic taxonomy to form a model with two dimensions, each with multiple levels. The first dimension consists of the original, cumulative categories of knowledge. Along this dimension, the first level is factual knowledge, which is comprised of basic information and simple definitions of a particular discipline, which allows students to solve simple problems and use terminology properly. The second level contains conceptual knowledge, which manifests in a deeper understanding of the

relationship between elements, including theoretical and structural explanations for more generalized topics. The third level is procedural knowledge, which enables students to apply techniques and algorithms to practical examples, including knowing when to use different procedures or methods. The last level is metacognitive knowledge, which is expressed as "thinking about thinking," that is, knowing not only the content of an area, but how one goes about getting and using that knowledge. Anderson and Krathwohl's second dimension catalogues the cognitive processes possible within the different learning objectives and is also structured hierarchically. The simplest process is remembering. Next is understanding, followed by application. Beyond that is analysis, then evaluation, and finally, the most complex process is creation.

Whichever taxonomical organization of learning objectives an instructor chooses to utilize, it is important to match the design of the course to the desired learning goals. Each type of learning described in such taxonomies is suited to different course components (e.g., discussion, writing assignments, etc.). Given prevalence of lecture-based courses at the undergraduate level, it is easy for new teachers to concentrate their efforts on this approach to classroom instruction (Boice, 1992; Lucas & Murray, 2002). Indeed, good lecturing requires a great deal of skill and preparation, and can be useful for presenting factual material, stimulating interest in topics, summarizing disparate sources, and explaining basic terms and definitions (Zakrajsek, 1998). Though lecturing is an efficient way to deliver large amounts of information to large audiences, it is not necessarily the most conducive to learning at the uppermost levels of the taxonomy (Vesilind, 2000). Other course components can be used to achieve these objectives. In-class activities, such as problem-solving exercises or demonstrations, require students to assimilate and apply knowledge to novel situations, using factual, conceptual, and procedural knowledge (Anderson & Krathwohl, 2001). For example, classroom discussion of reading assignments requires students to read ahead and think about the topic more deeply than they would if the students were not going to have to ask or answer questions about the assignments in class. This type of skill requires both factual and conceptual knowledge, and involves remembering, understanding, and applying recently acquired information (Anderson & Krathwohl). Depending on the objective of the discussion, students may also incorporate analysis and evaluation. Discussions are particularly useful for connecting personal experiences to course content, explaining and evaluating opinions and positions, and solve problems (Kramer & Horn, 1996).

As more empirical evidence becomes available about the benefits of matching teaching methods to desired learning outcomes, teaching styles are shifting away from the "sage on the stage" approach toward learner-centered methods in which the student assumes some responsibility for structuring the class content (Messino, Gaither, Bott, & Ritchey, 2007; Miserandino, 1999). Learner-centered pedagogy emphasizes the student's needs, experiences, and preferences as they pertain to motivation and knowledge structures (Wisher, 2004). The American Psychological Association (APA) has published a list of principles to guide learner-centered teaching (APA, 1993). Included in these principles are ways to move beyond basic didactic teaching methods and incorporate varied, active, and higher-level techniques to improve students' ability to construct and share knowledge while engaging in social interactions with their peers and teachers (Wisher). Teachers are less focused on choosing one style or method over another in favor of combining approaches to achieve multiple learning objectives simultaneously. An example of this type of hybridization is a large introductory-level course in which the instructor includes lecturing, small group activities, discussion, practicing application problems, and writing – utilizing some or all of those methods within the same class period.

This diversification requires students to process the information they received in class on several different taxonomical levels. This approach to teaching is sometimes referred to as "guide on the side," in contrast to "talk and chalk" lecturing (Lucas & Murray, 2002; Messino et al.). Instructors should make decisions about what kinds of components they want to include based on both their instructional goals and their learning objectives for the course (McKeachie, 2002). Furthermore, these should dovetail with the department and the institution's goals and objectives; besides asking colleagues and administrators, a good place to look for this information is in the school or department's mission statements (Lucas & Murray).

Syllabus Planning. Once the instructor has made the major decisions about the structure and objectives of the course, the next order of business is developing the syllabus. The syllabus serves several different purposes and can itself be a useful course planning tool (Appleby, 1999). First, the syllabus is a statement of all the basic information about a course, from where and when it meets to its objectives and goals, required materials, and course components and policies (McKeachie, 2002). As such, the syllabus is the first exposure students have to the instructor's pedagogical philosophy, personality, and style (Appleby). The syllabus should serve as a centralized source of answers to any major questions (i.e., an FAQ) students might have about the course (Lucas & Murray, 2002). Furthermore, the act of delineating all the course policies related to issues like absences, grade disputes, late assignments, and academic dishonesty requires the teacher to have thought through the reasoning behind and enforcement of those policies ahead of time (Lucas & Murray; McKeachie). Planning ahead for questions and problems ensures that policy decisions and consequences are consistent and fair, which is less likely if decisions are made on the spot or are influenced by the teacher's feelings toward particular students (Whitley, Perkins, Balogh, Keith-Spiegel, & Wittig, 2004). The instructor should ensure that listed policies are consistent with institution-wide and departmental policies. Ultimately, the syllabus can be viewed as a contract between the students and the instructor, explaining what is expected and required of both parties, and serving as official documentation of rules and regulations (Appleby; Lucas & Murray; McKeachie; Whitley et al., 2004). The syllabi from various courses represent the teacher's growth and professional development over time as well, which is useful for both the teacher's personal reflection and departmental oversight (Appleby).

Another important aspect of the syllabus is the class schedule. Writing out the schedule of topics and assignments on the syllabus forces the instructors to quantify their instructional goals in the context of time constraints for the semester (McKeachie, 2002). Purposeful scheduling requires that the teacher thinks critically about how much time to spend on each topic. The course schedule directly influences how much time the students and teacher should expect to spend on the course. A general rule is that students should plan to spend 1 or 2 h studying outside of class for every hour spent in class (McKeachie). This apportioning also allows an instructor to estimate realistically how much material he or she will be able to cover and evaluate in the time available. New teachers may inadvertently assign more reading than is reasonable to complete in the given time frame, which may necessitate either postponing coverage of the excess material to the next class meeting or disregarding it entirely. This practice can be very stressful for both students and teachers, especially if it affects the schedule for the remainder of the course (McKeachie). Teachers should include a disclaimer that the schedule may change, just in case (Lucas & Murray, 2002; Whitley, et al., 2004). Keeping this caution in mind, the teacher can think of the syllabus as the blueprint for a course, and use it to guide subsequent planning.

Textbook Selection. Preparation of a syllabus also necessitates selection of the text or other reading materials for the course. Choosing a textbook can be a daunting process, because there

are so many factors to consider. As textbooks proliferate, and publishing companies' sales representatives get pushy, it can be tempting to pick a text for arbitrary reasons (McKeachie, 2002). The text for a course should match the students' abilities and the instructional goals for the class. Rather than skimming through whole books superficially, instructors should choose two chapters to read closely: one in the teacher's area of expertise, and the other over a less familiar topic. This strategy allows the teacher to evaluate and compare the difficulty level, comprehensiveness, inherent interest, and educational objective levels the book achieves (McKeachie). One way to capitalize on the increasingly competitive publisher representatives' advances is to request the ancillary materials that come with the sample textbooks they are pushing. Accessories often include comprehensive instructor's resource manuals, premade lecture slides, test-item books or software, DVDs with collected video clips, and access to feature-packed online textbook companion Web sites. Even if the teacher does not choose that particular text, those materials are valuable (and usually free) accessories for lesson planning. Many teachers choose instead to assemble their own material from original sources (e.g., journal articles) or create their own course packet, particularly for upper-level undergraduate or graduate-level courses. Collecting an original set of readings is a good way to tailor class materials to specific needs; however, this is a time- and work-intensive process, because then the responsibility for synthesis and organization is placed entirely on the teacher's shoulders (McKeachie).

Technology Decisions. Traditionally, teachers had few choices when it came to technology. Where classrooms used to have overhead projectors, there are now fully integrated audio/visual presentation systems. Where grades used to be recorded in paper grade books, there are now institutionally supplied, network-hosted classroom management systems (e.g., BlackBoard). The newest trends include things like podcasting, asynchronous online discussions, usage-tracking statistics, and automatically administered, graded, and recorded exams. It is easy for teachers to be both seduced and overwhelmed by the technological options available. However, technological advances are best seen as tools to increase efficiency and aid in achieving instructional objectives, rather than toys to be used for their own sake (Sargent Mester, 2008). Teachers who are adding new technology to their courses might be afraid of inevitable technological difficulties, loss of control over students, and inability to achieve the same objectives they can using more traditional methods (Brink, 2004). Brink suggests that if teachers are willing to put time into learning how systems work, talking with colleagues about their experiences incorporating new tools, and accepting the inevitability of setbacks in the natural course of things, they can harness amazing power from new classroom technology. Brink also suggests that it can be fun to do so, as long as the teacher goes in with a positive attitude.

As with any other course components, different technologies are appropriate for different kinds of learning and instructional goals. For example, presentation software (i.e., Microsoft's PowerPoint) can add much to a class when used to augment what the instructor is saying (Sargent Mester, 2008). However, the excitement of possibilities raised by presentation software sometimes leads instructors to overdo their visual aid. As a rule, simplicity and brevity are the watchwords for slide content. A picture can stand in for a lengthy explanation, and key words or short bullet points may highlight important parts of the lesson (Vesilind, 2000). However, students are easily overwhelmed, either by trying to scribble down every word on a slide, or by overstimulation due to superfluous bells and whistles (Sargent Mester). Instructors should not only be able to operate their classroom technology and software properly, they should also familiarize themselves with the tips and tricks of good presentations before they become too invested in implementing technology into their courses (Brink, 2004; Vesilind). Oftentimes,

schools offer courses to faculty and staff, for free or at reduced rates, to learn how to use a wide variety of common software applications such as PowerPoint.

Course Logistics. Size of the enrollment and the venue are two physical features of classes that have a major impact on the manifestations of course goals and objectives. Class size is important because some course components and instructional strategies depend on the instructor's ability to reasonably manage the workload. For example, introductory classes with large enrollments often use multiple choice or other objective testing formats so that students can record their answers on bubble sheets, which are then machine graded. In most cases, instructors would not be able to grade subjective tests (e.g., essay tests) for large groups of students because of the time required to do so. Another example of a size-dependent course component is class discussion. In a large class, discussion meant to include the whole class leaves most students sitting silently while a few individuals dominate the discussion. A smaller class size allows more chances for students to contribute to discussion and lessens their ability to blend into the background and remain anonymous.

Research on the effect of class size on learning suggests that instructors' and students' emotional reactions to large classes are not supported by empirical evidence of learning outcomes (Hilton, 1999; Jenkins, 1991). Teachers, in particular, tend to have a negative response to the idea of large courses, though for meeting traditional, didactic course goals, large classes are very effective. Students, on the other hand, tend to feel more positive about large courses, especially in lower-level survey courses (Jenkins). In large-enrollment courses, the quality of instruction can have exponentially greater ramifications than in smaller, more casual classes. The sheer number of students can compound the negative consequences of poor preparation, ineffective methods, unsatisfactory materials, and unsophisticated testing methods. Conversely, large classes allow the few, highly skilled instructors in a department to influence more students (Jenkins). New instructors should be warned that good preparation and organization for teaching large courses is more critical than they might anticipate, and they should expect it to take a lot of time (Hilton).

Planning for the Time Commitment. Multiple sources recount the tendency for new academicians to become consumed with teaching, at the expense of their other departmental and scholarly responsibilities (Boice, 1992; Gibson, 1992; King, 2004; Lucas & Murray, 2002). The demands of teaching increase as class sizes grow and teachers add more courses to their plate. This overbalancing of teaching versus other work risks early burnout, and can stall academics' careers as they take time away from research and service to teach (King). In order to avoid teaching overload, instructors should make an effort to connect with their colleagues, turn down offers for new obligations when possible, and protect personal and writing time. One way for new teachers to manage their teaching load is to audit the time they spend during the workday. It might surprise a new instructor how much time he or she actually spends preparing lesson plans or grading assignments, and knowledge of the problem is the first step to solving it (Boice; King). Boice suggests spending 2 h in preparation for every hour of class.

Amount of time the instructor spends on a class varies based on several different facets of the course. The instructor's teaching responsibilities include course planning, lesson planning (including finding and reading materials to incorporate into class), the time actually spent in class, grading tests and assignments, and time spent with students outside of class (i.e., office hours or individual conferences, answering e-mails, etc.). There are hidden time-consumers within each of those categories as well. For example, in addition to the actual time it takes to evaluate each student's work, grading assignments also includes the time it takes to formulate

the grading rubric, configure the grade book (whether using an online system such as BlackBoard or making one using a spreadsheet program), and enter the grades. One way instructors can reduce this time commitment is to have students assume some responsibility for their own assessment. This can take the form of peer grading, peer discussion leaders, or peer forum moderators, among other methods. Any task that the instructor can delegate to students has the potential to be an additional learning opportunity, especially concerning non-content-related skills such as critical thinking and constructive criticism, while also lessening the time burden for the instructor. Because it is easy to be mired in the minutiae of planning and administrative tasks, the teacher should begin by deciding how much time he or she can afford to spend on teaching-related work and tailor the course to meet those projections, so teaching does not consume more time than it truly requires (King, 2004).

Lesson Planning. The final step of preparation that happens outside of the classroom is lesson planning. Because class time is the focus of teaching from the students' perspective, it might seem as though lesson planning should happen sooner in the process, or be prioritized higher than some of the previous steps described above. However, lesson planning is the culmination of all the preceding decisions. The learning goals, instructional objectives, course policies, technology use, logistics of the course, schedule, and time considerations all shape how class time is spent. Instructors' use of class time should also be guided by a set of principles of motivation and learning. Many teachers employ methods or techniques that work, but much of the time, those methods are arrived at via trial and error. A haphazard approach is inefficient though. Rather, it makes sense to draw on principles of active learning and motivation when choosing instructional methods. The current zeitgeist in higher education touts the benefits of active learning (Miserandino, 1999). In contrast to passive learning in which the instructor collects, organizes, and presents the content to the students, who listen and memorize the material, active learning approaches transform the classroom into a learning environment that allows students to engage with course content through problem-solving exercises, informal small groups, demonstrations and simulations, and other activities, with the focus on application (Gibson, 1992; Johnson, Johnson, & Smith, 1991). Active learning, sometimes called "discovery learning," allows students to reflect, evaluate, synthesize, and communicate information with their classmates, because the student is responsible for being intrinsically interested in and actively participating in structuring the content (Leonard, 2002; Machmer & Crawford, 2007). Students who are actively engaged with the material have to process it more deeply than those who are merely listening, and the instructor is not the sole source of information (Leonard).

One common active learning method is having students work in small groups within the class, discussing questions or solving problems. When teachers split their classes into small groups, they limit the time students are receiving direct instruction from the teacher. However, active learning techniques and strategies that refocus or increase students' attention and interest are a valuable antidote to passivity. Another useful active learning technique is the inclusion of demonstrations in class. Demonstrations serve to break up class time, and the change in pace allows students to refocus their attention and increase their interest (Bernstein, 1999). Some demonstrations may require elaborate materials and setup, and could take the entire period. Others may be quick interludes that take mere minutes, and yet serve as valuable illustrations and examples.

Just as it is useful to incorporate principles of active learning, so too should instructors consider the factors that motivate improved student performance. The expectancy-value theory

of motivation, for example, explains students' efforts from a social-cognitive perspective (Snowman & Biehler, 2002). According to this theory, individuals are motivated to continue doing something in which they have a reasonable expectation for success, and when they know the value of the task to their personal goals. Both conditions are necessary for students to continue to be motivated to complete a task (McKeachie, 2002). Instructors can take advantage of this system merely by being transparent with students about the purpose of assignments and the relevance to the overall course goals (Boice, 1992). Motivation also encompasses students' choice, effort, and persistence (McKeachie). Thus, when students feel as if they have some control over their grade, they are more motivated to comply with course requirements (Burke, 2008). Instructors can use this tendency to increase students' compliance with expectations. For example, Burke recounts a way he improved attendance in an undergraduate course from 70% to 90%. He told the students that those who missed fewer than five classes over the semester did not have to take a cumulative final. Conversely, those who missed five or more classes had to take *and pass* the cumulative final in order to pass the class. He contends that students felt like they had the power to choose to not take the final through their behavior, and that motivated them to attend class consistently (Burke).

Teaching Assistant Management. In schools with graduate programs, graduate teaching assistants (TAs) can be immensely helpful in increasing efficiency by handling administrative tasks associated with the course, such as grading objective assignments, entering grades, holding office hours, and responding to e-mail inquiries. Although TAs can be helpful, there are many elements involved in TA management that must be considered. In general, TAs learn how to fulfill their responsibilities through direct experience, by observing the supervising instructor, and via mentorship (Komarrajou, 2008). Some graduate programs leave TAs to learn by trial and error, but if an instructor institutes an apprenticeship model instead, not only do TAs build more confidence and retain enjoyment of teaching, but they also become more successful teachers in the future (Komarrajou). For example, TAs must know all course policies and objectives, so the instructor might include the TA in elements of course planning. This enables the instructor and the TA to present a united and coordinated front, so that students do not receive mixed messages or attempt to take advantage of inconsistent information. Furthermore, it is important that the instructor endows the TA with the appropriate amount of authority, so that students respect and trust the TA with their grades.

Communication of feedback and support for the TA is critical as well (Komarrajou, 2008). In this context, support means two things. First, the instructor should make an effort to be a conscientious mentor to the TA by setting a good example of professional behavior, and being transparent about the reasoning behind decisions and strategies. For example, an instructor might copy the TA on an e-mail response to an upset student, as a way to model an appropriate way of handling provocative or troublesome situations. Doing so not only allows the TA to be part of the official documentation of the interchange, but also provides a template for the TA to use for similar situations in the future. Second, whenever possible, instructors should support the TA's decisions. This condition is predicated on the TA being fully informed of the instructor's standards and preferences. When an instructor overrules an assistant's decision, the instructor risks stripping the TA of his or her authority; it communicates that the students do not need to take the TA seriously. This risk is why it is so important for the TA and the instructor to be clear about the course policies, consequences, procedures, and priorities from the very beginning.

21.2.2 In the Classroom

Once planning and preparation are finished, the instructor is ready to step into the classroom. Common wisdom suggests that the earliest interactions between the teacher and the students shape much of what follows throughout the semester. Indeed, many writings emphasize that the first day of class is the most important day for the teacher to establish his or her role as the authority, the tone of the class, his or her professional boundaries, and approach to teaching (Henslee, Burgess, & Buskist, 2006; Perlman & McCann, 2004; Vesilind, 2000).

Self-presentation should reflect the tone the teacher desires for the class. Young instructors should be especially mindful of this because their age may not easily distinguish them from their students. Depending on the teacher's personality and style, he or she may promote a casual or more formal atmosphere for the class, which is conveyed in part through the teacher's movement around the room, use of humor, manner of presenting course policies, and adherence to the schedule. If the instructor makes a point of being sensitive to impropriety, it will reduce the likelihood of inappropriate interactions in the classroom and foster comfortable discussion. For example, one way the tone of the class manifests might be students' inclusion of slang or expletives in discussion with the teacher or other students. Some instructors may not personally mind if students use such language in class; however, it is important to consider the opinions and preferences of the other students who may be alienated by some words. In most cases, less experienced teachers should err on the side of conservatism when it comes to tone.

It can be tempting on the first day of class to merely distribute the syllabus and then adjourn; however, that strategy might communicate to students that class time is not particularly structured or important (Perlman & McCann, 2004). McKeachie (2002) recommends that the first day includes introductions and presentation of the syllabus, but also that the instructor begins covering content and keeps the class the full time period. Henslee et al. (2006) report that students, on the other hand, do not appreciate delving straight into content unless the course has been clearly and thoroughly introduced first. One of the best ways to convey authority and competence is to be forthright with students about the reasoning behind the design of the course and use of different course components. Especially on the first day, transparency about class policy and pedagogical decisions communicates that the teacher respects the students and intends to treat them as adults.

Norms of behavior in the classroom vary by instructor and course. Students in small seminar courses may sit with their desks in a circle and speak without waiting for the instructor to call on them. Students in a large introductory-level course may keep their headphones on or have a crossword on their desk because they are invisible to the instructor. One instructor may have students respond to each other in discussion, whereas another instructor may ask all the questions and then solicit answers from the students. These kinds of differences are all incorporated into the general scripts students know for how to behave in college classes, and it is the instructor's responsibility to convey what types of classroom behaviors are appropriate for the course. Some of these decisions will be influenced by the physical space of the classroom (e.g., if the room has fixed or moveable seating), and others will be determined by the instructional goals for the course (e.g., if one goal is to improve students' critical thinking, both asking and answering their own questions would be useful).

It is important for the instructor to clearly communicate the expected norms of behavior (Perlman & McCann, 2004; Vesilind, 2000). For example, there will inevitably be students

surfing the Internet instead of taking notes on their laptop computers, sending text messages to friends, sleeping, chatting, and doing any variety of nonclass-related activities. Policies regarding these issues can run the gamut from strict prohibitions of these distractions to a more laissez-faire attitude toward such behaviors. In either case, instructors should decide what kinds of behaviors they care about and why, and state the policy and consequences for these actions in the syllabus. For example, one of us (B.C.J.) has a policy of answering any cell phones that ring during class, which has resulted in conversations between the instructor and grandmothers, bosses, and girlfriends, in front of the entire class. This policy serves as a humorous but effective motivator for students to set cell phones to silent mode before class starts. The critical point here is that competent classroom management involves premeditated policies that are applied consistently and are commensurate with overarching instructional objectives and learning goals.

21.2.2.1 Relating to Students

Teaching is a skill that can be practiced and improved, and which benefits from research and reflection, but the personal qualities of the teacher cannot be separated from how he or she teaches. Interestingly, students and teachers differ somewhat when asked to name the attributes of good teachers. Whereas teachers usually focus on instructional skills, students list teachers' rapport with students as a key quality (Benson, Cohen, & Buskist, 2005). Indeed, efforts to identify the essence of good teaching suggest that the best teachers are approachable and open-minded, show patience and respect for students, care about students' success and are fair, show enthusiasm and humor, are good communicators, are creative, and make an effort to establish rapport with the students (Benson et al., 2005; Lucas & Murray, 2002). Developing rapport with students pertains to the immediate verbal and nonverbal interactions between a teacher and the students, such as eye contact and knowing students' names, as well as the personality characteristics of the instructor (Benson et al.; Vesilind, 2000). In a survey of students' experiences of rapport with instructors and its effect on their interest in the subject, attendance, and other academic behaviors, students reported that few of their instructors established rapport with them (Benson et al.). In classes where they did feel rapport with the instructor, students expressed more interest and enjoyment in the subject, claimed better attendance, and said they would be interested in more classes with the instructor.

Cultural and generational differences also can influence interactions between instructor and student. One of the best ways to illustrate concepts in class and develop rapport with students is to share personal anecdotes as examples. However, differences in cultural or generational backgrounds can make sharing personal stories less effective, if the students are not able to relate to the instructor's examples, or if the stories feel disingenuous. For example, a student might feel frustration with an older instructor using illustrative references to popular entertainment (e.g., music or television shows) that the student is too young to have experienced.

Teachers have a responsibility to promote a safe learning environment in their classes. It is a given that instructors should avoid prejudice and discrimination toward their students. It is also advisable to refrain from promoting their personal, noncontent-relevant views in class. In particular, it is probably wisest not to share personal political and religious leanings, even when politics and religion may be the topics at hand. For example, political campaigns and elections are rife with wonderful illustrations of many psychological topics and principles.

However, people in general tend to feel very strongly about their political views. To avoid alienating students who identify with particular social or political groups, examples from politics used in class should be neutral or equally balanced between various sides of an issue. To do otherwise and favor one side or the other is likely to alienate a segment of students and potentially distract the class from the topic at hand.

Varying Academic Backgrounds. Students come from a variety of scholastic backgrounds, arriving in class with varying levels of proficiency for basic skills. Teachers must therefore attempt to accommodate students' various starting points and bring them all up to the same level by the end of the course. One way to do this is to break assignments into segments that allow students to practice and master skills in sequence, gaining a new skill set through the course of the assignment. For instance, a teacher who wants lower-level undergraduate students to write a research paper would break the assignment into discrete sections, and provide feedback for each step before moving on to the next (Burke, 2008). Splitting an assignment into segments achieves several objectives. The first is that students are able to benefit from teacher support throughout the sequential steps of assignments requiring cumulative competence. The second is that students are required to work on the assignment gradually over time, avoiding the common pitfall of last minute, desperate attempts to complete complicated assignments. Third, because the early stages of the assignment are monitored and students are able to correct missteps before compounding them, the final product is of higher quality overall. Finally, receiving assignments in good condition expedites the process of grading, and the students are able to gain a common outcome regardless of differences in their ability upon beginning the assignment. The approach of breaking assignments into their components so that students can be guided and supported throughout the process works for presenting content as well. Teachers should begin with simple concepts and terms, and work up to the more complicated and complex concepts by building up the foundation of information (Zakrajsek, 1998).

Learning Styles. In addition to students' varying academic backgrounds, there are individual differences in learning styles among students. There are multiple theoretical explanations for differences in how students learn (Fletcher & Patrick, 1999). Without knowing the specifics for each student in every class, teachers can accommodate these differences merely by using a variety of modalities to present information and teach skills. One classification of learning styles might separate students who prefer hearing information from those who prefer visual representations, whereas a third benefits most from personally performing a task to understand how it works (Fletcher & Patric). An example of how to take into account these different styles would be if an instructor for a research methods course explains how correlations work, shows them sample scatterplots of positive and negative correlations, and then has them practice calculating correlations themselves. By presenting the same information in three different ways, the instructor can accommodate the students' different learning styles in his or her class (Fletcher & Patrick; Gibson, 1992; Vesilind, 2000).

Class Time Management. It is tempting for new academicians to attempt to apply the depth and breadth of their knowledge of their specialty to course assignments, under the impression that more is better when it comes to sources (Boice, 1992). However, findings suggest that students can absorb approximately four new topics in 1 h, and less if they have had no previous exposure to the information (Zakrajsek, 1998). Relatedly, students' attention also wanes throughout the period in a predictable curve. Students are most alert during the first 10 min of the class, retaining approximately 70% of the material presented, and then their attention drops precipitously, until the last 10 min of the class when they are likely to retain approximately 20%

of the material presented (Fletcher & Patrick, 1999; Vesilind, 2000). Teachers can derail this progression by varying tasks throughout the class, such as lecturing for a little while and then presenting a short video clip before discussion.

Dealing with Problems or Difficulties in the Classroom. Problems and difficulties in the class-room can be anticipated in some situations, or in others, completely take an instructor by surprise. Some problems may be common enough that the institution has a standard policy, such as procedures for addressing academic misconduct (e.g., cheating, plagiarism). Other dif-ficulties may be harder to predict, but teachers can deal with them effectively by using their own personal teaching philosophy, in conjunction with the learning objectives for the course, to guide their decisions. Occasionally, a student will test an instructor's limits or resolve, by pressing some issue beyond the instructor's reasonable expectations. This challenge might manifest as a grade dispute, an unacceptable excuse for missing an exam, or an objection to the enforcement of a policy, for a few examples. Students can occasionally be vexing, and their behavior might prompt a strong emotional response from the instructor. In cases where the instructor needs to make a decision about how to handle a problem *post hoc*, it may be impor-tant to gain some distance from the confrontation in order to calm turbulent emotions and think more objectively about the problem.

Class Disruptions. Teachers may also encounter difficulties handling disruptive students in class. Students might do a variety of things that disturb or distract their classmates or the instructor, and the instructor, as the manager of the class, has to address the problem directly. It might be something relatively benign, such as whispered conversations while the instructor or other students are talking, or it could be something more disturbing, such as a student who says something extremely offensive during class discussion. Sometimes disruptions happen because students are not aware of the norms for appropriate conduct in class, but other times a student might act out of malice. The most important step in addressing problems such as these happens on the first day of class, when the instructor clearly lays out the rules for proper class-room behavior. Students will respect a teacher who takes firm control of a classroom, and most of the time, a warning is all it will take to head off a major issue.

Instructors' approaches to different disruptions vary based on the instructor's personality as well. New instructors should take several steps to deal with problems or disruptions in the classroom. The first step is to cultivate the all-important practice of documentation. The teacher should keep record of his or her interactions and exchanges with problem students, so that, in the event of escalation, he or she has evidence backing up his or her claims. This includes tak-ing notes on things that happen during class. Second, instructors who are having continued problems with students disrupting class should seek out colleagues for support, and to exchange ideas for solutions to the problem based on others' experiences. Finally, instructors should be consistent with their enforcement of course policies and the application of consequences for misconduct. Students might interpret inconsistency as an injustice and take affront, which can make touchy situations worse. The *sine qua non* for dealing with disruptions in class is that advance preparation is the key to avoid problems before they happen; as the aphorism goes, "an ounce of prevention is worth a pound of cure."

Sensitive topics can also provoke disruptions in class. In psychology, especially, controver-sial or emotion-laden topics are de rigueur, as in classes covering topics like prejudice and discrimination, sexuality and gender, politics and law, developmental issues, or mental illness (Poe, 2004a). First, there needs to be a concrete and explicit reason provided for broaching each touchy topic. There is value in discussing these topics, both in terms of teaching critical

thinking and also in presenting the empirical evidence supporting claims. Poe suggests that instructors announce their own biases and opinions, in order to clearly differentiate between them and material presented as a fact. To further avoid land mines, the instructor might present both sides at the beginning, in order to communicate to students that either perspective is a legitimate part of the discussion. They might start class with a disclaimer about the sensitive nature of the topic of the day, and reiterate the need for students to remember to be respectful of their classmates. In cases where the students might disagree with the instructor, or with other students, the instructor should model how to respectfully disagree without disparaging each other. It may be necessary to explicate injunctions against criticizing peers as opposed to ideas, avoid monopolizing the discussion, and refrain from sharing personal information that might identify someone else to the class (Poe). Finally, to accommodate students who may have been too shy to speak up in class, or students who did not get a chance to express their opinions, a useful exercise is to have everyone write questions or comments and turn them in (Poe). Touchy subjects can produce teachable moments, but the teacher should plan ahead to take advantage of them, and to be able to handle them carefully enough that the learning objective is achieved without traumatizing the students.

Students with Disabilities. Some challenges teachers face pertain to meeting students' special needs adequately and compassionately. It is important that teachers consider how students with disabilities will be able to manage their courses. The most common disabilities, such as attention deficit or physical handicaps, are usually addressed by the school's institutional support services for students with disabilities. Many times, such students will be able to take exams under special circumstances, proctored by school staff trained to assist them, or outfitted with special equipment. It is a good idea to require that students taking exams outside of class take them at the same time as the rest of the class, if possible, to make it fair to the other students in the class (Boyd, 2008). Instructors should provide information in their syllabi about availability of services to provide equal opportunity to disabled students, and note the importance of students notifying the instructor of special needs early in the semester. As part of the course planning, the instructor should also think ahead about how requirements and deadlines may be adjusted for students with disabilities, including, for example, scheduling due dates with enough time to fit extensions in before the end of the semester (Boyd). Instructors might consider implementing written contracts with disabled students, explicitly stating the requirements and expectations for both the student and the instructor. By law, the instructor is responsible for providing equal opportunity to succeed, and it is imperative that instructors be informed of their school's services and policies (Boyd).

Students with disabilities may be proactive about addressing the issue with their instructors at the beginning of the semester, but some may not. Two students whose circumstances required special dispensation, each with differently satisfying outcomes, serve as good examples of the kinds of accommodations that might be necessary. The first student was an exemplar of proactive helpfulness. He approached one of the authors (B.C.J.) before class the first day and explained that he had an illness that occasionally made him so weak that he could not write, and other days not make it to class at all. He came with the paperwork I needed to sign for the Services for Students with Disabilities (SSD) Office filled out, a letter from a doctor explaining his circumstances, and the student worker assigned to be his note-taker in class. His conscientiousness made it so that the only action needed on the part of the instructor was to send his tests to SSD ahead of time. Most of the time, SSD offices require students who register with them to have documentation of their disability, and then SSD contacts the instructors for

each student in order to arrange accommodations while keeping the nature of the student's disability confidential (Boyd, 2008).

Another student presented a much more complicated case, and he was not proactive about informing the teacher (B.C.J) about how to best accommodate him. This student suffered from severe cerebral palsy, thus needing a large motorized wheelchair, and he could not speak or write. He enrolled late in a senior-level seminar course, which had been specifically designed to be very active, with demonstrations and simulations, small group and class discussions, short in-class writing assignments, and out-of-class reading and writing projects. The student did have a computer that would speak aloud what he typed into it, and that helped with discussions and small group work, but he had enough difficulty typing that his spontaneous replies were always delayed. He could not easily hold a paper to read it, which made handouts troublesome, but he had arranged with a classmate to take notes for him. His condition made it necessary to retool many of the lesson plans, and required that the instructor be prepared ahead of time enough to send him materials for class the day before so he could read handouts or type out responses on his computer. The instructor was confronted multiple times with decisions about whether to excuse him from certain requirements or hold him to different standards when compared to the other students in the class. This student ultimately dropped the class after failing the midterm. Though unsatisfying, the experience is a reminder that, when a disabled student does not offer information about how to meet his or her special needs, the teacher should reach out to other instructors and the SSD office to get help and advice. As Boyd (2008) notes, instructors may feel either exploited or ineffectual when dealing with students with various disabilities, if for example, a student claims a disability when asking for an extension, or conversely, if all the instructor's best intentions fail to reach a student. Careful preplanning and open communication with colleagues lessens the magnitude of either emotional possibility.

Whether thinking through adjustments in expectations, or finding materials that provide equal accessibility, it behooves the instructor to be well informed. The school will have an official policy and procedure in place to accommodate disabled students, as dictated by law, but instructors can also become more informed on how they personally can adjust their own teaching methods. The decision whether to hold disabled students to the same standards as the other students in the class on course components affected by their disability is dependent on philosophical, legal, and ethical considerations, in addition to the pedagogical facets. Instructors have a growing wealth of technology at their disposal to help them accommodate students with visual impairments, for example. Instructors who are recording their classes to podcast lectures on their Web sites can use that same technology for students with disabilities as well (Boyd, 2008). Occasionally, students may request to record classes for themselves. In either situation, instructors should get permission from the other students in the class before any recordings are made (Boyd,). Another option for instructors is to contact the publishers of course material to inquire about alternative formats. Many textbook publishers have either preprepared audio recordings of their texts, or plain text (*.txt) files of the books that can be fed into computer programs that will speak it aloud (Boyd). Depending on the typical population of a school, instructors might take into account the availability of alternative formats when choosing course materials in the first place. The bottom line is that instructors should plan for students with disabilities to be in their courses, and think about how to best accommodate their needs.

Troubled Students. Sometimes, issues in students' lives outside of the class enter into the classroom. Teachers are at times the first to notice if a student is experiencing a personal

problem, for instance because the student's work changes suddenly (Perlman, McCann, & Kadah-Ammeter, 2008). It might be that a student seems to be suffering from a condition such as extreme depression or an eating disorder, for example, and the teacher feels like the problem is severe enough that he or she is morally obligated to approach the student to try to help. However, teachers should be aware that there are risks involved with dealing with troubled students, and therefore there are some general rules to remember. Students are somewhat more likely to open up to psychology teachers, especially those with clinical or counseling backgrounds, because the students think that they will be able to help them better than a teacher of another subject might (Perlman et al., 2008). Furthermore, students might be more likely to turn to new teachers if they are closer to the students' age, because they feel like they can identify with the teacher better. Unfortunately, students' personal problems are, for the most part, outside the jurisdiction of the instructor's relationship with them, and in cases where the problem is severe, the instructor's most important intervention is to refer the student to the appropriate authority or service. The university health center will sometimes offer free counseling and psychological services for students, or the student might be able to get the help they need from campus police, the university's legal counseling office, or the dean's office. The point is that the teacher should avoid establishing a dual role with the students. Most teachers are not trained to handle students' personal problems, but even if they are, as in the case of clinical psychologists in academia, it is not appropriate for them to try (Keith-Spiegel, 1999; Perlman et al.).

The APA publishes the organization's ethical principles and their code of conduct, and those documents provide guidelines that all instructors can use. For the most part, if teachers remember that they should avoid doing harm, and try to be helpful, they can address student problems without stepping outside the boundaries of propriety (Perlman et al., 2008). For example, instructors should make an effort to listen carefully to students, respond in a way that demonstrates their respect for the student, and follow through on promises to help by providing resources or directing them toward the people best suited to help them (Keith-Spiegel, 1999). Keeping a student's secrets confidential is important, but the instructor should remember that if they find out that the student is planning to hurt others or themselves, he or she is bound by law to notify the proper authorities. The recent instances of campus shootings serve as vivid examples of how not addressing obviously troubled students can produce tragic outcomes. Teachers should also be aware of the school's policies and available services, and observe departmental norms for closed doors for meetings with students, if they attempt to address students with personal problems (Perlman et al.).

Dual Relationships with Students. Teachers dealing with troubled students should endeavor to avoid allowing a dependant relationship to form between them. A troubled student might become emotionally invested in a teacher who is especially helpful during a trying time, especially because of the hierarchical social arrangement wherein teachers have more power than students do (Keith-Spiegel, 1999; Poe, 2004a; Vesilind, 2000). This risk is why it is important to refer students to the proper services to help with their problems, rather than taking it on personally, even if the teacher is trained to deal with the students' problems. The teacher is still in charge of evaluating the students' performance in the class, and that can be complicated if the teacher has another relationship with the student besides being his or her instructor. Therefore, the instructor might need to be firm about limiting the time spent in conference with the student, or the amount of contact the student has with him or her outside of class (Poe). It might also be necessary for the instructor to carefully derail a student's attempt to over-share personal

information, especially if that happens in class (Poe). In order to be fair to the other students in the class, and to minimize the risk of negative consequences if the nature of their relationship changes, instructors should refrain from forming dual relationships with students.

There are other ways that students and teachers can create problematic dual relationships. Under no condition should teachers become involved in personal, romantic relationships with their students. The school may have a formal policy against this type of behavior, but if not, it is still ill-advised. However, that simple dictate is complicated by the possibility of a prior relationship with a person who then enrolls in the class. Aside from romance, there are a couple of types of preexisting relationships that present a problem for the instructor. The instructor might have been friends with the person or belong to the same circle of friends. A student might have worked as a research assistant in the lab with or for the instructor, or the student might have worked in another capacity in the same place as the instructor. It can be uncomfortable to change the nature of the relationship into one wherein the instructor is suddenly in a position of authority over the person as they might not have been so before. There is a threat that other classmates might feel like the instructor is favoring a particular student, and indeed an instructor's opinion of a student can color his or her grading of the student's work (Keith-Spiegel, 1999).

When instructors and students have the same extracurricular interests or activities, such as recreational activities, local establishments, or religious services, they can be forced into proximity, especially in small college towns (Keith-Spiegel, 1999). A newer manifestation of an inappropriate dual relationship is connecting with students through online social networking Web sites. For example, students may find their instructor on sites such as MySpace or Facebook, and request to be "friends" online. Most of these networking sites offer privacy controls that disallow strangers searching for instructors' pages, and instructors should be mindful of the kind of information they publish about their personal lives online. In general, it is not a good idea to form nonacademic relationships with students outside of class, and prior relationships should be handled with care and in compliance with school regulations.

Instructors Missing Classes. The students do not generate all the problems that might arise in the classroom. Occasionally, life intrudes into the classroom and causes the instructor to miss class. Reasons include everything from jury duty to health problems, and absence might be for one class or the remainder of a long semester. Some absences are predictable, such as attendance of out of town conferences, while others arise completely unexpectedly. In any case, colleges and universities do not provide substitute teachers like in lower grade levels. The options for an instructor who needs to miss class include canceling class entirely or asking a colleague or graduate student to teach in his or her absence. Either approach has its drawbacks and benefits (Poe, 2004b). If there is room in the schedule of a course to accommodate missing a day, it might be that the students just enjoy the day off and class continues when the instructor returns, as if nothing out of the ordinary happened. Other times, however, it might be impossible to stop in the middle or drop whatever material would have been covered on the day an instructor must miss. If an instructor is going to ask someone else to cover the class, there are several things he or she should do to prepare (Poe). A movie or guest speaker might be brought in to advance the topic coverage in the instructor's absence. If the instructor knows another person who has experience teaching the course or satisfactory knowledge of the subject, he or she might be able to provide lecture slides and notes that the substitute can use to present the regularly scheduled material. In this case, the information needs to be accessible, either electronically or organized in such a way that another person could find it in the

instructor's office. Storage and organization are especially important in cases where the instructor's absence is permanent, and another instructor must take over the class mid-semester (Poe). The value of good record-keeping practices cannot be understated when it comes to having someone else step in to lead a class.

Missing or canceling class causes enough difficulty for the school, instructor, and students that instructors should be warned about the repercussions. It might sound self-evident, but instructors should avoid missing class if at all possible. This means scheduling personal or optional traveling around semesters, or planning the course schedule around anticipated absences before the course begins. Colleagues asked to fill in repeatedly should be offered something of equal value in return for their time, both in preparation and class, lest their willingness to help in a pinch wears out. Additionally, the power disparities between faculty and graduate students might make requests for assistance a compulsion to the graduate students, so instructors should be careful not to exploit them unnecessarily (Poe, 2004b). The final warning pertinent to missing class is the effect repeated absences might have on the instructor's professional reputation within the department. New academicians should remember that their promotion and tenure chances can be negatively impacted by injudicious absence. As more departments include student evaluations in the review process, the deleterious effect of excessive absences, or absences that are not handled well, on students' opinions of the instructor gains relevance (Poe).

Aside from the basic work of teaching students in the classroom, and the planning that goes on outside of the classroom, a key element of basic competence is self-assessment and reflection. Teachers who do not critically and empirically evaluate themselves and their methods for efficacy are blindly grabbing for success. Because the pressures of teaching, both in time consumption and emotional investment, can be so distracting, it is important to be methodical about improving teaching effectiveness. The following section describes the basic components of this self-evaluation.

21.2.3 Assessment and Professional Development

Academicians should always be thinking of the future, for practical reasons such as tenure review, as well as for the personal gratification gained from having a successful career; however, success is defined (Savory, Burnett, & Goodburn, 2007). For many new academics, teaching consumes most of the time spent working for the first few years at a new position. Boice (1992) observed that many new teachers expect the efficacy of their teaching to improve, but treat it as a passive process that will happen automatically over time. He reported that, regardless of the type of school, new teachers experienced similar obstacles and evinced comparable strategies for professional development. Many taught defensively in an effort to avoid failure, and based the estimations of their teaching prowess on the tenor of students' comments in course evaluations. However, the best way to go about growing and improving as a scholar is to be methodical about reflection and self-evaluation, and make steady but gradual changes.

Three main audiences care about the professional developmental trajectory of academics. Students, colleagues, and supervisors are all directly affected by the decisions teachers make about their careers, and it is important to establish trust with them all. The first and most important step in growing as a teacher is systematic reflection on pedagogy and learning outcomes (Boice, 1992; Gibson, 1992; Savory et al., 2007). Learning outcomes can be generally

described as changes in knowledge, cognition, behavior, skills, attitudes, or beliefs (Gibson). This manifests itself in simple tasks, such as taking notes on how assignments or lecture presentations were received, or more complicated measures, such as testing iterations of assignments across semesters and measuring students' performance. The point of formative evaluation is to determine if a teacher is effective, and how he or she might become more effective (Buskist, Keeley, & Irons, 2008). One way for instructors to begin this process, taking into account the three audiences, is to formally write down the impression he or she is trying to create. This means consideration of the things the instructor wants the students, and his or her colleagues and supervisors, to say or not say about his or her teaching. The idea is that consideration of the question, "Who shall I be?" naturally leads to the question, "What shall I do?" which leads to a plan for action (McGovern & Miller, 2008). To make the project even more specifically applicable to instructional objectives, and to avoid a myopic focus on classroom performance as the entirety of teaching competence, the instructor might then go through the same process for each of his or her course components (e.g., tests, assignments, lectures, etc.) (Buskist et al., 2008). During this process, the instructor might consult a taxonomy of learning objectives, revisit his or her teaching philosophy statement, and refresh his or her memory for motivation and learning theories. The goal of the exercise is to find and make connections between what the instructor wants to achieve, and how he or she is putting plans into action (Savory et al.). This exercise is furthermore useful for avoiding the tendency of instructors to teach in a haphazard manner, using trial-and-error or default methods (Wilson & Kipp, 2004, for an in-depth treatment of the benefit of talking about teaching with colleagues).

The standard method of reflection that is typically imposed on instructors by their department is student course evaluations. These evaluations solicit both global and summative feedback on instructors' behavior, but while they are certainly necessary, they are not a sufficient tool for assessment of instructors' development and competencies (Fletcher & Patrick, 1999; Gibson, 1992). Some instructors get distracted by the "popularity" aspect of course evaluations, contending that instructors who give the highest grades and have the lowest expectations will score well with students. Others argue that students are not in a position to evaluate the efficacy of pedagogy they do not know or understand. Students are notorious for not appreciating the things that educators know are good for them. An evaluation of recent literature on teaching of psychology by Wesp and Miele (2008) determined that there is diminishing reliance on student opinion as a measurement of teaching competence. They note that student evaluations are a fine instrument for assessing students' enjoyment of methods or activities, but not learning outcomes. Research has determined that student opinions of teachers do not correlate with pedagogical effectiveness (Wesp & Miele). Many instructors object to course evaluations being used by supervisors in promotion and tenure reviews, for these very reasons.

There are, however, ways to make student course evaluations more helpful measures of teachers' efficacy. First, instructors should offer evaluations more than once during the term, so that there is time to make adjustments that affect the current class, which motivates the students to put more stock in evaluations overall. Second, evaluations should collect both summative feedback that is personalized to the instructor and the course. However, students should have a chance to write replies to open-ended questions in order to supply examples or explanation of their ratings. Finally, evaluations should assess specific aspects of the course and instructor, as opposed to being restricted to overarching generalizations that do not allow for nuance.

One of the foundations of good, reflective teaching is good record-keeping. Teachers who want to systematically assess their development over time need to collect and organize their information in a way that allows them to monitor changes (Savory et al., 2007). These records consist of both the records generally collected in the normal course of teaching a class (e.g., grades), as well as notes about ideas and outcomes. Another good exercise that all teachers should complete is video or audio recording of their teaching and evaluating the recording for both style and substance. Many problems or distractions that are invisible to the teacher doing it can be discovered and eliminated, benefiting the students. Though it can be a painful exercise, teachers can only improve issues they know about.

Once instructors have gotten into the habit of creating and collecting records of their teaching, the next step is to immerse themselves in understanding the principles of teaching and learning (Savory et al., 2007). This might mean reading general teaching instruction books (McKeachie's, 2002) or reading current research in peer-reviewed journals about teaching. An instructor's colleagues are an invaluable resource for learning about teaching and developing professionally. Conferences or workshops about teaching can expose instructors to innovative research, allow them to network with other skilled teachers, and offer a forum for discussion with like-minded colleagues from outside of their home institution (Gibson, 1992).

Exposure to sources of new methods and strategies allows teachers to pool their effort and time when they share their discoveries and developments with each other. New teachers may begin their jobs with a limited arsenal of teaching methods, or little to no experience with practical applications for theoretical teaching principles.

21.3 Expert Competencies

Novice teachers and academicians need necessarily start at achieving basic competencies while teaching selected content material. As teachers gain experience, and as their content knowledge expands in depth and breadth, they can begin to build their repertoire of teaching skills and course offerings. Experienced teachers who are experts in their areas should be able to present content information at different levels of complexity. Instructors may need to teach the same content area at an undergraduate introductory level, a senior level, and/or a graduate level. The conversion requires that teachers be able to know both how to choose information that will interest and benefit students at different levels, and prioritize information that students need to understand whether they are interested or not.

It is important when teaching different level courses in the same area that the departmental standards support the educational objectives set out in each course (Marsh & Poepsel, 2008). Departments design their curricula based on what students need to know to be properly trained in the area, and this means that courses at different levels (e.g., introductory or advanced) need to be complementary. For instance, a sophomore-level course in a topic should prepare students for a senior-level course in the same topic, and if required as a prerequisite, it should be necessary not just sufficient for success in the senior-level course. Furthermore, courses that build upon each other across topics (i.e., abnormal psychology before clinical psychology courses) should be both necessary and sufficient in the progression of students through the program.

Expert teachers should be more systematic about designing their courses in accordance with their desired learning outcomes. This planning process is streamlined in experts because

they have achieved facility with both content materials and pedagogical methods, and are able to draw from known alternatives the best way to meet those goals. While novice teachers work from a more static script based on their rudimentary understanding of pedagogy, expert teachers can look ahead to the long-term ramifications of their decisions about course design and execution. For instance, expert teachers who use scientific experimentation to test the efficacy of teaching innovations or interventions can design their educational goals and instructional objectives to produce learning outcomes that are able to serve as dependent variables (Smith, 2008). Teachers who demonstrate expert competence have the entire course, from planning to assessment, purposefully designed to meet goals on multiple levels: learning goals for the students, integration with the department's overall outcome goals, and the teachers' own personal professional development goals.

21.3.1 Outside the Classroom

21.3.1.1 Course Planning

Expert competencies can be distinguished from basic competencies on at least two important dimensions. The first is how well the teacher himself or herself understands the content material and is able to synthesize that information for the students. The second is how well the teacher organizes the presentation of that content material based on pedagogical principles. For both dimensions, a similar progression is the most effective approach to planning and presenting the material. As a teacher gains expert competencies in a given content area, either because he or she specializes in that material or in the process of learning the content to teach it, his or her understanding of the information reaches the highest taxonomic levels of knowledge. The instructor has taken the basic principles and jargon, built cognitive structures to organize that foundational material, and is able to use the information practically, having an understanding of procedural applications or steps. An expert in a content area will then be able to look critically at how the knowledge he or she gained was produced, attaining metacognitive knowledge. Likewise, experts not only have the highest levels of knowledge of an area, but are also equipped to use the more complicated cognitive processes of analysis, evaluation, and creation of new knowledge.

Taxonomic Integration. It is important for instructors to think from the perspective of the naive students when planning how to teach a subject, instead of approaching the process from their own expert point of view. Students need to move through the same sequence of taxonomic levels that the instructor originally followed himself or herself. They will not be able to grasp the organization and structure of information if they are only given the lowest level of basic knowledge (i.e., jargon). Instead, teachers should guide students through the steps, allowing them to build their own understanding from the foundation up, using the principles of scaffolding. While the uppermost levels of knowledge require a solid grasp of the lower levels, understanding of the basic information is also augmented when seen in the context of the higher levels. One way to plan this guiding process in course design at an expert level is to approach the instructional objectives from the end to the beginning. This is called *backward design* (Wiggin & McTighe, 1999). If the point of a course is for students to gain a practical skill or procedural understanding of a content area, then the examinations should test for that level of knowledge. From the exams, the teacher should plan how the students need to practice the

action scripts in order to gain the needed procedural knowledge, and make those activities or exercises the course components (e.g., discussion, assignments, demonstrations, etc.). The last step is to figure what the students need to understand about how the concepts fit together, and organize instruction to achieve it and ensure that instruction encompasses the presentation of basic elements and factual knowledge. Inexperienced teachers may be distracted from the necessity of thinking of the end goal when putting together content material, and end up missing important foundations, mismatching the exercises to the cognitive structures of knowledge, or not practicing the proper skills. An expert teacher is able to not only keep sight of the hierarchical levels of content information, but to also approach instruction methodically according to pedagogical best practice.

Textbooks designed for undergraduate courses tend to be organized around a single guiding principle. The principle might be a common application of the content, an overarching theme to draw disparate areas together, or a particular theoretical perspective. Structural organization of knowledge may differ between that presented in textbooks and that used by theorists or practitioners in the field. An expert teacher, however, can use his or her proficient knowledge of the area to decide on the best organization of the content to suit his or her educational goals. Expert teachers, therefore, benefit from reviewing a variety of sources or textbooks, in order to take advantage of the different perspectives and examples. Teaching at higher levels, such as in upper-level undergraduate courses or training graduate students, is fraught with gray areas and equivocation that lower-level students are not equipped to evaluate and assimilate. For example, one textbook might present information about cognitive behavioral therapy (CBT), but an academic clinician would know that there is a variety of methods included under that omnibus label that might even contradict each other. An expert teacher and a professional-level clinician would be able to discern what of that complexity is important to learn, as well as be able to pull in resources from different sources to support their conclusions.

Integration of Methods and Content. In addition to the benefit of customizing curricula to suit individual teaching priorities, an expert is able to bring together information about the genesis of content knowledge, meaning and the empirical research responsible for perpetuating psychological discovery and innovation, in a way that illustrates the proper breadth of study. For example, one potential downfall of textbooks for lower-level courses is that they present classic and contemporary research in a manner that might suggest to students that there are a few seminal studies or revolutionary researchers who determine what is "true," and that the rest of the field merely elaborates on what those luminaries find. This perspective is somewhat evident in collections of selected readings generally produced as textbook supplements, or in the anthologies of current studies that comprise the various psychology annuals. Far from the idea of a "critical experiment" approach sometimes insinuated in textbooks, psychological inquiry is comprised of programmatic research and convergent evidence. In comparison to either supplemental compilations or professional annual reviews, a suitable mid-level approach is the series of books that present current controversies in select subfields of psychology and offer opposing research reports for students to evaluate on their own.

Along the same lines, expert teachers should strive to incorporate methods with content in order to continue students' progress toward metacognitive levels of knowledge. It is important to know *how* psychologists know the things they know, and understand how inextricably intertwined the *way* knowledge is gained is with the knowledge itself. Social psychology offers an exemplary model for integrating research with content information, because social psychology explores everyday human phenomena that lay people are already motivated to explore

themselves. The simplest way to achieve this goal is for teachers to include information about which research methods are appropriate for investigating which types of psychological phenomena simultaneously with the content information. Instructors might require that students evaluate the research used to support claims for soundness, or better yet, practice designing their own research to test ideas and conclusions. Though in many schools, undergraduate students are not able to conduct independent research as a course component, they may still benefit from the mental exercise of choosing the proper methods, formulating hypotheses, selecting and operationalizing variables, and thinking through questions of analysis and validity. Graduate students are able to pursue their ideas more often, which is why many graduate-level seminars require students to write research proposals within the content area as the major requirement in the course. When students are able to evaluate, analyze, and synthesize both the content knowledge *and* the methods of investigation necessary to achieve it, they have reached the most sophisticated level of knowledge in that area.

Adapting Existing Courses. Another aspect of modifying courses to increase a teacher's repertoire is converting classes across venues, such as making in-person courses available in an online format. The first thing to consider is what aspects of the course are imperative to competency in the topic, and how those aspects will translate to a new setting. For instance, courses with laboratory portions, such as undergraduate methods courses, may suffer from adaptation to an online format, because the hands-on experiences possible in a lab cannot be reproduced effectively online. One of the most difficult attributes of a physical classroom to convert into an online format is immediacy of the material and the instructor. There is a powerful motivation and inspiration in the fact of having to be somewhere at a specific time, surrounded by classmates and an instructor. However, if the teacher is mindful of the overarching educational objectives, and grasps the structural organization of the topic area at a conceptual level, he or she should be able to design exercises that guide students to the same procedural knowledge that the original activities did in person, using principles of backward design. This harkens back to two different aspects of course design and classroom management mentioned earlier in the chapter. First, when making courses available to differently abled students, teachers need to be imaginative and resourceful in designing course components that are accessible to a variety of students. Second, though most novice teachers do well to take established teaching methods and course design from existing sources (e.g., textbooks or colleagues who have previously taught the course) as a starting point, as they become more proficient in both the subject area and pedagogy, instructors should be equipped to produce innovations. This reflects their achievement of the highest taxonomic levels of knowledge, which are creativity and metacognition (i.e., "thinking about thinking"). In research, this process manifests as replication with different operationalizations of the same variables, which provides both external validity and convergent evidence of the conclusions drawn. In the classroom, those outcomes are equally important to good teaching and learning.

Other changes a more experienced teacher might make would be to accommodate new populations of students in the class (for instance, if the course were cross-listed with other departments), or present a course during the summer as opposed to the semester. Both of these differences in course presentation are affected by the way the teacher instructs students on the cognitive structuring of the information. From other majors, especially psychology's cousins in the social sciences (e.g., sociology, anthropology, etc.), the students coming in may have been taught completely different ways to organize and evaluate the basic information of an area. For example, psychology places great value on experimentation and multivariate approaches to

investigating psychological phenomena, whereas sociology students might be trained to prefer ethnographic research methods, or anthropology students might favor appreciative or participatory inquiry. When students from other disciplines are allowed to enroll in courses without fulfilling departmental prerequisites, the class's progress can be delayed by the necessity of working backward until a common denominator can be found in the organizational cognitive structures of different students, and beginning from there. Summer courses can indeed have the advantage over semester courses when the students need intense guidance to build cognitive structures, because most summer courses operate on a condensed schedule, and therefore gain momentum more quickly when accruing a critical mass of information upon which to found their understanding.

Increasing Technological Sophistication. Some of the technological advances in teaching make such conversions, or sometimes the modernization of an existing course, easier due to the parallel nature of in-person versus technology-driven methods. The most straightforward example of comparison may be the online discussion board versus in-class discussion. While the in-class version of discussion benefits from immediacy and nonverbal cues to enhance communication, online discussion boards boast several, possibly more valuable alternative virtues. First, online discussion boards offer asynchronous interaction between students, allowing discussion to occur even when students are not able to be in the same place at the same time. This is good for nontraditional students, or for allowing discussions to extend beyond the confines of a single class period in time. It also keeps a permanent record of discussion contributions, which is useful for both the instructor when grading participation, but also to students wishing to refer back to previous statements. Finally, it allows students to not only think through what they want to say without the influence of the same types of personal or social pressures (e.g., shyness, monopolizing by classmates), but also to increase the likelihood that students will process the information at a deeper level, in order to express themselves in writing. If an educational objective for a course is to make students be able to evaluate, synthesize, and communicate their understanding of topics, then discussion is a good method for practicing those skills. Online discussion and in-person discussion both achieve those ends, and either would be a suitable adaptation for different settings of a course.

Injecting new technology into the classroom should always serve to increase the effectiveness of instructional objectives, not as technology use for technology's sake. Some technologies allow teachers to solve a logistic problem or strengthen the efficiency of certain teaching methods. In the same way that online discussion boards might allow distance students to interact with each other despite not sharing a classroom, some new classroom technologies permit teachers to do activities or exercises with classes that would otherwise not benefit from such techniques. In large-enrollment courses, for instance, small groups may be able to work through problems or practice exercises using online discussion boards out of class, whereas in-class discussion in small groups would be impractical because of the sheer size or configuration of a large-enrollment classroom. An example of technological innovation especially effective for large-enrollment courses is "clicker" technology, where students have individual, wireless communication devices, with which the teacher can administer and score impromptu test questions, take roll, or conduct informal surveys in the class and immediately integrate it into the electronic presentation of the lecture. Clickers allow students to be more actively participatory even in classes with hundreds of students enrolled. Occasionally, the integration of new technology into a course forces instructors to reevaluate their course components, delivery, or instructional objectives, as inconsistencies or flaws are highlighted by the new medium.

As described in the basic competency section of this chapter, use of technology should be carefully informed by the educational goals of the course, in order to ensure that there is a good fit between the strengths of the tool and the desired learning outcome.

21.3.2 In the Classroom

Differences in students' learning styles necessitate that teachers incorporate a variety of methods and techniques in their classes in order to improve the chances of reaching all the students. Advanced teachers can go further to improve the utility of their methods and materials for a wide array of students by taking advantage of some more complicated approaches. Calvin P. Garbin, one of the authors, asks his students to think about how they learn best, whether by listening or by reading, and use their weaker learning style to "warm up" before attempting to learn new material via their stronger learning style. For example, a student who is an auditory learner would benefit from reading the text before attending class, in order to begin to establish the jargon and cognitive structures necessary to assimilate the material presented in class. This allows students to get more out of the lecture than if they were to attend "cold." Likewise, a student who benefits more from reading would use the lecture as a "warm up" for doing the reading assignment, so as to get more out of the text. Another way to think of this two-step process is metaphorically. Aside from one or another learning style, students need a preliminary foundation of information upon which to build understanding (see the taxonomies of learning objectives), and they are only able to absorb small amounts of completely novel information in a sitting. Therefore, if students prepare for class by reading the assigned text or completing some other introductory activity, for example, it is as if they have been provided a coat rack in their own minds, and then in class, the instructor hands them the coats to hang upon it. Without the rack in place first, the coats presented in class just fall to the floor. Following this two-step approach allows students to get more benefit from time spent studying and in class.

21.3.2.1 Responsive Teaching Methods

An increasingly common method for maximizing the utility of class time spent with the instructor is called *Just-In-Time Teaching* (JITT; Novak, Gavrin, Christian, & Patterson, 1999). Teachers using this method require students to complete brief web-based assignments shortly before coming to class, which the instructor then uses to tailor class time to meet specific students' needs. For instance, students might take a quiz over the material to be covered, and based on what most students are or are not grasping, the instructor can adjust the day's lecture to focus on areas that are most challenging. This technique is a highly responsive way to make class an active learning environment, in which students are clearly and explicitly participating in the construction of their own understanding. Frequency with which an instructor employs such methods may vary based on the complexity of the material, the level of knowledge students bring to the class to begin with, or the instructor's comfort with the material.

   As a complement to the spirit of JITT, one of the authors (C.P.G.) developed a technique that is similarly responsive to students' spontaneous needs, but in the opposite direction from JITT. He dubbed this method *Barely Late Teaching* (BLT). Instructors can accommodate spur of the moment issues, such as providing clarification or further examples and demonstrations

of complicated processes covered in class, by producing and providing further instruction or material soon after class adjourns. For example, after students struggled in an undergraduate lab with running a statistical analysis using instructions presented in paper handouts, the instructor (C.P.G.) prepared an Adobe Captivate flash animation of the process and sent it to the students. Captivate allows a user to "record" what they do on a computer screen, such as clicking through the guided user interface of a statistics program, in a video file, and then insert labels and narration if desired. The result is largely the same as demonstrating something to students in person. Another instance of BLT that proved the method's usefulness was when the instructor, after going over the same exam review for a series of students visiting office hours individually, audio-taped his explanation and e-mailed it to the rest of the class, under the assumption that most of the students would benefit even if they could not make it to office hours. Teachers can employ the BLT technique for handouts needing modification, additional lecture presentation slides, audio files of explanations, or other assorted tools.

In discussion of the possibilities and merits of BLT, one of the concerns that arises is whether this method makes the instructor appear unprepared versus committed because of taking that extra effort. Though instructors should always put effort into planning ahead for contingencies when preparing their courses and lesson plans, the reality is that unexpected questions do surface, while other times inspiration strikes after the fact. Sometimes, the best laid plans fall flat. Rather than lamenting the occasional unpredictability of "teachable moments," instructors can take advantage of unanticipated opportunities to improve their instruction, and then incorporate those new materials into the original plan for the next time he or she teaches the course. Teaching is a dynamic process, and expert teachers are able to adapt their methods in response to changing students' needs.

21.3.3 Assessment and Professional Development

Development as a teacher is dependent on reflection and systematic self-evaluation. Instructors might feel discouraged when they read books describing the personal characteristics of the best teachers, because those qualities are usually stated in global, immutable terms (Keeley, Smith, & Buskist, 2006; McGovern & Miller, 2008). However, it is much more practical to think of the *behaviors* of good teachers, because behaviors can be changed through effort, while personality characteristics often cannot. McGovern and Miller reported that while researchers can distill the personality characteristics that might underlie the behaviors evinced by master teachers, the qualities that stand out to students are particularly effective instructional techniques. It makes more sense for teachers to practice the skills of teaching than to focus on the dispositional virtues found in many good teachers. Whether novice or experienced, teachers' habits and practices are what make them good teachers or not. (Buskist et al., 2008, for a comprehensive overview of evaluating and improving teaching).

Teachers wishing to move beyond basic competency toward expert status should be systematic about their self-evaluation (Boice, 1992; Savory et al., 2007). In addition to the normal reflective writing recommended for simple examination, teachers might turn to empirically tested scales and assessments. For example, Buskist, Sikorski, Buckley, and Saville (2002) developed the Teacher Behavior Checklist (TBC) based on students' and teachers' ranking of the characteristics of the best teachers, and the behaviors that reflected those qualities. Keeley et al. (2006) adapted the TBC for use as an assessment tool that teachers wishing to advance

their teaching development could use to identify problem areas. A factor analysis of the measure determined that two subscales were represented in the checklist. The first, which they interpreted as "caring and supportive," echoes the emphasis in previous research on the importance of developing rapport with students (Benson et al., 2005; Fletcher & Patrick, 1999; Lucas & Murray, 2002). The other factor identified was "professional competency and communication skills" (Keeley et al.). As Boice noted, novice teachers may approach improvement as a passive process; an expert teacher, employing a psychometrically sound, diagnostic instrument such as the TBC, can identify concrete areas to target for improvement and develop a plan for action.

Having a plan of action is important for professional development as well as triage. The statement of a teaching philosophy is another manifestation of a plan. Many novice teachers do not develop a teaching philosophy that is any more complex than a few guiding principles. However, it is a good thought exercise as teachers grow and mature to formalize their priorities and goals. Oftentimes, sentiments that are not articulated fail to influence actions meaningfully or regularly. In the same way that careful planning up front helps a course to actually achieve its goals and objectives, formal thought about the reasons behind pedagogical decisions and overarching goals increases the likelihood that they will be successful. As teachers move through their careers, improvement requires reflection and attention to empirical evidence of learning outcomes.

21.3.3.1 Scholarship of Teaching

In addition to the learning outcomes for students in each course, teachers define themselves and their careers the same way researchers do. The most defining product of the hard work that goes into teaching professionally is dissemination of the results (Smith, 2008). Publications, presentations at professional conferences, and closer to home, "brown bags" and colloquia offered within the department are appropriate venues for both sharing personal experiences and benefiting from others'. If an instructor belongs to a department where teaching is not supported by these kinds of activities, it stands to everybody's advantage to initiate them (Boice, 1992). These kinds of discussions can allow colleagues to share variations in pedagogical philosophies, success (and failure) stories, techniques and methods, or approaches to grading and testing, for example (Gibson, 1992). The obvious corollary is that teachers need to keep apprised of new teaching developments by reading publications and attending teaching presentations.

Instructors satisfied with basic competency are coasting on what works well enough, but expert teachers will endeavor to incorporate more sophisticated teaching methods and strategies. There are always going to be trends, new ideas, and rebirths of old techniques that sweep through the discipline and inspire teachers. The best way to choose which new things to try is to look at what needs changing first. The difference between trying anything randomly and selecting specific tools to meet known needs is an instructor's time and energy spent with measurable benefit (Savory et al., 2007). Again, it behooves teachers to behave as researchers in this exercise. The first thing to clarify is whom innovations are meant to benefit. Between the students and the instructors, there will always be those who are excelling, those who are struggling to stay afloat, and everybody else.

Innovations and Interventions. Innovations might first be applied to those students needing remediation. Using empirical evidence of learning outcomes, teachers can identify the students

who are not achieving the objectives of the course, and attempt to determine the reason why they are not (Boice, 1992; Savory et al., 2007). Most classes will have a relatively normal distribution of student success (with the possible exception of mastery based courses wherein students redo assignments until they pass them), and not all students who fail do so because the teacher has not met their needs. Some students will fail on their own merits, and while that can be disheartening, it is unavoidable. However, some of the newer technological tools teachers have at their disposal can be used to distinguish between students who are not holding up their end, and students who are struggling but have the potential to succeed. For example, in the BlackBoard classroom management system, instructors can elect to track students' access of both general areas of the class's site and individual files posted for download (e.g., exam study guides). By collecting usage statistics, the instructor can analyze that behavior's relationship to student performance (e.g., exam scores). If the students who did poorly on the exam did not access the study guide, that information can be included in a reminder about downloading study guides for upcoming exams to increase compliance. However, if students who did access the study guide did poorly on the exam, it might behoove the instructor to examine the study guide to ensure that it is truly representative of the kinds of skills or information the exam covered. These small investigations can do much to dispel the role of conjecture in determining what elements of a course might benefit from revision, and some of the new tools at the instructors' disposal simplify the process.

Another factor to consider when including innovations that can improve students' learning outcomes is what static resources can be provided to further scaffold their learning process. For instance, many instructors will provide examples of assignments, either exemplary or otherwise, to demonstrate how the assignment should be completed to earn the desired grade. The samples may be graded or ungraded, but students who look at the examples will better understand what is expected of them. The idea behind this is not to tell them what the answer is, but to improve students' understanding of the expectations, and thus increase their chances for success. One thing that sometimes happens when instructors provide extra resources, however, is that some students will not take advantage of them. That self-defeating behavior is truly frustrating for some instructors, but the students who do take advantage of the tools, and subsequently benefit, make it worthwhile.

A particularly valuable innovation is one that increases instructor efficiency without any loss of instructional quality. The Internet has made innovations of this type easily available to teachers at any level. From institutionally hosted classroom management systems to independent Web sites instructors set up for their own classes, online resources are a boon. Technology that automates processes falls into this category. For instance, several online systems are available that allow students to take quizzes outside of class, and have them automatically graded and entered into the grade book. This tool is good for JITT methods, particularly. Another example of a way to automate a process to augment instructor efficiency is using a word processor to grade written assignments. The time involved in grading assignments partially depends on how much feedback the instructor plans to give for each assignment. Writing comments to foster improvement and detailed explanations of grading decisions takes a lot of time. If the instructor has students turn in assignments electronically, the grading process can be streamlined by using a set of preprepared, typed remarks and notes to copy and paste into the file. For example, Microsoft Word's clipboard feature holds up to 24 items at a time, and each can be chosen and pasted into documents as needed with the click of a mouse. This strategy ensures that comments are consistent across classes or assignments, allows instructors to ascertain the

most common errors, keeps a record of what is said on each paper, and avoids abbreviations or shorthand that might be necessary if comments were going to be written out by hand.

Finally, teachers can save time by talking with their colleagues and sharing ideas for short-cuts or time-savers that they have developed or discovered; the whole department benefits if teachers do not have to reinvent the wheel for themselves. One of the author's colleagues shared a spreadsheet program she designed for grading lengthy written assignments and calculating the grade automatically. In one sheet, a set of preprepared comments, compliments, and critiques was written out and assigned numeric values according to the grading rubric (i.e., a three-point deduction for APA style errors, 8 of 10 points for a reasonably well-written introduction, etc.). The instructor imported the class roster into another linked sheet. By selecting the comments that applied (using a true/false contingency formula), the instructor could prepare a personalized printout of the feedback for the assignment, with the score automatically calculated and reinserted into the roster for uploading into the online grade book. Although this tool required some time to prepare the first time, it more than made up for it with the time saved grading large piles of essays, and was especially valuable in cases where there was more than one person grading the assignment (i.e., an instructor working with a TA). These types of innovations, especially shared with colleagues, are incredibly valuable for increasing instructor efficiency.

Introduction of any innovation can be seen as an intervention geared toward those the instructor decides need help. There are two ways to approach interventions to address specific issues in the class. The first way to conceptualize interventions is as a way to avoid failure; is the goal is to have fewer students earn bad grades? Along this line, an instructor might use a systematic analysis of learning outcomes to isolate possible sources of confusion, or identify students' behaviors that might be impairing their success. Another approach to intervention is to seek success, in terms of improving methods that may work well enough, but could work better. The difference between being a good teacher versus not being a bad teacher is complex. Whether attempting to fix existing problems, or trying something new to make a course even better, the key is to act as a scientific practitioner of teaching (McGovern & Miller, 2008; Savory et al., 2007).

Research on Teaching. Methodical reflection on, and assessment of, teaching efficacy is as important as the scholarly approach to research (Savory et al., 2007). There is a false equivalence in the literature between the ideas of scholarly teaching and the scholarship of teaching and learning (Smith, 2008). For some, the sense is that scholarly teaching, wherein instructors conduct systematic analysis of their students' learning outcomes, is done "on the side" of their normal responsibilities, and therefore goes largely unrewarded (Smith). On the other hand, the scholarship of teaching and learning is widely recognized as a legitimate field of study. Smith contends that teachers typically do some kind of analysis of learning outcomes, but do not do so rigorously enough to count as scholarship (by, for example, including control groups). Scholarly teaching does not become scholarship until it is subjected to peer review and publication (Smith).

When using the classroom as a research venue, the same principles of protocol and ethics apply. The process should begin with a literature review, include necessary design elements such as randomization, if possible, data collection, and presentation of conclusions for critical review and dissemination (Smith, 2008). Teachers who know that they are going to be analyzing students' learning outcomes must attain consent from their students in order to include their information in research that might appear in publications (Savory et al., 2007). This must be done with care to avoid being coercive; students are a captive and vulnerable population, in that they may

feel pressured to comply or risk their grade in the course. According to the standards set by the institution's Institutional Review Board (IRB), data collected over the normal course of conducting a class might be exempt from review, but it behooves the instructor to check published parameters for use before making any assumptions. If the instructor is conducting the research for his or her personal growth, the IRB may not require a review (Savory et al.). Likely, the IRB will require that any information (i.e., grades) be de-identified before inclusion in research, to ensure the anonymity of the student participants, if the results are meant to be published.

Expert teachers wishing to introduce innovations or interventions into their courses may want to formally experiment with it, in order to increase scientific rigor (LoSchiavo, Shatz, & Poling, 2008; Savory et al., 2007). There are different ways to do this type of manipulation. First, a teacher who has more than one section of the same course might have students in one experience the intervention, and compare them to their peers in the other section as a control. The possible downsides of this strategy are both methodological and ethical in nature. First, in order to conduct proper experiments, there must be random assignment of participants to each condition (LoSchiavo et al., 2008). Students who enroll in different sections of the same course may differ from each other in some systematic way, which would introduce confounds to any conclusions drawn from the results. Furthermore, if a teacher thinks that he or she knows how to provide a better learning experience for his or her students, then it should not be withheld from some students while others benefit from it (Tomcho & Foels, 2008). Within-subjects designs, such as pretests and posttests, are a way to circumnavigate ethical quandaries of this nature (Tomcho & Foels). LoSchiavo et al. extol the virtues of online technology (such as web-based course management systems like BlackBoard) for allowing teachers to engineer random assignment or management of groups. They also suggest that in-class manipulation of interventions can be done by splitting a class period in half and having half the students attend one or the other portion. Another way to experimentally manipulate interventions is to do so across semesters, using a longitudinal comparison for the baseline measurement or control condition (Gibson, 1992). In this case, the instructor offers the same quality of educational opportunities to all of his or her students, without sacrificing the opportunity to test the efficacy of a new method empirically. Finally, when class time or size renders experimentation impractical, individual demonstrations or activities can be tested on volunteers drawn from a departmental participant pool of students (LoSchiavo et al.).

While disagreement remains over the ability of student evaluations to determine a teacher's quality, course evaluations do offer a wealth of information that can be mined for analysis (Gibson, 1992). Summative information, from statistical analysis of students' ratings for different elements or characteristics of the course or instructor, identify whether there is a problem that needs to be addressed (Boice, 1992). The formative information gleaned from student evaluations, including responses to open-ended questions, can identify areas in need of attention (Gibson). In the case of experimentation with new methods, course evaluations can serve as a source of students' subjective feedback on their experience (Boice), in contrast to objective measures of learning outcomes in the form of grades and scores (Tomcho & Foels, 2008, for a discussion on the utility of exam scores as dependent variables). Instructors should tailor their evaluations to probe the specifics of the course, instead of relying upon the standard and sometimes rather general evaluations used by default in the department.

Instructors engaged in scholarly teaching can further benefit from in-house grants for developing teaching innovations. Many schools set aside funds for teachers to use in pursuit of improving their methods and techniques or developing new courses. For instance, the authors'

institution offers instructors funding for developing new online summer courses, as the needs of modern students prompt the university to further diversify its course offerings. Institutional support for these endeavors may encourage more experienced instructors to adopt an evidence-based approach to their teaching, which they might not have otherwise been motivated to do. These small grants can be seeds for developing long-term programs of research, which can then yield publications and conference presentation opportunities. The more teachers think of teaching as a scholarly activity, the better their students are served.

Programs for Teaching Development. In addition to funding for teaching research, many institutions offer formal programs for their teachers' professional teaching development (Boice, 1992; Gibson, 1992). This support might manifest as a peer-review network that provides teachers with an organized method for acquiring special student evaluations in the forms of mid-semester questionnaires administered by a third party, colleagues willing to observe classes and offer feedback, and feedback on teachers' reflections and materials. Boice recommends that campus initiatives to improve teaching quality begin with basic skills, teach critical thinking and evidence-based approaches, and offer advice for developing resilience to disappointment. Teacher development programs will also generally supply instruction as to how to go about making learning outcomes more visible. One of the tools that is helpful in tracking growth over time is the teaching portfolio (Bernstein, Burnett, Goodburn, & Savory, 2006). Portfolios are typically overarching collections across a teacher's entire repertoire of courses and materials, including evidence of the efficacy of those methods in the form of self-evaluation and assessment of learning outcomes (Bernstein et al., 2006). Portfolios also include summary statistics from student evaluations, or brief entries describing the development of certain techniques. In contrast, a narrower course portfolio is a collection of the elements of a single course (e.g., syllabus, assignments, etc.), including the reflections on how the course design, structure of elements, and assessments all worked toward student learning (Bernstein et al.). It is useful for peer reviews of teaching efficacy because it comprises the whole picture of what went on during a single course. As part of a peer-review process, course portfolios can be used across disciplines to further or deepen conversations about different methods, objectives, and assessments that best promote student learning for individual teachers or for departments or institutions looking for evidence to support their procedures and projected student learning outcomes. As a tool, portfolios are useful either for instructors' independent professional development, or for use in promotion or award considerations.

21.4 Summary

Although teaching is sometimes treated as the least important activity on an academic's priority list, as a component of any academic clinician's professional responsibilities, teaching should be undertaken with the same kind of purposeful rigor with which research, service, and clinical practice are pursued. It takes considerable time, effort, and heart to acquire the repertoire of materials, abilities, and habits of a competent teacher. Basic skills underlie the foundation of competence, while more complex and sophisticated teaching methods and materials can be built up from that establishment as professionals gain experience. At the same time, high-quality teaching may come more naturally for clinicians than for other types of psychologists. After all, like clinical work, teaching is all about learning to listen and supply useful information at useful times. In that respect, teaching can be viewed as an extension of clinical skills, and

clinicians should take full advantage of those skills as they develop a teaching approach. Moreover, clinicians know the value of basing their practice decisions on the research literature, and so, again, need only apply this to teaching to realize the importance of keeping abreast with changes and improvement in teaching practices. In other words, the behaviors that comprise teaching competency should be practiced, informed by empirical evidence, and subject to the same kind of scrutiny as other scholarly work.

22 Management and Administration

Philinda S. Hutchings · Deborah Lewis · Ruchi Bhargava

Abstract: Clinical psychology competencies in management and administration are often considered to develop in advanced stages of careers, but these competencies are developing at all stages. In addition, although management and administrative functions are often considered ancillary to the practice of clinical psychology and are not acquired through formal instruction, they are central to successful practice; regardless of skill in assessment and intervention, for example, the psychologist who does not perform well in the management and administrative functions of practice will have difficulties. Four areas of competency in management and administration are described; planning and organizing work; administration; leadership; and executive management. Planning and organizing work includes abilities to plan and organize tasks for self and for others, skills and activities in time management, professionalism, and adaptation to change. Administration includes knowledge and skills in business, marketing, and finance, organizational and community systems, ethical and legal policies and procedures, quality improvement, and information management. Leadership includes vision and mission development, skill in providing guidance and direction, and characteristics and attitudes appropriate for leadership in clinical psychology. Executive management includes skills in management of personnel and resources, provision of oversight, team development, and organization and systems management. The knowledge, skills, and activities within each of these areas are described and discussed at basic and advanced levels of competence.

22.1 Overview

Students in clinical psychology training programs rarely think about developing skills in management and administration, since their classes and assignments do not typically focus on this area. They study assessment and intervention skills, research and evaluation, and integration of science and practice. In fact, sometimes psychologists receive management and leadership training after they are placed in such positions rather than in graduate school (Picano & Blusewicz, 2003). Skills in management and administration are sometimes regarded as implicit in or incidental to becoming a skilled practitioner or researcher, but the focus and skill in client care are very different than those in organizational leadership and management (McAlearney, Fisher, Heiser, Robbins, & Kellerher, 2005). Even though our education and training programs have not kept pace with some of the dynamic shifts in the business of health care as they concentrate on training practice and research skills (Hoge, Tondora, & Marrelli, 2005), there is a growing recognition that competency in management and administration is necessary, not just because psychologists move into management roles in health-care organizations (Picano & Blusewicz), but in order to effectively practice (American Psychological Association [APA], 2007a; Hatcher & Lassiter, 2006; National Council of Schools and Programs of Professional Psychology [NCSPP], 2007). This part of a psychologist's professional role can

make or break a practitioner, because if the practice is not well managed, even a skilled clinician cannot continue to function. There are also implications for agencies that hire professional psychologists presuming that they have expertise in managing other mental health professionals, but only to find that their doctoral programs did not include training in management.

Since professional psychologists are more often called upon to assume management and administration roles (Hoge et al., 2005; Picano & Blusewicz, 2003), sometimes, soon after completing the doctoral degree, if specific training in management and administration skills were included in the doctoral curriculum, students would be better prepared to function in these roles. Some doctoral programs may offer electives in such areas, but exposure to the body of knowledge in this area is not a requirement for APA accreditation (APA, 2007b). In recognition of the fact that addition of at least practice management skills would be very useful to early career professional psychologists, NCSPP, APA Practice Directorate, and APA Division 42 (Independent Practice) collaborated in 2007–2008 to create a model syllabus on practice management, listing topics and resources (NCSPP, 2008). Some of the topics include entrepreneurship and business strategies, creation of a mission statement and business plan, business strategies and decisions for private practice, marketing strategies, practice finances and maintenance, office space, policy issues, documents and record-keeping, insurance issues, health policy issues, technology and communications, and preparation for leadership and administrative positions.

Some students may question the need to acquire knowledge or skill in management and administration, since at the beginning of their graduate education, they do not aspire to leadership or management positions. Some may even question whether everyone will be able to acquire these skills or will have the temperament for such positions. This is true even in the more traditional skill sets of the professional psychologist. All students study assessment and intervention skills, even when they practice, some will only use certain tests and not others, some will limit their practice to psychotherapy, while others pursue neuropsychological assessment, and some will engage in a broader range of assessment and intervention services. We assert that all students need to acquire a basic set of skills for entry to practice, and we think it is likely that many professional psychologists will go on to acquire at least a subset of advanced competency in management and administration as they advance in their careers. At the very least, they should be able to identify and promote good management and administration practices regardless of the setting or position of employment.

While the inclusion of some management and administration knowledge and skill development in the doctoral curriculum may require a change of attitude and/or a change in the training of faculty members, we do not propose that all professional psychologists become experts in business administration. Students of professional psychology enter the field typically because they are motivated to help people rather than because they are interested in business or finance. However, service provision is a business, and some business acumen is required in order for even the most altruistic service provider to continue to provide services.

Competency has been defined as "a measurable human capability required for effective performance" (Hoge et al., 2005, p. 511). Perhaps the earliest attempt to define and measure competency in administrative and management skills was the Chinese empire system of civil service examinations over 3,000 years ago. In modern times, early descriptions of management and administration came from the realm of business and manufacture during the industrial revolution (Russakoff, 2003). Administrative theories continued to develop throughout the

20th century, and the tasks of management and administration included "planning, organizing, staffing, directing, coordinating, reporting and budgeting" (Russakoff, p. 57). The application of administrative theories to health-care services must accommodate changes from management of manufacture by skilled or unskilled labor to the management of service provision by professionals, but the tasks described are quite similar. The definitions of the terms management, administration, and leadership are often used interchangeably, but there are some differences between them. Administration generally refers to routine tasks associated with work, while management implies a broader area of responsibility, often including oversight of others (Veenhuis, 2003). Leadership implies venturing into the unknown territory and/or motivating workers, while management applies to maintenance of established endeavors. Yet, leadership is often included in descriptions of management: "The practice of management is in essence leading, planning, organizing, and maintaining operations; monitoring results; and making corrections as necessary" (Veenhuis, p. 103).

There are many descriptions of the activities of management and administration. We have organized them into four areas of competency: (1) planning and organizing work; (2) administration; (3) leadership; and (4) executive management. There are tasks that overlap more than one of these competency areas, but we describe the characteristics of each area as distinct from the others. After a brief description, we provide a bulleted summary of the basic and expert competencies in these areas. Then, detailed descriptions and examples of the basic and expert competencies in each area are provided.

22.1.1 Planning and Organizing Competency Summary

Planning and Organizing includes timely completion of tasks, time management, prioritization of work, strategic planning, delegation of tasks and oversight of workers, implementation of work toward goals, and organization of the components of work. The design of work strategies in order to complete tasks by their deadlines requires orientation toward the future and recognition of the amount of time to be devoted to the components of the tasks (Veenhuis, 2003). At its most basic level, this may include arriving promptly for appointments with clients and organizing the daily workload with time for writing therapy notes and reports (Hatcher & Lassiter, 2006). Setting priorities for task completion and effectively using the time available require recognition of the relative importance of practice components and the responsiveness to changing priorities (NHS Education for Scotland [NES], 2006). Strategic planning involves predicting trends, planning for future development, and identifying the resources required to accomplish goals and objectives (Veenhuis). Planning and organizing work for other workers involves assignment and delegation of tasks, and this includes oversight of accomplishments. Awareness of organizational requirements and implementing tasks focused on goals is an integral function of planning and organizing, similar to a process called "initiating structure," described in early industrial leadership studies (Steger, Woodhouse, & Goocey, 1973).

Planning component:
- Basic competency includes the ability to plan one's own work, understand the purpose of meetings, and participate appropriately.
- Expert competency includes the ability to plan work for others, formulate strategic plans, plan and conduct meetings, and link structure and function.

Organizing component:
- Basic competency includes the ability to organize and manage one's own workload and balance self-care with work demands.
- Expert competency includes the ability to organize and coordinate work for others and initiate structure.

Professionalism component:
- Basic competency includes the ability to complete tasks in time and comply with policies and procedures.
- Expert competency includes the ability to set reasonable deadlines for others and create policies and procedures.

Flexibility component:
- Basic competency includes the ability to adapt to change.
- Expert competency includes the ability to forecast change and plan for contingencies.

22.1.2 Administration Competency Summary

Administration includes financial and fiscal management issues, economics, budget development and monitoring, information management, regulations, standards, and compliance oversight. The skills of administration are found at all levels of management, including the supervisory level, program management level, and executive management level (Patti, 1983). Paying bills and collecting fees are basic tasks in fiscal management (Wiger, 2007). More advanced skills may pertain to the ability to develop a budget and monitor revenue and expenditures, which are central to the financial health of a practice or organization. Providing information to the public and potential referral sources about services in marketing strategies and creating maintaining service records are skills that the advanced administrator should obtain. Additionally, there are a variety of standards and regulations that apply to practice and record-keeping (APA, 2007c), for accreditation of organizations and electronic communication of records and billing (Wiger). Policies and procedures of the organization and funding sources must be recognized, followed, and communicated to employees. Administration includes oversight of compliance with various standards and regulations, policies and procedures, and quality control and improvement principles.

Business, marketing, and finance component:
- Basic competency includes knowledge of health-care fees, billing and reimbursement, the ability to inform the public about services, understand liability and other insurance, and function within a budget and understand a business plan.
- Expert competency includes skills in budgeting and financial management, knowledge of accounting principles, market research and advertising, ability to maintain insurance and financial records, entrepreneurial skills, and ability to develop contracts.

Organization and community systems component:
- Basic competency includes understanding of organizational function and hierarchy.
- Expert competency includes ability to develop organizational function, hierarchy, and governance, establish systems, maintain and monitor operations, direct organizations, and cooperate with communities.

Policies and procedures, ethical and legal issues component:
- Basic competency includes the ability to conform to policies and procedures and guidelines, and knowledge of legal and ethical requirements.
- Expert competency includes the ability to develop policies and procedures in accordance with the ethical and legal requirements, knowledge of public policy, and the ability to integrate these in program planning and implementation.

Quality improvement component:
- Basic competency includes the ability to use information to monitor and improve quality and conduct individual outcome assessment.
- Expert competency includes the ability to conduct program evaluation, develop record-keeping methods that aid monitoring of quality, and conduct organizational outcome assessment.

Information management component:
- Basic competency includes information literacy, the ability to organize and present information, and verbal and written communication skills.
- Expert competency includes the ability to develop information systems and implement lines of communication throughout organizations.

22.1.3 Leadership Competency Summary

Leadership focuses on development of vision, values, and mission; goal-setting; policy development; and guidance or motivation of workers. Developing a clear vision of the goals to be achieved and communicating that vision to others with a set of values are the responsibilities of a leader (Reid & Reid, 2003). Then, the leader translates the vision to a set of goals to be accomplished and motivates others to accomplish them. Leadership also involves team-building and inspiration in task-oriented activities, and responsibility or accountability for the outcomes. Personal characteristics are important because effective leadership requires engendering trust; trust must be earned. Leaders are empowered by followers (Russakoff, 2003), and must be mindful that any power or authority to lead depends upon the support of followers.

There is a much larger body of literature on styles of leadership which is beyond the scope of this chapter. Although leadership style is important, especially to followers, and has been studied extensively, the focus of this chapter will be on the leadership competencies in psychology rather than on the styles or personality characteristics of leaders.

Vision, mission, and purpose component:
- Basic competency includes the ability to articulate mission, and set and pursue goals.
- Expert competency includes the ability to develop and create missions, goals, and objectives, and to motivate others.

Guidance component:
- Basic competency includes the ability to provide direction to peers and participate in policy development and change of public policy.
- Expert competency includes the ability to provide direction to others, build teams, coordinate multidisciplinary efforts, and develop skills in advocacy.

Leadership characteristics component:
- Basic competency includes the ability to be trustworthy, reliable, and resourceful.
- Expert competency includes the ability to engender trust, be consistent, recognize achievement and performance, and resolve conflicts.

22.1.4 Executive Management Competency Summary

Executive Management has to do with oversight and development of other workers and facilities. It includes resource management, personnel, human resources, facilities management and maintenance, interagency and consumer relations, and systems management. Executive management is not to be confused with clinical supervision, which involves training clinicians to develop increasing skills in psychological service delivery. Executive management involves supervision and oversight of operations, professionals and other staff. There are many styles of management (O'Donohue & Fisher, 1999) that may describe different managers in various settings, some of which are more effective than others, but regardless of the style, executive managers are responsible for similar activities.

Human resources and personnel component:
- Basic competency includes the ability to recognize staff roles and functions, manage one's own career, and negotiate one's own compensation.
- Expert competency includes the ability to recruit credential staff, and negotiate benefits and compensation, promotion, discipline, conflict resolution and termination.

Oversight and development component:
- Basic competency includes the ability to provide direction appropriately and promote individual conflict resolution.
- Expert competency includes the ability to train and evaluate staff and promote systems conflict resolution.

Team development and management component:
- Basic competency includes the ability to recognize contributions of team members and work cooperatively with others.
- Expert competency includes the ability to build and manage interdisciplinary teams, set expectations for performance, and monitor progress.

Organizational and systems management component:
- Basic competency includes the ability to use resources wisely and function within organizational structures.
- Expert competency includes the ability to obtain, allocate, and shepherd resources, and implement organizational structures and hierarchy.

22.2   Basic Competencies

22.2.1 Planning and Organizing

In the area of planning and organization, there are several essential skills that should be demonstrated at the basic level. Psychologists need to be able to develop plans to accomplish goals,

including identifying the steps necessary to reach goals and the order in which they should be attempted and achieved. Then they need to recognize the amount of work they need to accomplish and plan their time accordingly. This forms the rudiment of strategic planning, and understanding the purpose of strategic planning is one of the basic competencies expected of psychologists before entry to practice (Hatcher & Lassiter, 2006). Planning is not as simple as it may appear on the face, even though most students in psychology have been exposed to the process. Students are aware that they need to take a series of sequenced coursework and activities in order to receive the doctoral degree in professional psychology, but they are rarely aware of how the sequence and content of the coursework and activities were assembled in order to produce a professional psychologist with the requisite knowledge, skills, and attitudes. This is a rather complex goal, one usually planned by experts, but beginning psychologists have had some experience in similar tasks. They have often had the opportunity to plan scholarly works, such as dissertations. Planning a dissertation requires identifying resources, addressing a question, developing a method to test the question, carrying out the method, and examining the result. In both large and small tasks, planning is an essential skill.

The ability to plan applies to both individual efforts and cooperative efforts, such as teamwork and meetings. Understanding the purpose and structure of meetings and participating appropriately and constructively in order to accomplish tasks are included in planning. Students and psychologists need to be prepared for meetings. Such preparation may include gathering and/or presenting needed information or materials, using the meeting time efficiently by addressing the tasks at hand and not distracting the participants with irrelevant conversation, and offering information and skills to promote task completion. One might expect that the ability to use time wisely is implicit in the functioning of anyone who has managed to complete college studies, but many training activities and priorities are planned for students. New practitioners may find themselves having to structure their professional obligations for the first time, and they will need to set priorities and organize their own time to accomplish their assigned tasks.

At its most basic level, organizational skills including organizing one's day, including setting time for essential activities, such as meeting with clients, recording notes, writing reports, and for rest and recovery (Hatcher & Lassiter, 2006). Beyond organizing a day's activities, long-term and short-term scheduling ability is required, such as planning for vacations, conferences, meetings, and budgeting enough time to accomplish necessary tasks. Students often learn to budget time for reading, writing professional papers, and completing other class assignments. This requires some self-awareness and knowledge of how long it takes to accomplish certain tasks. Students are often encouraged to record course assignments in a day planner, and work backward from the deadlines to schedule the time to accomplish parts or stages of the assignments. Advanced students often encounter some difficulty structuring their time effectively when faced with relatively unstructured tasks, such as writing a dissertation. Scheduling and budgeting time in order to meet educational demands are required to complete the degree.

Organizing time and activity in order to meet demands of the agency or practice continues through the levels of training to the level entry to practice (APA, 2007a), and requires the ability to manage one's own workload (NES, 2006). Students may find it difficult to balance the demands of work and self-care, motivate themselves, and create their own structure, but at the level of entry to practice, psychologists are expected to be able to effectively organize their time and work. Practicing psychologists may need to adjust their schedules for crises and unexpected demands, such as family emergencies, urgent client needs, and even weather and traffic disruptions. Flexibility and accountability are likely to be required.

Planning and organizing also requires a set of skills that might be described as professional behavior. Basic competency in these skills requires timely completion of tasks, meeting deadlines for assignment completion, and arriving in time for appointments and meetings (Hatcher & Lassiter, 2006). It also requires prompt response to the requests and demands of the supervisor, agency, or third parties (APA, 2007a). Psychologists should develop a disciplined approach to writing and maintaining records from the point of entry to practice (Hatcher & Lassiter), whether they choose to work in an agency or in private practice. Although there may be no rules or ethical guidelines about time limits for documentation, evaluation reports should be written and placed in the chart promptly, certainly within the time frame that constitutes the standard for the area of practice. Psychotherapy progress notes are often most productive and accurate, if written immediately after the session, and certainly by the next day. Some jurisdictions may impose deadlines for such documentation, e.g., Arizona requires that progress notes be written on the day that service is delivered (Arizona Administrative Code, R9–20–211). Awareness of and compliance with the APA Record-Keeping Guidelines (APA, 2007c) as well as federal, state, and agency policies and procedures are included in the basic competencies of beginning practitioners.

Students often find documentation requirements rather daunting, because their lack of familiarity with the process means that they take longer to write notes and reports than experienced psychologists. If they get into the habit of documenting their services promptly, they are likely to continue to do so as they become more expert and advanced in their training. If they fail to do so, they run the risk of sanctions that interfere with their practice and professional development. Practitioners who fail to comply with documentation deadlines may not receive repeat referrals, have delayed payment for services, or even have privileges suspended or revoked, and may face other penalties. So, development of a disciplined approach to documentation is a basic competency expected by entry to practice.

Finally, plans change in response to changing markets, strategies, agencies, and supervisors. The ability to adapt to changes in plans, accommodate interruptions, and remain focused on task completion is a basic competency expected of psychologists (Russakoff, 2003). Students often encounter such changes in the process of completing a dissertation or other scholarly product. Such tasks often seem simple and straightforward in their early development, but students almost inevitably encounter difficulties in the course of their studies and are required to adjust the course in a variety of ways. An attitude of persistence in the face of obstacles and adversity is essential if one is to be successful.

22.2.2 Administration

Administrative skills keep organizations functioning effectively, involving all of the necessary but ancillary activities surrounding the central endeavor; these activities include business, marketing and finance, organizational and community systems, ethics, legal issues and policies, quality improvement of service delivery, and information management. There are several foundational skills and abilities that contribute to all administrative efforts, including good oral and written communication, interpersonal skills, judgment, and understanding of cultural and individual differences.

Most students of psychology receive little formal training or information about business principles, marketing strategies, or financial management. Most early development in this

competency comes from supervised practice and experience, or "the school of hard knocks." Basic competency in this area includes knowledge of consumers of psychological services and activities such as answering the phone, setting up appointments for services, setting, negotiating, and collecting fees and payments, and paying bills (Gaver, 2000; Hatcher & Lassiter, 2006; Wiger, 2007). Understanding of health-care insurance and third-party payer requirements for records, billing, and reimbursement is essential at the level of entry to practice. Beginning practitioners must have a basic understanding of the financial operations of psychological services, how to set fees for service, how money is obtained, what is required to collect it, and how it is disbursed, as a business model for health care (Hatcher & Lassiter; Kiesler, 1999; McAlearney et al., 2005; NCSPP, 2007). Students are often uncomfortable with the idea of talking to clients about fees for service. They are focused on helping clients feel better or overcome difficulties, and to many students, talk of fees, billings, and collections seem far removed and even antagonistic to the clinical process. However, with practice and supervision, they can overcome this discomfort, and find that negotiating fees and payments can be as straightforward and useful as ensuring informed consent for treatment and sharing records and information with other providers; it is not antagonistic to the clinical process, but is a necessary activity to allow the clinical process to take place. One colleague joked that the term "professional psychologist" was a good one, because it implies that the psychologist is paid, as opposed to an "amateur psychologist," who presumably provides services as a hobby. Psychologists often deal with other sources of payment and they need to be able to understand and fulfill contracts for such services, e.g., with schools, attorneys, or governmental agencies.

Practitioners must also have a basic understanding of the purpose and importance of liability insurance and how to maintain it (Gaver, 2000). There are other basic costs of operating a practice, and budgeting expenses becomes an important facet of business. Basic financial competency includes the ability to function within a budget, given an understanding that expenditures must not exceed revenue, and identification of resources in order to develop a business plan (APA, 2007a). A basic business plan includes these components: the services or product to be offered, the consumers identified, fees set and revenues identified, resources necessary to offer services or product, and the costs of service provision or production. Although few beginning psychologists would assert that they have the knowledge or skill to develop a business plan, most of them often do as they open a practice or go into practice with a group.

Making potential clients aware of services offered forms the rudiments of marketing. Basic competency in marketing includes an understanding of referral sources and the information that must be provided to them, including levels of training and areas of practice competency. Providers must learn how to confidently describe the level and quality of their services, appropriately evaluating their skills and articulating descriptions of the range, scope, and availability of services offered. Early career psychologists may need to overcome reticence and a degree of shyness to be able to market a practice; learning to "toot one's own horn" is not bragging. Accurate and descriptive marketing may require beginning psychologists to present their strengths to referral sources, an activity outside of their comfort zone. Some awareness of marketing methods is necessary, in order to attract clients to the services offered (Gaver, 2000), and may include applying for membership on insurance panels, developing brochures or fliers to describe services, and developing strategies to distribute brochures. It also requires understanding of ethical and legal guidelines for advertising. Several sections of the ethical principles of psychologists and code of conduct refer to standards on paid and unpaid advertising, media presentations, and information presented on Web sites and through electronic

means (APA, 2002; 5.01–5.06). Truthfulness and accuracy are what are expected in curriculum vitae, directory listings, brochures, printed materials, and oral presentations.

In order to provide essential and effective services, psychologists must have a basic understanding of the organizational and/or community system within which they work (Fraser, 2003). In a clinic or institutional setting, an understanding of the system includes how patients/clients enter, register, wait, turn in forms, make appointments and payments, and exit. It also includes awareness of the system hierarchy and contributions of other professionals, staff, consultants, and others. At the point of entry to practice, psychologists should be aware of how their work fits into a larger schema of community resources, and have some understanding of where clients can obtain needed services that the psychologist does not provide. Psychologists should have some basic understanding of group and organizational process (Fraser).

Within the profession of psychology, there are ethical and legal principles designed to guide behavior, creating boundaries and structure, and within every organizational setting, there are standards and policies, regulations, and procedures. One of the first things new employees are likely to be required to do is to read the organization's policies and procedures manual. Knowledge of policies and procedures, ethical issues, and the ability to conform one's behavior and practices to these rules is a basic competency (APA, 2007a; Wiger, 2007). At the level of entry to practice, it is essential that psychologists have knowledge of the legal and ethical requirements for maintenance of records (NES, 2006) and the APA guidelines for keeping records (APA, 2007c). They must also be familiar with legal and ethical requirements for delivery of professional services. This may include case law and risk management strategies (NCSPP, 2007). In general, at the point of entry to practice, psychologists should be familiar with the principles and regulations that apply to practice and be prepared to function in compliance with them, avoiding transgressions of omission and commission (Scott, 2000), and able to integrate these principles and regulations into implementation of programs (NCSPP).

Quality improvement principles, especially as applied to service delivery, are included in administrative competencies. At the most basic level, psychologists should be able to monitor the efficacy of their services and take steps to improve the quality of services as indicated. This may include devising methods of measurement, setting goals for training and learning, monitoring and evaluating outcomes, and incorporating process changes in service delivery to improve outcomes of their own services (World Health Organization [WHO], 2003). While they should be able to keep accurate records as discussed earlier, they also should be able to use documentation and records to assist them in quality improvement efforts (Kapp & Mossman, 2000). Students may be introduced to this process as they are encouraged to monitor the progress of their clients in psychotherapy or other interventions, which is basically a quality improvement strategy. If the client does not improve, the intervention should be modified, and if the client does improve, the intervention may be maintained. Basic quality improvement skills involve generalizing this process to the aggregate of clients or the organizational system. Applied to the aggregate, monitoring progress may suggest continuing education or training in some area of practice, modification of practice strategies, or modification of organizational systems.

Information management has become an important area of administrative competency with the expansion of computer and information technology. While personal and professional communication skills remain important components of all professional services (Veenhuis, 2003; Wiger, 2007), information literacy and the effective use of technology as applied to professional practice have become essential (Levin, Hanson, & Kuppin, 2003). Many organizations

are converting to electronic records. Although small organizations and private practices continue to use paper records, many functions have become computerized. Basic understanding of computer information systems and management of information to facilitate organizational functioning (Freeman, 1999) and knowledge of regulations governing electronic records are part of administrative competency for beginning practitioners. Although many students and beginning professionals have far more sophisticated understanding and facility with computer technology than their older supervisors, they may need to learn to use the computer information technology in the discourse community of psychology. Some students and early career psychologists have had to deal with removal of embarrassing photos or information from public access Web sites as they move into professional positions, and may have to modify their use of casual language and emoticon symbols in professional communications.

At the beginning levels, skills for effective communication in addressing and resolving conflicts with peers and supervisors (Patti, 1983) and to ensure clear understanding of administrative tasks as well as professional presentations and reports (Hatcher & Lassiter, 2006; Wiger, 2007) are expected. Working groups must establish lines of communication in order to cooperatively accomplish their assigned tasks or their goals and objectives. Conflicts naturally and inevitably arise, and although effective communication does not ensure resolution, it is necessary to attempt resolution.

22.2.3 Leadership

Leadership is usually seen and developed at an advanced level, and most students in psychology training programs do not think of themselves as leaders or as developing leadership skills. However, the groundwork of leadership competency is developed relatively early. Leadership involves moving into new areas or activities, rather than maintaining familiar or established ones. One may think of leadership as involving a large number of followers, but leaders may lead only one or a few. The number of followers does not determine the skills or functions of the leaders, and leaders may also be followers of other leaders, in a chain, hierarchy, or cooperative organization of responsibility.

Since part of leadership involves creating a vision, purpose, or mission for psychological services, basic competency in leadership requires the ability to articulate the primary mission of the organization (NCSPP, 2007), and to reconcile this mission with personal goals. As a student embarks on their supervised training experience in practicum in a state hospital, for example, the student needs to understand that the mission of the hospital is to care for the seriously mentally ill residents of the state. The student needs to be able to understand how supervised training in this environment with these patients serves his/her personal goal of developing skills in professional psychology. It is not always easy for the student to understand this, especially if his/her personal clinical ambitions lie with other clinical populations or services. But eventually, the student usually realizes that some basic clinical skills are ubiquitous and can be learned in almost any setting, such as the ability to develop rapport, conduct a clinical interview, and develop a treatment plan and implement it.

Even in their early training, psychologists should be motivated and responsive, understand the context of work and training, establish and maintain a positive attitude, and be responsive to internal and external pressures (Russakoff, 2003). If students entering doctoral programs listed all the readings, assignments, tasks, papers, examinations, and supervised practice

training experiences they would need to complete by the end of their doctoral training, would they embark upon the venture? That might be overwhelming, so most students limit their lists of tasks to one term or year at a time. Still, it may be hard for some to maintain their focus on the reasons they set upon the course in the beginning, to become a professional psychologist. The ability to maintain focus upon the mission and goals and persevere in the face of obstacles is one of the necessary qualities of leadership. It is equally important in developing a practice in early career stage as it is in graduate training.

Most students in training voice relatively nonspecific career goals, such as the practice of psychology, work with adolescents, or teach psychology. However, by the point of entry to practice, they are able to formulate more specific goals, such as developing a hospital and out-patient practice, focusing on children and adolescents, or teaching Developmental Psychology courses as an adjunct professor at a local college. They also may be able to develop a mission for an organization or a group, and set specific goals for that purpose as well as for their personal careers. Students often involve themselves in service organizations and efforts, volunteering to organize events to raise funds for charitable purposes, to advocate for improved conditions, or to accomplish related goals. For example, a student in practicum at a women's prison became aware of the need for education in breast cancer screening and treatment as she was providing psychotherapy to a woman recently diagnosed with breast cancer. The student obtained permission from the prison administrators and contacted the local cancer society to arrange for a volunteer to come to the prison regularly to talk to the inmates about self-examination, diagnosis, and treatment of breast cancer. Recognizing and responding to a need and setting specific goals to accomplish a mission or purpose is a basic leadership competency.

Leadership involves providing guidance and direction, and basic competency in leadership includes the capability to provide direction to peers and staff when appropriate (APA, 2007a). For students, this may involve mentoring junior students and providing direction to peers, but it may also involve participation in the development of policies. Student leaders may be involved in governance, representatives to faculty organizations, or involved in student professional organizations at the state, regional, or national level, such as the American Psychological Association of Graduate Students (APAGS). At the point of entry to practice, psychologists should understand the principles of the policies and procedures for organizations, and be willing and able to take an active part in developing or changing policies, including public policy, that have an impact on their clients, their services, or the profession (NCSPP, 2007). Willingness to advocate on behalf of the profession and those they serve with regard to policy and personal action is a basic leadership competency. Such advocacy may take the form of participating in professional organizational efforts to improve health care, or, for example, the 2000 rally by graduate students in psychology at the APA convention to gain recognition for the amount and worth of services provided by graduate assistants (Chamberlin, 2000).

Multidisciplinary teams in health-care settings include a variety of professions, and psychologists may be one of a few of these trained at the doctoral level. So, other professionals may look to the entry-level psychologist to lead research and evaluation efforts, program evaluation, or sophisticated assessment and psychotherapy efforts, because of their comparatively advanced level of education and training. In this case, other health-care professionals seek guidance and direction from the beginning psychologist in the area of their education and training, and recent psychology graduates may find themselves chair committees or task groups.

Leadership skills include engendering trust (Russakoff, 2003); so, a basic competency in leadership is the capacity to be trustworthy. This is demonstrated by consistency in performance,

reliability, accountability, and responsibility within functions and operations. An unreliable leader who betrays the trust of his/her followers, or worse, exploits them, may be abandoned. The beginning leader promotes the institution to both internal and external audiences and behaves in ways that are consistent with the stated mission and purpose. Leaders are inspirational and help to motivate workers (Steger et al., 1973), so beginning leaders help to motivate peers and team members as well as themselves. Without followers, a leader is simply an individual marching off into the wilderness, so a basic attitude of accountability to followers and the ability to share the vision in order to motivate others are essential as a basic competency in leadership.

22.2.4 Executive Management

The transition from clinician to clinic manager is one that usually takes place at an advanced level of practice, ironically transporting the seasoned clinician into the rather unfamiliar world of management. Again, this is an area or competency not usually included in the doctoral program curriculum, although management of mental health systems seems to become more complex and demanding every year (Drum, 1999). Mental health care might be characterized as a turbulent field, in which uncertainty, complexity, and unexpected change make management tasks more difficult. Executive management competency involves oversight of other workers and resources, such as human resources, facilities management, and systems coordination.

Human resources and personnel management is a major area of executive management. Basic competency in this area is awareness of the functions of various staff, their background and training, necessary credentials, and participation in recruitment and retention efforts. At the basic level, psychologists should have an awareness of the qualities and abilities needed in various staff openings, such as clerical or reception staff, and should be able to participate in screening and selection of staff (Wiger, 2007). Even while they are in doctoral training, students in psychology training clinics need to have an awareness of the support staff functions and the qualities necessary for such positions. Although they will likely not be made responsible for personnel decisions at this level, they may take part in interviews for open staff positions, even with fellow students.

Psychologists should be knowledgeable about the job and performance expectations for various clinical and nonclinical staff positions, so as to be aware when someone is performing well or needs improvement. Psychologists should be respectful of the cooperative contributions of clinical and nonclinical staff (Picano & Blusewicz, 2003). Some students may be confused about this, and behave less respectfully toward administrative staff members than they do with faculty, unaware that such behavior will most likely be communicated to the faculty members and that it may be grounds for disciplinary action. At the level of entry to practice, psychologists are expected to be able to evaluate the performance of support, clerical, and administrative staff members, and be familiar with their roles and expectations for performance.

By the same token, basic competency in this area would include the knowledge of one's own performance expectations, credentialing, and worth. Managing one's own career, seeking advice or counsel from mentors, consideration of the impact of job changes or positions in pursuit of career goals, and presenting well at job interviews could be considered part of this basic competency (Fraser, 2003; Wiger, 2007). Students are often introduced to this process in their

doctoral program as they prepare for interviews for practicum placement and/or internship. Doctoral programs now often conduct training sessions in the nonspecific aspects of internship applications and interviews, including manner of dress and appearance, how to conduct oneself during an interview, how to ask for, and receive, information about the selection process, and what sorts of settings and training sites to include in the search for placement. The training continues as the intern prepares for postdoctoral training or placement, and considers when to sit for the licensing examination and what sorts of positions for which they may choose to apply.

Basic competency in executive management includes an awareness of safety and security measures (Gaver, 2000), and of necessary physical facilities and furnishings. Supplies are needed for office functions, offices must be furnished, and files require file cabinets for storage. These are all basic functions of the executive manager, and even psychologists employed in large organizations or institutions are aware that someone must be monitoring supplies and ensuring that the infrastructure of the organization supports the clinical activities and functions of the agency. The dean of an academic program repeatedly teased the associated clinic directors that part of their jobs involved ordering toilet paper. The teasing might be regarded as demeaning, but the necessity of a continuous supply of toilet paper for the smooth function of the clinic cannot be denied. Although the clinic directors were not directly involved in ordering office supplies, they supervised the staff who monitored and ordered supplies to keep the office running. Someone is also responsible for safety and security measures, and this may include an oversight of security staff, or safety measures, such as evacuations plans, panic buttons, and emergency procedures.

Nonclinical supervisory development is another area of competency in executive management. At a basic level, the psychologist must be capable of providing others with verbal or written direction (APA, 2007a), and should be aware of group processes and lines of reporting (Fraser, 2003). Psychologists in early career stages are often called upon to supervise support staff, such as clinic managers, receptionists, or contract with billing services agencies or answering services. Some basic strategies for conflict resolution are also expected in developing skill in nonclinical supervision (Patti, 1983). At the level of entry to practice, the psychologist should be able to give instructions to staff in understandable language, be aware of the reporting lines involved, so that he/she is not violating organizational hierarchy in giving directions, and should be able to avoid egregious organizational violations in the process. For example, the psychologist should be able to avoid directing her or his supervisor to make coffee, making comments that might be construed as sexual harassment, or promoting disputes between office workers. The psychologist should exercise good judgment as well as clarity in directing others, and so, use power responsibly, taking responsibility along with authority (Steger et al., 1973). Psychologists need to use awareness of personality styles and communication styles to promote cooperation and avoid creating conflict. It is sometimes difficult for the beginning professional to learn that it is not advisable to develop overly friendly relationships with support staff, for instance to go to lunch every day with the receptionist instead of with one's peers, since establishing friendly and cooperative relationships with peers facilitates operations. The early career psychologist, in a hospital, for example, may need to learn to go to lunch in the doctor's lunchroom instead of sitting out in the open cafeteria with nurses and aides, even though it may be uncomfortable at first. Avoiding gossip about one's coworkers and maintaining pleasant, cooperative communication with subordinates and peers is also a skill expected at the level of entry to practice.

Staff and team development is another function of executive management. Early in training, we expect psychology students to develop an attitude that values lifelong learning and motivation to develop professional skills (APA, 2007a; Cohen, Shore, & Mazade, 1991). At the level of entry to practice, psychologists should take responsibility for their learning and professional skills (Steger et al., 1973). They need to be able to set learning goals, seek out opportunities for development, and incorporate feedback. This may require an awareness of organizational requirements for training, such as annual certification in emergency procedures, or licensure requirements for training, such as required continuing education units in certain areas for renewal of the license to practice.

They also need to be good team members, who are knowledgeable about other professions and can work cooperatively in interdisciplinary teams (Nash, 1983). Psychologists should be able to articulate the contribution of their own expertise to the team effort, and be easily managed by others, that is, follow the policies and direction of management to optimize the outcomes of the team effort. Good team members are aware of their own strengths and challenges, as well as the strengths and challenges of the other members. They are willing to contribute their strengths and pass off to other team members the tasks that are best dealt when addressed by others. A poor team member operates individually in the presence of others, neither recognizing nor utilizing the strength of the team. Knowledge of team-building and operations is within the purview of the executive manager. In this process, the beginning manager contributes to the development of self as well as to other team members.

Executive management includes oversight of organizational systems. At the most basic level, one must understand the relationship between the roles and functions of supervisors, managers, and executives (Hatcher & Lassiter, 2006). Students in training often learn about these differences by observing the functions and the people performing them, rather than in the classroom. However, such learning can be very effective, as they operate within training clinics and other settings. Students become familiar with the interaction between budget and fiscal forces and clinical service delivery, between staff support and supervision, and between consumers and providers. At the level of entry to practice, psychologists should be aware of typical organizational charts and how they translate into operations (Veenhuis, 2003). Beginning psychologists, therefore, should recognize the difference between a reporting line and a communication line, and should be able to articulate their purposes. They should know the difference between operations that are organized around function, e.g., medical transcription, and those that are organized around purpose, e.g., the oncology ward. They should be able to identify basic resources, including personnel and facilities, and use them wisely and effectively to serve the organizational purpose.

Basic competency in executive management also requires awareness of basic system structures and how they interact (McAlearney et al., 2005). This allows students and early career psychologists to effectively work within various organizational structures, understand hierarchical relationships and become a multidisciplinary team member (NCSPP, 2007). Early in their training, students learn that it is not sufficient to obtain a client's permission to request records from another service provider and place the signed consent form in the chart. They learn that someone has to send that request to the other service provider and document the delivery and receipt of any information. In some organizations, the student may be the one to do this, while in other agencies, such tasks may be performed by support staff, who must be directed by the student. At the level of entry to practice, psychologists should be aware of the various functions of the parts of the organization. They should know, for instance, to whom

they should report a problem with medical charts, or to whom they should direct a question about how to arrange a patient's discharge from the hospital. They should be aware of the strengths and any weaknesses or difficulties in the organizational functions, and how to address them, overcome them, or compensate for them. In any case, basic competency requires knowledge of the organizational structure to facilitate ancillary and support functions.

22.3 Expert Competencies

22.3.1 Planning and Organizing

Expertise in planning involves the ability to plan beyond what is required for one's own workload. It involves planning for others: organizations, agencies, and systems. While beginners understand the function of meetings and participate constructively, advanced competency includes the ability to plan and run meetings well, develop agendas, gather information and participants, and keep participants focused on the task (Hatcher & Lassiter, 2006). There is, perhaps, nothing quite so frustrating to participants than a poorly planned meeting. The expert planner uses meeting time effectively. In order to do this, the purpose for the meeting must be identified, and the agenda developed, allocating meeting time and resources to accomplish the purpose. Resources, such as materials, literature, and information, must be gathered and distributed to participants, either in advance if preparation is required or at the meeting. Then the expert must manage the process of the meeting, allowing sufficient time for discussion and bringing participants back to the purpose when they inevitably stray without stifling good ideas and comments.

Experts in planning understand the process of strategic planning, including forecasting future trends, planning to acquire resources, outlining the necessary objectives, and implementing work toward the organization's mission, goals, and objectives (Veenhuis, 2003). Strategic plans for organizations must link structure to function (Russakoff, 2003), so that organizations are able to perform the expected functions. For instance, if an agency decided to provide integrated health care including psychological services in primary care, consideration might be given to the structure of the service area. Traditional, colocated structures would have a psychology clinic separate from the primary care or medicine clinic, in two, separate or "silo" spaces. A structure that would facilitate integrated care would be to share the service space, so that psychology interview rooms are directly adjacent to or in the same space with primary care or medicine examination rooms to increase the interaction between physicians and psychologists. Similarly, an organizational infrastructure that facilitates integrated care would avoid "silo" reporting infrastructures in favor of integrated ones, such as creation of multidisciplinary teams focused on patient populations, rather than creation of discipline-specific teams.

Strategic planning includes developing strategies to ensure that programs consistently provide appropriate, timely services to consumers in an ever-changing market (Patterson, 2000). Experts in strategic planning develop farther planning horizons, forecasting and planning strategies years into the future. They predict and analyze internal and external factors in order to make decisions. Similarly, they predict and proactively attempt to solve problems that might interfere with the accomplishment of goals and objectives (McAlearney, Fisher, Heiser, Robbins & Kelleher 2005).

While beginners organize their own work, experts organize work to be done by others and systems. The expert organizer spells out the tasks and roles of staff in order to promote a coordinated team effort of work toward goals and objectives (Steger et al., 1973). This requires analysis of the various parts of the effort, the skills necessary to perform them, the quality of performance expected, and the timing of the different facets of the effort in order to promote smooth service delivery. In planning a conference, for instance, speakers must be identified and invited, brochures prepared, venues located and booked, registrations received and processed, along with a variety of other tasks. These tasks must be completed on a time line, so that registrations cannot be received and processed until brochures with registration forms have been prepared and distributed, for example. Complex projects require complex planning, and this is the realm of the expert planner.

Expert organizers both initiate structure and maintain structure, keeping teams and systems organized and coordinated (Veenhuis, 2003). When problems occur, the expert analyzes the sources of the problems and makes corrections to the organization in order to improve performance, expand or contract services, or change the nature of the service provision. Since problems in the system can often create the appearance that a worker is ineffective (Russakoff, 2003), the expert investigates the nature of the organization to identify system structures that impede the function of employees. Rapid staff turnover with continuing performance problems may often indicate a structural problem. In such a case, staff replacements will also find themselves to be ineffective, not because they lack skill or training, but because something in the system continues to block performance, and the system needs to be adjusted or changed in order to allow staff members to perform well. Finally, when the system is operating well, expert organizers ensure that it continues to do so, acting as organizational stewards, monitoring and checking expected outcomes and maintaining operations (Picano & Blusewicz, 2003).

Beyond the basic competencies of professional behavior, an expert competency in planning and organization involves ensuring professional behavior for organizations and other workers. This may include encouraging prompt and timely task completion, record-keeping, and reasonable assignment of tasks and deadlines for completion. The expert has an awareness of the purposes of policies and procedures and ensures that others understand them as well, so as to enhance compliance with standards and regulations. In short, the expert extends personal professional behavior into the work environment, setting not only the example and providing a model for others to follow, but also setting standards for the professional behavior of subordinates and organizations.

Finally, while basic competency calls for adapting to change, expert competency requires flexibility in planning so as to respond to changing priorities and predicted trends. Not only are experts aware of the need to change plans resulting from external and internship forces (Veenhuis, 2003), they have the ability to monitor and review ongoing effectiveness of planned activities and respond according to this assessment (NES, 2006), making adjustments in future plans to accommodate new directions provided by ongoing assessment. The practice of professional psychology underwent a profound change years ago with the advent of managed care. Some providers thrived with the changes, while some floundered and experienced severe decreases in services and income. Some practitioners managed to change direction, practices, or services to respond to the new market pressures, including strategies from directing managed care operations to establishing private-pay-only practices, others had great difficulty changing their policies and practices. The most successful expert planners anticipate difficulties

to overcome them, develop contingency plans in the case of obstacles, and quickly react to unexpected developments by adjusting their plans and strategies to accomplish goals.

22.3.2 Administration

Expert competencies in administrative skills extend beyond the level of one's own functioning within systems to other professionals and staff in organizations and agencies. This level of expertise is usually acquired well after entry to practice, and sometimes by "on the job training," as psychologists move into administrative management positions. Expert competencies in business, marketing and finance, organizational and community systems, ethics, legal issues and policies, quality improvement, and information management involve extending the range of influence from self to others and from compliance to creation and development.

Administration experts have developed more sophisticated knowledge of business and financial systems. They are able to use their knowledge of consumers and vendors, the marketplace, and the changes in the market to develop successful business plans. They monitor pricing of services, costs of operating, and utilization of review to develop budgets and report revenue and expenditures to financial managers (Picano & Blusewicz, 2003; Russakoff, 2003; Silver, 2003; Wiger, 2007). They have the capacity to manage the finances of practice (Cohen et al., 1991; McAlearney et al., 2005), which requires a general knowledge of bookkeeping and accounting principles (Newman, 2000). At expert levels, this knowledge may include financial analysis, balance sheets, income statements, and cash-flow statements. Knowledge of the costs of starting a business, how to locate funding sources, and how to reflect the values of the profession and the professional in the business plan are skills of the expert administrator (Silver, 2003). The ability to develop and manage contracts depends on a financial analysis of the services to be contracted (Fraser, 2003), and this may require knowledge of the methods of capitation, fee-for-service funding, billing, and pricing (Crowell, 1983; Gaver, 2000), along with the ability to negotiate and set fees and payments for organization and agency contracts. The impact of staff and faculty recruitment and retention efforts must be understood and planned (Hayes et al., 1999). Financial management skills also include knowledge about the purpose and conduct of audits (Crowell). These business and financial skills have been described as entrepreneurial savvy (Staton, 2000), but supply and demand principles that govern other markets do not fully explain the health-care market, which is supported and policed by government agencies and influenced by the vast insurance industry. Psychologists, who are trained to care for people, must have knowledge and experience in public policy administration and governmental and insurance regulations in order to function as effective administrators. While some psychologists may acquire this knowledge and experience themselves, and some even obtain degrees in business administration, other psychologists must understand the principles and either follow information provided by their professional association or understand the need to employ financial officers to manage the complexities.

Above and beyond maintaining malpractice and/or liability insurance for an individual provider or practice, liability insurance for organizations must be priced and analyzed as well as maintained, and cover a variety of professionals in multidisciplinary systems (Gaver, 2000). Risk management and insurance for larger organizations also include insurance of facilities and against accidents and injuries, unemployment, and workman's compensation. At this level of administration expertise, one must consider the costs and liabilities of organizational operation.

Expert marketing skills extend beyond simply making information available to include market research, forecasting, and understanding the concepts of demand, and positioning services in the marketplace (Whyte & Martin, 2000). Knowledge of the methods of market research allows the administrator to assess the needs, wants, and demands of potential consumers and the purchasers of services. This allows an administrator to position the agency or organization in a favorable stance in comparison to competitors. It also facilitates prediction and understanding of the forecasted demand for services, so that the agency can respond to expected changes in need. Forecasting requires familiarity with trends in business models of psychological service delivery as well as changes in clinical procedures (Freeman, 1999).

Expertise in marketing also includes more sophisticated methods of making information about services and products available, as well as more focused delivery methods to potential consumers. Efficiency of marketing, in order to get the most return on one's investment, becomes more important in marketing management (Fraser, 2003; Gaver, 2000; Wiger, 2007). Media communications, press releases, and public service announcements are some of the more sophisticated methods available (Dyer, 1999). The same ethical principles apply to sophisticated marketing and advertising strategies as to basic advertisement (APA, 2002).

Basic administration competency in organizational and community systems requires understanding of functions, but expert competency in this area involves development and oversight of systems. Expert administrators are able to establish systems for management and monitoring information (NES, 2006), build and maintain clinics or institutions to serve a vision or goal (Wiger, 2007), and maintain operations and monitor results (Veenhuis, 2003). They direct and coordinate interdisciplinary programs, community services, developing internal operating procedures and managing external communications and relationships (Crowell, 1983; Dyer, 1999; Patti, 1983). Administrators are often faced with the task of creating systems to accomplish goals and monitor results, and must take into account the mechanisms of service delivery and all of the ancillary activities. There are many activities involved in directing programs and systems, and are too many to describe here. Staff members are often unaware of what administrators of large systems do and how they spend their time, until the administrator is not available and some essential activity needs attention.

Creating and managing an organizational hierarchy requires knowledge of governance issues, and may include developing a board of directors, advisory board, officers, members, and others (Fowler, 1999). Political, social, diversity, and other issues must be considered in the development and direction of service provision and professional organizations. The expert administrator needs to balance the talents and skills of the people in the organizational hierarchy with the needs of the organization, and create governance structures to serve not only the organization and its consumers, but also the communities within which it operates. Dealing with the political and social context of the organization is a necessary skill for expert administrators (Dyer, 1999).

As discussed earlier, beginning practitioners must be aware of the policies and regulations that impact upon their practice, but the expert administrator develops the policies and procedures for agencies and organizations (Wiger, 2007). The policies and procedures created will serve as guidelines for a variety of purposes, some directly related to operations, and some related to difficulties which may arise in the process of operations. For instance, an administrator will be called upon to address complaints from consumers and others, and will need to develop strategies to protect clients, clinicians, and the institution from unethical practices. Administrators may find themselves in the role of investigator and judge in evaluating

complaints and appeals, and must be familiar with the principles of due process and ensure considerate and fair treatment of all parties concerned.

Further, expert administrators should be able to design and develop programs that integrate the pertinent legal and ethical issues, by writing regulations to ensure compliance in program implementation. Policy development, analysis, and guiding procedures through any political process to adoption or approval are within the purview of an administrator (Cohen, Shore & Mazade, 1991). Then administrators must interpret policy and mandates, train staff to operate within policies, and develop mechanisms to allow them to do so (Patti, 1983; Staton, 2000). For example, when the Health Insurance Portability and Accountability Act (HIPAA) was enacted in 1996, administrators reviewed the implications for their organizations and operations, developed policies and procedures to ensure HIPAA compliance, trained staff and professionals in both the meaning of the act and the new policies and procedures, implemented these mechanisms, and monitored compliance. For some clinics, this meant changing procedures for checking clients in at a front desk, the way charts were stored, and even the methods of obtaining informed consent for services.

Quality improvement principles and methods become much more sophisticated while moving from basic to expert competency in administration. While beginning, practitioners must be aware of the need to provide quality services and monitor and document progress and services; expert administrators are responsible for evaluating the quality of systems of service delivery. Although most students of psychology learn the principles of program evaluation in graduate school (APA, 2007a), conducting program evaluation for external funding sources and accrediting bodies is an expert competency (Cox, 1983). This requires experience and knowledge in mental health care and clinical settings (Wiger, 2007), but also includes the ability to identify markers or indicators of quality and problems, with plans for evaluating and addressing problems that might be identified (Cohen et al., 1991). The ability to develop record-keeping methods that aid the organization's function, and use these records to monitor the results of programs and assess outcomes applies to large and small systems of services (Krousel-Wood, 2000; Veenhuis, 2003). For local agencies, regions, states, and even nations, the principles include alignment of policy for quality improvement, development of standards and accreditation procedures, methods to monitor results, review policies, integrate reforms, and improve programs (WHO, 2003). Management of program evaluation requires continued vigilance to not only identify opportunities for improvement in outcomes, but to create methods and processes to accomplish improvement (Crowell, 1983), and include consideration of perceived cost to the organization in the improvement of quality (Veenhuis). Such processes may include evaluation of forms, updates, chart-keeping methods, systems for paperwork completion and reduction, and electronic record-keeping systems. Client satisfaction surveys may include information about support systems that are not related to clinical outcomes, e.g., waiting lists, front desk reception, or billing issues.

In the area of information management, expert competency in administration involves more than the professional presentations and reports, clear oral and written communication, and information literacy expected at entry to practice. The expert administrator is able to create systems for accurate dissemination of needed information (Veenhuis, 2003). Management decisions are meaningless unless they are accurately communicated up and down the conduit of supervision in a timely manner. Agencies and organizations often suffer from communication problems when there is no mechanism in place to convey information to those who may need it. The mechanism may be a series of meetings, distribution of manuals, reports, memoranda,

or newsletters, but regardless of the method, expert administrators must develop and implement ways of communicating information necessary to system and program operation to the people who are involved in the system. Similarly, they must be able to develop and implement methods to gather information needed for decision making and problem resolution.

22.3.3 Leadership

In some ways, leadership is an expert competency, since most psychologists do not fully develop leadership skills until they are advanced in their careers. Even though the groundwork of leadership skills may have been gained before entry to practice, competency in leadership expands greatly at the advanced level. Leadership involves creating something new, and inspiring others to assist in the creation, rather than maintaining established operations.

While basic competency involves the ability to articulate the primary mission and limits of settings (NCSPP, 2007), expert competency in leadership involves creating the mission of organizations and institutions (Drum, 1999; McAlearney et al., 2005). At this level, leaders develop a vision of what they want to achieve, convert that vision into attainable goals, and motivate others to work toward those goals (Reid & Reid, 2003). In order to do that, a leader needs to be both creative and pragmatic to visualize organizational purpose, philosophy of treatment, core values of operations (Drum), and then devise practical methods to accomplish the purpose, all the while guided by the values inherent in the purpose. Leaders become symbols of their mission.

Translating the mission into operation requires developing goals and objectives. Leaders must understand the context of work, culture, gender, ability, and other diversity factors in order to articulate the goals (Russakoff, 2003). Familiarity with affirmative action principles, organizational design, and organizational development is desirable (Fraser, 2003). In addition, leaders must be prepared to change goals and methods and be responsive to internal and external forces. Logical change, based upon input from other participants, is preferable to random or unreliable change, because allowing others to participate in the planning, decision-making, and goal-setting processes inspires confidence and loyalty (Steger et al., 1973). Leadership may even require recognition that change is likely and should be welcomed (Reid & Reid).

At the expert level of competency in leadership, one is capable of providing direction to other professionals, staff, and organizations (APA, 2007a). Expert leaders create policy (Hatcher & Lassiter, 2006) and participate in internal and external system change (APA) through advocacy efforts. Leaders bring people together to work toward the goals of the organization and guide their actions (Reid & Reid, 2003), foster collaboration, build teams (McAlearney et al., 2005), and coordinate the efforts of teams focused on the different aspects of the operation. For instance, the expert leader may act as a bridge between the clinical and business sides of a practice organization (Wiger, 2007). Or the leader may act as a conductor, coordinating the efforts of many instruments, setting the tone and pace, in the overall direction of effort. An example of this type of leadership activity is the office of the APA President. The elected President of APA develops initiatives within the general scope of APA activities, selects several members to work on these initiatives, and sets the tone and pace of these initiatives within the context of many ongoing APA activities in order to lead the entire organization and profession or discipline into future endeavors.

There are many different styles of leadership, and psychologists have studied these styles for quite some time. Lewin, Lippit, and White (1939) identified three major leadership styles: authoritarian (autocratic), participative (democratic), and delegative (laissez-faire) (1939). According to Lewin et al., autocratic leaders establish clear expectation for what needs to be done, the deadline for the assignment, and the structure of how it should be completed. There is a clear boundary between the leader and the employees. Usually an autocratic leader makes all of the decisions with little or no input from others. The democratic leader often includes group members in the decision process. The leader offers guidance and support to employees and encourages each member to participate. Though the leaders are more inclusive, they often, make the final decision. This leadership style has been found to be the most effective. Delegative leaders often allow the employees to make decisions; however, the leader is responsible for all decisions made. The leader offers little to no guidance while decisions are being made. At times, this type of leadership style leads to ineffective work quality due to poorly defined roles and expectations.

Regardless of the style and the various personal characteristics of leaders, all of them need to motivate followers. They inspire workers to move toward the goals that the leader has set, bring them together for that work, engender trust in leadership, and empower workers to act (Reid & Reid, 2003). Expert leaders give credit for success and take visible responsibility for failure in order to be credible to their followers. There are indicators that clinical and other staff members prefer their leaders to keep them informed of important issues, represent them well, promote their services, provide mediation in the event of conflict in order to assist in resolution, shield them from unnecessary administrative interference, and be a resource for clinicians (Crowell, 1983). A rather democratic leadership style, one that allows for and values the participation of clinicians, is generally well suited for organizations providing psychological services (Wiger, 2007). Consistent, predictable leadership that allows colleagues to share ideas about the organizational process may be generally effective (Steger et al., 1973). Personal mastery, the ability to take another's perspective, flexibility (Picano & Blusewicz, 2003), relational skills, assertiveness, and the ability to deal with others individually and in groups promote a healthy and safe work and office environment (Wiger).

Not all psychologists want to be leaders, and not all leaders want to lead. Sometimes, psychologists may find themselves in the position of leadership without having actively sought the responsibilities, or feel that they lead out of necessity, because no one else was willing to step up or because those they serve needed leadership. Some psychologists step into leadership positions by promoting transformative ideas, while others are encouraged by colleagues who recognize their knowledge and skill. Whether psychologists assume leadership positions within agencies, professional organizations, or in other public forums, expert competency in leadership involves development of vision or mission, motivation of others, and response to the needs of followers.

22.3.4 Executive Management

Expert competency in executive management involves nonclinical supervision and oversight of others, dealing with human resource and personnel issues. This area of competency becomes far larger, more sophisticated, and advanced at the expert level than at the basic level. First, the executive manager analyzes and creates a position description and expectations, including

necessary qualifications and credentials for essential functions (Armenti, 1999; Cohen et al., 1991; Hirsch & Reed, 2003; Martin, 2000; Veenhuis, 2003; Wiger, 2007). This applies to clinical, nonclinical, or support positions, psychiatrist, social worker, billing clerk, or receptionist. Next, applicants for the positions must be recruited, screened, and interviewed. Selections to fill open positions are then made. The process may sound simple, but it is actually quite complex. Recruiting suitable applicants takes more than a simple notice; it requires placing position notices in places such that suitable applicants, those with particular talents, interests, and credentials, are likely to see them. The executive manager then needs to evaluate the applicants' strengths and challenges in relation to the position opening, and make ranking decisions regarding the applications, both confirmatory and exclusionary. For instance, the manager may seek applicants for a clinical service position who have clinical experience with children and adolescents, group therapy, and psychological testing, but exclude those with an inactive license to practice or with felony convictions. Managers also may need to determine and negotiate salaries, benefits, and other conditions (Wiger).

Once a new staff member is recruited, selected, and hired, he/she must be oriented and trained (Armenti, 1999; Cohen et al., 1991; Hirsch & Reed, 2003; Martin, 2000). Even the most skilled clinician or experienced clerical staff member will need to receive training and orientation to new settings and procedures. The executive manager provides for, or directs, this training and orientation. Similarly, the executive manager devises and/or communicates employee evaluation methods, including the criteria for retention, promotion, disciplinary action, and termination (Fraser, 2003; Hirsch & Reed; Hoge et al., 2005; Martin; Wiger, 2007). This may involve merit-based awards, recognition programs, such as "employee of the month" programs (Hoge et al.), or promotion in rank and tenure in academic settings. Executive management skills include devising reward programs based upon demonstration of competencies and skills that the organization values and identifies as important for success. Additionally, the executive manager is responsible for methods to convey negative or critical feedback and those of progressive disciplinary action up to and including termination. This unpleasant but necessary task must be accomplished with consideration for client care, health of the organization, legal and regulatory standards, and rights of the employee, so it demands sensitivity, careful, clear, and forthright communication.

For continuing employees, executive managers are often responsible for devising or delivering in-service training or education (Hirsch & Reed, 2003; Wiger, 2007) and staff development (Fraser, 2003; Steger et al., 1973). Professional staff need to obtain continuing education, and both clinical and nonclinical staff need to be advised of changes in standards of care, legal and ethical changes, and policy and procedural changes (Crowell, 1983). Proper training promotes growth and development by providing opportunities to learn new approaches to treatment. All staff members need to be informed about broad influences affecting their organization and services, how these influences might affect their work environment and responsibilities, and their productivity and accountability. Training experiences also promote good communication and team function.

The expert manager may also need to pay particular attention to workforce development and career management for women and minorities in order to recruit and retain diverse professional and staff members to serve client populations. Executive managers are also called upon to deal with cutback and retrenchment, reduction-in-force, employee assistance programs, unionization, and other human resource issues, such as vacation scheduling and family leave, so they need to be cognizant of employment law. In mental health service delivery,

executive managers are often involved in advocacy efforts to secure operating funds and assess and justify the need for their programs in a culture that often views mental health treatment as optional or exceptional (Patti, 1983). This may require expertise in utilization management, and recording and analyzing records of service utilization (Armenti, 1999). For instance, Bridges, Goldberg, Evens, & Sharpe (1991) noted that patients were far more likely to accept referrals to mental health service providers when the services were available in the same location as their primary health-care provider. This study has been frequently cited as psychologists develop models for provision of psychological services in primary care settings.

Another unpleasant but necessary task that executive managers must perform is resolution of disputes between employees (Patti, 1983; Picano & Blusewicz, 2003). In any organization, conflicts arise between individuals or between different sections of the organization, and it falls upon the expertise of the executive manager to assist in addressing and resolving these conflicts. In so doing, the manager must focus on the health, values, and function of the organization, and again, respond with sensitivity, clear communication, and knowledge of interpersonal interactions.

The expert executive manager is responsible for the management of physical facilities (Gaver, 2000). Acquisition and planning of office space, layout, furnishings, and supplies are more complex than they may appear. Mental health service delivery systems often require special attention to client flow, soundproofing, and safety and security issues than other service systems or businesses. It is often noted that, unlike some other professions, psychologists do not like to talk to clients or students across a desk, because it poses a psychological barrier to communication, so they even prefer a different layout of furniture than some other professionals. Other considerations include methods to call for emergency assistance, such as using "panic buttons," ensuring that people in the waiting room cannot hear conversations in interview rooms, and ensuring secure storage of records. Expert competency in executive management involves obtaining, shepherding, and allocating resources, including materials and time (Patti, 1983; Steger et al., 1973; Veenhuis, 2003).

In the area of staff and team development, expert competency in executive management includes management of interdisciplinary teams (Nash, 1983). Managers must identify the strengths and weaknesses that each individual team member brings to the effort as well as the skill and knowledge base of the discipline represented by each team member. The manager is then responsible for coordinating the team effort, to ensure that the team is working together effectively toward the common goal. This requires ensuring that each team member has or can acquire the skills they need to function effectively and that they are following organizational policies. But teamwork does not just happen; the executive manager promotes effective team communication and fosters group dynamics to allow for coordinated efforts.

Executive management skills require a rather delicate balance between providing direction and allowing others to do their work with associated responsibility and authority (Steger et al., 1973). While the manager provides feedback, suggestions for improvement, sets goals, and assigns responsibilities, he/she also needs to allow others to accomplish tasks without "micromanagement." While a new and inexperienced worker needs and appreciates very specific and detailed instruction and direction, the experienced or middle-management staff member may view such attention as demeaning and irritating. The expert manager recognizes the level of oversight required for the developmental level of the subordinate, and provides that level of attention.

The executive manager is, in part, responsible for the morale of the staff, creating the conditions to promote job satisfaction for employees and contractors (Reid, 2003). Loyalty and trust are earned (Russakoff, 2003), and the expert manager earns them from employees by balancing direction with consistent dialogue, support, encouragement, development, and delegation (Hoge et al., 2005). While many factors, both internal and external, may impact morale, if staff members are demoralized, the manager is called upon to address and improve the overall working atmosphere of the organization. The techniques used by the expert to address morale range widely, but usually include expressions of appreciation and recognition for effort and good performance.

In order to accomplish these tasks, the executive manager must have knowledge of group dynamics and organizational structures. Expertise in organizational assessment and systems analysis is competency at the expert level of executive management (Fraser, 2003; McAlearney et al., 2005). The ability to analyze systems allows the manager to differentiate between a problem employee and a problem in the system (Russakoff, 2003), so as to be aware when an organizational dysfunction causes a staff member to appear to be ineffective. Without this knowledge and analytic ability, managers may find themselves facing continuing turnovers in personnel without resolving the problem, because the dysfunction lies within the system rather than in the lack of skill or performance of the employee. This expertise then allows the manager to make corrections in systemic operations as necessary to improve outcomes and productivity (Veenhuis, 2003).

Systems analysis applies to the system outside of the organization, within which the organization functions, as well as to the internal systems. Expertise in executive management includes collaboration with external agencies, interagency relations, political advocacy, and positioning within the community (Cohen et al., 1991) and the profession (Wiger, 2007). While basic competency in this area focuses on working effectively within the internal organizational structure and hierarchy, expert competency involves ensuring that the organization works effectively with the community and the external structure of agencies as well.

22.4 Summary

In summary, four areas of competency in management and administration are identified, and the basic and expert competencies in each area are described under several themes. Planning and organizing includes basic and expert skills in planning, organizing, professionalism, and flexibility. Administration includes basic and expert skills in business, marketing and finance, organizational and community systems, policies, ethical and legal issues, quality improvement, and information management. Leadership includes basic and expert skills in vision, mission and purpose, guidance, and leader characteristics. Executive management includes basic and expert skills in human resources and personnel, oversight and development, staff/team development and management, and organizational structure. In general terms, the basic competencies in these areas apply to one's own activities, while expert competencies apply to activities of others, whether in small or large organizations. The amount and extent of knowledge and skill also increases, extending outward in time, horizon, and numbers of people and operations managed.

Competencies in management and administration are not as familiar to psychologists as those that are more closely associated with clinical or research skills. Most training programs

do not offer specific didactic or experiential training in management or administration, since it is often seen as expertise that is acquired with experience later in the career stages. However, changes in the health-care marketplace in recent years have placed increasing emphasis on the need for skills in management and administration for psychologists. It is not anticipated that all psychologists will develop all of the expert competencies we have described. Most will develop some of them, depending on their career paths, and a few will develop consummate expertise in all of these areas. A few will lead us to new competencies in management and administration.

Volume II
Intervention and Treatment for Adults

Adults

1 Major Depression

Patricia A. Arean · Liat Ayalon

Abstract: Major depression is the most common condition treated by psychologists. In this book chapter, we first outline the typical symptoms that characterize major depression as well as common risk factors for the development of the disorder. Next, we discuss common diagnostic tools that assist clinicians in the initial recognition of the disorder as well as in further monitoring of the disorder across time. Potential pitfalls and complicating factors related to the diagnosis and monitoring of major depression are also addressed. We then discuss maintaining factors and mechanisms of change associated with major depression, as any psychological intervention has to take these into account when tailoring an appropriate intervention. Finally, we conclude by describing several evidence based treatments available to treat depression and the various outlets available for psychologists who are interested in learning how to apply these treatments in their clinical practice. We conclude by outlining the main competencies required of clinicians interested in working with individuals with major depression. These include: the ability to adequately detect and monitor depression, the ability to make an informed case formulation, the ability to tailor treatment strategies based on existing knowledge concerning maintaining factors and mechanisms of change, and the ability to apply evidence based treatments in the context of evidence based practice.

1.1   Overview

Major depression is one of the most common mental disorders in adult populations and is the most common illness that psychologists treat. Major depression is considered to be the fourth leading cause of disability in the USA (WHO, 2000). It can affect people at any stage of life, and once a person experiences one episode of major depression, that person is likely to experience at least two to three relapses in his or her lifetime (Parashar et al., 2006). Major depression is also the leading cause of suicide in adults, particularly adults aged 65 and older (Conwell, 2001), and it is associated with increased morbidity and mortality when related to medical illness (WHO).

It is particularly important that all clinical psychologists be familiar with major depression, specifically how to diagnose the disorder and differentiate it from other, similar disorders, how to determine a treatment plan, and how to use evidence-based interventions in treating it. Fortunately, major depression is one of the most widely studied mental disorders, and as such, there are numerous peer-reviewed studies, books, and manuals on the topic. Further, it has been studied widely across adult age groups and in a number of cultural groups. Our aim in this chapter is to synthesize the extant information on major depression and detail the core and expert competencies that clinical psychologists must have when working with this disorder.

1.2   Recognition of Symptoms and Their Assessment

Major depressive disorder (MDD) is characterized by at least one *major depressive episode*, with no history of mania (e.g., period of intense energy, euphoria, distorted thinking, and behavioral excesses). To qualify for a major depressive episode, either depressed mood or lack of interest or pleasure in usual activities (anhedonia) must be present most of the day, nearly every day, and the episode must last at least 2 weeks. In addition, at least five out of nine possible symptoms must be present during the same period. The symptoms must be severe enough to interfere with the individual's social or occupational functioning. MDD is further qualified by its severity, chronicity, and remission status. Severity is generally determined by the degree of disability experienced by the afflicted person. If the person can continue to pursue his or her obligations (work, family, and social activities), the depression is ranked as *mild*. If the person has trouble getting out of bed and can no longer engage in any obligated activities, the depression will be ranked as *moderate*. If a person is thinking of death or dying or is so vegetative that she or he has not left his or her bed, eaten, or engaged in any self-management activities or is exhibiting psychotic behavior, then the depression will be ranked as *severe*. Although rare, a depressed person can exhibit symptoms of *Catatonia*, which is characterized by immobility, excessive motor activity, extreme negativism or mutism, and bizarre posturing. A person will be diagnosed as having *recurrent type* MDD, if there has been more than one episode of MDD. *Chronic* MDD is characterized by symptoms of MDD for as long as 2 years. As research has found MDD to be a recurrent disorder (single episodes are rare), if a person has had an episode of MDD and is no longer experiencing any depressive symptoms, that person is considered to be *in remission*.

MDD can be further delineated by type. *The Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition* (DSM-IV) describes the concept of *endogenous depression* and is subsumed under the category of *melancholic depression*. This category is characterized by lack of reactivity to pleasurable stimuli, experiencing more severe depression in the morning, and excessive guilt. Some researchers have suggested that this subtype is more typically associated with biological etiology and that it may be more responsive to psychopharmacological intervention (Simons & Thase, 1992). *Atypical features* of depression include temporary brightening of mood in response to actual or potential positive events, weight gain, hypersomnia, heavy feelings in arms or legs, and interpersonal sensitivity to rejection. These symptoms tend to be interpreted as suggesting a depressive disorder that is more likely to respond to psychosocial interventions rather than medications and may be more stress-related (Angst, Gamma, Sellaro, Zhang, & Merikangas, 2002).

1.2.1   Risk Factors

Most scientists now believe that MDD is multifaceted, with causes resulting from interactions of psychological, social, and biological factors (O'Keane, 2000). We note here that no factor is thought to be exclusively causal of depression; rather, most scientists believe that strength in one area can compensate weakness in another. As an example, someone with a strong genetic loading for developing MDD but over the years has developed effective coping strategies to modulate mood may never develop an episode of MDD. When working with MDD patients, therapists should keep this compensatory model in mind.

1.2.2 Psychological Resilience

In the 1980s and 1990s, there was a considerable amount of interest in the role that coping style or psychological resilience has on the risks for developing MDD. Such interest waned in the mid- to late 1990s, but because of recent interest from institutions such as the National Institute of Mental Health in individualized treatments for mental illness (Zarhouni, 2007), study of factors that prevent MDD from developing in the face of genetic loading for the illness have again become an area of important inquiry. Psychological factors related to prevention or risk of MDD include one's perception of the world or cognitive set and an active versus passive coping style (Southwick, Vythilingam, & Charney, 2005). Research has found that cognitive set and coping style tend to be a function of one's experiences with difficult problems. Behaviors develop as a function of either observing others in one's environment coping with stress or through experience with behaviors that have either successfully or unsuccessfully resulted in problem resolution and positive mood. These experiences also help to shape one's perspective of the world and one's ability to function in it. If attempts at solving problems have been largely successful in producing positive mood or in reducing negative mood, then individuals will engage in those successful behaviors in the future and see themselves as being able to successfully manage problems (Haeffel & Grigorenko, 2007; Roy, Sarchiapone, & Carli, 2007; Yi, Vitaliano, Smith, Yi, & Weinger, 2008). Similarly, coping skills have been found to be related to depression. Most researches have found that people who use active forms of coping, such as problems solving, are less likely to become depressed than people who use passive forms of coping, such as avoidance. In fact, one study found that prevalence of major depression was 59.4% in people with avoidant coping styles (Garcia, Valdes, Jodar, Riesco, & de Flores, 1994; Welch & Austin, 2001). Studies show that when faced with a problem to solve, depressed people are more likely to produce less effective solutions than nondepressed people, such as using distraction to cope with a stressor, rather than trying to solve it (Haeffel and Grigorenko).

1.2.3 Life Events

The literature is replete with data indicating that stressful life events contribute to the development of MDD (Hammen, 2005). Although not everyone who is faced with difficult problems becomes depressed, it is evident that prolonged exposure to psychosocial stress can precipitate a depressive episode (Hyde, Mesulis, & Abramson, 2008). Several studies have found that most depressive episodes are preceded by a severe life event or difficulty in the 6 months prior to the onset of the episode (Beck, 2008). In addition, patients with more long-term or chronic depression were more likely to report past abuse, though the causal relationship is unclear (Keita, 2007).

1.2.4 Social Support

Other studies find that the relationship of life events with depression is mediated by social support (Huhman, 2006). Severe life events are significantly more likely to provoke a major depressive episode in individuals without social support (Merry, 2007; Patel, 2007). Support systems give an individual external support when internal coping skills are put to the test. Therefore,

while negative life events do influence the occurrence of depressive disorders, the social and psychological resources available to the person facing the stressful life event generally mediate the impact on mood (Robinson & Shahakian, 2008).

1.2.5 Biological and Physical

Much research effort has gone into determining biological determinants of depression. The literature not only shows evidence of the effects from both neurotransmitters and hormones, but also physiological changes arising from stress that can increase susceptibility to depression (Robinson & Shahkian, 2008).

Biological explanations for depression indicate that MDD is caused in part by a disregulation in three major neurotransmitters in the brain: serotonin, norepinephrine, and dopamine. Antidepressants to regulate production and distribution of these neurotransmitters are effective in their ability to increase the availability of receptor sites rather than increasing the production of the neurotransmitters (Celada, Puig, Amargós-Bosch, Adell, & Artigas, 2004). Recent research into neuroendocrinology has added to our understanding of the biological causes of depression. Evidence points to an overabundance of cortisol in the systems of depressed patients as well as abnormalities in the thyroid functions (Bondy, 2005; Krystal, D'Souza, Sanacora, Goddard, & Charney, 2001). Finally, physiological changes in the brain structure of depressed individuals lend to further support for structural changes in the brain with MDD. Some researchers suggest that dysfunction in the mesial temporal lobe may be related to recurrent MDD (Malhi, Parker, & Greenwood, 2005). These physical changes that can occur during stressor illness and are associated so closely with depression give a more comprehensive picture and explanation of the causes of depression.

1.2.6 Genetics

Recent advances in science have led investigators to better understand the role that genetics plays in the development of MDD. Past studies of identical and fraternal twins found that identical twins have greater concordance rates for depressive disorders ($r = 0.46$) than do fraternal twins ($r = 0.20$) (Flint, Shifman, Munafo, & Mott, 2008). Furthermore, family studies show that even though having a relative with a mood disorder increases likelihood for developing MDD, rates are not compelling, as having a relative with a mood disorder only confers a 21% risk (Trivedi et al., 2008). Recent research has been able to conduct direct genetic comparisons, where the actual DNA from depressed and nondepressed people is compared. This method is helpful in finding a specific gene that expresses MDD. Early research in this area has been able to uncover differences in the genetic location of dopamine and serotonin receptors between MDD and non-MDD patients (Iga, Ueno, & Ohmori, 2008).

1.2.7 Summary: Knowledge of the Causes of Depression Increases the Competency to Treat

Clinicians who are knowledgeable about how depression is presented and the various risk factors associated with depression are often better at determining an effective course of treatment

for patients than those who do not keep abreast of the field. In determining the best course of treatment for patients with MDD, providers should do a thorough assessment of family history, life events, culture, illness, and coping style before determining the treatment needed. As an example, someone with a particularly severe depression who also has a family history for mood disorders may need to consider both psychotherapy and antidepressant medication in the treatment plan. As biological and genetic research proceeds, we may also be seeing a development toward individualized treatment based on genetics, biology, and behavior. As an example of work related to this notion of individualized treatment, Alexopoulus et al. (2008) have recently completed an National Institute of Mental Health (NIMH)-funded study of problem-solving therapy (PST) for depression in older adults with vascular depression. This depression is characterized by increased apathy, trouble with problem solving, planning, and initiation and is also known to be unresponsive to antidepressant medication. This study has found that a targeted intervention, with PST targeting the behavioral deficits associated with vascular depression, is a very successful treatment in case where antidepressant medication is not.

1.3   Assessment

One of the most critical tools that competent providers who treat depression have is the assessment tool that they use to diagnose MDD and track treatment outcomes. Tools are generally used as guides to help providers make decisions about the severity of the case and whether or not treatment needs to be adjusted along the way. These tools, however, are not the only means by which treatment decisions are made, but rather support and contribute to providers' clinical judgment. Early in training, providers often rely more heavily on these tools in making treatment decisions, but as they gain more experience, these tools often begin to serve as a means for confirming advanced clinical judgment. Below, we describe the different tools that providers can access in working with their clients with MDD.

1.3.1   Diagnostic Tools

Diagnostic tools were originally developed to help researchers characterize their clinical samples and to conduct large-scale epidemiological studies. The principle behind these tools is consistency from assessor to assessor in deriving a diagnosis. The need for such accuracy and consistency came from research indicating that even experts, when left to their own devices, make considerable mistakes when making diagnosis, and rarely there is a consistent agreement between expert evaluators about how to best diagnose patients. Although the need for diagnostic accuracy and consistency is clear for research, some have argued that this level of accuracy is not as important in clinical work. We beg to differ. Given that the effects of evidence-based treatments are ascertained on groups of patients who were diagnosed in a specific way, it behooves the provider to make similarly accurate diagnosis in order to pick the right treatment for their client.

The most widely known diagnostic tools used in research are the Structured Clinical Interview for DSM-IV (SCID), the Composite International Diagnostic Interview (CIDI), and the Mini-International Neuropsychiatric Interview (MINI). Our focus will only be on the SCID and the MINI. The CIDI was developed for lay interviewers working in epidemiological

studies and is neither feasible in clinical practice nor does it allow for clinical judgment in determining a diagnosis. The SCID and MINI are considered semi-structured interviews. Questions or prompts in the tools are meant to help to guide providers toward a diagnosis, but can be answered through clinical observation of the client. Both tools cover all Axis I disorders in the DSM. In both tools, each diagnosis starts with a few gating questions, that if answered positively, guides the clinician to continue to assess for the presence of that disorder. If the gates are answered negatively, the interview, if deemed appropriate by the clinician, moves onto the next diagnosis. There is no particular advantage in selecting one instrument over another. Both are highly accurate in detecting Axis I disorders, and both have been translated into several languages. Both are also in the public domain.

1.3.2   Treatment Tracking Tools

Treatment tracking tools, sometimes referred to as screeners, are self-report/client-completed tools that measure the severity of clients' symptoms. These tools were originally developed as screening tools, that is, instruments to help identify potentially depressed clients. There are several tools on the market, but the best known are the Beck Depression Inventory (BDI; Beck, 1961), the Geriatric Depression Scale (GDS; Yesavage, 1982), and the Patient Health Questionnaire (PHQ-9; Spitzer, Williams, Kroenke, Hornyak, & McMurray, 2000). All of these instruments share in common a solid research base with excellent psychometric properties, brief administration times, easy readability, and translation in several languages. Selecting one tool over another becomes one of convenience and patient population. Our own personal favorite is the PHQ-9 because it is very brief, taking only 2 min to complete, the questions map on directly to the DSM-V symptoms of depression, it assesses for suicide and impact of symptoms on daily functioning, and is the only tool listed that has shown to be sensitive to changes in depression over time, making it an excellent treatment tracking tool. The BDI has several advantages including extensive use in research, and additional mood-related questions that extend beyond the DSM. It also assesses for suicide. The main disadvantage is that the BDI is not in the public domain. Copies must be purchased. The GDS is also an excellent tool, the main advantage being its widespread use in older adults and disabled populations. The main disadvantage is that the items do not map exactly onto DSM criteria, and it does not ask about suicide.

1.3.3   Factors to Consider in Diagnosis

Despite high prevalence of depression in the general population, the well-documented negative consequences associated with untreated depression, and the ample assessment and screening tools available for early detection and recognition of depression, this disorder often goes unrecognized in a variety of clinical settings. For instance, researchers found that only 50% of the depressed individuals who sought assistance in primary care clinics were diagnosed as depressed (Perez-Stable, Miranda, Munoz, & Ying, 1990). Similarly, others found that about half of community-dwelling older adults who suffered from depression were recognized as depressed by a health-care provider (Garrard et al., 1998). Barriers to early detection and recognition of depression may be at the system level, at the provider level, and at the consumer

level. In this chapter, we focus on three major barriers to early detection and recognition of depression: health, age, and culture in relation to these three levels.

1.3.4 Health

As already stated in this chapter, there is a strong connection between depression and physical health (Cassem, 1995). This connection goes both ways, as research has shown that higher levels of depression can cause greater medical comorbidity and vice versa. Given this bidirectional relationship (Benton, Staab, & Evans, 2007), it is not surprising that the rates of comorbid depression and medical illness can be over 40% in certain medical populations (Bukberg, Penman, & Holland, 1984; Burg & Abrams, 2001). Hence, physical health is certainly a factor one has to consider when assessing for depression.

A thorough assessment requires attention not only to emotional functioning, but also to physical functioning and medication intake. This is because many medical conditions, including neurological disorders, endocrine disorders, chronic pulmonary disease, and sleep apnea, may cause or worsen depression. Similarly, medications, such as corticosteroids, antihypertensives, and certain cancer chemotherapeutic agents, may also cause or worsen depression.

Many medical patients do not present with clear psychological symptoms, such as depression or anhedonia, but instead report considerable somatic symptoms of fatigue, lack of appetite, and poor concentration. Hence, the diagnosis of depression in medically ill populations is often a challenge (Katon, Kleinman, & Rosen, 1982). Four approaches can be used to assess for depression in the medically ill (Cohen-Cole & Stoudemire, 1987). According to the *inclusive approach*, depressive symptoms are counted regardless of whether they may be related to physical illness (Rifkin et al., 1985). The *etiological approach* suggests that physical symptoms are counted only if they are not considered to be a result of the physical illness (Rapp & Vrana, 1989). The *substitutive approach*, on the other hand, suggests that psychological symptoms of depression replace the physical ones (Endicott, 1984). Finally, the *exclusive approach* suggests removing symptoms from the diagnostic criteria of depression, if they are not found to be more frequent in depressed physically ill individuals compared to nondepressed physically ill (Bukberg et al., 1984).

Nonetheless, there is still considerable debate as to which approach is most appropriate. One study evaluating the effect of using the various approaches in the case of post-stroke depression concluded that modifying the DSM-IV criteria because of the presence of physical illness was unnecessary (Fedoroff, Starkstein, Parikh, Price, & Robinson, 1991). On the other hand, others found that a diagnosis of major depression based on criteria modified for patients with medical illness is a better predictor of mortality than a diagnosis based on the inclusive criteria, arguing that the substitutive approach is preferable (Cavanaugh, Furlanetto, Creech, & Powell, 2001).

Because medically ill individuals usually seek treatment within primary care clinics or other medical settings, the specific setting has to be taken into consideration. Many medical settings may not allow for more than a short visit and in some settings privacy may be compromised (Schappert, 1992). In addition, medical illness often takes the priority and less attention is usually given to psychological conditions. Hence, adequate evaluation of depressive symptoms might be extremely challenging in medical settings.

Another potential barrier for adequate evaluation of depression in the medically ill is a potential bias at the provider level. It is not uncommon for providers to think that depression is justified given the medical situation of the individual. Hence, normalizing depression by the provider may result in underdiagnosis (Goldman, Nielsen, & Champion, 1999).

1.3.5   Age

Old age may pose yet another barrier for accurate diagnosis of depression. Similar to the medically ill, depression often goes unrecognized in older adults. For instance, a recent study has shown that whereas 17% of the nursing home residents suffered from depression, depression was detected in less than half of these individuals (Davison et al., 2007). A different study conducted at hostels for individuals with cognitive impairments found that whereas 39% of participants suffered from depression, less than 50% were diagnosed as depressed (McCabe, 2006).

Because medical illness is a common occurrence in old age, many of the considerations discussed in the previous section also apply here. Yet, older adults have several additional characteristics that may complicate the diagnosis of depression in this population even further. In this section, we discuss the differential symptom pattern of depression in old age, cognitive impairment, and beliefs about depression and old age as important factors that have to be taken into consideration when evaluating depression in older adults.

Differential Symptom Pattern of Depression in Old Age. There is some research suggesting that manifestation of depression is different in older adults versus younger adults. One study of over 6,000 participants found that dysphoria was less likely to be endorsed by older adults (Gallo, Anthony, & Muthen, 1994). This difference between older and younger adults remained even 13 years later at a follow-up study, suggesting that this is not a cohort effect, but potentially an age-related effect (Gallo, Rabins, & Anthony, 1999). Similarly, another study found that relative to younger adults, older adults were less likely to exhibit cognitive-affective symptoms, but the two groups did not differ in relation to report of somatic-performance symptoms (Goldberg, Breckenridge, & Sheikh, 2003).

Cognitive Impairment. Cognitive impairment is common in old age, with as many as 20% of the general population of older adults suffering from mild cognitive impairment (Manly et al., 2008), and about 5% suffering from dementia (Eefsting, Boersma, Van den Brink, & Van Tilburg, 1996). Depression is considered one of many neuropsychiatric symptoms (e.g., agitation, hallucination, apathy) that often co-occur in the presence of dementia, with over 20% of the individuals who suffer from dementia also suffering from depression (Ballard, Bannister, Solis, Oyebode, & Wilcock, 1996). To complicate things even further, in some older adults, depression may present as pseudodementia, characterized by slowness of thought and speech as well as concentration difficulties (Saez-Fonseca, Lee, & Walker, 2007). Unlike dementia, pseudodementia can be reversible; there is clearly an incentive to differentiate the two. Nonetheless, treating depression is obviously an important task also in the case of individuals with cognitive impairment or dementia as depression significantly compromises their quality of life.

A major difficulty associated with the diagnosis of depression in this population of older adults with cognitive impairments is the fact that many older adults at the more severe stages of dementia are unable to express themselves or to provide reliable information about their situation. To address these difficulties, specific depression rating scales that are based on observational data or informant report rather than self-report were developed. One example is the

Cornell Scale for Depression in Dementia. A measure that was specifically developed to assess signs and symptoms of major depression in dementia based on informant report (Alexopoulos, Abrams, Young, & Shamoian, 1988).

Another barrier to accurate diagnosis of depression in older adults with dementia is the fact that depression in patients with Alzheimer's disease (AD) has different qualities from the depression seen in major depression with no concomitant AD (Olin, Katz, Meyers, Schneider, & Lebowitz, 2002). A group of experts under the National Institute of Mental Health sponsorship proposed specific criteria for the diagnosis of depression in AD. These criteria place a lesser emphasis on verbal expression and include irritability and social isolation as symptoms of major depression. In order to meet the criteria for depression in AD, the individual has to have AD accompanied by a change in functioning characterized by three or more of the symptoms listed in ❯ Table 1.1 within a 2-week period. At least one of the symptoms has to be depressed mood or reduced pleasure in usual activities. A study comparing the utility of this diagnostic mechanism relative to standard DSM-IV criteria found that the NIMH provisional criteria for depression in AD yielded a much higher prevalence rate of depression in patients with AD (Vilalta-Franch et al., 2006).

Beliefs About Depression and Old Age. The stigma of mental illness may be yet another barrier for accurate diagnosis of depression in older adults, especially when accompanied by lack of knowledge about depression (Sirey et al., 2001). Both older adults and their physicians may attribute depression to normal aging, grief, or physical illness (Gallo et al., 1994; Uncapher & Arean, 2000). As an example, researchers found that older adults with depression who attributed their depression to old age were less likely to seek professional care or discuss their symptoms (Sarkisian, Lee-Henderson, & Mangione, 2003).

1.3.6 Culture

Culture is considered as the cumulative deposit of knowledge, beliefs, values, and meanings shared by a group of people. There is ample research demonstrating ethnic disparities in the

◘ **Table 1.1**

National Institute of Mental Health Provisional Diagnostic Criteria for Depression of Alzheimer's Disease

Significant depressed mood: sad, hopeless, discouraged, tearful
Decreased positive feelings or reduced pleasure in response to social contacts and usual activities
Social isolation or withdrawal
Disruption in appetite that is not related to other medical conditions
Disruption in sleep
Agitation or slowed behavior
Fatigue or loss of energy
Feelings of worthlessness or hopelessness or inappropriate excessive guilt
Recurrent thoughts of death, suicide plans or suicide attempts

diagnosis of depression (Stockdale, Lagomasino, Siddique, McGuire, & Miranda, 2008). These differences may be partially attributed to variability in symptom report in different ethnic groups. The report of distress among different cultural groups is related to the nature of the stresses presented, the attitudes toward mental illness, the meaning attributed to the symptoms, and the coping mechanisms and resources available to the particular cultural group (Chung & Singer, 1995).

Researchers have argued that level of "Westernization" is associated with variations in self-report of depressive symptoms. People from Western cultures are said to psychologize their depression (i.e., emotional and cognitive report of distress), whereas people from non-Western cultures are said to somatize their depression (i.e., report of distress in the form of bodily complaints and physiological symptoms) (Katon et al., 1982; Kleinman, 1982). Somatization of depressive symptoms has been observed in various cultures such as China (Ryder et al., 2008), United Arab Emirates (Hamdi, Amin, & Abou-Saleh, 1997), and India (Raguram, Weiss, Channabasavanna, & Devins, 1996), whereas psychological report of depression was found among more "Westernized" groups of non-Western societies (Kim, Li, & Kim, 1999). Nonetheless, research suggests that somatic report of depression is common among Western cultures as well (Mattila et al., 2008).

Provider characteristics have also been identified as potential factors that impair the accurate diagnosis of depression in different cultural groups. According to Adebimpe (1981), race of the clinician, social and cultural distance between client and clinician, stereotypes of psychopathology in different cultural group, and biased diagnostic instruments may explain misdiagnosis of ethnic minorities. For instance, whereas epidemiological studies suggest equivalent prevalence rates of depression among Black and White Americans (Zung, MacDonald, & Zung, 1988), in clinical practice, Blacks are more likely to receive a diagnosis of psychotic disorder and less likely to receive a diagnosis of mood disorder relative to Whites (Strakowski et al., 2003).

1.3.7 Genetics

As already noted, depression is at least partially accounted for by genetic makeup. Hence, the inevitable question is whether we could or should screen for genetic susceptibility of depression (Morley, Hall, & Carter, 2004). Apparently, the predictive strength of the various candidate genes is modest at best, suggesting that an individual who has a particular allele that has been found to be associated with depression has around twice the risk of developing a mood disorder relative to an individual who does not. However, because multiple susceptible alleles and environmental factors are considered to increase the risk for depression, information from genetic testing becomes less useful. In addition, to date, there are no clear pharmacological or psychological interventions that could be used for prevention in individuals who have genetic susceptibility to depression in the absence of the condition. It is also unclear what the impact of genetic testing would be on the mental health and social standing of genetically at risk individuals and their family members (Morley et al., 2004).

1.3.8 Family

Although familial screening for depression is not the norm, the one instance in which familial screening has been recommended is the case of mothers bringing their children for the

treatment of depression. Reportedly, a substantial number of mothers who bring their children for depression treatment are also depressed, yet their depression often goes unrecognized and untreated (Ferro, Verdeli, Pierre, & Weissman, 2000). It also is recommended to screen for depression in family caregivers of individuals with severe medical illness, psychiatric impairments, or cognitive impairments, as caregiving is a highly taxing role associated with high levels of depression (Carol, 2003; Ratnakar et al., 2008).

1.3.9 Placebo Effects

The placebo effect in depression is considered to be of great magnitude. One factor that has shown to increase the placebo effect is the therapeutic effect of assessment contacts. A recent meta-analysis found that follow-up assessments in antidepressant treatment trials account for 40% of the therapeutic effect for participants on placebo. Moreover, these researchers have argued that the therapeutic effect of the initial evaluation meeting is even larger (Posternak & Zimmerman, 2007). Hence, clinicians should be aware of the fact that attention and care exhibited during standard assessment procedures are of great impact and often account for improvement in depressive symptoms.

Provider Competencies: Understanding Factors Related to Diagnosis. Clinicians facing the diagnosis of major depression have to conduct a thorough assessment not only of the mental health functioning of the individual, but also of his or her medical and cognitive functioning. In this chapter, we outline some of the potential barriers for accurate diagnosis of depression. These barriers may be at the consumer, provider, or setting level.

1.4 Maintenance Factors of the Disorder

As already noted, depression is more often a recurrent or chronic condition than a single episode (Kessler et al., 2003). Relative to acute depression, chronic depression is characterized by greater medical comorbidity, impaired functioning, and increased health-care utilization (Crown et al., 2002; Weissman, Leaf, Bruce, & Florio, 1988). One major problem associated with the understanding of chronic depression is a lack of consistent definition. According to the DSM-IV, the specifier "chronicity" can be applied to major depression, if it has lasted for over 2 years. The specifier "incomplete inter-episode recovery" is applied, if symptoms no longer meet criteria for major depression, but residual symptoms are still present. Dysthymia (i.e., as episode of less severe depressive symptoms that lasts at least 2 years) is also characterized by a chronic course. Furthermore, although not listed in the DSM-IV, the term "double depression," which refers to depression superimposed on dysthymia also characterizes a chronic course of depression (Keller & Lavori, 1984). In addition, the DSM-IV proposed a classification of depressive personality as a category for further research. To date, there have been several attempts to differentiate between these various classifications of chronicity, but the majority of the studies did not yield consistent differences (McCullough et al., 2000; Remick, Sadovnick, Lam, Zis, & Yee, 1996). To complicate issues even further, there is the term "treatment-resistant depression," which is characterized by failure of at least two consecutive antidepressant trials. Although treatment-resistant depression is not synonymous with chronic depression, it often results in a more chronic course of depressive illness.

Here, we will discuss several factors responsible for the maintenance of depression, including inadequate diagnosis and treatment, genetic/familial predisposition, early childhood experiences, comorbid medical and psychiatric illnesses, and personality style/disorder.

Inadequate Diagnosis and Treatment. As we have already noted, there is ample research demonstrating inadequate detection of depression in a variety of settings. Moreover, even when depression is detected, it often is poorly managed. According to results from the National Comorbidity Survey Replication, 57% of depressed individuals receive some type of treatment, but only 21% receive treatment that is considered adequate (Kessler et al., 2003).

Although the course of untreated or poorly treated depression has not been extensively studied due to ethical reasons, a meta-analysis of randomized controled trials, in which one group was a wait-list control, found that about 20% experience a spontaneous remission in their depressive symptoms without any treatment. Although impressive, compared to a 50–60% response rate to pharmacological and nonpharmacological interventions, this finding reemphasizes the importance of early detection and adequate treatment of depression (Posternak & Miller, 2001). Similarly, research has shown that a longer interval between the onset of depression and the receipt of treatment is associated with a poor prognosis (Scott, Eccleston, & Boys, 1992).

Genetic/Familial Predisposition. There is some research suggesting that individuals who have a family history of dysthymia or personality disorder are more likely to suffer from chronic depression (Klein et al., 1995). Chronic depression was also found to be familially aggregated especially in the early onset cases (Mondimore et al., 2006). Others found that having a co-twin with a history of depression predicted a slower recovery from major depression (Kendler, Walters, & Kessler, 1997).

Early Childhood Experiences. The finding that early onset depression is associated with a more chronic course of depression has led to hypotheses about early childhood experiences as predictors of chronic depression. There is considerable research demonstrating that early childhood adversities are associated with a more chronic course of depression (Riso, Miyatake, & Thase, 2002). Although, both childhood trauma, loss of object relations, and early separations have been examined as potential predictors of chronic depression, childhood trauma has received the strongest support (Akiskal, King, Rosenthal, Robinson, & Scott-Strauss, 1981; Durbin, Klein, & Schwartz, 2000; Kendler et al., 1997; Weissman & Klerman, 1977; Zlotnick, Warshaw, Shea, & Keller, 1997).

Comorbid Medical and Psychiatric Illnesses. Comorbid medical illness and psychiatric illness have shown to be associated with a chronic course of depression. In a 5-year follow-up study of the outcomes of dysthymic disorder, researchers found that comorbid anxiety disorder was associated with a lower probability of recovery (Hayden & Klein, 2001). Comorbid substance abuse disorders and suicidality were also found to predict a more chronic course of depression (Mondimore et al., 2007). Others have used the term "chronic secondary depression" (Akiskal et al., 1981) to refer to individuals with chronic medical conditions, such as dementia, stroke, and arthritis who suffer from chronic depression.

Personality Style/Disorder. The term depressive personality proposed by DSM-IV as a research category implies that some aspects of chronic depression are thought to share characteristics with personality disorders. Indeed, personality disorders are more commonly found in individuals who suffer from chronic depression, such as dysthymia relative to individuals who have acute depression (Hayden & Klein, 2001; Pepper et al., 1995). In addition, there is considerable research demonstrating that neuroticism (i.e., emotional instability characterized by vulnerability to stress and anxiety) is a strong predictor of chronic depression (Duggan, Sham,

Lee, Minne, & Murray, 1995; Weissman, Prusoff, & Klerman, 1978). However, it has been argued that it is hard to tell whether personality disorders are a precursor of chronic depression or whether the two share a common etiology (Riso et al., 2002).

1.4.1 Provider Competencies: Understanding Maintenance Factors

In this section, we outline several mechanisms responsible for the maintenance of depression. Because these are largely nonmodifiable, clinicians may use this information as "red flags" indicating that further attention is necessary. Particularly in cases where clients are not responding to treatment, providers may need to reassess for family and genetic contributions to depression that may point in a different treatment direction, or providers may need to assess for potential comorbid substance abuse or personality disorder. Having an understanding of the factors that contribute to persistence of depression will help in better treatment decisions for those clients who fail to respond.

1.5 Mechanisms of Change Underlying the Intervention

As one would expect, there is a considerable interest in the mechanisms responsible for change and reduction in depressive symptoms. Gaining a better understanding into these mechanisms can assist in the development and refinement of theories about the etiology of depression as well as assist in the development of specific therapeutic interventions for depression. Given the magnitude of research on the topic, this section is focused on some of the more prominent mechanisms.

Illness Characteristics. Ample research has demonstrated that a more severe level of depressive illness (Lam, Green, Power, & Checkley, 1994; Trivedi, Morris, Pan, Grannemann, & Rush, 2005), a greater number of past depressive episodes, a family history of depression (Trivedi et al., 2005), a longer depressive course, and an early onset of depression are all associated with poorer prognosis. Hence, those individuals who suffer from milder depression are more likely to experience change either following therapy or spontaneously.

Placebo. As already noted, the placebo effect is particularly strong in individuals with depression. According to a meta-analysis comparing the placebo effect to pharmacological treatment of depression, the mean proportion of patients who respond in the placebo group is about 30%, whereas the greatest response in patients receiving medication is 50%. In fact, there is some research suggesting that as the attributed effect of psychotropic medications of the new generation had increased so did the placebo effect (Walsh, Seidman, Sysko, & Gould, 2002). Given the strong effect placebo has on the course of depression, clinicians should utilize the placebo effect for their benefit by instilling in patients beliefs in the ability to change. Importance of beliefs in the successful treatment of depression is demonstrated by a study that found that at the end of successful treatment, individuals assigned to the medication arm were less likely to believe in psychotherapy as an effective treatment for depression, whereas those assigned to the psychotherapy arm were less likely to believe in the effectiveness of medication (Leykin, DeRubeis, Shelton, & Amsterdam, 2007).

Motivation. Research suggests that depression is often associated with a deficit in motivation (Cohen, Weingartner, Smallberg, Pickar, & Murphy, 1982; Layne, 1980). Instilling motivation

in patients is important because higher motivation for change has been associated with better treatment outcomes. Although not specific to depression, the technique of motivational interviewing designed to prepare and activate individuals in the direction of change has gained considerable popularity in treating a variety of disorders, including depression (Westra, 2004).

Adherence to Treatment. Despite the many innovations in the field of psychotherapy and pharmacotherapy, rates of treatment nonresponse are still significant. This is at least partially due to nonadherence or inadequate adherence to treatment. There is ample research demonstrating that those individuals who adhere more closely to their treatment regime are more likely to benefit from their medication treatment (Melfi et al., 1998). It is also true for psychotherapy trials that have consistently shown that those individuals who complete their homework assignments are more likely to benefit from therapy (Cowan et al., 2008). In fact, one hypothesis suggests that the combination of psychopharmacology and psychotherapy in the treatment of depression is more effective than psychopharmacology alone because the psychotherapy component encourages adherence to psychopharmacological treatments (Basco, 1995).

Cognitive Changes. The study of cognitive changes as mediators of change in depressive symptoms is largely attributed to the cognitive theories of depression. According to these theories, depression is a result of maladaptive schemas or core beliefs (Beck, Rush, Shaw, & Emery, 1979). Hence, one would expect that changes in these maladaptive schemas would result in lower levels of depression. Research has largely supported this assumption and shown that changes in dysfunctional thoughts and attributions mediate the effect of depression treatment (Barber & DeRubeis, 2001; Quilty, McBride, & Bagby, 2008).

In many cases, however, the effects of certain cognitive changes as a result of therapy were not specific to cognitive-behavioral therapy, but were instead observed in patients undergoing behavioral therapy or medication therapy as well (Garratt, Ingram, Rand, & Sawalani, 2007; Jacobson et al., 1996). Furthermore, acquisition of adaptive skills is considered common to both cognitive-behavioral and psychodynamic approaches despite the fact that the two use different terminology and radically different approaches (Badgio, Halperin, & Barber, 1999). Hence, it appears that unrelated to the therapeutic modality employed, those individuals who are able to adapt a more adaptive form of thinking are more likely to recover from their depression.

Social Support. The beneficial effects of social support are well documented and include higher rates of quality of life and lower medical and psychiatric illness (Bell, LeRoy, & Stephenson, 1982). Furthermore, there is a strong body of evidence demonstrating that individuals of greater social support and those married or living with a partner are more likely to benefit from therapy and overcome adverse life events (Brown, Adler, & Bifulco, 1988; Paykel, 1994; Trivedi et al., 2005). Interestingly, even expected social support plays a role in recovery from depression. Specifically, those individuals who expressed higher levels of ideal social support were less likely to recover from their depression (Lam et al., 1994).

Religiosity. Similar to social support, the beneficial effects of religiosity are also well documented. Religious individuals have shown to enjoy a longer life span as well as better physical and psychological health (Clark, Friedman, & Martin, 1999). A recent study has shown that religiosity also plays a role in recovery from depression. A retrospective study followed 94 medically ill older adults, diagnosed with depression. The study found that those individuals who reported intrinsic religiosity, but not those who reported more frequent church visits, had a shorter time to recovery from their depression (Koenig, George, & Peterson, 1998).

Provider Competencies: Understanding the Factors Related to Change. This section has outlined several mechanisms thought to be responsible for change. Whereas some, such as illness characteristics, are nonmodifiable, others such as the placebo effect, motivation, and adherence to treatment may be utilized by the therapist to enhance the effects of therapy. A great advantage of the majority of these mechanisms is that they have not shown to be specific to a certain therapeutic modality, but instead affect change across a variety of treatment options.

1.6   Evidence-Based Treatment Approaches

It is important to distinguish between what is meant by evidence-based practice (EBP) and evidence-based treatment (EBT). EBP is a concept that was derived from medicine in the 1970s (McKibbon, 1998). The concept was developed to help clinicians move beyond clinical lore in making treatment decisions, by ensuring that clinicians and clients have sufficient information about the efficacy and safety of a treatment before deciding to employ it. In order to improve health care, physicians must be aware of the state-of-the-art treatment and assessment and select those treatments based on clinical judgment and client input. EBP has been conceptualized as a three-legged stool, with clinical judgment, evidence-based treatment, and client preference all equal in developing effective treatment plans (McKibbon). EBT, on the other hand, is one of the legs on the three-legged stool that is EBP. EBT is the actual intervention selected by the clinician and client to address an illness, and is an intervention that has been researched sufficiently to determine its efficacy and safety in treating the disorder. For MDD, a number of effective interventions are available. Interventions with an evidence base include antidepressant medication, electroshock therapy, and psychotherapy. A whole book, let alone a chapter, could be dedicated to the array of evidence-based treatments available to people with major depression. We dedicate our discussion here to evidence-based psychotherapies for adult populations with major depression.

How an Intervention Becomes an EBT. There are several guidelines for determining whether interventions can be an EBT, and the most reliable guidelines evaluate the quality of the research and the degree to which there is an agreement between the studies that the intervention is effective. The most notable guidelines include the Kaufman Best Practice Approach, which specifies that an EBT should be based in sound theory, have treatment guidelines, have been studied in at least one randomized clinical trial, and is safe (Kaufman Best Practice Project, 2004); The Center for Reviews and Dissemination (Khan, 2001) considers treatments to be EBTs, if there are more than two randomized clinical trials that ensure true randomization and concealment about treatment condition, thorough description of the intervention, and the use of intent-to-treat analyses only; the National Registry of Evidence-Based Programs and Practices (NREPP, 2008) specifies that interventions are evaluated on the quality of the research supporting it and readiness for dissemination. Quality of the research is judged on a 0–4 scale on several quality criteria that include reliability of the measures used, validity of the measures, intervention fidelity, management of missing data, potential alternative explanations for outcomes based on the data, and the appropriateness of the data analysis and interpretation. Readiness for dissemination is determined by the same 0–4 quality scale regarding how available implementation materials are, if there are training and support services, and if any quality improvement materials exist; and finally, the American Psychological Association Guidelines focuses primarily on the rigor to which an intervention has been studied,

existence of a manual, and the degree of agreement between studies regarding treatment effects (Chambless & Hollon, 1998).

In considering these methods for determining EBT, we compiled our own list of chatacteristics defining EBT: there are two or more randomized trials demonstrating positive outcomes, the research is of high quality with regard to methods, measures, implementation, and data analyses, and finally there is a mechanism by which others can replicate the treatment in their settings. Using these criteria, the following psychotherapies have been found to be EBTs for MDD: cognitive-behavioral therapy (CBT), behavioral activation (BA), interpersonal psychotherapy (IPT), and problem-solving treatment (PST). We discuss each intervention in terms of the theory, practice, evidence base, and safety.

Cognitive-Behavioral Therapy (CBT). CBT has become an umbrella term for a series of interventions that share commonalities with regard to how depression is viewed and treated. Cognitive-behavioral treatments share in common a focus on cognitions, assumptions, beliefs, and reactions that are a function of, or contribute to, major depression symptoms, with the aim of changing appraisals to affect emotional change.

These interventions include cognitive therapy (CT; Beck, 1993) and mindfulness-based cognitive therapy (MBCT; Segal, Teasdale, & Williams, 2002). Although these two interventions are similar in theory and focus, they vary in how emotion and change in behavior are addressed. We note here that some authors have also included problem-solving therapy (PST; Nezu, Nezu, & Perri, 1998; Mynors-Wallis, Gath, Day, & Baker, 2000) under this category of EBT, but because of its unique process, its relatively recent designation as an EBT, and its growing popularity in non-mental-health settings, we discuss that treatment in a separate section. Similarly, authors will often include behavioral activation under the CBT category of treatments, but because of its unique process and its minimal focus on cognition and appraisals, we will give this intervention its own section.

Cognitive Therapy. CT was developed by a psychiatrist, Aaron T. Beck, who conceptualized his theory of affective disorders after concluding from his clinical practice that clients who improved from treatment did so through a process of changing their interpretation of events in their current lives and their belief in themselves as effective change agents. In his earlier work, Beck focused primarily on helping clients overcome common "errors in thinking" that he found to be related to depressive emotion and behavior. Errors in thinking included making arbitrary and negative inferences of events in clients' lives, overgeneralizing negative events and minimizing positive events, and selective attention to the negative things in life. These errors in thinking are considered to be just below clients' level of awareness, and in the process of helping become more aware of those thoughts; the correlation between those thoughts and moods and subsequently, how they interact with other people and solve problems are the paramount aims of treatment (Beck, 1993). Beck has since amended his theory to also include the concept of "schemas," which are the lens by which clients process information about themselves and the world. Errors in thinking arise from these schemata, and the ultimate way to treat depression is to better understand the schema underlying the errors in thinking and change that lens to a more objective, realistic perspective. Once the schema changes, errors in thinking change creating more positive affect.

The evidence base for CT as a depression intervention is very strong, and highly positive (Whitfield & Williams, 2003). In a recent review of the CBT literature, Kuyken, Galgliesh, and Holden (2007) found that CT was as effective as antidepressant medication for treating acute depression and for preventing relapse of depression as well. However, there are clients with

chronic recurrent depression, where cognitive schemas are so ingrained that they are resistant to change. Additionally, there has been little evidence that when compared directly to other interventions, such as behavioral activation and brief dynamic therapy, the intervention has any added advantage in treating this type of major depression (Whitefield & Williams). One review found that investigator allegiance to CT seemed to result in better outcomes than when CT was studied by an independent group (Gaffan, Tsaousis, & Kemp-Wheeler, 1995). However, most experts in depression treatment consider CT to be an efficacious treatment alternative that has ample support for adults in all age groups (Mackin & Arean, 2005) and ethnic minority populations (Miranda et al., 2003).

Mindfullness-Based Cogntive Therapy (MBCT). MCBT (Segal et al., 2002) is a combination of CT and mindfulness-based stress reduction intervention developed by Jon-Kabat-Zin in the 1980s. Segal et al. took the MBSR model and adapted it for use in patients who have chronic recurring depression. It is an 8-week, often group-based course, that has been studied primarily as a relapse prevention intervention. Mindfulness has its roots in Buddhism, in which people are taught to focus on the present, acknowledge thoughts from moment to moment without passing, one way or another, and instead respond to the situation, rather than react to it. Instead of challenging errors in thinking, as is done in traditional CT, clients are taught to just be aware of their thoughts and subsequent impulses to act on those thoughts and are then taught how to reshift their focus from the thoughts to the situation in front of them. The main principle taught to clients is that no amount of meditation or therapy can make clients' lives pain-free; however, the way to cope with pain is to be continually shifting one's focus from reacting emotionally to a situation, and then respond to the situation, without passing judgment.

Treatment consists of a combination of CT techniques and mindfulness exercises. Using experiential exercises, such as object focus techniques and thought journaling, clients learn to recognize patterns in their thinking early on, and then how to respond to thoughts as ideas, rather than facts. Additionally, clients learn to see patterns in how they react to situations, with the aim of helping them choose a different way to respond to negative situations, rather than being on automatic pilot.

MBCT has largely been studied as an intervention to recurrence of major depressive episode: and thus, most of the research has focused on prevention effects. The research has largely been positive. One study found that in 145 participants with chronic recurrent depression who were successfully treated with medication, only 35% of those receiving MBCT as a prevention measure relapsed 1 year after treatment compared to 66% of those who did not receive MBCT (Teasdale et al., 2000). The UK National Institute for Health and Clinical Excellence (NICE) has recently endorsed MBCT as an effective treatment for prevention of relapse. However, it should be pointed out here that there has been no independent replication of MBCT as a prevention intervention; a majority of the research on MBCT is done by the MBCT group in Ottawa.

1.6.1 Behavioral Activation

Behavioral activation (BA) is a third-generation behavioral therapy for depression. BA was originally one component of Beck's original incarnation of CBT. It became a stand-alone intervention when Jacobson et al. (1996) conducted a dismantling study, comparing CT, BA, and CBT as treatments for depression and found that the CT component added little to the

treatment effects of CBT. This finding has been supported several times, most recently by Dobson et al. (2008) who found that CT did not add any benefit, and in more severe depression, BA was superior to CT as a treatment for depression and as effective as an antidepressant medication.

Operant theory of behavior is the main theoretical underpinning of BA. According to this theory, depression is a function of punishment and negative reinforcement and too little positive events. Take for instance a client who moves to a new city and is looking for a new group of friends. The client may initially feel optimistic about his or her chances of finding new friends because of past successes in acquiring friends in his or her hometown. However, as months go by and the client unsuccessfully makes new friends, his or her attempts at friendship become punished by the feeling of rejection. Over time, the client stops trying to make new friends and avoids social situations all together. This avoidance results in a decrease in the negative consequences of engaging socially, and so, the act of avoidance is reinforced. Eventually, because of the social isolation, the client eventually begins to have too few positive social events. As a result, the client becomes lonely, isolated, and eventually depressed.

Based on the above theory, BA attempts to change the clients' behavior by increasing the likelihood that they will experience positive consequences to behavior they have given up, or, in cases where the behavior itself may be the cause of the negative consequences, teach clients new behaviors that will produce more positive consequences. Using our relocated client as an example, the BA therapist works with the client to create a list of social activities that are ordered from most likely to pursue to least likely to pursue. Starting with the easiest task, the client creates a plan to engage in that positive situation between sessions and measures his or her mood before and after engaging in the activity. In the case of our client, he or she may feel more comfortable starting a conversation with someone at work before joining an activity with people the client does not know. The task would be small and doable, perhaps to ask the co-worker if they want to step out for coffee. If the therapist and client determine that part of the problem is a lack of social skills, then together, the client and therapist will practice new skills to ensure the client has a positive interaction. Over the course of therapy, the client works through this list of activities until their depression remits and they feel comfortable pursuing more complex activities on their own.

As stated above, the evidence for BA is growing strong. In the 1990s, Jacobsen et al. studied the relative merits of BA compared to CT and found consistently that BA was an effective, stand-alone intervention. More recently, researchers found that BA was particularly good for patients with severe depression (Coffman, Martell, Dimidjian, Gallop, & Hollon, 2007). In a recent meta-analysis by Cuijpers, van Straten, and Warmerdam (2007), BA was found to have very large effect sizes, although the differences in effect sizes of BA compared to CT were not statistically significant. In addition to having positive effects as a depression treatment, BA is particularly attractive because it is a cost-efficient intervention, requiring very little additional skill learning for the therapist and client, and could be delivered by people with varying levels of expertise.

1.6.2   Interpersonal Therapy

Interpersonal therapy (IPT) is a brief supportive therapy for depression that was originally developed as a psychotherapy control condition for the Collaborative Treatment for Depression

Study, a large randomized trial comparing CBT to antidepressant therapy for treating major depression. The intervention was developed by Gerald Klerman and Myrna Weissman, after reviewing hundreds of hours of therapy tapes and identifying the commonalities between all therapies (Klerman, Weissman, Rounsaville, & Chevron, 1984). In the collaborative study, IPT was found to be as effective as CBT in treating depression, and because of its supportive nature and similarities to psychodynamic therapies, IPT became a popular depression intervention.

Although it was originally a control condition for research, it has since been indicated that IPT is based in Sullivanian Theory of social behavior. Harry Stack Sullivan was an analyst who felt that traditional psychodynamic theory did not capture the current state of society well, and that main issues driving psychopathology and neurosis were interpersonal needs and interactions. People who are depressed are unaware of their effect on others, and only pay attention to certain aspects of their social interactions. He felt that for analysis to be effective, therapists must elicit specific details about interpersonal interactions, so that facts about behavior become conscious, and the client is more aware of his/her impact on others and their role in interpersonal problems. IPT takes this conceptualization of human behavior and further refines it. According to IPT, depression is a function of interpersonal difficulties and the goal is to help clients realize what they can do to change maladaptive relationships. Depression is considered a function of four main conflict areas: grief, role dispute, role transition, and interpersonal deficits.

The evidence for IPT is quite strong and largely positive. IPT has been found to be quite effective for treating depression in younger adult populations and young Latina mothers, in particular. However, its efficacy in older or geriatric populations is not promising. Most research on IPT in treating geriatric depression has found it to be relatively ineffective, and in some cases, worse than placebo (Reynolds et al., 2006).

1.6.3 Problem-Solving Treatment

Problem-solving treatment (PST) is a relatively new EBT for treating major depression. Although it was originally conceptualized by Nezu and D'Zurilla in the 1980s, it has not been until recently that this intervention has received any recognition as an effective depression treatment. There are two forms of PST, the original developed by Nezu et al. (1998) called social problem-solving therapy (SPST), and the one developed by Mynors-Wallis as a depression intervention for primary care medicine (PST-PC; Mynors-Wallis et al., 2000). Although developed independently and in two different countries, the two models are nearly identical in theory and practice, differing only in how problem-solving process is taught to clients. In SPST, each step of the process is taught sequentially; the first session involves explaining the whole problem-solving process, the first week details the first step, the second week the second steps, and so forth. Further, SPST includes a step called problem orientation, an explicit exercise to help clients overcome negative perceptions about their ability to solve problems. PST-PC teaches the process in one session, as one cohesive tool to help clients solve problems, and refinement in the execution of each step is done over each subsequent session and application of the tool. Because PST-PC was meant to be an intervention for non-mental-health providers, problem orientation is not taught explicitly, as the creators found that non-mental-health providers had a difficult time grasping and teaching this concept effectively. The theory behind both interventions is identical. Depression is a function of either poor

problem-solving skills or learned helplessness, a concept originally posited by Seligman, Weiss, Weinraub, and Schulman (1980). People with poor problem-solving skills are vulnerable to become depressed because of a lack of effective skills in proactively developing solutions for day-to-day problems. In other cases, people who where originally effective problem solvers stop using these skills when they are faced with repeated failed attempts to solve problems. The goal of PST therefore is to either teach an effective method for solving social problems or help reinforce existing problem-solving skills that may have fallen by the wayside because of depressed mood.

The evidence for PST is quite positive as a treatment for major depression. According to a recent meta-analysis by Cuijpers et al. (2007), PST is effective in treating depression, but it is an effective intervention for some groups of patients and not for others. For instance, the effects of PST on geriatric depression, even in older adults with mild cognitive impairments, physical disability, or severe illness are very strong (Arean et al., 1993; Arean, Hegel, Vannoy, Fan, & Unuzter, 2008); however, clients with milder depression do not appear to do quite as well (Williams et al., 2000).

1.6.4 EBTs for Special Populations: Older Adults, Ethnic Minorities, Disabled Populations, and Co-occurring Disorders

One of the limitations of psychotherapy research in general is that most of the research is focused on physically healthy volunteers. Further, to study efficacy of these treatments on depression, the samples have often excluded older adults, physically ill, and adults with co-occurring illnesses. Thus, the generalizability of the research has been called into question by providers who work in community-based settings where clients are not similar to the participants in research. In the last 15 years, however, there is a growing evidence base that the EBTs discussed above can be effective for special populations.

With regard to ethnic minorities, a number of studies have found that CBT (Miranda et al., 2003), IPT (Rossello & Bernal, 1999), and PST (Arean et al., 2008) can be effective in these populations, and each intervention has been translated into several languages. Older adults also respond well to CBT (Gallagher-Thompson & Thompson, 1996) and PST (Arean et al., 1993), but not to IPT (Reynolds et al., 2006). Those with chronic illnesses also respond to CBT and PST. For instance, CBT has been found to be effective for patients with multiple sclerosis (Mohr, Hart, & Vella, 2007). CBT is also useful for disabled populations, in that it has been adapted for telephonic delivery, with highly positive results. Unfortunately, there has been very little research on the effects of these interventions in dually diagnosed populations.

1.6.5 Training Competencies in EBTs

Each EBT discussed below has training programs that any provider can participate in, for a cost. These trainings have many similarities, which include an introductory workshop, followed by provider application of the intervention, under the guidance of a trained expert. Below, we describe the process for each intervention reviewed above.

CT. Training in CT can be acquired in a number of ways, but the first place to go if providers are interested in training in this model is the Beck Institute for Cognitive Therapy

(www.beckinstitute.org-training). Interested providers must hold at least a master's degree in a mental health or health profession. Providers apply to participate in the training, which can be online or in person. Providers first participate in a 2-day workshop, either at a national conference, the Beck Institute, or one arranged by the provider in training. The workshop provides an overview of CT. Providers can elect a 6-month or 1-year training, which involves audiotape or videotape review of CT sessions and weekly individual telephone supervision. Once a provider becomes competent in CT, he or she is eligible to become a trainer. This requires weekly telephone review of supervision cases. As of this writing, tuition for the 1-year program is US$8,075 and US$4,550 for the 6-month program.

PST. Providers interested in learning PST can find trainers from the University of Washington IMPACT Web site (www.impact-uw.edu). This Web site is funded by the Hartford Foundation and provides a free introduction to PST, and access to a PST trainer. Feedback is not free, although the cost of training is reasonable. PST experts can be found throughout the USA, but if there is no expert in your location, the training can be done over videoconferencing, telephone, or Skype. As of this writing, training is approximately US$2,500 for the workshop and supervision. If the workshop is online, then the cost is US$1,500.

Providers do not need to have a prior working knowledge of major depression or experience in mental health, although Hegel et al. (2004) found that people with a mental health background, particularly in CT, tend to need less training than those who are mental health novices. Training consists of a 1-day overview workshop, which can be done online for free, and two to three supervised training cases. Training cases are audio taped, and the first, middle, and last session for each case is sent to the expert for review. Reviewers rate each tape on the provider's ability to cover each of the problem-solving steps, as well as basic clinical functions, such as structuring the therapy hour, working collaboratively with the client, demonstrating warmth and empathy, and ability to handle difficult or crisis situations. The difficulty level of the client is also considered in the ratings; however, providers in training are encouraged to find mildly depressed patients for their very first PST case. Once the provider in training has demonstrated proficiency in PST, he or she is then certified and is eligible to participate in a monthly, toll-free call to discuss new or complicated cases. In our experience, most providers are basically competent by the end of the training period, but usually appreciate the opportunity to discuss difficult cases after certification. Providers are eligible to become expert trainers after having used PST for 1 year on at least 20–30 cases.

BA. We were unable to locate any formal training program in BA. Based on our review of the research standards for BA research therapists, the training criteria is similar to that of PST. Providers interested in BA participate in a workshop on the principles of BA. Once they complete the workshop, providers participate in audio taped or videotaped supervision of at least three cases, which are rated for fidelity to the model by an expert in BA. Providers receive feedback on their cases, and are certified once they have successfully completed cases.

IPT. We report here the guidelines for IPT training that are listed on the International Society for Interpersonal Therapy (ISIPT) Web site (http://www.interpersonalpsychotherapy.org). Providers interested in learning IPT should have a good understanding of major depression and experience in mental health before beginning training (contrary to PST and BA). Training can be obtained by contacting the ISIPT Web site for locations of workshops and official trainers.

ISIPT delineates training into four levels: level A provides general information on IPT to curious providers, level B involves basic IPT training, level C involves more intensive

supervised training, and level D is training to become a trainer. Level A training is a 2-day introductory training course that is offered at professional conferences or occasionally as continuing education units. Those who complete level A and wish to learn how to provide IPT participate in level B. (Only those who have participated in an ISIPT-approved level A workshop can move onto level B training.) Providers must have the IPT manual for major depression and identify at least two cases that are willing to be videotaped or audio taped for training. All 16 sessions of IPT are sent to a certified IPT trainer, who reviews a random sample of 12 tapes. Providers receive a minimum of 4 h of supervision on their cases, either in individual or group format. Level C training occurs when the provider has been carrying at least two cases in IPT for a year. These providers still receive monthly supervision during the year and are encouraged to attend IPT-focused conferences. Level D training can only happen once level C training is completed. The provider must have a minimum of ten supervised cases in IPT. Providers wishing to be trainers must join a regional group of trainers, and if none exists, they must create one. They must also attend the Trainers' Workshop and two conferences a year in IPT.

1.7 Basic Competencies of the Clinician

After each section detailed above, we provided a summary of how the information in each section represents an important competency for providers working with MDD clients. In this section, we discuss how providers can acquire these basic competencies. To reiterate, the basic competencies for treating major depression are:

- Ability to adequately detect and monitor depression and rule out other competing diagnoses
- How to use assessment, research, and client history to make an informed case formulation
- Ability to apply what we know about maintenance factors and mechanisms of change in MDD to amending treatments
- Ability to apply evidence-based treatment in the context of evidence-based practice

All new providers should begin the process of developing competencies by working with an expert in major depression, particularly an expert in at least one EBT. This expert can help new providers fine-tune their assessment, formulation, and treatment skills, and provide information on the latest developments in the depression field. To illustrate how novice providers can acquire these skills, we describe the process we have used to train psychology interns, psychiatry residents, research therapists, and community providers at the University of California, San Francisco, Over-60 research and training program.

1.7.1 Detecting and Monitoring Major Depression

Our typical approach to training providers in the assessment of major depression involves a combination of in-services reviewing of the information discussed in the sections on assessment and risk factors for major depression, participant observation of assessment, and guided, in vivo training opportunities. After novice providers have completed the didactic part of our training, they then watch videos of clients with different presentations of major depression,

and while watching the videos complete a SCID on the videotaped client. Afterwards, novice providers and assessment experts discuss the cases and the results of the SCID. Once the expert and novice feel that the novice provider is ready, the provider then watches the expert conduct two to three clinical interviews with clients. This is followed by expert observation of the novice provider conducting two to three interviews. The novices are then ready to conduct interviews on their own, some of which are videotaped for continued training opportunities. Depending on the providers' backgrounds and experience with mental health issues, novice providers generally become competent assessors of major depression within 6 months of training.

1.7.2 Case Formulation

As detailed in the excellent article by Sim, Gwee, and Bateman (2005), case formulation is the working hypothesis that guides treatment decisions, without which the process of therapy would become haphazard. Case formulations involve combining information from assessment tools, client history, knowledge of the common causes of depression, and a treatment theory. Information detailed in a case formulation varies by the theory from which the case is being conceptualized. As an example, Persons' case formulation model for CT indicates that to make a CT formulation, seven components must be in place, including the clients' problem list, schema, triggers, client problem history, a hypothesis, treatment plan, and barriers to treatment. Whereas an interpersonal formulation includes a summarizing statement, assessment of the primary area of conflict, self-psychology model, prognosis, and prescription. Sim et al. (2005) indicate that while the content of a formulation may theoretically vary, the quality of case formulation can be measured across all theoretical types from these five aspects of a competent case formulation: integrative, explanatory, prescriptive, predictive, and therapist.

An integrative case formulation is one that succinctly combines all the information on a case and identifies the key issues to be worked on clearly. A competent formulation also provides a theoretical explanation for presenting problem and is supported by evidence collected in the initial assessment, client's history, and over the course of treatment. Competent formulations are also prescriptive, in that a clear treatment plan evolves logically from the explanation of the factors contributing to the presenting problem.

At UCSF, we train novice providers in case formulation in the following way. As stated in the section on assessment, our providers are given in-services on the latest information about risk factors, causes, and correlates of major depression, and the factors that are likely to contribute to relapse. We provide a comprehensive overview of biological, genetic, psychosocial, cross-cultural, and developmental research on major depression. Trainees are required to make case presentations of initial formulations based on one of the EBTs they are learning during the course of treatment; the trainer periodically asks the trainee to make adjustments in their formulation based on the course of treatment. At the end of treatment, the formulation is again reviewed and refined.

1.7.3 Application of Evidence-Based Treatment

Competent application is more than knowing how to do an EBT and how to apply it in the context of evidence-based practice. Under the section on EBTs, we discussed how one can

become accredited in each psychotherapy. Here, we describe the process involved in applying those treatments competently.

In order to be an effective psychotherapist in treating major depression, providers must have the following set of competencies. First, they must be well trained in at least one evidence-based practice, ideally two. The advantage of knowing two EBTs allows the provider to be flexible for clients who may have a preference for a certain type of therapy. Second, providers should know how to formulate a treatment plan based on the EBT being used. Third, providers should not apply EBTs in a vacuum. As described in the section under evidence-based practice, clinical judgment and client preferences should be part of the decision regarding which treatment to use. Fourth, providers must learn to be flexible within the EBT they are using, not applying the specifics of a manual in a cookbook fashion, but adjusting the pacing and specifics of the intervention to be most effective. Fifth, providers must be aware of the limits of the research and keep abreast of new developments in treatment development; in other words, good psychotherapists do not form firm allegiances to theories, but keep an open and objective mind when new information is available about existing interventions, modifications of these interventions, and new theories and treatments for major depression. No one intervention is appropriate for all client populations.

1.8   Expert Competencies of the Clinician

A definition of an expert in any field is someone who possesses the latest information about the field and can apply and teach that information flexibly and innovatively. In MDD, that amounts to having ample exposure to working with clients who are suffering from MDD and learning the latest developments in MDD. The main difference between being competent and being an expert is in the depth of understanding. Competent MDD providers typically are trained to conduct state-of-the-art assessment and treatment and can create useful treatment plans based on case formulation. Competent therapists sometimes have trouble in working with clients suffering from MDD that is complicated by other comorbidities, or who are not making improvements to treatment as expected.

In training providers in PST, providers who are newly certified tend to still need guidance on how to use PST in situations where the client does not understand the model or who behave differently in treatment than the clients in the certification phase. Expert opinion and advice are often needed in the first 6 months post certification to help the competent PST provider work with the model in a flexible way and tailor the intervention to the unique characteristics of the client or help the PST provider decide whether or not PST will be effective for the client. In our experience, after 6 months of such expert consultation, most competent PST providers no longer need expert guidance, and can often offer advice to others who are just learning the ropes. Thus, competent PST providers understand the PST model and provide the intervention under the best situations; expert PST providers can not only use PST in more complex cases, but also have enough judgment and flexibility to know when PST may not be the best treatment for a client.

1.9   Transition from Basic Competence to Expert Competence

How one becomes an expert in MDD is a bit more difficult to describe. Based on our personal experiences and in pooling MDD experts around the USA about when and how one becomes

a depression expert, we were able to delineate the process by which one moves from being simply competent in MDD to being an expert. First, the most important factor in becoming an expert is the working time with MDD patients. The more you assess and treat, the better you become as an MDD provider. A second and important addition to time is working and communicating with other MDD experts. It is not enough to simply treat clients with MDD. One must also confer with colleagues and consider fresh perspectives on the illness. An advantage in being a researcher in MDD is that through academic activities, one routinely works and interacts with other experts, reading their work, engaging in discussion about MDD, and having others comment on their work related to MDD. Clinicians can emulate this practice by attending meetings, joining groups of MDD clinicians, and routinely reading the literature. Another avenue toward being an expert is training others in how to assess, understand, and treat MDD. Many experts in MDD are often educators who work with professionals and students wanting to learn the state-of-the-art assessment and treatment. Finally, although no one was willing to put a timeline to when one can be considered an expert, most felt that if a provider worked primarily with clients suffering from MDD and routinely interacted with other experts in the area, expertise could be reached on an average after 2 years of this exposure. Everyone conceded that this timeline would vary from person to person.

1.10 Summary

MDD is one of the best-studied mental health illnesses. We have considerable information about how MDD presents, factors that put people at risk for MDD, factors that complicate treatment, what assessment tools work best, and which treatments are most effective for most people with MDD. Although more research is needed to understand how to best treat specific clients with more complex presentations of MDD, providers do have enough information available to effectively assess and treat a majority of the clients they will see with MDD. Becoming competent as an MDD therapist requires learning all one can about the illness and the different treatments available and becoming skilled at delivering evidence-based treatment within the context of evidence-based practice.

2 Bipolar Disorder

Timothey C. Denko · Michael E. Thase

Abstract: Bipolar Disorder has long been considered to be a condition best managed by pychopharmacologically and psychotherapy specific to bipolar disorder has only recently been a subject of interest.

In our overview in this chapter on bipolar disorder we examine nosology of the DSM-IV bipolar disorders, review diagnostic criteria for manic and hypomanic episodes, discuss epidemiology and psychiatric co-morbidities and describe the clinical course of bipolar disorder.

Prominent agents in the pharmacologic management of bipolar disorder are discussed as the foundational maintenance factors in bipolar disorder with a review of the putative pros and cons of management with lithium, anti-epileptic drugs, atypical antipsychotics, and standard antidepressants.

Three manual based psychotherapies have been studied under controlled conditions in bipolar disorder; family focused therapy, cognitive therapy, and interpersonal social rhythms therapy. We summarize the principles of these interventions as well as outcome data of clinical studies for these interventions in the management of people with bipolar disorder.

In basic competencies, some of the more common and difficult issues with differential diagnosis are considered, including differentiating unipolar major depressive disorder, borderline personality disorder, and schizophrenia from bipolar disorder. Topics in psychoeducation are presented. The section on expert compentencies expands on these principles, and discusses the use of diagnostic instruments such as the Structured Clinical Interview for Diagnosis (SCID) of DSM-IV TR Mental Disorders, screening instruments such as the Mood Disorders Questionaire (MDQ), and rating instruments such as the Young Mania Rating Scale (YMRS) Hamilton Rating Scale for Depression (HAM-D) and the Montgomery-Asberg Depression Rating scale (MADRS).

2.1 Overview

Nosology, epidemiology, and clinical course will comprise our overview of bipolar disorder.

2.1.1 Nosology

Bipolar disorder, formerly termed "manic depression," actually comprises four diagnoses (using DSM-IV nomenclature) – bipolar 1 disorder, bipolar 2 disorder, bipolar disorder not otherwise specified (NOS) and cyclothymia. A diagnosis of bipolar 1 disorder is assigned to an individual who has experienced at least one lifetime episode of mania (see ❯Table 2.1), provided this episode is not considered to have been triggered by a substance (such as an

◉ Table 2.1
DSM-IV criteria for a manic episode

A. A distinct period of abnormally and persistently elevated, expansive, or irritable mood, lasting at least 1 week (or any duration if hospitalization is necessary) is required for the diagnosis
B. During the period of mood disturbance, three (or more) of the following symptoms have persisted (four if the mood is only irritable) and have been present to a significant degree:
(1) Inflated self-esteem or grandiosity
(2) Decreased need for sleep (e.g., feels rested after only 3 h of sleep)
(3) More talkative than usual or pressure to keep talking
(4) Flight or ideas or subjective experience that thoughts are racing
(5) Distractibility (i.e., attention too easily drawn to unimportant or irrelevant external stimuli)
(6) Increase in goal-directed activity (either socially, at work or school, or sexually) or psychomotor agitation
(7) Excessive involvement in pleasurable activities that have a high potential for painful consequences (e.g., engaging in unrestrained buying sprees, sexual indiscretions, or foolish business investments)
C. The symptoms do not meet criteria for a mixed episode
D. The mood disturbance is sufficiently severe to cause marked impairment in occupational functioning or in usual social activities or relationships with others, or to necessitate hospitalization to prevent harm to self or others, or there are psychotic features
E. The symptoms are not due to the direct physiologic effects of a substance (e.g., a drug of abuse, a medication, or other treatment) or a general medical condition (e.g., hyperthyroidism). Manic-like episodes that are clearly caused by somatic antidepressant treatment (e.g., medication, electroconvulsive therapy, light therapy) should not count toward a diagnosis of bipolar 1 disorder

antidepressant, steroid, substance of abuse) or metabolic disorder (hyperthyroidism, for instance). Please note that there is no requirement for any depressive episodes in assigning a diagnosis of bipolar 1 disorder, although major depressive episodes (MDEs) are very common in individuals with this diagnosis.

International classification of disease (ICD-10) offers a more colorful description of a manic episode.

Mood is elevated out of keeping with the individual's circumstances and may vary from carefree joviality to almost uncontrollable excitement. Elation is accompanied by increased energy, resulting in overactivity, pressure of speech, and a decreased need for sleep. Normal social inhibitions are lost, attention cannot be sustained, and there is often marked distractibility. Self-esteem is inflated, and grandiose or overoptimistic ideas are freely expressed. Perceptual disorders may occur, such as the appreciation of colors as especially vivid (and usually beautiful), a preoccupation with fine details of surfaces or textures, and subjective hyperacusis. The individual may embark on extravagant and impractical schemes, spend money recklessly, or become aggressive, amorous, or facetious in inappropriate circumstances. In some manic episodes, the mood is irritable and suspicious rather than elated. The first attack occurs most commonly between the ages of 15 and 30 years, but may occur at any age from late childhood to the seventh or eighth decade.

The episode should last for at least 1 week and should be severe enough to disrupt ordinary work and social activities more or less completely. The mood change should be accompanied by increased energy and several of the symptoms referred to above (particularly pressure of speech, decreased need for sleep, grandiosity, and excessive optimism).

A diagnosis of bipolar 2 disorder is made in the person who has experienced recurrent MDEs and has had at least one lifetime episode of hypomania (see ❯ Table 2.2 for DSM-IV criteria for a hypomanic episode). The MDEs should meet DSM criteria for major depressive disorder (MDD), but if an individual is diagnosed with any of the bipolar disorders, an additional diagnosis of MDD should *not* be made.

What distinguishes bipolar 1 from bipolar 2 is the severity of the episode of mood elevation, with mania being more severe and requiring a diagnosis of bipolar 1. Mania can be distinguished from hypomania in a number of ways. Mania requires 7 days duration, while hypomania requires only 4 days. Psychosis is only found in mania, and its presence automatically "upgrades" a mood episode from hypomania to mania. Admission to a psychiatric facility because of behavior associated with mood elevation similarly automatically requires a diagnosis of mania to be made instead of hypomania. One more difficult aspect of differentiating mania from hypomania is "marked impairment in social or occupational functioning," which mania causes and hypomania cannot cause (by definition). There can be significant room for judgment with this criterion, and decisions pertaining to important personal relationships (i.e., romantic relationships begun or ended) or professional (changing jobs) or academic choices made may not be clearly attributable to mood elevation, and as such may not clearly indicate a diagnosis of mania.

A diagnosis of bipolar disorder precludes certain additional diagnoses. For instance, one individual cannot simultaneously be diagnosed with MDD and bipolar disorder. Bipolar disorder "trumps" MDD. Certainly an individual can have a MDE associated with bipolar disorder. DSM-IV uses specifiers for both bipolar 1 and bipolar 2 disorders, that is, the most recent episode (MRE) depressed, if in fact, a MDE is present. Additionally, a

◘ **Table 2.2**

DSM-IV criteria for a hypomanic episode

A. A distinct period of persistently elevated, expansive, or irritable mood, lasting throughout at least 4 days, that is clearly different from the usual non-depressed mood is required for the diagnosis
B. During the period of mood disturbance, three (or more) of the following symptoms have persisted (four if mood is only irritable) and have been present to a significant degree:
(1) Inflated self-esteem or grandiosity
(2) Decreased need for sleep (e.g., feels rested after only 3 h of sleep)
(3) More talkative than usual or pressure to keep talking
(4) Flight of ideas or subjective experience that thoughts are racing
(5) Distractibility (i.e., attention too easily drawn to unimportant or irrelevant external stimuli)
(6) Increase in goal-directed activity (either socially, at work or school, or sexually) or psychomotor agitation
(7) Excessive involvement in pleasurable activities that have a high potential for painful consequences (e.g., the person engages in unrestrained buying sprees, sexual indiscretions, or foolish business investments).
C. The episode is associated with an unequivocal change in functioning that is uncharacteristic of the person when not symptomatic
D. The disturbance in mood and the change in functioning are observable by others
E. The episode is not severe enough to cause marked impairment in social or occupational functioning, or to necessitate hospitalization, and there are no psychotic features
F. The symptoms are not due to the direct physiologic effects of a substance (e.g., a drug of abuse, a medication, or other treatment) or a general medical condition (e.g., hyperthyroidism)

Note: Hypomanic-like episodes that are clearly caused by somatic antidepressant treatment (e.g., medication, electroconvulsive therapy, light therapy) should not count toward a diagnosis of Bipolar II disorder.

person cannot be diagnosed with both schizophrenia and bipolar disorder. If an individual has prominent symptoms of hypomania or mania in the context of chronic symptoms of schizophrenia, then the correct diagnosis would be schizoaffective disorder-bipolar type.

Other specifiers used to categorize current symptomatology of the bipolar disorders include: MRE manic (bipolar 1), mixed (bipolar 1) hypomanic (bipolar 1 or bipolar 2). A mixed episode describes an individual having simultaneously symptoms sufficient to make a diagnosis of mania and symptoms sufficient to diagnose a MDE. Additional specifiers include, with postpartum onset, with catatonic features, mild/moderate/severe with or without psychotic features. Course specifiers can also be used and include with/without interepisode recovery, seasonal pattern, and rapid cycling.

Rapid cycling is defined as four or more mood episodes during the previous 12 months, and can be used in describing bipolar 1 or 2 disorder. The four (or more) episodes can be of any polarity, and are demarcated by either remission (for 8 weeks) or switch toward the opposite polarity.

Bipolar disorder NOS would be an appropriate diagnosis for the individual with recurrent MDEs, but never having had a DSM hypomanic episode (i.e., sub-threshold hypomania). Frequently in clinical practice, the duration of 4 days is what keeps a period of mood elevation from meeting the threshold for a DSM-IV hypomanic episode. However, a diagnosis of bipolar disorder type 2 can be made using clinical judgment, even with, let us say, only 3 days duration of hypomania, as DSM stresses on diagnostic criteria as guidelines and as such DSM-IV permits flexibility in the assignment of diagnoses.

Cyclothymia remains a DSM-IV diagnosis in the bipolar category and is used for individuals who have depressive episodes that do not meet criteria for MDEs, and periods of mood elevation that may or may not meet criteria for hypomania (but never mania – this would automatically make the diagnosis bipolar disorder type 1). These episodes are "numerous," both depressive and hypomanic, and this mood disturbance needs to be present for at least 2 years. Curiously, if a manic or mixed episode emerges after 2 years, both diagnoses, bipolar disorder type 1 and cyclothymia, may be diagnosed. If an episode of depression meets threshold criteria for a MDE after 2 years, both cyclothymia and bipolar disorder type 2 are diagnosed.

Cyclothymia has elicited minimal interest as a diagnostic entity, and to our knowledge no Food and Drug Administration (FDA)-approved treatment for cyclothymia is available. Very little clinical research is published on this condition and we remain curious if this diagnostic category will survive another iteration of the DSM.

2.1.2 Epidemiology

According to the National Comorbidity Survey Replication (an epidemiologic survey of mental illness that included more that 9,000 households), the lifetime prevalence for bipolar 1 or bipolar 2 disorder is 3.9% (Kessler, Berglund et al., 2005) and the 12-month prevalence for these disorders is 2.6% (Kessler, Chiu, Dempler, & Walters, 2005). Individuals with bipolar disorder are at high risk to also suffer from comorbid anxiety spectrum disorders, impulse control disorders, and substance use disorders. For instance, 60.3% of people with bipolar 1 disorder had a lifetime substance use disorder with rates falling in bipolar 2 disorder to 40.4% (Merikangas et al., 2005). Lifetime anxiety disorder prevalence in people with bipolar disorder is even more striking with rates exceeding 80% for both bipolar 1 and bipolar 2 disorder (Merikangas et al.).

In addition to high frequency or comorbid axis 1 disorders, people with bipolar disorder are thought to have very significant rates of personality disorder, although small sample sizes, nonrandom selection of subject population, as well as overlap between characteristics of certain personality disorders and mood disorder symptoms make definitive estimates of comorbidity difficult. One large epidemiologic survey, the Wave 2 National Epidemiologic Survey on Alcohol and Related Conditons reports borderline personality disorder (BPD) comorbid with bipolar disorder (Grant et al., 2008) in 50.1% of people with bipolar 1 disorder and 39.4% in bipolar 2 disorder. Men with bipolar disorder in this sample were slightly more likely than women to have co-occurring BPD. This study interviewed more than 34,000 individuals, and overall rates of BPD (5.6% of men, and 6.2% of women) in this sample were much higher than reported in the National Comorbidity Survey Replication (NCS-R) estimate of less than 1.5%; i.e., all cluster B personality disorder 1.5%. (Lenzenweger, Lane, Loranger, & Kessler,

2008). The NCS-R, however, also reported an odds ratio of 12.5 for bipolar 1 or bipolar 2 disorder co-occurring with BPD.

2.1.2.1 Clinical Course

Bipolar disorder primarily affects the young, with 25% of cases seen by age 17, and 50% of cases by the age of 25, but an estimated 10% of cases emerge after the age of 50. (Kessler, Berglund et al., 2005) While mood elevation is the hallmark of bipolar disorder, depression is much more common. In a prospective study or patients with bipolar 1, 146 patients were followed with weekly mood charting for an average of 14 years. (Judd et al., 2002) Roughly 50% of the time, patients were euthymic, and patients spent about one third of the time with some level of depression (ranging from a MDE to dysthymia). Roughly 10% of the time, patients had some degree of mood elevation, and 6% of the time was mixed of cycling. Another large study of bipolar patients, The Stanley Foundation Bipolar Network, reported 1 year clinical outcomes of patients undergoing optimal pharmacologic care and were disappointed with only 32.9% of patients being considered minimally ill or well, 40.7% intermittently ill and 26.4% of patients being ill most of the year. (Post et al., 2003).

Patients with bipolar 2 disorder were also followed prospectively for more than 14 years (Judd et al., 2003) Only 46% of time was spent euthymic, with some degree of depression present 50% of the time. Less than 4% of the time was spent hypomanic or cycling.

Bipolar disorder is often a recurrent, relapsing illness. With subsequent episodes, time spent well interepisode (i.e., cycle length) is thought to shorten. (Goodwin & Jamison, 2007) Untreated episodes, both manic and depressive, are thought to last approximately 3 months (Goodwin & Jamison). Long-term outcomes can be variable, but as described above, depression appears to predominate. Rates of all causes of mortality are inordinately high in people with bipolar disorder, and death attributed to suicide estimated in one large cohort study in Sweden was calculated to be about 15–20 times higher than that of the general population. (Osby, Brandt, Correia, Ekbom, & Sparen, 2001)

	Mania/hypomania	Depression
Appearance	Common to be "overdressed," possibly seductive, excessive makeup	Trending toward disheveled, ill-kempt, depending on severity of depression
Psychomotor	Agitation (can be pacing, leg jigging), movements quick	Retardation
Speech	Rapid, pressured, loud	Less spontaneity, slower, can be excessively quiet
Thought process	Illogical, flight of ideas, loose associations	Less commonly thought disordered
Thought content	Grandiose delusions Hyperreligiosity	Less often delusional, may have nihilistic delusions or delusions of catastrophe
Insight	Many times poor to nil	Usually intact

2.2 Recognition of Symptoms and Their Assessment

Bipolar disorder symptomatology can reflect a manic/hypomanic state, mixed state, euthymia, or depression. Signs of mania or hypomania that can be observable include level of arousal, dress, or speech. Individuals experiencing mania or hypomania can exhibit psychomotor agitation with restlessness, fidgetiness, as well as movements that are quicker than normal. They may display impatience in the waiting room. In elevated mood states, men may "overdress" for the occasion, such as wearing a suit jacket solely for a clinician visit. Women may be dressed more provocatively, or more colorfully, and be wearing more makeup or perfume than is customary when the individual is euthymic. A cardinal symptom of elevated mood can be rapid or pressured speech. At its most extreme, pressured speech is difficult to interrupt, and the person with mania can talk without the clinician being able to get in appropriate responses or questions before the subject is back to talking. Pressured speech may be louder than normal, but not necessarily so.

Elevated mood is also associated with disturbances in thought. Prototypically, grandiosity, or at its most extreme, delusions or grandeur can be exhibited by the bipolar individual in a manic condition. Grandiosity is the unfounded belief that someone is more talented or has abilities outside what would be expected from someone's background or educational achievements (i.e., a manic person might believe they will end world hunger, or discover a cure for cancer). Grandiose people might wish to have an audience with the President of the United States. Not all disorder in thought content (as opposed to thought process) in a manic person is grandiose. Paranoia – that is fear of being harmed or watched – is common, as is hyperreligiosity. Formal thought disorder – flight of ideas and loose associations – can be coincident with delusions or independent of delusions in mania. Illogical thought processes at times are necessary in order for delusional beliefs to be maintained.

The depressed condition in bipolar disorder is in many ways opposite to mania in terms of what is observable. Instead of psychomotor agitation as seen in mania, bipolar depression can have an associated psychomotor retardation. Patients might take extra time going from the waiting room to the office. Dress and appearance (i.e., grooming, makeup) can be less neat. Clothes may be wrinkled or dirty.

The opposite of pressured speech can be displayed by the person with bipolar depression. Speech characteristic of depression is in general slower, with less prosody (i.e., the natural rise and fall of tone in normal speech) and less spontaneous. At its most extreme, the profoundly depressed individual may have latency in response, little more than monosyllabic responses, monotony, and low volume.

2.2.1 Maintenance Factors

2.2.1.1 Pharmacotherapy of Bipolar Disorder

There are currently 11 agents with FDA labeling for some aspect of bipolar disorder. (i.e., depression, mania, mixed episode, maintenance). Most of these treat mania, with only two agents FDA-approved for bipolar depression (quetiapine and olanzapine/fluoxetine combination [OFC]), and four maintenance drugs; lithium, aripiprazole, olanzapine, and lamotigine. Most clinicians view any antimanic drug as a maintenance drug, particularly if it appeared beneficial when used to treat an episode of elevated mood.

2.2.1.2 Antimanic Drugs

Currently FDA-approved treatments for acute mania include the standard "mood stabilizers" carbamazepine (Tegretol, Equetro), lithium (Eskalith, Lithobid) and divaproex (Depakote, Depakote ER) and most of the second generation, or "atypical" antipsychotics (AAPs): aripiprazole (Abilify), quetiapine (Seroquel), olanzapine (Zyprexa), risperidone (Risperdal) and zipasidone (Geodon). Chlorpromazine (Thorazine), a first-generation antipsychotic, also carries an indication for the treatment of mania. Lithium and divalproex have been studied in numerous head-to-head clinical trials in the treatment of mania, without there being a clear cut "winner." While head-to-head studies of the second-generation antipsychotics are quite rare (see Perlis, Baker et al., 2006, for example), a meta-analysis of AAPs in the treatment of mania (Perlis, Welge et al., 2006) concludes that there is not a significant difference in response rates among the five currently available AAPs.

2.2.1.3 Divalproex (Depakote)

Originally an antiepileptic drug (AED), divalproex (Depakote) has been used in the treatment of acute mania since the early 1990s, and in the USA, is the most popular traditional mood stabilizer prescribed. In clinical trials, divalproex typically yields response rates of approxima-tely 50%, while placebo response rates tend to fall in the 25–30% range. Divalproex is thought to be preferred in dysphoric mania (Swann, Bowden, Calabrese, Dilsaver, & Morris, 2002). Patients are usually "loaded" with 25 mg/kg in three divided doses, and a target blood level of 75–125 μg/dL has been shown to yield optimal clinical results. (Allen, 2006). Patients require hepatic enzyme and complete blood count monitoring, quarterly, while on this agent, as divalproex can suppress platelet production, and can be somewhat hepatotoxic.

Side effects from divalproex can include alopecia (hair loss), weight gain, and cognitive dulling. In women, divalproex has been linked to hyperandrogenism (high levels of androgen) which leads to hirsutism (hair growth where it does not belong), acne, male-pattern alopecia (hair loss) and irregular menstruation. In a sub-study of the Systematized Treatment Enhancement Program for Bipolar Disorder (STEP-BD) Joffe et al. (2006) compared menstrual period abnormalities and androgen levels in women in treatment for bipolar disorder. They reported androgenizing in divalproex-treated patients at a rate of 10.5% (9/86 patients) as compared to 1.4% (2/144 patients) for patients on other AEDs or lithium. Divalproex is also teratogenic, that is linked to birth defects, specifically with neural-tube closure, leading to spina-bifida.

Divalproex ER (extended release) is a new formulation of divalproex which can be administered once daily. Absorption of divalproex ER is approximately 80% of the comparable original divalproex formulation (confusingly called "DR" – delayed release). For example, 2,000 mg of divalproex ER is thought to have the bioavailabilty equivalent to 1,600 mg of divalproex DR. Time to peak level after ingestion is 7–14 h, and the manufacturer recommends morning dosing so that the peak plasma levels occur closer to bedtime. Trough levels, which should be drawn to guide dosing, need to be 24 h after ingestion, so as to avoid spuriously elevated levels. Divalproex is commonly not administered correctly – dosing at bedtime, with blood sampling in the morning. This can lead to daytime somnolence (when divalproex

levels are peaking) and underdosing (due to blood-level peaks being drawn in the morning) rather than a 24 h trough as is recommended.

2.2.1.4 Lithium

Lithium, for decades the mainstay in bipolar disorder pharmacologic management, has fallen out of favor among many prescribers of late, despite thousands of patient-years of clinical data supporting its utility in both the maintenance phase and manic phase of treatment. Lithium continues to perform well, generally equivalently, when compared to newer agents such as divalproex (Bowden et al., 1994) and quetiapine (Bowden et al., 2005) in acute mania trials, and is often used as an active comparator in maintenance studies, being compared to lamotrigine and olanzapine. (Goodwin et al., 2004) (Tohen et al., 2005) Lithium remains a first-line recommended agent for the treatment of bipolar depression, according to the Texas Medication Algorithm Project (Suppes et al., 2005).

Lithium can have troublesome adverse effects including weight gain, acne, polyuria (excessive urine production) and increased thirst. Patients require blood monitoring for renal and thyroid function, as these both can be negatively affected by lithium. Care must be taken by anyone prescribing medication to individuals already on lithium, particularly blood pressure medications, as ACE inhibitors (captopril, enalapril, capoten, vasotec) and thiazide diuretics (hydrochlorothiazide [HCTZ]) can impair renal excretion of lithium leading to lithium toxicity. Capozide is a branded antihypertensive combining a thiazide and an ACE inhibitor as is Vaseretic.

Lithium appears to confer some protection against attempted and completed suicide (Goodwin et al., 2003). Interest in lithium may be returning with a large **National Institute of Mental Health** (NIMH) study looking at the effects of moderately dosed lithium (600 mg for the first 8 weeks of a 26-week study), the results of which are unavailable at the time of publication.

2.2.1.5 Carbamazepine

While popular in Europe for decades, carbamazepine, originally an AED, only recently became an FDA-approved treatment for mania in the USA. Carbamazepine requires hepatic and complete blood count monitoring, as it is rarely associated with leucopenia (low white cell count). Side effects for carbamazepine can include cognitive dulling, skin rash (rarely serious), bone marrow suppression, as well as gastrointestinal upset.

Dosing of carbamazepine generally falls in the 400–1600 mg total daily dose range, usually taken twice daily. There is no clear "therapeutic" blood levels for carbamazepine, although most practitioners aim to keep patients in the 4–12 µg/dL range.

Carbamazepine has numerous drug interactions, including many psychotropic medications. Carbamazepine induces the metabolism of lamotrigine, requiring dosing schedules for lamotrigine that are twice what is standard. Carbamazepine also induces the metabolism of all of the atypical antipsychotics, requiring compensatory dose increases as well. Carbamazepine is also known to induce its own metabolism, which sometimes leads to relapse in symptoms a month or two after the onset of therapy, which can be rectified by a compensatory dose increase.

2.2.1.6 Other Antiepileptic Drugs and Mania

Psychiatrists have a somewhat embarrassing history of prescribing AEDs "off-label," in the virtual absence of data, for psychiatric conditions. Unfortunately, patients are rarely informed about recommended medications being "off-label," leading patients to believe that what they are prescribed "works" for their condition. Gabapentin (Neurontin) and topiramate (Topamax) are examples of AEDs used by psychiatrists as "antimanic" agents.

Under rigorous study conditions, off-label AEDs sometimes fail spectacularly. In one large study patients were treated for a mixed, manic, or hypomanic episode with lithium, divalproex, or both, and incomplete responders had gabapentin or placebo added. (Pande, Crockatt, Janney, Werth, & Tsaroucha, 2000). Patients randomized to gabapentin actually had statistically significantly poorer outcomes than those randomized to placebo. While gabapentin does have some anxiolytic qualities, it must not be considered a meaningful antimanic agent.

Topiramate is another such AED used off-label as an antimanic for a number of years. In 2006, one article, describing four RCTs of topiramate in acute mania was published (Kushner et al., 2006). All four studies concluded topiramate as being no better than placebo as an antimanic agent. Two of these studies used an active comparator, lithium, which did perform well, validating the results of the studies. Topiramate does appear to have for some individual anorectic qualities (i.e., acts as an appetite suppressant), and in patients who have experienced weight gain associated with psychotropic medication, topiramate at times can ameliorate this.

Oxcarbazepine (Trileptal) is another AED commonly used for mania or mania prophylaxis, and is considered a legitimate second-line antimanic by the Texas Medication Algorithm Project (TMAP, Suppes et al., 2005), probably due to its chemical similarity to carbamazepine. There is a paucity of data from adequately powered RCTs in support of this position.

2.2.1.7 Atypical or Second-Generation Antipsychotics

The Texas Medication Algorithm Project (TMAP) considers any of the five newer AAPs, with the exception of olanzapine, a reasonable "first-line" treatment for mania. Olanzapine is not recommended as first line due to the potential for causing a very significant amount of weight gain as well as dysregulation in glucose and lipid metabolism. Patients undergoing treatment with any of the AAPs require periodic weight, lipid, and glycemia monitoring, as well as surveillance for involuntary muscle movements (tardive dyskinesia). Clozapine, despite being the first AAP, is not widely used as an antimanic agent, due in part to concerns with potential for agranulocytosis (very low white blood cell count), very poor metabolic profile (worse even than olanzapine), and difficulty with titration.

Risperidone (Risperdal) was the first widely used AAP, and is also the first available as a generic. Risperidone is given as either single or twice daily dose. Effective antimanic dose ranges from 2–6 mg. As risperidone doses get higher, it acts more like a first-generation high-potency antipsychotic such as haloperidol (Haldol), with tremor and muscle stiffness becoming more likely adverse effects. Women especially can be sensitive to risperidone's potential for elevating prolactin levels, and this can lead to galactorhea (formation of breast milk). Advantages to risperidone are cost as well as predictable clinical response.

Olanzapine (Zyprexa) was the second widely used AAP. Dosing of olanzapine is the 5–20 mg/day range, and olanzapine is usually dosed once daily (at bedtime). Olanzapine has a highly

unfavorable metabolic profile, i.e., weight gain, worsening of glucose and lipid metabolism, which has relegated olanzapine to a second-line treatment at this point. Olanzapine is also available as part of a combination drug, with fluoxetine, marketed as Symbyax, which has been FDA-approved for bipolar depression. A recent 25-week extension of a clinical trial comparing lamotrigine to olanzapine in the management of bipolar depression (Brown, et al. 2008) reports that one third of patients randomized to olanzapine/fluoxetine combination experienced at least a 7% of baseline body weight increase, and 37% of patients had a meaningful elevation of triglyceride (associated with coronary artery disease). Only 2.9% of lamotrigine-treated patients had 7% weight gain, and 13.4% elevated triglycerides. Cholesterol was also much more likely to be elevated in olanzapine/fluoxetine-treated patients than in lamotrigine-treated patients, 15.9% versus 3.7%. In this study, treatment-emergent high blood glucose was rare and similar in the two groups.

Quetiapine was the next available AAP, and is becoming quite popular for a number of phases of bipolar disorder. For mania, quetiapine is dosed to 600 mg daily, usually in two divided doses. Quetiapine is also one of two FDA-approved treatments for bipolar depression, but for this indication is dosed at 300 mg daily in a single HS dose. Quetiapine can be quite sedating, which for some patients limits its usefulness. Metabolically, quetiapine is more like risperidone than it is like olanzapine, with moderate weight gain and glucose metabolism abnormalities. Quetiapine is now FDA-approved as a maintenance treatment for bipolar disorder, when used in conjunction with lithium or divalproex.

Ziprasidone has the most favorable metabolic profile of the AAPs, but the fewest data demonstrating efficacy in bipolar disorder. Low doses of ziprasidone can be highly activating for the patient with bipolar disorder. For the treatment of mania, ziprasidone should be started at 40 mg twice daily, and increased to 80 mg twice daily on day two. Absorption of ziprasidone is facilitated by lipid (fat) in the stomach, and as such must be taken after eating. Dystonia (muscle contraction) can be problematic with this agent.

Aripiprazole, besides being approved for mania, is one of the four medications indicated as a bipolar maintenance drug. Lower doses of aripiprazole, like ziprasidone, can be activating, and as such, starting doses in the treatment of mania should be in the 15–30 mg range. Akithesia (restlessness or need to move about) is seen commonly with aripiprazole. Metabolically, aripiprazole appears to fall somewhere between ziprasidone and quetiapine. It is certainly not weight neutral, with 20% of patients gaining >7% of baseline body weight over the course of a 100-week maintenance study. (Keck et al., 2007)

2.2.1.8 Maintenance Treatments

Lithium, lamotrigine, aripirazole, and olanzapine constitute the four FDA-approved monotherapies for bipolar maintenance. In practice, any of the antimanic medications can be considered reasonable maintenance treatments, with the possible exception of ziprasidone which as of yet has incomplete data. Of these maintenance treatments, lamotrigine is the only medication that lacks an indication for any acute treatment. Lamotrigine was hoped to have been a useful treatment for bipolar depression, following one positive study (Calabrese et al., 1999) but four subsequent RCTs (Calabrese et al., 2008) did not replicate this finding.

Lamotrigine was demonstrated to be useful as a maintenance treatment when data were pooled (Goodwin et al., 2004) from two studies, one of lamotrigine in bipolar depression

(Calabrese et al., 2003) and the other enrolling recently manic or hypomanic patients who were placed on lamotrigine (Bowden et al., 2003). Putative responders were then randomized to placebo, lithium, or continuation of lamotrigine. Lithium and lamotrigine were more effective than placebo in time to any mood episode, with lamotrigne having more robust effect-preventing depression and lithium more effect-preventing mania. Lamotrigine should be considered primarily as a treatment for the prevention of depression, and not as a robust mania prophylaxis treatment.

2.2.1.9 Bipolar Depression

There are currently two FDA-approved treatments for MDEs associated with bipolar disorder-bipolar depression. These are quetiapine (Seroquel) and olanzapine/fluoxetine combination (OFC, Symbyax). In addition to these two agents, lithium and lamotrigine are considered "first-line" interventions both by the Texas Medication Algorithm Project (TMAP) as well as the Canadian Network for Mood and Anxiety Treatments (CANMAT) (Yatham et al., 2009). However, lamotrigine did not perform better than placebo in five RCTs for bipolar depression (Calabrese et al., 2008), but when data were combined from these studies in a meta-analysis (Geddes, Calabrese, & Goodwin, 2009), a modest advantage was demonstrated for lamotrigine over placebo, favoring patients with more severe depression at baseline.

The utility and safety (i.e., can antidepressants induce affective switch to mania or hypomania) of standard antidepressants in the treatment of bipolar depression is controversial. Standard antidepressants are considered "first-line" in the CANMAT treatment guidelines, but are considered fourth line by the TMAP. We believe the new American Psychiatric Association treatment guidelines for bipolar depression will not recommend standard antidepressants. There is a general consensus that standard antidepressants should not be used alone (i.e., in the absence of a concurrent antimanic agent, either a traditional mood stabilizer such as lithium, valproate, or carbamazepine, or an atypical antipsychotic).

Evidence refuting the effectiveness of standard antidepressants in the treatment of bipolar depression is accumulating. Nemeroff et al. (2001) compared imipramine (a tricyclic antidepressant), paroxetine, and placebo in bipolar patients already maintained on lithium, finding no advantage for patients treated with antidepressant. Sachs et al. (2007), in a sub-study in the Sequenced Treatment Enhancement Program for Bipolar Disorder (STEP-BD), randomized approximately 180 patients on an antimanic agent with bipolar depression to paroxetine or bupropion and a similar number to placebo. Durable recovery, that is, 8 weeks of euthymia, was achieved by 27.3% of patients on placebo, as compared to 23.5% on antidepressant ($p = 0.4$). Rates of treatment-emergent affective switching were similar across both groups.

The disparity of opinion as to the risks and benefits from antidepressant therapy in bipolar depression may stem somewhat from the time frame which one is examining. A number of 8–12-week studies of antidepressant have found them to be effective in bipolar depression (Gijsman, Gedded, Rendell, Nolen, & Goodwin, 2004) but none of these studies use the Sachs "durable recovery" of 8 weeks of euthymia as end point. Regarding safety, 8–12 weeks may not be long enough for the detection of rapid-cycling induction, or to detect increased risk of mania or hypomania. Ghaemi, Wingo, Fikowski, & Beldessarini (2008) performed a meta-analysis of antidepressant studies of at least 6 months. They report that when compared to mood stabilizer alone, the number needed to treat with antidepressant to protect from a new

episode of bipolar depression was 16, as was the number needed to harm by inducing a manic or hypomanic episode with ongoing treatment with standard antidepressant.

2.2.1.10 Evidence-Based Treatment Approaches

In this section, we will describe and evaluate outcomes data for three manual-driven psycho-therapies for bipolar disorder.

Family-focused therapy (FFT), cognitive therapy (CT) and interpersonal social rhythms therapy (IPSRT) constitute the three manual-based psychosocial interventions with random-ized-controlled trial (RCT) outcome data currently used in the management of people with bipolar disorder. Data are limited in support of these interventions, and will be reviewed below.

All three manual-based psychosocial interventions were studied in a large RCT under the umbrella of the Systematic Treatment Enhancement Program for Bipolar Disorder (STEP-BD) program. STEP-BD was a 5-year, multicenter NIMH-funded study that enrolled more than 4,000 patients with bipolar disorder, and was meant to assess interventions and outcomes in the "real-world" settings. Patients suffering an episode of depression were encouraged to enter a sub-study, comparing placebo to paroxetine or bupropion, and these patients were then eligible for the additional psychosocial intervention in STEP-BD. Toward the end of recruiting, the requirement to participate in the medication portion of the depression study was waived. Outcomes for each psychosocial intervention will be reviewed when discussing that specific intervention. Globally, intensive psychotherapy performed better that the control condition (three sessions of psychoeducation). (Milkowitz et al., 2007), but did not significantly differ from one another.

Each of these interventions has been studied in patients concurrently being treated with optimized bipolar disorder medications, i.e., they are not at this point recommended as "stand alone" interventions. Many of the patients enrolled in these RCTs had been recently hospitalized, and most frequently the index episode was depression.

2.2.1.11 IPSRT

IPSRT was developed by Frank (2007) based on the belief that individuals with bipolar disor-der have circadian rhythms that are particularly sensitive to perturbations of daily routines, such as sleep/wake cycle, timing of work, timing of meals, etc., and such disruptions can induce relapse in affective symptoms.

IPSRT targets three paths thought to lead to relapse in bipolar patients: medication non-compliance, stressful life events, and disrupted social rhythms. IPSRT is delivered in four phases, and generally is provided in roughly 20 sessions. In the initial phase of treatment, last-ing 3–5 sessions, a thorough history is taken of mood episodes stressing their relationship to disrupted social routines and interpersonal problems (akin to some aspects of motivational interviewing). Education about bipolar disorder is provided to patient and family when appli-cable. An assessment of interpersonal relationships is obtained. Social routines are assessed using the social rhythm metric. This social rhythm metric resembles in some ways a daily plan-ner and is used to record such activities as waking, going to bed, eating, and social contact. Finally a target for interpersonal therapy (IPT) is selected (i.e., role transition, role disputes,

interpersonal deficits, grief). The continuation phase of IPSRT seeks to reinforce regular social rhythms as well as to continue to progress toward IPT target goals. In the continuation phase, frequency of sessions is reduced from weekly to semi-weekly or monthly. The final phase of IPSRT is to prepare for termination. Skills and routines are reinforced. Sessions are made more infrequent (monthly or less). While absolute termination is not necessary, frequently financial concerns or relocation can make this necessary.

IPSRT performed equivalently to CT and FFT is the study of intensive psychosocial interventions in the STEP-BD treatment of bipolar depression (Milkowitz et al., 2007) as defined by time to recovery and 1-year recovered status. These data are difficult to interpret, as when correcting for family availability, the proportion at 1-year assigned IPSRT (17/30, 56.7%) was no better that those assigned the control condition (37/64, 57.8%).

A second large study compared IPSRT to a nonspecific control condition (Intensive Clinical Management (ICM)) consisting of education about bipolar disorder, medication, sleep hygiene, and careful monitoring of symptoms and side effects (Frank et al., 2005). Patients could be enrolled in any state of illness (depression, mania, mixed). All patients were managed also with manual-driven pharmacotherapy. This study had four cells, with IPSRT and ICM being options for acute phase treatment, as well as options for maintenance phase treatment (i.e., patients were randomized to ICM/ICM, ICM/IPSRT, IPSRT/IPSRT, or IPSRT/ICM). Time to remission and proportion achieving remission were similar for ICM and IPSRT, after controlling for variables such as polarity of index episode, marital status, age, and gender. However, time to recurrence in the maintenance phase favored patients assigned IPSRT acutely ($p = .04$). Assignment in the maintenance phase made no difference in survival time. Patients with high medical burden and those patients with anxiety disorders fared better when assigned ICM.

2.2.1.12 Family-Focused Therapy (FFT)

FFT was developed originally for individuals with schizophrenia and their families and is based on the concept of highly expressed emotion (EE). High EE can be irritability, criticism, anger, or over-involvement, and pertains to the family member's interactions with the patient. In theory, when a person with bipolar disorder (or schizophrenia) interacts with a close family member who has high EE, that rekindles reciprocal emotion in the patient, and this excess of negative emotion is thought to increase vulnerability to relapse.

FFT can include different "family," (i.e., spouses, children, parents, and can even include close friends over the course of treatment). It is delivered in 21 sessions covering 9 months. Not all family members must attend all FFT sessions. Frequency of visits starts as weekly, then is reduced to semi-weekly, then monthly. FFT is delivered in three modules.

At the outset of FFT, patients and their families are educated about bipolar disorder, including symptoms, course, need for medication, as well as stress management. Patients and families identify historic behaviors or situations thought to exacerbate affective relapse. Relapse recognition, the ability to recognize prodromal symptoms of an incipient mood episode, is explored, and patient and family are encouraged to document steps that they will take in such an eventuality.

Communication Enhancement Training (CET) is the focus, beginning at approximately session eight, and continuing for up to ten sessions, of module two. Patients and families are educated about communication styles that can diffuse negative emotion and affect.

The therapist can model and coach both family members and the patients in communication techniques such as active listening, how to make positive requests for change in another's behavior, and how to clearly communicate both positive and negative information to other family members. Families are asked to practice between sessions.

Problem-solving skills training is the focus of module three. Families are asked to identify a target problem, assess potential risks and benefits of proposed solutions, and agree to a strategy and a plan. Less-imposing issues are addressed first, with the hope of mastery experiences facilitating future successes. The final sessions review achievements and facilitate termination.

FFT has performed well in RCTs, although data remain few. The first RCT of FFT in bipolar disorder (Milkowitz, George, Richards, Simoneau, & Suddath, 2003) randomized 70 patients to crisis management (CM), consisting of two 1 h sessions focusing on education, monthly telephone calls, and as-needed crisis sessions. Thirty-one patients were randomized to FFT, consisting of 21 sessions. Survival curves favored the FFT intervention. Interpretation of these results is difficult, as FFT-randomized patients had so much more treatment contact than CM-assigned patients. A smaller RCT (53 total patients) (Rea et al., 2003) compared FFT to an identical number of individual supportive, educational sessions, albeit 30 min in length versus 60 min for FFT. Relapse rates at 1 year did not differ significantly, but at 2 years favored FFT. In the STEP-BD RCT of intensive psychosocial interventions for bipolar depression, patients assigned FFT had a 1-year recovery rate of 77% compared to the control condition recovery rate of 51.5%.

2.2.1.13 CT

CT, originally developed by Beck (Beck, 1979) for the treatment of unipolar depression, has been adapted as a treatment for bipolar disorder. Central to CT is the belief that thought, behavior, and mood are interdependent. While original elements of CT- identifying and modifying maladaptive thinking and behavior remain, certain bipolar disorder-specific elements have been added (Lam, Jones, Bright, & Hayward, 1999). Patients are educated about the stress-diathesis model of bipolar disorder and the need for stress management as well as pharmacotherapy. CT for bipolar disorder also stresses the importance of regulating the sleep cycle as well as levels of daytime activity seeking to prevent over- or understimulation. Patients are educated about signs of relapse (prodrome) and methods to prevent full-blown syndromic relapse. Finally, Lam in particular targets "overcompensation" for time lost to illness, hoping to prevent excessive striving for achievement, which may lead to elevated mood state, or conversely, depression if these efforts are unsuccessful.

Effectiveness data from RCTs of CT for bipolar disorder are equivocal. Scott et al. randomized 253 bipolar patients to treatment as usual (TAU) or CT in a 1:1 ratio. They excluded rapid cyclers and people with severe BPD. Patients received 20 sessions or CT and those randomized to TAU followed up with mental health professionals on an as-needed basis, unconstrained. There was no difference in outcomes between the two groups in rate or severity of recurrence or in medication compliance. Patients with 12 or fewer lifetime mood episodes fared better with CBT, suggesting this may be better utilized early in the course of treatment.(Scott et al., 2006).

Lam et al. (2003) randomized 103 patients with bipolar 1 disorder to CT or TAU. Patients randomized to CT were significantly less likely to have relapsed by 12 months – 28.3% versus

50% (p = .001) Patients assigned CT also had significantly fewer days of depression or manic over 12 months. A 30-month follow up to this study (Lam, Hayward, Watkins, Wright, & Sham, 2005) concluded that CT had no effect on relapse reduction in the last 18 months of the study.

In the STEP-BD study of bipolar depression, CT recovery rates were 60% as compared to 51.5% in the control group. When controlling for the availability of a family member (a positive predictor of recovery), CT recovery rates were 59% versus 57.8% for the control condition.

2.2.1.14 Basic Competencies of the Clinician

We will consider differential diagnosis, psychoeducation, and collaboration with the prescribing physician to be the basic competencies of the clinician.

2.2.1.15 Differential Diagnosis

Errors in making the diagnosis of bipolar disorder can be both of omission (i.e., missing the diagnosis) or commission (i.e., diagnosing bipolar disorder when it is not present). Both types of errors are frequently made, leading in many cases, to treatments that will not be helpful (errors of omission will lead to nonbipolar-specific treatment) or subjecting patients to the morbidity of bipolar-specific medication unnecessarily (errors of commission). Furthermore, erroneously diagnosing bipolar disorder in a person without bipolar disorder will usually preclude the institution of a more effective therapy, such as treating a person with BPD with a mood stabilizer rather than with dialectic behavior therapy.

A frequent diagnostic error of omission – missing the diagnosis of bipolar disorder – occurs when a person presents with symptoms consistent with a MDE. Unfortunately, the diagnostic criteria for an MDE are identical whether the episode is part of MDD or bipolar disorder. The key to diagnosing bipolar disorder in a person with a MDE is eliciting a history of manic or hypomanic episodes. Elevated mood episodes are often missed in retrospect when irritability is more prominent than euphoria or feelings of well-being. A collateral informant (spouse, parent, etc.) can often offer insight into periods of abnormal mood not necessarily considered pathologic by the patient. Many times a patient will endorse periods of elevated mood in the past, that under closer scrutiny are simply nonpathologic reactions to favorable life events. Associated features, such as rapid or pressured speech, decreased need for sleep, impulsivity in potentially harmful areas need to be explored to accurately diagnose historic episodes of mania or hypomania.

While criteria for a MDE are identical for MDD and bipolar disorder, there are some clinical characteristics in patients that can help guide the practitioner in differentiating between unipolar depression and bipolar depression. A large study in Great Britain compared 443 patients with bipolar 1 disorder to 593 patients with MDD (Forty et al., 2008). Patients with bipolar depression were more likely to have diurnal variation (consistent mood fluctuation within each day), a higher number of lifetime MDEs, shorter duration of MDEs, hypersomnia (excessive sleep), and a history of psychosis. In Canada, McIntyre, Soczynska, Konarski, & Kennedy reviewed charts of 1,000 patients in a specialty mood disorders clinic (McIntyre et al.,

2007) seeking to find ways to distinguish bipolar from unipolar depression. Patients with bipolar disorder were more likely to have been hospitalized, had earlier age of onset, more numerous lifetime MDEs, were more likely to have substance use disorders, and were less likely to be employed. Of note, 16% of these patients had been misdiagnosed with MDD when in fact they were found to have bipolar disorder. Finally, a large outpatient study compared clinical characteristics and history of 126 unipolar and 187 bipolar 2 patients (Benazzi, 2003). Bipolar depression was more likely to have atypical features (hypersomnia, hyperphagia) (49.7% versus 18.2%), earlier age of onset (mean 21 years versus 29.5 years), family history of bipolar 2 disorder (54.2% versus 9.8%), and family history of bipolar 1 (10.8% versus 4.9%). Psychosis was less common (7.4% versus 10.3%) in bipolar 2 disorder than MDD.

Another potentially troublesome differential diagnosis can occur in patients with a history of psychosis. Until the advent of lithium in the 1970s, most individuals when presenting with psychosis were diagnosed as having schizophrenia. This has changed dramatically in the last 20 years. A review of discharge records of patients admitted with psychosis to six psychiatric teaching hospitals (Stoll et al., 1993) from 1972–1991, reveals a threefold decrease in schizophrenia diagnosis, coincident with a fourfold increase in affective disorder diagnosis – that is unipolar depression and bipolar disorder. In the USA, African-Americans continue to be disproportionately diagnosed with schizophrenia (Strakowski et al., 2003) when compared to whites, rather than bipolar disorder. Clearly, elucidating significant affective symptoms, especially coincident with psychotic symptoms, will differentiate schizophrenia from bipolar disorder. A patient with significantly reduced need for sleep when psychotic should alert any diagnostician to strongly consider bipolar 1 disorder.

Duration of impairment is another way to differentiate schizophrenia from bipolar disorder, with "continuous signs of disturbance persist for at least 6 months" (American Psychiatric Association, 1994, p. 285) necessary for a diagnosis of schizophrenia. Social and occupational functions tend to be more insidiously and chronically affected by schizophrenia than bipolar disorder, as described by Criterion B of schizophrenia.

▶ For a significant portion of the time since the onset of the disturbance, one or more major areas of functioning such as work, interpersonal relations, or self-care are markedly below the level achieved prior to the onset.(American Psychiatric Association, p. 285)

A diagnostic category, schizoaffective disorder is reserved for patients who have had a manic, depressive, or mixed episode during a period of "uninterrupted illness" (American Psychiatric Association, p. 295) and also meet criterion A for schizophrenia – criterion A being 2 or more of the following: delusions, hallucinations, disorganized speech, grossly disorganized or catatonic behavior, negative symptoms. In schizoaffective disorder the delusions or hallucinations must be present in the absence of affective symptoms, and the affective symptoms are present for a substantial portion of the episode. If delusions and hallucinations are present only during affective episodes, a diagnosis of bipolar 1 or MDD (with psychotic features) is made.

Differentiating bipolar disorder from BPD can also be challenging, as these disorders can share some similar symptoms, including impulsivity, affective instability, intense irritability, and suicidal behavior. These disorders are not exclusive; that is, both can co-occur in the same individual. Several diagnostic criteria are specific to BPD, however, and can be helpful in differentiating the two conditions. People with BPD can display "frantic efforts to avoid real or imagined abandonment," as well as have a pattern of unstable personal relationships (nonspecific to borderline personality) "characterized by alternating extremes of idealization

and devaluation"(much more specific for borderline personality). Another area that can differentiate borderline personality from bipolarity is in the duration of the affective instability, with bipolar affective episodes usually lasting much longer than affective episodes found in borderline personality episodes. As described in criteria number 6 of the DSM-IV for borderline personality, "affective instability due to a marked reactivity of mood" (e.g., intense episodic dysphoria, irritability, or anxiety, usually lasting a few hours and only rarely lasting more than a few days). This mood reactivity is in response to environmental triggers, usually interpersonal ones, which is not seen so typically in bipolar disorder. Finally, "transient, stress-related paranoid ideation or severe dissociative symptoms" is one of the nine diagnostic criteria of borderline personality; dissociation is rarely seen in bipolar disorder. Diagnositic errors of omission, missing bipolarity in a person believed to have BPD, as well as commission, diagnosing bipolarity in a person with only borderline personality, are frequently made.

Diagnosis of bipolar disorder in a person with a significant history of substance abuse or dependence can be particularly challenging, especially if a stimulant such as cocaine or amphetamine is involved. This can lead to a diagnostic error of commission, i.e., diagnosing bipolar disorder where it does not exist. Individuals with substance use disorders can display and report unstable mood – depression, irritability, anger, as well as impulsivity in the context of ongoing substance use. Stimulant drugs can lead to symptoms identical to mania – decreased need for sleep, grandiosity, auditory hallucinations or paranoia, and irritability. The golden standard (outside of observing manic symptoms in a patient in a controlled environment with no access to substances) lies in reviewing with the patient manic or hypomanic episodes during periods of abstinence from substances, when possible. A review of 85 patients admitted to a dual-diagnosis psychiatric unit in the USA (Goldberg et al., 2008) and diagnosed with bipolar disorder, revealed only 33% actually meeting DSM-IV criteria for bipolar 1 or bipolar 2 disorder. The majority of these people who failed to meet diagnostic criteria were due to insufficient symptoms of mania or hypomania (i.e., racing thought, grandiosity, flight of ideas) during their period of "mood elevation." More than one third of this population also did not have periods of abstinence of sufficient duration to identify manic symptoms independent of substance use.

2.2.1.16 Psychoeducation

A primary function of a therapist when working with a person with bipolar disorder is that of psychoeducation (❯Table 2.3). Psychoeducation, when delivered in a group setting, has been shown to delay time to affective relapse (Colom et al., 2003, 2009), when compared to a control nonspecific group intervention. Psychoeducation seeks to inform the patient as to the cyclical, recurrent nature of bipolar disorder and stresses the benefits of adherence to medication recommendations. Psychoeducation reinforces to the patient the biologic basis of bipolar disorder and helps ameliorate shame related to behaviors influenced by mood episodes. Patients are taught that bipolar disorder is a chronic condition, similar in some ways to diabetes and hypertension that requires lifestyle changes, as well as frequent monitoring and consistency in medication compliance. Consequences of affective episodes are explored, seeking to bolster the motivation of the individual to remain in treatment. Psychoeducation appears to be most useful when delivered to a more euthymic patient.

◘ **Table 2.3**

Elements of psychoeducation (Barcelona Bipolar Disorders Program) (Colom et al., 2003, with permission)

1. Introduction
2. What is bipolar illness?
3. Causal and triggering factors
4. Symptoms (1): mania and hypomania
5. Symptoms (2): depression and mixed episodes
6. Course and outcome
7. Treatment (1): mood stabilizers
8. Treatment (2): antimanic agents
9. Treatment (3): antidepressants
10. Serum levels: lithium, carbamazepine, and valproate
11. Pregnancy and genetic counseling
12. Psychopharmacology versus alternative therapies
13. Risks associated with treatment withdrawal
14. Alcohol and street drugs: risk in bipolar disorder
15. Early detection of manic and hypomanic episodes
16. Early detection of depressive and mixed episodes
17. What to do when a new phase is detected
18. Regularity
19. Stress management techniques
20. Problem-solving techniques
21. Final session

Psychoeducation for bipolar disorder can be thought to encompass four main topics – the first being broad education about bipolar disorder. This includes symptoms of mania/hypomania, depression, and mixed states. The clinical course of bipolar disorder is presented, as well as factors associated with relapse. In this phase of treatment, patients can be helped to adjust to life with a chronic illness. Patients may need to grieve the loss of their "well" self. Some patients may be relieved that there is a biologic basis that has driven much of the chaotic interpersonal or professional decisions made in the past. The second main theme includes pharmacologic treatments for the disorder. Standard mood stabilizers, antidepressants, a typical antipsychotics, benzodiazepines can all be discussed. Patients can identify what is beneficial as well as problematic about somatic treatments they have experienced, including active treatments. Expectations as to outcomes with medication compliance can be explored and adjusted. The third main theme addresses identification of relapse – both elevated and depressed mood, as well as relapse management strategies. Regularity in daily routines is stressed (a theme common to all psychosocial treatments for bipolar disorder) as well as the association of substance abuse and relapse. The final section can include stress management and problem-solving skills, and depending on the ability of the patient to internalize such material, it can be time-limited or not. Patients may continue to require boosters targeting any of

the previously covered material, and may continually struggle with ambivalence toward pharmacologic management.

Commonly the individual providing psychoeducation or any of the psychosocial interventions is not the person prescribing medications to the patient with bipolar disorder. An open line of communication is essential between these two providers, as issues with medication may be discussed with the therapist that the patient may choose not to discuss with the prescriber. Conversely, the prescribing clinician may identify issues that would be amenable to psychotherapeutic intervention, but time limitations may preclude immediate attention from the prescriber.

Of additional benefit to the person with bipolar disorder is open communication between family members, significant others, and the therapist. These individuals can be in a position to first detect signs of relapse, and alert members of the treatment team. Frequently, patients with bipolar disorder lack insight, or symptoms may impair judgment, leading to not reporting signs of relapse in standard sessions. A collateral informant is in the unique position of knowing the patient, knowing signs of relapse, and being present to a degree that they are often the first to detect relapse in the bipolar patient.

2.3   Expert Competence

To our knowledge, there are no formal guidelines or processes that would lead to explicit recognition as an expert practitioner in the areas of assessment or treatment of bipolar affective disorder. We therefore review in the following paragraphs some suggested guidelines to establish expertise in the most important areas of practice for a clinical psychologist. To this end, we cannot underscore enough that mastery of the requisite skills requires clinical exposure to a wide range of individuals of bipolar affective disorder in both ambulatory and hospital-based care settings and appropriate supervision that far surpasses the standards for licensure and clinical accreditation.

2.3.1   Diagnosis

We consider being able to make a correct diagnosis of the type I, type II, and NOS forms of bipolar affective disorder according to DSM-IV TR criteria and to be able to make an informed differential diagnosis between bipolar affective disorder and the most common alternate diagnoses (i.e., recurrent MDD, schizophrenia, schizoaffective disorder, BPD, and mood disorders related to various substance misuse disorders) to be a core competence. The expert practitioner should be able to help clarify the diagnoses of individuals with more complex and challenging conditions and, when certain points of differential diagnosis cannot be resolved based on available information, should be able to outline a plan that will lead to collecting the necessary information. This includes willingness to interview loved ones and significant others and have the wisdom to contact past care providers and review prior records.

Although standardized instruments such as the Structured Clinical Interview for Diagnosis (SCID) of DSM-IV TR Mental Disorders are not used in day-to-day clinical settings, we would suggest that the expert practitioner obtain training and certification in the use of this interview

and remain current with the changes in the nomenclature and diagnostic criteria that inevitably will follow (e.g., DSM-V and subsequent editions). If sufficient supervisory expertise is not available during training, the motivated learner may wish to follow the suggested training program developed by the faculty and staff of the Biometrics Research Department of the New York State Psychiatric Institute (http://cpmcnet.columbia.edu/dept/scid/training/overview.html), which is affiliated with the Columbia University College of Physicians and Surgeons. This training program includes an 11 h, eight DVD series, known as SCID 101, as well as a suggested stepwise program for establishing diagnostic reliability. Importantly, experienced diagnosticians will be able to sort out the endemic problems with comorbidities (i.e., a majority of individuals with bipolar disorder will meet DSM-IV criteria for at least one other Axis I or Axis II disorder). We suggest that the true expert has sufficient mastery of the SCID to serve as a local or regional trainer for the next generation of interviewers.

In many care settings even the most skilled interviewer will encounter people seeking treatment for episodic, fluctuating, or chronic mood disorders that present with a challenging admixture of behavioral and temperamental characteristics seem to suggest that the proper diagnosis is not simply a MDD, but which fall well below the threshold for a formal diagnosis of bipolar 1 or bipolar 2 disorder. Some clinicians tend to view these conditions within a broader transitional grouping, referred to as bipolar spectrum disorders; in DSM-IV TR most of these individuals would be classified as having a bipolar disorder NOS. In recent years, a self-report measure known as the mood disorder questionnaire (MDQ; Hirschfeld, 2002) has been increasingly used as a screening tool for bipolarity; like other screening tools, this scale is strong on sensitivity (i.e., most people with bipolar disorder have high MDQ scores), at the expense of limited specificity (i.e., about 50% of people who score high on the MDQ do not meet SCID criteria for bipolar 1 or bipolar 2 disorder).

The past decade has witnessed introduction of a large number of newer therapies for bipolar disorder and, as inevitably happens, more therapeutic options are associated with an increased "recognition" of the disorder. The expert practitioner has the wisdom to view the term bipolar spectrum as a potentially useful heuristic, with the perspective to understand that any decision to approach treatment as if the individual had a confirmed diagnosis of bipolar disorder was akin to hypothesis testing. As recently reported by Zimmerman, Ruggero, Chelminski, & Young (2008), a fairly large proportion of people presenting for treatment with a "known" diagnosis of bipolar disorder actually do not meet full DSM-IV criteria on the basis of a SCID interview.

2.3.2   Assessment

Beyond expertise in using the SCID and making an accurate diagnosis, an expert practitioner should be a reliable rater of disease state severity with standardized rating scales. With respect to the depressive pole of the illness, the Hamilton Rating Scale for Depression (HAM-D; Hamilton, 1960) and the Montgomery-Asberg Depression Rating Scale (MADRS; Montgomery & Asberg, 1979) are the most commonly used in research studies, though the Inventory of Depressive Symptomatology (IDS; Rush et al., 1986) has the added advantage of being also available in self-report and abbreviated or "quick" versions. A number of scales are likewise used to rate the severity of mania, with the Young Mania Rating Scale (YMRS; Young, Biggs, Ziegler, & Meyer, 1978) currently having the broadest use in treatment research.

Other more specialized areas of assessment in bipolar disorder include personality (i.e., DSM-IV TR Axis II) and neuropsychological and neurocognitive performance. Expertise in these areas goes far beyond mastery of a particular interview or test protocol, but instead is based on recognition when it is most productive and valid to administer such measures and when and how the data should be interpreted. Specifically, both Axis II assessments and neuropsychological test performance are highly state-dependent. Depressive states – even subsyndromal ones – tend to be associated with greater endorsement of Cluster C traits and psychomotor slowing and decreased effortful processing. Conversely, hypomania and mania are associated with greater endorsement of Cluster B traits and greater impulsivity on cognitive tasks.

2.3.3   Treatment

We believe that a clinical psychologist with established expertise in bipolar disorder should have a working knowledge of the major classes of medications used to treat bipolar disorder, as well as the common side effects associated with these medications. Although it would not be the psychologist's job to actually manage these medications, it is possible that the psychologist will be seeing the treated individual more frequently than the prescribing physician and, as such, may be the first health care provider to recognize when a treatment is having an intolerable side effect or some other untoward effect. An expert practitioner would not only be able to recognize such problems, but also be able to facilitate addressing the problem in a timely manner, without inadvertently fostering a split in the triadic therapeutic alliance. This includes the clinical judgment to know when it is best to contact the physician immediately (with, of course, the client/patient's consent) and when it is best to encourage their client/patient to make the call themselves. Clinical sophistication also is needed to avoid falling into the trap of harboring "secret" information about the individual's dissatisfaction with treatment.

Expertise in psychotherapy of bipolar disorder should begin with being able to provide accurate psychoeducation about the illness and its treatment, including comfort and familiarity with discussing medication adherence. As many individuals with bipolar disorder make unilateral decisions to stop their medications at some point, the expert practitioner should be comfortable openly talking about the reasons for and against medication adherence and be able to elicit negative thoughts and feelings about the diagnosis and psychotropic medications, both more generally and more specifically. As there is an increasing evidence that both group and individual models of psychoeducation can significantly improve the outcomes of individuals with bipolar disorder (Colom & Lam, 2005), we suggest that one standard for expertise within a clinical care setting such as a mental health clinic would be to implement and oversee such activities and monitor outcomes.

Finally, although we do not believe that, at this time, it is an essential standard for the expert practitioner to master one of the empirically supported individual or group psychotherapies for bipolar disorder, we do believe that the evidence base for these therapies is growing such that it would be wise to seek training and ongoing supervision in FFT, cognitive behavior therapy (CBT), or IPSRT for bipolar disorder. For individuals who have not been exposed to one or more of these therapies during training, the following plan is recommended: buy (and read) the book and attend a 1- or 2-day long training workshop conducted at the

annual meetings of the American Psychological Association, the American Psychiatric Association, or the Association for Behavioral and Cognitive Therapies. Typically, criteria for minimum clinical competence require at least two supervised cases; generally, at least several years (and some requisite number of cases) are necessary before one has sufficient mastery to teach and train.

2.4   Summary

Bipolar disorder is a commonly recurrent psychiatric illness that is frequently diagnosed, yet at times difficult to diagnose accurately. People with bipolar disorder have high rates of comorbid substance use disorders, anxiety disorders, and personality disorders, making this a challenging population with which to work. Some people with bipolar disorder have excellent interepisode functioning, which can make this also a rewarding population for the clinician.

Pharmacotherapy remains a mainstay to successful management of bipolar disorder, but psychotherapy appears to offer added benefit. Common in all of the psychosocial interventions for bipolar disorder is stressing regularity in sleep/wake cycle, reduction or elimination of substance use, medication adherence, and relapse prevention. Approaches adapted from unipolar depression (IPT, CBT) and schizophrenia (FFT) can be added seeking to modify interpersonal stress, maladaptive cognitions and behaviors, and decrease high EE in the family unit, with the hope of reducing affective relapse that is so prevalent in this population.

3 Specific Phobia

Josh M. Cisler · Jeffrey M. Lohr · Craig N. Sawchuk · Bunmi O. Olatunji

Abstract: This chapter summarizes basic and expert clinical competencies in specific phobia. Familiarity with diagnostic nomenclature and use of behavioral approach tasks facilitate accurate assessment of specific phobia. The clinician should be familiar with basic processes maintaining specific phobia, such as the use of safety behaviors. Knowledge of exposure-based intervention protocols is mandatory. Expert clinical competencies include knowledge of procedures to augment exposure-based interventions as well and cultural influences in specific phobia. Mobilization of non-specific factors, conducting therapy outside of the consultation room, and collaborative problem solving with the client may facilitate the transition from basic to expert clinical competencies.

3.1 Overview

Specific phobia is one of the most common psychological disorders with a 12-month prevalence rate of 9% (Kessler, Chiu, Demler, & Walters, 2005). It is characterized by excessive fear and/or avoidance of circumscribed objects/situations (American Psychiatric Association [APA], 2000). The circumscribed nature of fear in specific phobia facilitates controlled laboratory experiments; thus, specific phobia has been widely utilized in the past 4 decades to study the basic processes of fear and anxiety. Indeed, McNally (2007, p. 751) makes the following remark during a review of mechanisms of change in exposure therapy: "Many … analogue studies concerned fears of snakes in college students, prompting one wag to quip years later about the Great Snake Phobia Epidemic that had swept through American psychology departments during the 1960s and 1970s." The extensive research utilizing specific phobia has consequently resulted in a wealth of knowledge about the assessment, maintenance, and treatment of specific phobia. It is no surprise that specific phobia has been described as "one of the best-understood psychological disorders" (Antony & Barlow, 2002; p. 380). This chapter outlines the vast specific phobia literature for the purpose of facilitating the development of basic and expert clinical competencies in specific phobia. The following is a brief overview of the chapter.

3.1.1 Assessment

The clinician should first be familiar with the diagnostic nomenclature and criteria for specific phobia. Structured clinical interviews can assist in minimizing false positives and negatives. Behavioral assessment, including behavioral approach tasks, is a useful clinical tool in assessing specific phobia as well as tracking treatment progress. Numerous self-report measures exist and can also assist in assessing the presence of symptoms.

3.1.2 Maintenance

Cognitive factors have received increased empirical support as maintenance factors for anxiety disorders in general and specific phobia in particular. Attentional biases refer to hypervigilance for threat-related stimuli, which increase awareness of sources of danger and can consequently maintain levels of fear by reinforcing phobic beliefs (e.g., spiders really are everywhere). A tendency to overestimate negative outcomes with phobic stimuli similarly serves as a maintenance factor for phobias. Spider phobia and blood-injection-injury (BII) phobia have been linked with disgust, and heightened disgust responses toward these stimuli may potentiate fear. Safety behaviors refer to behaviors an individual performs to prevent feared outcomes. Safety behaviors may maintain fear by preventing exposure to corrective information and attributing nonoccurrence of the feared outcome to performance of the safety behavior.

3.1.3 Evidence-Based Treatment

Exposure has been widely accepted as the treatment of choice for specific phobia. Exposure may entail in vivo exposure or imaginal exposure to the feared objects/situations. Exposure has demonstrated superior efficacy compared to wait-list control groups, nonspecific factor control groups, and alternative credible treatments. Accordingly, exposure is a specific active treatment component for specific phobia. One session of prolonged exposure has been shown to be as effective as five sessions.

3.1.4 Mechanisms of Change in Exposure

Emotional processing theory (EPT; Foa & Kozak, 1986) posits that exposure reduces fear through exposing the individuals to information that is incompatible with their fear structure. For example, individuals may believe that they will asphyxiate in enclosed places. Exposing individuals to those feared outcomes and allowing the individuals to learn that the feared outcomes do not occur weaken the fear response. Contemporary research on mechanisms of change in exposure similarly emphasizes ways to bolster the inhibition of fear responses, such as performing exposure in multiple contexts.

3.1.5 Basic Clinical Competencies

The basic clinical competencies for specific phobia should include knowledge of the basic information about specific phobia and emotions in order to educate the client about the problem. The clinician should be familiar with procedures to assess specific phobia and track changes in symptoms throughout treatment. Familiarity with how to conduct exposure protocols is mandatory.

3.1.6 Expert Clinical Competencies

Expert clinical competencies in specific phobia include knowledge of the procedures to augment the efficacy of exposure. Psychological procedures that potentiate exposure efficacy

include conducting exposure in multiple contexts and preventing the use of safety behaviors during exposure. Pharmacological procedures include the use of D-cycloserine, a partial N-methyl-D-aspartate agonist, that has been found to bolster extinction learning. Finally, expert clinical competencies include appreciation for cultural issues that may affect the presentation and maintenance of specific phobia.

3.1.7 Developmental Trajectory

Several principles may help a clinician develop expert clinical competencies in specific phobia. These principles include mobilizing the nonspecific treatment factors, mapping the structure of the client's fear in order to help elucidate the content and organization of the subjective experience of the client, identifying signals of danger and safety for the client, conducting exposure outside of the consultation room, and using collaborative problem-solving skills with the client to treat the phobia.

3.2 Assessment of Specific Phobia

3.2.1 Diagnostic Criteria

The Diagnostic and Statistical Manual of Mental Disorders, fourth edition text revision (DSM-IV TR; APA, 2000) outlines the following diagnostic criteria for specific phobias:

(A) Marked and persistent fear that is excessive or unreasonable cued by the presence or anticipation of a specific object or situation.
(B) Exposure to the phobic stimulus almost invariably provokes an immediate anxiety response, which may take the form of a situationally bound or situationally predisposed panic attack. In children, the anxiety may be expressed by crying, tantrums, freezing, or clinging.
(C) The person recognizes that the fear is excessive or unreasonable. In children, this feature may be absent.
(D) The phobic situation(s) is avoided or else is endured with intense anxiety or distress.
(E) Avoidance, anxious anticipation, or distress in the feared situation(s) interferes significantly with the person's normal routine, occupational (or academic) functioning, or social activities or relationships, or there is a marked distress about having the phobia.
(F) In individuals under age 18 years, the duration is at least 6 months.
(G) Anxiety, panic attacks, or phobic avoidance associated with the specific object or situation is not better accounted for by another mental disorder.

Clinicians are also encouraged to specify the phobia subtype based on one of the following categories: animal, such as dogs, snakes, and insects; situational, including driving, flying, and enclosed spaces; natural environment, such as storms, heights, and dark; BII, including injections, blood draws, and medical procedures; and, other, which encompasses a broad range of potential phobic stimuli, such as choking, vomiting, and clowns. The BII subtype is unique from other phobia subtypes due to a history of fainting or partial fainting episodes in approximately 80% of cases (Öst, 1992). Furthermore, many patients report disgust or aversion, rather than fear, upon exposure to phobic-relevant cues (Olatunji & Sawchuk, 2005). While fainting

symptoms and disgust are not necessary to establish a diagnosis of BII phobia, they do need to be routinely evaluated as they can serve significant roles in phobic avoidance, functional impairments, and treatment planning.

3.2.2 Clinical Interview

Several well-validated, structured clinical interviews exist that can assist in the thorough evaluation of specific phobias and their associated comorbidities. The Anxiety Disorders Interview Schedule for DSM-IV (Brown, Di Nardo, & Barlow, 1994) and the Structured Clinical Interview for DSM-IV (First, Spitzer, Gibbon, & Williams, 1996) have received the most empirical support, and are routinely used in clinical trial research. Beyond structured clinical interviews, the following questions during an initial evaluation can assist in the recognition of phobic cues, symptoms, and behaviors: (1) Do you feel intense anxiety or fear when confronted by certain animals, objects, or situations? (2) Do you think this fear is excessive or unreasonable? (3) Are you avoiding these animals, objects, or situations because of your fear? (4) In what ways has this anxiety or fear interfered with your life? (5) How would you react if you were exposed to the animal, object, or situation right now? (6) Have you ever fainted or almost fainted around blood, injuries, or needles?

The clinical interview may also cover additional, relevant areas including biologic risk factors for anxiety (e.g., familial heritability), age of onset, nature of onset (e.g., direct or vicarious acquisition; onset in the absence of negative experiences), beliefs and behaviors that have maintained the phobia across time, the evolution of substance use and safety behaviors as a way of attenuating anxiety-related symptoms, and previous treatment seeking and response.

Select questions during the clinical interview can also assist in differential diagnosis. The most common differentials include: panic disorder (high anticipatory anxiety across a range of situations; recurrent, unexpected panic attacks in the absence of any phobic cues; and, interpretation of physical symptoms as dangerous); social anxiety disorder (focus of concern over being embarrassed and negatively evaluated by others); obsessive compulsive disorder (experience of intrusive, unwanted thoughts; avoidance of objects related to obsessional theme); and posttraumatic stress disorder (onset following a potential life-threatening stressor; emotional numbing and reexperiencing the trauma). A common rule out among children is separation anxiety disorder, in which the focus of the fear involves perceived and actual separation from specific family members and loved ones.

3.2.3 Behavioral Assessment

Behavioral observation can be a simple, highly efficient, and informative method for assessing phobias. While individuals may become noticeably anxious or nervous when discussing their phobic fears, a behavioral approach/avoidance task (BAT) is an ideal part of the assessment process as it allows the clinician to directly observe the patient's reaction to various representations of phobic cues in "real time" (Antony & Swinson, 2000). Phobic cues, by definition, reliably elicit a fear response upon actual or anticipated exposure. The primary limitation of clinical interviews is the potential for retrospective recall biases. Furthermore,

pervasive avoidance behavior may also result in a lack of contact with the feared object or situation across time, thereby underscoring the importance and value of conducting BATs. While BATs should be planned in the same manner as an exposure-based intervention, the goal for the BAT is not to gain fear reduction in the presence of the phobic cue. Rather, BATs offer a current baseline of the nature and intensity of the fear response, including subtle and overt avoidance tendencies. Such a baseline can be used strategically as an index of treatment progress and outcome across time. The rationale and procedure for the BAT as part of the assessment process should be thoroughly explained to the patient and proceeded within a gradual, predictable, and controllable manner. Common areas to assess would include subjective units of distress rating (e.g., 0 = no fear at all, to 100 = intense anxiety), relevant physical reactions, fearful thoughts and beliefs, degree of approach, and subtle and overt avoidance behaviors.

3.2.4 Self-Report Measures

A plethora of self-report questionnaires is readily available and relatively easy to administer at any point during the assessment process. Self-report questionnaires can be an efficient means for gathering specific information on the range of phobic cues and triggers, especially when time is limited during the in-person clinical interview. Similar to the limitations of the clinical interviews, questionnaire responses are subject to recall biases and only provide an approximation of the individual's actual phobic response. Selecting the appropriate battery of questionnaires should consider including those measures directly relevant to the phobic condition of interest, screening for associated comorbid conditions (e.g., depression, substance use), and ruling out other related conditions (e.g., panic disorder). Furthermore, self-report measures can be readministered as a means of tracking treatment response and outcome, and may also provide useful information for designing exposure exercises. Clinicians are encouraged to select measures with sound psychometric properties and those with established norms to compare with community and clinical populations. The *Practitioner's Guide to Empirically Based Measures of Anxiety* (Antony, Orsillo, & Roemer, 2001) is an excellent resource with sample measures across a range of phobic conditions, easy to interpret scoring criteria, and brief summaries of normative studies. The portability and ease of administration of self-report questionnaires should be tempered with caution as to not overload patients with too many unnecessary measures at the outset. A stepwise approach of selecting additional measures based on the course of the evaluation process is a reasonable way of minimizing burden on the patient.

3.3 Maintenance Factors of Specific Phobia

3.3.1 Development

There is a significant heterogeneity in the expression of specific phobias, which is consistent with multiple pathways of etiology. The pathways to development of specific phobia may include classical conditioning, modeling or vicarious learning, and negative information transfer (Rachman, 1977). Although not without controversy (McNally, 1987), there is also

considerable evidence that some phobias are "pre-wired" for development through evolutionary selection (Davey, 2004). Indeed, phobias tend to be focused on a limited set of fears (i.e., snakes) that have evolutionary significance. In the context of a psychological vulnerability to experience anxiety (i.e., trait anxiety), experiences along any one of the different pathways may facilitate the development of phobic responses. Such responses are generally automatic and are not moderated by conscious cognitive control (Öhman & Soares, 1993). According to Öhman and Mineka (2001, p. 515), "[i]n the context of phobia, cognitions may be viewed as evolutionary shaped mechanism to assure that fearful individuals keep avoiding threatening situations. Thus, cognitions are important in maintaining phobic behavior."

3.3.2   Attentional Bias for Threat

Cognitive theories consider attentional biases to be central to the phenomenology of phobic behavior (Beck & Clark, 1997). Accordingly, the tendency for phobic individuals to display hypervigilance toward threat may maintain their propensity to respond with fear by reinforcing phobic beliefs. Although not without limitations (see MacLeod, 1991, for a review), the most frequently used paradigm for examining attentional bias among phobic individuals is a modification of the Stroop (1935) color-naming task (see MacLeod, for a review). In the Stroop task, participants are asked to name the color in which each word is presented while ignoring the meaning of the word. In the "emotional" Stroop task, slower color-naming of threat-relevant words is said to represent an attentional bias toward threat material. Color-naming interference as an indicator of attentional bias has been found in specific phobia (e.g., Lavy & van den Hout, 1993; Lavy, van den Hout, & Arntz, 1993) with phobics taking significantly longer to color-name phobic-relevant words.

The intensity of phobic complaints also appears to be significantly associated with the degree of color-naming interference for threat-relevant words (Van Den Hout, Tenney, Huygnes, & de Jong, 1997). Furthermore, it has been shown that the emotional Stroop interference effect for spider words in spider phobia is a function of threat rather than the emotionality of spider words (Thorpe & Salkovskis, 1997). Similar findings have also been reported with snake phobics, who take significantly longer to color-name snake words than do nonphobics (Wikstrom, Lundh, Westerlund, & Hogman, 2004). The heightened selective attention toward threatening stimuli that is captured by the Stroop task may also be magnified by perceptual distortions among phobic individuals. For example, spider-fearful individuals often inaccurately perceive spiders as "looming" or jumping toward them (Rachman & Cuk, 1992). Analysis of eye movements during visual exploration of threat-relevant stimuli has also shown that, relative to controls, phobics detected spiders faster and fixated closer to spiders during the initial search phase (Pflugshaupt et al., 2005).

3.3.3   Judgment Bias for Threat

Another cognitive bias that has been implicated in the maintenance of specific phobias is covariation bias, which refers to the tendency to overestimate the association between phobic stimuli and aversive outcomes (Tomarken, Mineka, & Cook, 1989). In a prototypical covariation

bias experiment, phobic participants are exposed to a series of images consisting of fear-relevant (e.g., snakes) and neutral (e.g., mushroom) stimuli. The offset of the image is followed by one of the three outcomes: an aversive shock, a tone, or nothing. Fear-relevant and fear-irrelevant images are equally often followed by each of the three outcomes. After the series of images, participants are asked to estimate the contingencies between images and outcomes. A consistent finding from studies employing this experimental design is that phobic participants systematically overestimate the contingency between phobic stimuli (snakes) and aversive outcomes (shock). This pattern of findings has been observed in snake phobia (McNally & Heatherton, 1993), spider phobia (Cavanagh & Davey, 2000; van Overveld, de Jong, & Peters, 2006), and flight phobia (Pauli, Wiedemann, & Montoya, 1998). Furthermore, the tendency to overestimate the association between phobic stimuli and aversive outcomes at posttreatment significantly predicts treatment relapse (de Jong, van den Hout, & Merckelbach, 1995). Covariation biases in phobias may also be reinforced by ex-consequentia inferences ("if I feel anxiety, there must be danger") as specific phobics believe that dangerous situations elicit anxiety and that experiencing anxiety implies the presence of danger. These inferences may legitimize avoidance and maintenance of fear (Arntz, Rauner, & van den Hout, 1995).

3.3.4 The Role of Disgust

The propensity toward experiencing disgust ("disgust propensity") may be a risk factor for the development of spider phobia and BII phobia (Olatunji & Sawchuk, 2005). It has been shown that spider phobic individuals respond with greater disgust-specific facial EMG activity than nonfearful individuals when exposed to spiders (i.e., activity of the m. levator labii; de Jong, Peters, & Vanderhallen, 2002). Although experimental evidence for a *causal* mechanism has not consistently been found (Thorpe & Salkovskis, 1998), disgust propensity may contribute to the *maintenance* of spider phobia and perhaps reinforce the behavioral avoidance (Woody, McLean, & Klassen, 2005). Indeed, disgust propensity appears to be a more potent predictor of behavioral avoidance of spiders among phobic individuals (Olatunji, Cisler, Meunier, Connolly, & Lohr, 2008; Woody et al., 2005). Research has also implicated disgust in the maintenance of BII phobia (Olatunji, Sawchuk, de Jong, & Lohr, 2006). Unlike spider phobia, disgust appears to be the primary emotion in BII phobia with fear being a secondary emotional response (Sawchuk, Lohr, Westendorf, Meunier, & Tolin, 2002). There is also evidence that BII phobics demonstrate an implicit memory bias for disgust-relevant stimuli (Sawchuk, Lohr, Lee, & Tolin, 1999).

3.3.5 Safety Behavior

Biased interpretations in specific phobia typically manifest in the overestimation of the likelihood and severity of a dreaded outcome. For example, people with acrophobia may assume that they are likely to fall and individuals with claustrophobia may believe that they will run out of air. Such biases may lead to the use of safety behaviors during exposure to threat. Safety behaviors (e.g., wearing long pants to prevent spiders from touching one's legs) contribute to the maintenance of specific phobia by preventing phobic individuals from experiencing an unambiguous disconfirmation of their unrealistic beliefs about feared behaviors and their

outcomes (see Rachman, Radomsky, & Shafran, 2008; Salkovskis, 1991). This is because phobic individuals attribute the nonoccurrence of feared outcomes to the safety behaviors in which they engaged. For example, an acrophobic individual may grip a rail (safety behavior) when confronted with a precipice. The individual may attribute not falling to gripping the rail. However, gripping the rail may signify that that there is something to be afraid of, which in turn maintains phobic fear of the situation (Salkovskis, 1991). In addition to cognitive and affective vulnerabilities, safety behaviors also maintain specific phobia.

3.4   Evidence-Based Treatments

3.4.1   Overview

Empirical research over the last 40 years has demonstrated that exposure to the feared stimulus is an efficacious treatment for specific phobia. Barlow, Raffa, and Cohen (2002, p. 315) state that: "a consensus has developed that the treatment of choice for specific phobias is exposure-based procedures, particularly in vivo exposure." Antony and Barlow (2002, p. 408) state: "almost all experts agree that exposure to feared objects and situations is both necessary and sufficient for treating the vast majority of patients with [specific phobia]."

Given the wealth of research on treatment for specific phobia, the current chapter uses a selective review for the purpose of highlighting the specific efficacy of particular treatment procedures for specific phobia. Growing concern over the proliferation of empirically supported psychological treatments has led contemporary research to focus on the development of empirically supported principles by which therapeutic change occurs (Barlow, Allen, & Choate, 2004; Lohr, DeMaio, & McGlynn, 2003; Lohr, Olatunji, Parker, & DeMaio, 2005; Rosen & Davidson, 2003). This latter movement emphasizes the elucidation of active treatment ingredients (i.e., therapeutic "mechanisms" of change) instead of credentialed, trademarked, treatment packages. Elucidation of active treatment components is achieved through the experimental analysis of treatment efficacy. This type of analysis refers to a systematic approach in which (1) a treatment's efficacy is tested against a logical progression of comparison groups, and (2) the treatment package is broken down into its constituent components that are independently tested in order to determine which are the active ingredients of the treatment (i.e., "dismantling studies"; Borkovec & Castonguay, 1998; Lohr et al., 2003, 2005). Strength of evidence for treatment efficacy increases linearly when demonstrated against the following comparison conditions: wait-list control, attention control, nonspecific factor control, and alternative credible treatment. In the following section, we present an experimental analysis of treatment efficacy for exposure-based procedures. The interested reader is referred to Choy, Fyer, and Lipsitz (2007) for a recent exhaustive qualitative review of treatment outcome research in specific phobia, and to Wolitzky-Taylor, Horowitz, Poweres, and Telch (2008) for a recent meta-analysis of specific phobia treatment efficacy.

3.4.2   Exposure-Based Treatments for Specific Phobia

Exposure refers to a therapeutic procedure in which the client is presented with the feared stimulus or situation in either an in vivo or imaginal manner (see Antony & Swinson, 2000;

chapters 5 and 6). For example, exposure for a person with spider phobia may entail approaching a live spider (i.e., in vivo exposure) or imagining oneself approaching a live spider (i.e., imaginal exposure). Exposure can be graded, in which the client approaches a series of increasingly fear-provoking situations. For example, a client with height phobia may look over a balcony at 10 ft, then 20 ft, then 30 ft, etc. Exposure can also involve confronting the most feared situation only (also known as "flooding"). For example, a person with claustrophobia may be shut into a small dark closet for a prolonged period of time. Exposure procedures have numerous variations, such as number of sessions, length of exposure duration, duration between sessions, therapist directed versus self-directed, etc. (Antony & Barlow, 2002), but all variants share the common theme of presenting the client with the feared situation or stimulus. Importantly, exposure procedures are repeated until the client no longer experiences a distressing degree of fear or discomfort.

3.4.3 Wait-List Control

Numerous studies have demonstrated that exposure-based treatments led to better treatment outcome compared to a wait-list control group (Choy et al., 2007), which only controls for measurement reactivity and regression to the mean (Lohr et al., 2003, 2005). For example, Öst, Alm, Brandberg, and Breitholtz (2001) found that individuals with claustrophobia who were treated with either one or five sessions of in vivo exposure to enclosed spaces exhibited significant posttreatment reductions in behavioral avoidance compared to the wait-list control group. Exposure-based procedures result in improved outcome relative to a no treatment group across phobia types, including flying phobia (Walder, McCracken, Herbert, James, & Brewitt, 1987), height phobia and driving phobia (Williams, Dooseman, & Kleifield, 1984), spider phobia (Gotestam & Hokstad, 2002), and dental phobia (Jerremalm, Jansson, & Öst, 1986). Additionally, exposure-based procedures are efficacious compared to no treatment among children and adolescents (Öst, Svensson, Hellstrom, & Lindwall, 2001).

3.4.4 Nonspecific Factor Control

A few studies suggest that exposure-based procedures lead to better outcome compared to nonspecific factor control groups, which control for elements that are common to most treatments such as a therapeutic ritual, treatment rational, and working alliance (Wampold, 2001). Efficacy when compared to this type of control demonstrates that the procedure contains an active ingredient that adds incremental efficacy to the treatment beyond that attributable to nonspecific factors, which is a strong evidence of therapeutic efficacy (Lohr et al., 2003, 2005). Powers, Smits, and Telch (2004) found that in vivo exposure resulted in greater fear reduction for claustrophobia compared to a sham physiological treatment in which participants were deceptively told that a treatment device would change their brain activity and help reduce their fears. Gilroy, Kirby, Daniels, Menzies, and Montgomery (2000) found that in vivo exposure resulted in improved outcome for spider phobia compared to a group who only received relaxation training. These studies demonstrate that exposure-based procedures contain an active therapeutic ingredient that add incremental efficacy above and beyond the benefits of nonspecific factors.

3.4.5   Credible Alternative Treatment Control

Research demonstrates that exposure-based procedures lead to better outcome compared to an alternative nonexposure-based treatment. Better efficacy when compared to a credible alternative treatment suggests that it is justifiable to market and disseminate the target treatment procedure as an efficacious treatment to the mental health community (Lohr et al., 2003). Biran and Wilson (1981) found that guided in vivo exposure produced better treatment outcome compared to cognitive restructuring for a variety of phobias, including fear of heights, elevators, and darkness. Booth and Rachman (1992) found that in vivo exposure for claustrophobia led to significant reductions on six outcome measures relative to an untreated control group, whereas as cognitive restructuring treatment and interoceptive exposure treatment (i.e., exposure to feared internal sensations) led to reductions in only two outcome measures relative to an untreated control group. In contrast, Öst, Alm et al. (2001) found that five sessions of cognitive restructuring for claustrophobia was as effective as either one or five sessions of in vivo exposure. These data suggest that in vivo exposure for specific phobia is likely to be more efficacious than cognitive therapy (also see Craske & Rowe, 1997), but future research is needed to resolve the current equivocal results.

3.4.6   Applied Tension and BII Phobia

BII phobia appears to be unique in that it is often associated with a fainting response in the presence of disorder relevant-stimuli (Page, 1994). Öst and Sterner (1987) have developed applied tension as a treatment procedure to target this fainting response. Applied tension involves exposure to the feared stimulus with concurrent tensing of the large muscle groups in order to prevent or attenuate the blood pressure drop accompanying the fainting response. While one study found that in vivo exposure alone was more effective than exposure plus relaxation (Öst, Lindahl, Sterner, & Jerremalm, 1984), either one or five sessions of applied tension is more effective than in vivo exposure alone (Hellstrom, Fellenius, & Öst, 1996; Öst, Fellenius, & Sterner, 1991). Additionally, Öst, Sterner, and Fellenius (1989) found a trend favoring applied tension over exposure plus relaxation.

3.4.7   Long-Term Follow for Exposure-Based Treatments

Choy et al. (2007) exhaustively review the treatment outcome research in specific phobia with regard to long-term follow-up. Available evidence suggests that treatment gains following in vivo exposure "were either maintained or improved further over time" (p. 274) for various types of phobias at follow-up assessments up to 14 months after therapy.

3.4.8   Efficacy as a Function of Different Exposure Procedures

Therapist-directed exposure tends to produce better outcomes compared to self-directed exposure (Öst, Salkovskis, & Hellstrom, 1991), and therapist-directed exposure is particularly better than self-directed exposure conducted at the client's home (Hellstrom & Öst, 1995).

Öst, Ferebee, and Furmark (1997) found that direct exposure led to better treatment outcome compared to either watching another person undergoing exposure or watching a video of another person undergoing exposure. One session of massed exposure tends to lead to similar outcomes compared to several sessions of exposure for spider phobia (Öst, 1996), claustrophobia (Öst, Alm, et al., 2001), or BII phobia (Hellstrom et al., 1996). Finally, Öst (1996) found that a single session of group exposure therapy, with up to eight clients per group, for spider phobia led to improvements comparable to individually administered exposure.

3.5   Mechanisms of Change in Exposure Therapy

3.5.1   Overview

Given the almost unanimous agreement that exposure is the treatment of choice for specific phobia (e.g., Antony & Barlow, 2002; Barlow et al., 2002; Choy et al., 2007), there is a surprising degree of current disagreement as to exactly *how* exposure works (e.g., Craske et al., 2008; Hofmann, 2008; McNally, 2007). In this section, we begin by describing one of the most influential theories, EPT (Foa & Kozak, 1986), and then discuss a contemporary alternative to this theory (Craske et al., 2008) and the resulting implications for how to conduct effective exposure therapy.

3.5.2   Emotional Processing Theory

EPT (Foa & Kozak, 1986) derives from Lang's (1977, 1979) bioinformational theory of fear, which posits a fear structure consisting of stimulus propositions, response propositions, meaning propositions, and interrelations between these propositional networks. Stimulus propositions refer to propositions about which stimuli elicit fear. For example, a spider phobic's fear structure would consist of stimulus propositions in which spider-related stimuli lead to fear (e.g., spider webs, spiders, basements, etc.). Response propositions refer to propositions about how the individual reacts when in the state of fear. For example, a spider phobic fear structure would consist of response propositions involving increases in heart rate, sweating, trembling, running away, finding someone else to kill the spider, etc. Meaning propositions refer to the subjective interpretations about stimuli that elicit fear or their responses during the state of fear. For example, an individual may interpret the spider as "scary," or their increased heart rate as "unbearable," etc. Interrelations between these three components comprise the "fear structure." Presentation of information consistent with these networks activates the fear structure.

EPT (Foa & Kozak, 1986) posits that the degree to which exposure therapy results in fear reductions is proportionate to the amount of information presented to the individual during exposure that is incompatible with the fear structure, once that fear structure is activated. Essentially, fear reduction occurs because of the "weakening" of the relations between the propositional networks. Within-session habituation refers to gradual reductions in fear after prolonged exposure to a feared stimulus. Such habituation may result from the disconfirmation of meaning propositions (e.g., "if I see a spider, it will bite me") during exposure. Within-session habituation also involves decreases in physiological responding, which then weakens

response propositions (e.g., "if I see a spider, my heart will pound uncontrollably") and the relation between stimulus propositions, response propositions, and meaning propositions. Disconfirmation of, and weakening relations within, these propositional networks comprising the fear structure is proposed to be the fundamental mechanism underlying exposure therapy. A weakened fear structure due to within-session habituation would lead to less initial fear during the following exposure session, termed between-session habituation. This between-session habituation is an indicator that weakening of the fear structure is occurring during exposure; thus, greater between-session habituation predicts better treatment outcome.

3.5.3 Optimizing Inhibitory Learning

Although EPT has been influential, Craske et al.'s (2008) recent review suggests that the basic postulates of EPT have not been consistently supported. That is, degree of initial fear activation, within-session habituation, and between-session habituation are not consistently predictive of positive treatment outcome. Craske et al. (Craske et al., 2008; Craske & Mystkowski, 2006) argue that instead of viewing exposure as "corrective learning" as explicated in EPT, exposure should be viewed as "inhibitory learning." That is, exposure works through new learning which inhibits the expression of the previous feared associations (e.g., snake – attack). This assertion is consistent with the basic science of Pavlovian conditioning suggesting that extinction does not involve erasure of previous associations, but instead involves new learning that inhibits the previous associations (e.g., Bouton, 2004; Bouton, Woods, Moody, Sunsay, & Garcia-Gutierrez, 2006; Rescorla, 1988).

Craske et al. (2008) outline several clinical strategies to bolster inhibitory learning during exposure that may lead to enhanced treatment outcome. Focusing on sustaining arousal during exposure, as opposed to focusing on habituation, would lead to better toleration of the sensations of fear as well as facilitate inhibitory learning. Using an exposure procedure tailored to an individual's negative expectancies, regardless of the level of experienced fear, may lead to enhanced fear reduction. For example, if a person with driving phobia expects a panic attack after driving 2 mi, driving 3 mi while not experiencing a panic attack may lead to better inhibitory learning of the previous driving – panic attack association. Using multiple feared stimuli during exposure may also enhance inhibitory learning. For example, presenting a spider phobic person with both a spider and a cobweb while in a dim-lit basement (i.e., three stimuli related to the person's phobia) may lead to enhanced treatment outcome. Another clinical procedure for enhancing inhibitory learning is preventing the use or availability of safety behaviors during exposure. For example, exposing claustrophobics to an enclosed space without the possibility of escape or fresh air leads to enhanced fear reduction compared to exposure to an enclosed space with the possibility of escape or fresh air (Powers et al., 2004).

3.6 Basic Competencies of the Clinician

3.6.1 Knowledge of Current Diagnostic Nomenclature and Criteria

Prior to the DSM-IV, specific phobia was known as "simple phobia." The terminology referring to excessive fears about specific objects or situations and the criteria by which an individual is

deemed to have these fears may continue to change as research on specific phobia continues to develop. A clinician treating or assessing for specific phobia should know the current diagnostic nomenclature and criteria for determining the presence of specific phobia.

3.6.2 Knowledge of Reliable and Valid Assessment Procedures for the Diagnosis of Specific Phobia

The use of structured clinical interviews may assist in the diagnostic process. BATs are also useful tools for assessing phobias and tracking progress throughout treatment. Various self-report measures also exist that can assist in measuring the presence and severity of symptoms. See the above "Assessment of Specific Phobia" section.

In a related vein, a clinician should have a basic understanding that comorbidity is common in the anxiety disorders (e.g., Barlow, 2002; Kessler et al., 2005). Such comorbidity may reflect common underlying diatheses across the anxiety disorders (e.g., negative affectivity; Barlow, 2002; Brown, Chorpita, & Barlow, 1998) or may also be due to shared diagnostic criteria across disorders (e.g., avoidance/endurance with distress; worry; panic attacks). Thus, a clinician should carefully conduct differential diagnosis and rule out competing anxiety-related diagnostic possibilities. For example, both specific phobia and generalized anxiety disorder may present with worry, but the worry in specific phobia will be circumscribed to a specific object or situation. An individual who avoids driving because of fear of a panic attack may have specific phobia of driving, but if that individual also avoids going to the mall, movie theaters, and the grocery store because of fear of panic attacks, the diagnosis is likely panic disorder.

3.6.3 Use of Nonspecific Treatment Factors

Therapeutic practices that are common to most treatments, such as therapeutic ritual, rationale, therapist's allegiance, and therapeutic alliance, can produce meaningful therapeutic change (Wampold, 2001). Basic competencies of the clinician treating specific phobia should include the use of nonspecific treatment ingredients. These should include, but may not be limited to, providing the client with (1) an explanation of what specific phobia is and how to treat it (i.e., a rationale), (2) a treatment protocol that maps onto the rationale, thus providing credibility, and is repeated until benefit occurs (i.e., a ritual), (3) a clinician with enthusiasm and understanding of the theory and treatment of specific phobia (i.e., therapist allegiance), and (4) a clinician who works collaboratively with the client to conceptualize the problem and design an ideographic treatment plan (i.e., therapeutic alliance).

3.6.4 Incorporate Psychoeducation of General Emotional Processes into Treatment

Emotion science has increasingly informed the theory and treatment of anxiety disorders (Barlow et al., 2004). Using the vast literature on emotion to educate the client about basic emotional processes may prove valuable for the client for a number of reasons. First, emotion

regulation has become an increasingly popular topic of research and theory in the anxiety disorders (e.g., Moses & Barlow, 2006). One component of emotion regulation is emotional awareness (Gratz & Roemer, 2004). Teaching the client to identify emotions, emotional experiences, and their meaning may help clients regulate negative moods effectively. For example, clients may misinterpret excessive anxiety responses as indicative of medical problems. Education about how to recognize anxiety may allow such individuals to identify their experience and respond with appropriate coping skills (e.g., breathing, reappraisal, etc.). Second, education about emotion may provide clients with increased prediction and control over their emotional experiences. Situations or experiences that are unpredictable and/or uncontrollable may elicit anxiety (Barlow, 2002). If a client can identify their experience as anxiety or fear and recognize that these emotions arise due to the particular situations, they may experience an increase in prediction and control over their dysfunctional emotional experiences. Third, Barlow (2002) argues that anxiety disorders commonly co-occur due to a shared diathesis, heightened negative affectivity. Specific phobia is no exception, with one model positing that the development of specific phobia includes a predisposition toward negative affect (Antony & Barlow, 2002). If specific phobia is associated with general heightened negative affectivity, then it is likely that clients with specific phobia experience excessive anxiety, either at the clinical or subclinical threshold, in other domains. Providing clients with basic emotion psychoeducation could help them identify and cope with anxiety in other areas of their life where it may be needed.

3.6.5   Use of Procedures to Monitor Fear During Treatment

A clinician treating specific phobia should continually monitor the client's level of fear throughout treatment as a means of testing treatment progress. Fear is typically assessed in three response systems (Lang, 1968; Lipp, 2006): behavioral avoidance, physiological arousal, and subjective distress (but note that correlations between these response systems is low; Lang, 1968). Accordingly, when assessing a client's level of fear toward the phobic object, the clinician should assess across these response systems, such as observe whether the client avoids the object, ask whether the client's heart is beating faster, and ask about the client's subjective distress. For example, to assess the current level of fear in an individual with claustrophobia, the client and clinician could go into a closed elevator (noncompliance from the client would be an indicator of avoidance) and the client could report physiological symptoms (e.g., sweating, heart racing, etc.) and distress.

3.6.6   Basic Knowledge of Maintenance Processes in Specific Phobia

A wealth of research has investigated the maintenance processes of specific phobia (see above Maintenance Factors section). An exhaustive familiarity with the processes is not necessary for basic clinical competency in specific phobia. We suggest that the most basic maintenance process with which the clinician should be familiar is safety behaviors. Safety behaviors refer to either overt or covert behaviors to prevent the occurrence of feared outcomes (Salkovskis, 1991; Rachman et al., 2008). The clinician should first assess which behaviors, either overt or covert, the client uses to avoid harmful outcomes associated with the phobic object. For

example, does an individual with spider phobia scan the bedroom for spiders to make sure it is spider-free before going to bed? Does a person with height phobia ask how many floors are in a building prior to scheduling an interview in that building? Does an individual with a phobia of driving over bridges plan out driving routes ahead of time to ensure not having to cross bridges? Safety behaviors may also entail ensuring the availability of avoidance behaviors in case of encounters with phobic situations. For example, an individual with claustrophobia may carry Xanax with them to use in case they cannot avoid contacting enclosed places. A person with a phobia of insects may keep spray bottles of insecticide with them in case of encounters with insects.

After assessing which safety behaviors the client uses to prevent feared outcomes, the clinician should educate the client about the problems with safety behavior use. For example, safety behavior use may interfere with corrective learning, such that safety behavior use prevents the individual from fully encountering the feared situation and allowing complete exposure to occur (e.g., Powers et al., 2004). Rachman et al. (2008) argue for the judicious use of safety behaviors, rather than the complete extinction of safety behavior use. They suggest that safety behaviors should be gradually weaned off throughout treatment instead of all at once in order to make exposure-based therapy more tolerable for the client. Accordingly, after identifying safety behaviors, the clinician and client should develop a plan to gradually stop the use of safety behaviors during treatment.

3.6.7 Familiarity with Empirically Supported Principles of Therapeutic Change for Specific Phobia

As reviewed above, exposure is considered the preferred treatment for specific phobia (Antony & Barlow, 2002; Barlow et al., 2002; Choy et al., 2007). Basic clinical competencies of a clinician treating specific phobia should include working knowledge of how to conduct exposure. The basic clinical competencies of conducting exposure should include the following basic concepts (also see Richard, Lauterbach, & Glostner, 2007 for a discussion of basic components of exposure therapy). First, the clinician should know that, when possible, in vivo exposure is typically the preferred mode of delivery (Barlow et al., 2002; Craske & Rowe, 1997). Second, a representative list of stimuli to which the client should be exposed should be generated collaboratively with the client in order to ensure that stimuli used in exposure are appropriate and relevant for the individual. For example, individuals with BII phobia may present with fears of vastly different objects, and individuals with spider phobia may present with fears of different types of spiders. Accordingly, the clinician needs to assess the specifics of the objects or situations that elicit fear for each individual with specific phobia.

Third, exposure therapy, by definition, must entail repeated and prolonged exposure to the relevant phobic stimuli. Fortunately, specific phobia has shown excellent clinical improvement to only a few sessions of prolonged and/or repeated exposure (see "Evidence-Based Treatments" section). Fourth, the therapist should model appropriate nonfearful performance of the desired behavior (Öst, 1997). Naturally, the clinician should ensure he/she is capable of confronting the client's feared situation prior to beginning exposure with the client. Fifth, the clinician should assess across response systems during exposure to the feared stimuli. These assessments should be repeated continually throughout exposure in order to provide continued assessment of treatment progress.

Sixth, once the client can approach all the previously fearful situations with minimal discomfort, the therapist and client should make maintenance a goal and be sure to conduct a collaborative assessment at a later date in the future (e.g., 6-month follow-up assessment). Seventh, therapist-guided exposure should be viewed as a starting point for living a life without excessive fear of the phobic situation, such that after therapy the client will need to continue to expose themselves to the phobic situation in order to maintain gains made in treatment (Öst, 1997). The interested clinician is referred to Antony and Swinson (2000; chapters 5 and 6) for a detailed description of how to plan treatment for specific phobia and conduct exposure therapy, including scripts for explaining the rationale as well as examples of homework to provide clients.

3.7   Expert Clinical Competencies

3.7.1   Awareness of Behavioral Strategies to Augment the Effectiveness of Exposure-Based Interventions

Extinction of the fear response to phobic cues is a generic and incomplete model of evidence-based exposure therapy. Relapse, return of fear, and incomplete treatment responders commonly occur over the course of phobia treatment. Learning-based models of fear reduction during exposure therapy now argue that the process of extinction is an active, new, associative process (Bouton, 2002, 2004). While therapy is designed to promote physiological habituation and exposure to corrective information, phobic individuals are also trying to learn inhibitory fear responding (e.g., resisting the urge to escape and avoid the phobic cues). Inhibitory fear learning is a new form of learning that is highly influenced by the situation or context in which it is learned (Bouton et al., 2006). Medications, presence of a therapist, and the physical characteristics of the environment(s) are all relevant factors to consider when conducting exposure therapy as many of these factors may change or not be present in the phobic individual's day-to-day living. Extinction trials can therefore be optimized by conducting exposure exercises in multiple contexts to reduce the risk of relapse due to shifts in context (Chelonis, Calton, Hart, & Schachtman, 1999; Gunther, Denniston, & Miller, 1998; Vansteenwegen, Dirikx, Hermans, Vervliet, & Eelen, 2005).

Studies with spider phobics have found that altering external and internal contexts during exposure treatment can have a negative impact on treatment outcome. For example, Mineka, Mystkowski, Hladek, & Rodriguez (1999) found that the return of fear among spider phobics was greater among those treated and retested in different environments than those phobics treated and retested in the same environment. Furthermore, Mystkowski (2003) randomized spider phobics to receive either the same (caffeine–caffeine or placebo–placebo) or different (caffeine–placebo or placebo–caffeine) internal contexts between exposure treatment and the time of retest. Greater return of fear was found among those participants tested and retested in discordant internal states.

The presence of safety-related cues during exposure therapy can also interfere with effective fear reduction as many safety cues that are present during exposure therapy sessions (i.e., presence of the therapist) are typically not present between sessions. Discordant safety and nonsafety cues represent a context shift that can negatively impact the return of fear. For example, Powers et al. (2004) showed that claustrophobic individuals undergoing exposure

therapy who had safety behaviors available (e.g., communicating with the experimenter, unlocking the chamber door, letting air in) interfered with fear reduction at both posttreatment and follow-up. The therapeutic mechanisms underlying exposure therapy should therefore be fully explained to patients, emphasizing the structure of within- and between-session exposure exercises in a manner that addresses these context shifts.

3.7.2 Awareness of Pharmacologic Strategies to Augment the Effectiveness of Exposure-Based Interventions

Technological advances in brain imaging have facilitated our understanding of the neurobiological mechanisms associated with fear responding. Translational research efforts have subsequently explored the role biological agents may play in enhancing learning, which in turn, may augment the durability of exposure-based treatments (Hofmann, 2007). Specifically, lower doses of D-cycloserine (DCS), a partial N-methyl-D-aspartate agonist, can facilitate extinction learning in both animals (Richardson, Ledgerwood, & Cranney, 2004) and humans (Ressler et al., 2004). DCS does not appear to facilitate extinction learning during fear reduction trials; rather, the mechanism of action appears to impact the consolidation of new extinction learning between exposure trials (Santini, Muller, & Quirk, 2001; Woods & Bouton, 2006). Randomized trials to evaluate the role of DCS in exposure-based interventions for anxiety disorders are preliminary and ongoing. One published study thus far has investigated the augmentation of DCS with standard exposure therapy for acrophobia (Ressler et al.). Participants ($N = 28$) were randomized to receive either DCS (50 or 500 mg) or a pill placebo while undergoing virtual reality exposure therapy for height-related fears. Both DCS conditions outperformed placebo on all subjective, behavioral, and physiological outcome measures, with no indication of dose-dependent enhancement for the DCS. Although further investigation is clearly warranted, clinicians should remain up to date with translational research findings that may enhance the retention and durability of treatment gains following exposure-based interventions.

3.7.3 Influence of Culture on Specific Phobias

Cross-cultural studies have found that animal, situational, natural environmental, and BII subtypes are similarly represented in other cultures (Arrindell et al., 2003; Davey et al., 1998; Pull, 2008). Relative to Caucasians, the prevalence of specific phobias tend to be lower among Hispanic and Asian adults (Stinson et al., 2007). These statistics, however, can be misleading as the DSM-IV TR diagnostic criteria for specific phobia are defined within a western cultural framework. Cultural idioms of distress and the listing of culture-bound syndromes have only been recently recognized in the transition from the DSM-III-R and the DSM-IV (Mezzich, Kleinman, Fabrega, & Parron, 1996). Culture can exert a strong influence over the conditioning process, and may predispose individuals to selectively attend to certain culturally relevant threat cues. Likewise, culture can shape the manifestation and expression of physical, emotional, cognitive, and behavioral symptoms associated with the phobic response (Manson, 1996). Consultation and collaboration with "cultural experts" (e.g., medicine men, spiritual/religious leaders) are particularly important to better

understand the nature and meaning of the phobic response and how evidence-based principles of exposure therapy may be delivered in a manner that is culturally appropriate. Expert clinicians should follow the progress of the DSM-V cross-cultural workgroup who are tasked with advancing knowledge on cultural factors affecting epidemiology, assessment, and treatment outcome among diverse populations.

3.8 Transition from Basic Competence to Expertise

3.8.1 Overview

The proliferation and marketing of "named" treatments has prompted Rosen and Davidson (2003) to call for the dissemination of treatments based on such empirically supported principles, rather than therapies per se. There are a number of such principles upon which to draw in the implementation of treatment, some of which have been specified earlier in our analysis. The following is an explication of several principles that can be incorporated in the transition from basic competency toward that of expert competency.

3.8.2 Mobilization of Nonspecific Factors

We would like to argue that the recognition of nonspecific factors and the mobilization of them in the process of helping is one aspect of the transition from basic competence to expert competence. One way to effect the transition is to identify contextual factors in which the helping process is imbedded (Frank, 1961) and processes that are common to many different treatments. These include, but are not limited to, suggestion, persuasion, treatment credibility, therapist attention, expectancy for improvement, effort justification, and therapist allegiance to treatment modality (Gaffan, Tsaousis, & Kemp-Wheeler, 1995; Luborsky et al., 1999).

The construct of "therapeutic alliance" has gained substantial currency in psychotherapy process research as one important common factor that has substantial predictive power for beneficial change (Ahn & Wampold, 2001; Wampold, 2001). The components of alliance (Hatcher & Behrends, 1996) include confident collaboration, goals and tasks, bond between therapist and client, and client dedication. Goldfried and Davison (1994) in describing the behavior therapy relationship identify similar processes: goal specification, positive expectations of treatment process and change, therapeutic contract, therapist as a significant other, and the relationship as representative sample of behavior for the change process. Although the functional role of the therapeutic relationship has been difficult sometimes to demonstrate (DeRubeis, Brotman, & Gibbons, 2005; Woody & Adessky, 2002), there is little doubt that it should not be ignored in the process of moving from apprentice, to yeoman, to master clinician.

3.8.3 Mapping and Modifying the Content and Organization of Fear

Communication with clients regarding what they fear and how they respond to such things and activities is the lynch pin of effective clinical intervention in the treatment of specific

phobia. The task of the clinician is to help elucidate the content and organization of the subjective experience of the client. One way to do so is to adopt and implement Peter Lang's (1977, 1979) characterization of the propositional network that serves as the functional basis for fear imagery and its relationship to physiological activation and somato-motoric adaptation (see "Mechanisms of Change in Exposure Therapy" section for description of Lang's propositional network). Lang et al. have provided clear evidence for the physiologic activation function of fear imagery across different phobic domains and imagery ability (Cook, Melamed, Cuthbert, McNeil, & Lang, 1988). Most important, however, is the demonstration that it is the response propositional features of the network that elicit the greatest physiologic reactivity and verbal report of the fear response (Lang, Levin, Miller, & Kozak, 1983).

Foa and Kozak (1986) have extended the analysis suggesting that effective treatment of phobia is that which "disintegrates" the fear structure by changing the propositional content and connective structure of the network. Grayson and Borkovec (1978) have shown that modifying the response propositional features of the fear narratives (e.g., hierarchy items) from avoidance and noncoping to that of mastery result in less-intense subjective fear. Moreover, Hodges, McCaulay, Ryan, & Stroshal (1979) showed that hierarchy narratives with coping imagery were as effective as the standard systematic desensitization of fear imagery in reducing test anxiety.

3.8.4 Changing Danger and Safety

The relationship between the prediction and control of aversive events in the acquisition and maintenance of anxiety disorders has received considerable research attention over the past 2 decades (Zvolensky, Lejuez, & Eifert, 2000). Aversive events that are unpredictable and uncontrollable have a stronger negative impact on functioning than the same aversive events that are predictable and controllable (Barlow, 2002; Mineka & Zinbarg, 1996). Such experimental research has led theorists to articulate how specific phobia (Craske, 1991), and other anxiety disorders (Foa, Zinbarg, & Rothbaum, 1992; Mineka & Zinbarg, 1996), may be mediated by dimensions of unpredictability and uncontrollability. Moreover, these domains have also been shown to contribute to the maintenance of avoidance behaviors that interfere with the modification of clinical anxiety (Barlow, 2002). A more complete understanding of the clinical application of these findings requires consideration of an important prior question: "Prediction and control of what?" The likely answer involves the psychological functions of danger and safety and those events that signal the occurrence of danger and safety (Lohr, Olatunji, & Sawchuk, 2007). The transition from competence to expertise may be facilitated by an understanding of these processes.

Danger signals may be broadly defined as stimuli that indicate the onset of a threatening event. Examples of external danger signals include objects, such as snakes and spiders, that become the focus of specific phobias (e.g., McNally, 1987). However, danger signals can also arise from the internal environment, such as physiological arousal (e.g., Schmidt, Forsyth, Santiago, & Trakowski, 2002). One kind of safety signal is defined as that which predicts the offset of an aversive event. This process is a form of signal learning that connects two distinctive events, such as when an auditory tone and shock offset occur contiguously. The consequence is the learning of "relief." However, there exists the potential for learning a second form of safety signal; stimuli that predict the absence of onset of an aversive event. Notice that this

type of safety signal predicts the absence of (expected) onset of an aversive event, which might be considered "respite" rather than relief.

We suggest that when administering specific treatment components, such as relaxation training or exposure, the therapist should emphasize the safety signal function of self-administration or "self-control." For example, it was demonstrated early on by Goldfried and Trier (1974) that when relaxation training is learned as an active coping skill, its effects on anxiety symptoms are better than standard progressive relaxation training. We propose that the phrases "self-control" and "active coping skill" are other labels for the increased ability to control safety and danger when circumstances (signals) call for it. Because safety signals mediate approach behavior in an instrumental fashion, exposure tactics could be redesigned to encourage travel through dangerous situations toward safe places or people (Rachman, 1984). For example, placing a trusted companion on the far side of a bridge may then encourage approach behavior in specific phobics, thereby facilitating habituation and/or fear-inhibiting mastery behavior (e.g., Sartory, Master, & Rachman, 1989).

A final point to consider in treatment is that all things threatening and safe cannot be completely and unequivocally predictable and controllable. Anxious patients maintaining such unrealistic expectations of complete predictability and controllability may not fare well over the course of treatment and may be prone to relapse over the longer term. Although behaviorally oriented interventions are designed to improve one's sense of prediction and control of danger and safety, a goal of treatment should also improve one's tolerance and acceptance of objects, situations, and events that are unpredictable and/or uncontrollable.

3.8.5   In Vivo Exposure as Validation of Consultation Room Exposure

Consultation room exposure is most formally implemented via imaginal rehearsal, as in progression through a systematic desensitization hierarchy, or through the flooding procedure. However, "exposure" can also occur in the process of mapping the propositional fear network. One or the other of these processes can be followed by structured exposure to the feared events outside the consultation room. The transition from basic to expert will likely require the clinician to leave the consultation room and accompany the client to the criterion situations. Active clinician participation can be the vehicle for participant modeling, coaching, and the acquisition of nonfearful behavior. It may facilitate the inhibition of fear responses and/or the acquisition of fear-incompatible response, such as those involved in active coping (Grayson & Borkovec, 1978) and mastery skills (Hodges et al., 1979). Moreover, clinicians may gain the satisfaction of directly experiencing the clinical gains that they might only hear about in the consultation room.

3.8.6   Intervention as a Collaborative Problem-Solution

It is our opinion that a substantial amount of clinical skill is manifested in "behavioral nonspecifics," one of which is the collaboration among clinician and client in problem definition and solution implementation. These processes have been rendered into treatment specifics in the intervention upon a number of psychological disorders (D'Zurilla, 1986), most notably that of depression (Nezu, Nezu, & Perri, 1989). Problem-solving has subsequently been extended to

decision making as a strategic clinical process (Nezu & Nezu, 1989) for a wide range of clinical disorders. The transition from basic competency to that of expert is facilitated by integrating the analysis of clinical conditions with the analysis of their modification into a broader consideration of skill and competency development that will incorporate more molar considerations (i.e., bigger problems). Moreover, the development of strategic problem-solving abilities will help generalize self-management beyond the original focus of intervention to other problems that will likely be experienced in other circumstances well into the future. The clinician may not initiate intervention with the strategic issues in mind, but the implementation of collaborative problem-solving on immediate and "molecular" problems should evolve and elaborate into applications upon future problems not immediately apparent.

3.9   Summary

This chapter has summarized the vast specific phobia literature in domains of assessment, maintenance, treatment, and mechanisms of change in treatment. Relevant findings in these areas facilitate the development of basic and expert clinical competencies in specific phobia. We have argued that basic clinical competencies should entail knowledge about assessment, psychoeducation, treatment planning, and protocols for conducting exposure. Expert clinical competencies may entail advanced understanding and enactment of procedures to augment exposure therapy as well as an understanding that cultural factors may affect the presentation and maintenance of specific phobia. Basic principles that may facilitate the developmental trajectory from basic to expert clinical competencies in specific phobia include mobilization of nonspecific factors, mapping the structure of the client's fear in order to help elucidate the content and organization of the subjective experience of the client, identifying signals of danger and safety for the client, conducting exposure outside of the consultation room, and using collaborative problem-solving skills with the client to treat the phobia.

4 Agoraphobia

Paul M. G. Emmelkamp · Mark B. Powers

Abstract: This chapter summarizes the literature on assessment, maintenance, treatment, and mechanisms of change in treatment of patients with panic disorder with or without agoraphobia. Relevant theoretical contributions which are discussed may help to understand the genesis and maintenance factors of panic disorder and agoraphobia. Further, we provide an overview of empirically supported treatment approaches for these disorders and discuss the mechanisms of change involved in these treatments Knowledge of the burgeoning literature in this area is relevant for the development of basic and expert clinical competencies in panic disorder/agoraphobia. It is argued that the clinician should first be familiar with the diagnostic criteria for panic disorder and for agoraphobia. Knowledge of structured clinical interviews is needed to be able to formalize the diagnosis. In addition, knowledge of self-report measures, behavioral assessment, and self-monitoring is needed to assess the quality and severity of panic disorder and agoraphobia and to evaluate progress of treatment. Further, basic competencies also require knowledge on which factors are involved in the maintenance of these disorders. In addition, basic clinical competencies should entail knowledge about psycho-education, and evidence-based protocols for conducting interoceptive exposure and exposure in vivo outside the therapist office. Expert clinical competencies may entail advanced understanding and skills of applying psychological and pharmacological procedures to augment exposure therapy, skills in enactment of cognitive therapy and couple therapy, knowledge and skills to deal with panic disorder and agoraphobia in cases with comorbid disorders (e.g. substance abuse/dependence, and depression) as well sensitivity to anxiety related cultural factors.

4.1 Overview

Panic disorder (PD) is characterized by recurrent panic attacks, which are the discrete periods of intense fear and discomfort, often occurring unexpectedly. Panic attacks are accompanied by a number of symptoms, such as shortness of breath, dizziness, palpitations, trembling, sweating, choking, abdominal distress, depersonalization or derealization, fear of dying, or fear of going crazy. PD often leads to extensive avoidance behavior (agoraphobia), since these patients fear being in places or situations from which it is difficult to escape, or in which there is no help at hand in case of a panic attack. PD usually starts between late adolescence and early 30s. In many cases, the first attack is triggered by psychosocial stress (e.g., living on one's own, physical illness, delivery, or medical treatment). It is notable that agoraphobia is much more common in women than men, where as PD is more equally distributed between the sexes, though still more common in women. A recent meta-analysis (Bekker & van Mens-Verhulst, 2007) provides the following female/male gender ratios: agoraphobia 4:1; and panic disorder 2:1. Interestingly, the female/male ratio of patients who suffer from both PD and agoraphobia is in between: 3:1.

In this chapter, we will first describe the clinical features of agoraphobia and PD in order to better recognize, diagnose, and assess these disorders. Then, we will discuss relevant theoretical contributions which may help understand the genesis and maintenance factors of PD and agoraphobia. Further, we will provide an overview of empirically supported treatment approaches for these disorders and discuss the mechanisms of change involved in these treatments. Finally, we will discuss the basic and expert competencies needed for clinical psychologists who will assess and treat patients with PD and/or agoraphobia.

4.2 Recognition and Assessment

4.2.1 Panic Disorder

The major features of PD are recurrent panic attacks, interspersed with anticipatory anxiety of further attacks and, in around 65% of individuals, agoraphobic avoidance. At some point, the panic attacks were unexpected. Panic attacks are discrete periods of intense fear associated with at least four physical and cognitive anxiety symptoms, which develop suddenly and peak within 10 min. Although DSM-IV-TR states that in panic attacks anxiety peaks within 10 min, in a number of patients, time to peak may take longer than 10 min, especially in very severe panic attacks (Norton, Zvolensky, Bonn-Miller, Cox, & Norton, 2008; Scupi, Benson, Brown, & Uhde, 1997).

Before DSM-III introduced the category of PD, two syndromes were commonly diagnosed: (1) "hyperventilation" with dyspnoea, paresthesiae, and fear of dying by choking; and (2) "cardiac neurosis" with symptoms resembling those of angina pectoris: chest discomfort or pain, palpitations, tachycardia, and fear of dying. Starting with DSM-III, both these groups of symptoms are listed under "panic disorder" in the Diagnostic and Statistical Manual (DSM). DSM-IV-TR lists 13 physical and cognitive anxiety symptoms, four of which must be present in order to formally qualify for a PD. Panic attacks with fewer than four symptoms are referred to as limited symptom attacks. Not all symptoms contribute equally to the severity of panic attacks. The best items to predict *severity* of panic attacks are paresthesia, choking, and fear of dying. The items such as shortness of breath, chest pain, and dizziness are markers of moderate severity. Although palpitation is the most frequently reported symptom among the panic attack symptoms, it is only discriminated between cases and noncases at low levels of panic attack severity (Ietsugu, Sukigara, & Furukawa, 2007).

In clinical practice, a number of patients with PD are characterized by blurred vision, headache, diarrhea, and frequent urination in addition to a number of the 13 symptoms currently listed in DSM-IV-TR. This might be especially relevant with respect to agoraphobia. Agoraphobic situations may be avoided by different patients for different reasons – fear of fainting, dying, urinating, or defecating, or just panic.

As reflected in the DSM-IV-TR, panic-related catastrophic thoughts include: (a) concern about having future attacks, (b) worry about the implications or consequences of the attacks, or (c) a significant change in behavior due to the attacks (i.e., agoraphobia). Most panic patients (about two thirds) fear that something is physically wrong (e.g., having a heart attack); about half of panic patients fear that the symptoms mean they will lose control

or go crazy; and approximately one third of them fear negative social evaluation by others due to the symptoms (e.g., people may think I am weird). In addition, one out of four patients fear that the discomfort from panic attacks will be intolerable (Raffa, White, & Barlow, 2004).

4.2.2 Agoraphobia

The classification of agoraphobia within the DSM for mental disorders has undergone significant changes over time. Originally in DSM-III, agoraphobia was classified as a phobic disorder that could occur with or without panic attacks. Agoraphobia is the anxiety about being in situations from which escape might be difficult or in which help may not be available in the event of having a panic attack or panic-like symptoms. This anxiety typically leads to a pervasive avoidance of a variety of situations such as being alone at home, being in crowded places, entering shops, and walking and traveling alone.

In DSM-IV-TR, agoraphobia is defined as following:

- Agoraphobia is the anxiety about being in places or situations from which escape might be difficult (or embarrassing) or help might not be available in the event of having an unexpected or situationally predisposed panic attack or panic-like symptoms. Agoraphobic fears typically involve characteristic clusters of situations that include: being outside the home alone; being in a crowd or standing in a line; being on a bridge; and traveling in a bus, train, or automobile.
- The situations are avoided (e.g., travel is restricted) or else are endured with marked distress or with anxiety about having a panic attack or panic-like symptoms, or require the presence of a companion. Phobic avoidance may be motivated by unrealistic fears of the *consequences* of having panic symptoms in particular situations where the person feels trapped or far from help.

4.2.3 Structured Interviews

A number of structured interviews are available to formally assess the diagnosis of PD and agoraphobia (e.g., Structured Clinical Interview of Disorders, Axis-I (SCID-I), First, Spitzer, Gibbon, & Williams, 1996; the Composite International Diagnostic Interview – CIDI. WHO, 1997; and the Mini-International Neuropsychiatric Interview – MINI, Sheehan et al., 1998). More specific structured interviews for anxiety disorders and for PD are the following:

Anxiety Disorders Interview Schedule-IV (Brown, DiNardo, & Barlow, 1994). The Anxiety Disorders Interview Schedule-IV (ADIS-IV) is a semi-structured clinical interview designed to permit differential diagnosis among anxiety and mood disorders and screens for other major disorders (e.g., substance abuse, psychosis, somatoform disorders). It includes the "number of panic attacks in the last month." The ADIS-IV has good-to-excellent reliability and validity (Brown, Di Nardo, Lehman, & Campbell, 2001).

Panic Disorder Severity Scale (PDSS; Shear et al., 1992). The PDSS is a seven-item clinician-rated scale measuring PD severity over the past month. Items are rated on a scale ranging from

0 (not present) to 4 (extreme/incapacitating) and assess panic attack frequency, distress during panic attacks, severity of anticipatory anxiety, situational fear/avoidance, fear/avoidance of panic sensations, and impairment in work/social functioning. The seven items are summed to derive a total score ranging from 0–28, with higher scores reflecting greater symptom severity. The PDSS has demonstrated high interrater reliability (0.73–0.88), validity, and sensitivity to change following the treatment of PD (Shear et al.).

4.2.4   Panic Registration

It is often helpful to have patients record their panic attacks in a specially designed panic diary (e.g., Clum, 1990; Emmelkamp, Bouman, & Scholing, 1993). Participants register the date, situation, intensity, duration, and symptoms of every attack, and whether the attacks are expected or unexpected.

4.2.5   Questionnaires

There are a number of questionnaires available to assess PD and agoraphobia such as: *Panic Disorder Severity Scale, Self-Report Version* (PDSS-SR; Houck, Spiegel, Shear, & Rucci, 2002). The PDSS-SR consists of seven questions and includes ratings (0–4) of five main components of PD (panic frequency, distress during panic, anticipatory anxiety, agoraphobic avoidance, and avoidance of activities that cause panic-like sensation) and the degree of work/home and social impairment due to panic. It has been shown to have good internal consistency (Cronbach's $\alpha = 0.92$) and test–retest reliability (intraclass correlation coefficient, 0.81) (Houck et al., 2002).

Anxiety Sensitivity Index (ASI; Reiss, Peterson, Gursky, & McNally, 1986). The ASI is a 16-item questionnaire assessing respondents' fear of physical sensations associated with anxiety. Items are rated on a scale ranging from 0 (very little) to 4 (very much), resulting in a total score of 0 to 64, with higher scores reflecting greater levels of anxiety sensitivity. The ASI has good internal consistency in clinical and nonclinical populations and good test–retest reliability (Peterson & Reiss, 1993) and has demonstrated sensitivity to change following treatment for PD (Hazen, Walker, & Eldridge, 1996).

Mobility Inventory for Agoraphobia (MI; Chambless, Caputo, Jasin, Gracely, & Williams, 1985). This questionnaire measures the degree of agoraphobia in a range of situations. The inventory has two parts; the patient rates the degree of avoidance when alone and when accompanied by a trusted person. The 27 items on two parallel dimensions have a scale range of 1 (low avoidance) to 5 (high avoidance).

Panic Appraisal Inventory (PAI; Telch, Brouillard, Telch, Agras, & Taylor, 1989). The PAI was developed to assess coping with panic, the perceived likelihood of panic across various situations, and the anticipated catastrophic consequences of panic. These are measured on separate scales: PAI–Panic Coping, PAI–Anticipated Panic, and PAI–Panic Consequences. In addition, the PAI–Panic Consequences scale has three subscales assessing the specific consequences: physical (e.g., "I may have a heart attack"), social (e.g., "I may embarrass my family or friends") and loss of control (e.g., "I may go insane"). The PAI has good test–retest

reliability and internal consistency (Cronbach's α) for its various scales and subscales (Telch et al., 1989).

The Body Sensations Questionnaire (Chambless, Caputo, Bright, & Gallagher, 1984) measures physiological sensations experienced by patients with anxiety disorders.

Further, several cognitive questionnaires have been developed to assess the content and frequency of agoraphobic patient's thoughts. The main ones with adequate psychometric properties are the *Agoraphobic Cognitions Questionnaire* (ACQ; Chambless et al., 1984) and the *Catastrophic Cognition Questionnaire* (CCQ; Khawaja & Oei, 1992). The ACQ was developed to assess (on a scale from 1 to 5) frequency of thoughts about catastrophic consequences of anxiety and panic. In addition to a total score that represents a mean value of scores on 14 individual items, the ACQ yields a mean score on two subscales: One reflects the anticipated physical consequences of panic attacks (e.g., "I will have a heart attack"), whereas the other refers to anticipation of loss of control as a result of panic (e.g., "I am going to go crazy"). Construct validity, discriminant validity, and its internal consistency (Cronbach's α) are satisfactory (Bouchard, Pelletier, Gauthier, Cote, & Laberge, 1997; Chambless et al.). The CCQ is also based on the fear of fear (FOF) model and contains two factors that measure maladaptive thoughts about the possible consequences of panic. The CCQ was constructed for measuring emotional, physical, mental, social, and bodily catastrophes. This questionnaire is based on danger themes rather than fear.

Both questionnaires have limitations for use. First, both questionnaires address only the catastrophic elements of agoraphobia. However, the assessment of more general negative (avoidance/escape, emotion-oriented) thoughts, next to catastrophic statements, seems to be a better reflection of the thoughts patients have during therapy. Another limitation of the ACQ and CCQ is that they focus exclusively on negative (catastrophic) cognitions and thereby neglect the positive side of an individual's internal dialogue. Some authors argue that treatment is directed at changing the balance or ratio between positive and negative self-talk although the optimal ratio is still unclear (Cox, 1996).

The *Agoraphobic Self-Statements Questionnaire* (ASQ; van Hout et al., 2001) was designed to overcome some of the perceived shortcomings of previous instruments and procedures. The content of the ASQ was derived from open-ended thought listings provided by a large sample of agoraphobic outpatients in response to an in vivo agoraphobic situation. Several researchers have suggested that thought listings are useful in providing ideas for inventory construction, but a valid endorsement measure is generally preferable to a production technique. Furthermore, a paper-and-pencil measure is easier to administer *during* the treatment process and is less time-consuming than production techniques. Finally, the ASQ is easy to use and score and can be administered in real-life anxiety-provoking situations to strengthen the ecological validity by relying less on recall. The ASQ differs on at least two dimensions from the ACQ and CCQ. The first dimension is timing: The ACQ and CCQ are retrospective measures, whereas the ASQ is a concurrent measure. The second dimension concerns the focus: The ACQ and CCQ consist of questionnaire items specifically related to the (catastrophic) consequences of anxiety, whereas the ASQ consists of a broad range (e.g., avoidance and escape behavior, anticipated consequences, coping, and approach behavior) of representative self-statements typically reported in an agoraphobic situation. Another difference between the ASQ and the ACQ is the presence of negative and coping self-statements as a part of the ASQ.

4.2.6 Behavioral Assessment

Behavioral avoidance testing is a substantial addition to self-report questionnaires in the assessment of agoraphobia. Several tests have been developed and have been used in research studies such as the *Behavioral In Vivo Measure* (Emmelkamp, 1982), which consists of a previously determined route that should be walked by the patient with the following standardized instruction: "You are asked to walk a route and to return to our clinic immediately once you feel tense." The therapist records both time spent on this test as well the distance the patient has covered. High correlations (in the 1990s) have been found between this measure and scales for anxiety and avoidance. Patients can afterwards be asked to complete the ASQ to assess the cognitions they had during this task. Another behavioral test to assess agoraphobia is the *Multitask Behavioral Avoidance Test* (M-BAT; De Beurs, Lange, van Dyck, Blonk, & Koele, 1991), which is more time-consuming, given that it consists of three different behavioral tasks. In comparison with self-report questionnaires, the M-BAT produced a more conservative picture of gains achieved in treatment.

4.3 Etiological and Maintenance Factors

4.3.1 From Panic to Panic Disorder

Panic attacks are fairly common even in normal populations. More than half of the people report an unexpected panic attack at some point in their lives, but most individuals will not develop PD. The prevalence of nonclinical panic attacks within the last year is also high. Approximately one out of three individuals reported at least one panic attack within the last year (e.g., Norton et al., 2008). The key factor in going on to develop PD then is not only unexpected panic but rather panic-related apprehension (Telch et al., 1989). Nonclinical panickers simply go on with their lives following a panic attack with little anxiety about future attacks. On the other hand, people who meet criteria for PD worry about future attacks and their perceived consequences (panic-related apprehension).

4.3.2 Cognitive Factors

Several authors have emphasized cognitive factors in the phenomenology of PD (e.g., Beck, Emery, & Greenberg, 1985; Clark, 1986). One such factor is anxiety sensitivity. Fear of benign bodily sensations (heart rate, sweating, etc.) caused by anxiety is referred to as anxiety sensitivity or FOF (Goldstein & Chambless, 1978; Reiss et al., 1986). Many researchers have suggested that FOF is critical in the development and maintenance of PD. Many lines of research support this "Fear of Fear" hypothesis (Emmelkamp & Powers, 2009). First, studies show that early learning experiences may influence FOF development that later result in greater emotional responding to panic provocation agents. Second, prospective studies show that people high in FOF are at a greater risk for naturally occurring panic attacks. Third, patients diagnosed with PD score higher than psychiatric and nonpsychiatric controls on measures of FOF such as the Anxiety Sensitivity Index (Peterson & Reiss, 1987) and the Body Sensations Questionnaire (Chambless et al., 1984). Although anxiety sensitivity is highest in PD, it should be noted that it

is common in other anxiety disorders as well (Taylor, Koch, & McNally, 1992). Finally, several studies suggest that FOF mediates improvement in the treatment of panic patients. For example, in a study of CBT for PD, FOF fully mediated improvements in disability and partially mediated changes in agoraphobia, anxiety, and panic frequency (Smits, Powers, Cho, & Telch, 2004). Also, changes in FOF precede reduction in panic symptoms showing temporal precedence.

In summary, anxiety sensitivity figures prominently in theories of PD etiology, maintenance, and treatment. However, high anxiety sensitivity is not specific to PD and thus may not confer incremental evidence of a PD diagnosis.

4.3.3   Development of Avoidance Behavior

There is a clear need for studies addressing the issue why some individuals with panic attacks start avoiding situations while others do not. It has been suggested that the addition of agoraphobia represents a more severe form of PD. Similarly, it has been proposed that PD with agoraphobia is a two-stage disorder with stage one including PD and stage two including the addition of agoraphobia. However, a recent review found little evidence for these two hypotheses (Emmelkamp & Powers, 2009). Although panic severity does not predict agoraphobic status, other factors have substantial support including: exaggerated prediction of panic occurrence likelihood, more catastrophic cognitions about the consequences of panic, and less confidence in personal resources to manage panic (Telch et al., 1989). Of these, the patients' exaggerated likelihood estimation of panic occurrence in situations is the best predictor of agoraphobic avoidance accounting for almost 80% of the variance in avoidance behaviors (Rachman, 1994; Telch et al.).

4.3.4   Personality Traits

Specific personality traits have also been assumed to predispose individuals to agoraphobia. Agoraphobic patients have been described as dependent, shy, anxious, depressive, unassertive, immature, and the like, but there is little empirical evidence that a clear "agoraphobic personality" exists (Chambless, 1982). One of the factors increasing the risk of subsequent agoraphobic avoidance after having a panic attack may be the use of an underlying avoidant-based coping style. There are some studies to suggest that avoidant-based coping strategies are also associated with higher levels of anxious response and increased distress in response to bodily sensations (Spira, Zvolensky, Eifert, & Feldner, 2004). Indeed, in reviewing the literature, Feldner, Zvolensky, and Leen-Feldner (2004) found that patients with PD utilize more avoidance-based coping strategies when compared with controls. Another personality factor that may predispose individuals to use avoidant strategies when experiencing panic attacks might be locus of control (Emmelkamp, 1982; van der Molen, van den Hout, & Halfens, 1988).

4.3.5   Respiratory Diseases

Anxiety disorders appear to be highly prevalent among persons with respiratory diseases such as asthma (Weiser, 2007), chronic bronchitis, and chronic obstructive pulmonary disease

(COPD). The prevalence of panic attacks (25%), PD (12%), and agoraphobia (12%) was considerably higher among adults with asthma than in the general population. In addition, respiratory disturbance at age 3 was a significant classification variable for PD at age 18 or 21 (Craske, Poulton, Tsao, & Plotkin, 2001). In a large population-based study in Canada in a sample of 36,984 subjects, the prevalence of COPD/lung emphysema and chronic bronchitis was substantially higher among individuals with PD (odds ratio of 2:1 and 3:8, respectively) than in persons without PD (Patten & Williams, 2007).

Breathing-related symptoms such as dyspnoea (shortness of breath), chest tightness, or feelings of suffocation are central features of respiratory diseases. Presence of asthma, COPD, or chronic bronchitis may increase the risk of developing PD through a variety of cognitive and behavioral mechanisms, including producing threatening bodily sensations that could trigger panic among susceptible individuals. Thus, panic and associated avoidance behavior may be a conditioned response connected to an earlier aversive or traumatic experience related to asthma, chronic bronchitis, or COPD; panic attacks may be classically conditioned responses to subtle physiological changes that resemble those occurring with respiratory diseases. Such interoceptive conditioning can occur without conscious representation of learning, and it is now generally assumed that implicit emotional memories can activate amygdala-based fear systems without individuals being aware of the reasons (Craske & Waters, 2005). This interoceptive conditioning model contrasts with the catastrophic appraisal model, in which misappraisals of bodily sensations (e.g., imminent death, loss of control) are viewed as central and necessary. According to this view, symptoms of asthma, COPD, and chronic bronchitis tend to be misinterpreted and catastrophized by patients with PD as signs of impending, dire harm. The consequent symptom confusion and misinterpretations of bodily sensations lead to a positive feedback loop between anxiety and physical sensations, eventuating in full-blown panic attacks. Thus, in individuals with respiratory diseases, there is ample opportunity for interoceptive conditioning, overperception, and catastrophic interpretation of body sensations.

4.3.6 Life Events and Interpersonal Loss

Although there is some evidence that life events often precede the onset of PD, it is not clear which specific life events are associated with PD. A series of studies has studied interpersonal conflict, especially with the partner, but results of these studies are still inconclusive (Marcaurelle, Belanger, & Marchand, 2003). According to DSM-IV, PD often arises in the context of interpersonal loss (APA, 1994, p. 389). Indeed, there are now a number of studies which found that a substantial number of PD patients (ranging from one third to two thirds) experience a significant interpersonal loss in the year preceding the onset of PD (Faravelli & Pallanti, 1989; Milrod, Leon, & Shear, 2004; Pollard, Pollard, & Corn, 1989; Scocco, Barbieri, & Frank, 2007). There is some evidence that interpersonal loss might moderate treatment outcome (Klass et al., 2009).

4.3.7 Substance Abuse and Dependence

High comorbidity rates have been found both in community and clinical studies for anxiety disorders and substance abuse, especially alcohol abuse (Grant et al., 2004). In the National Comorbidity Survey (NCS) study (Kessler et al., 1997), 35.8% of males diagnosed with alcohol

dependence also met the criteria for a comorbid anxiety disorder, as opposed to 60.7% of females. In alcoholic patients seeking treatment, Schneider et al. (2001) found an overall rate of 42.3% with anxiety disorders. The most prevalent were social phobia (14%), agoraphobia (13%), and PD (5%). Substance-abusing patients with PD/agoraphobia abuse alcohol, benzodiazepines, cocaine, and cannabis, and many of these comorbid patients report a history of emotional and physical abuse (Schade et al., 2004).

PD/agoraphobia often predates alcohol- or drug-use disorders. However, in a number of cases, the risk relationship is reciprocal, with PD/agoraphobia predicting increased risk of later substance abuse, and vice versa. Many individuals endorse the belief that alcohol reduces anxiety. Secondary substance abuse may be attributed to anxiety that promotes the use of alcohol and drugs as a form of self-medication. Substance abuse as self-medication is prevalent among patients with agoraphobia. Many individuals use alcohol or drugs as self-medication, which is confirmed by studies showing peak substance use on high-stress days. Symptoms of anxiety and panic are common after heavy drinking and during withdrawal and should be distinguished from primary anxiety disorders (Emmelkamp & Vedel, 2006).

4.4   Evidence-Based Treatment Approaches

There exist a number of evidence-based interventions focusing either on panic or the agoraphobic avoidance behavior. One core element in most treatments is exposure to anxiety arousing cues. *Exposure* therapy in the case of agoraphobia consists of exposing patients to situations they fear. Exposure can be carried out in two ways: (1) in imagination, in which patients must imagine themselves to be in a fearful situation; or (2) in vivo, in which patients are actually exposed to this situation, the latter being much more effective in agoraphobia (Emmelkamp, 1982). The treatment is based on the notion that anxiety subsides through a process of habituation after a person has been exposed to a fearful situation for a prolonged period of time, without trying to escape. Considerable evidence exists, both on subjective and physiological measures, that this is indeed the case (Craske, 1999). Exposure tasks can be ordered hierarchically from low anxiety to high anxiety (gradual exposure) or patients can be confronted with the most difficult situation from the start (flooding). Exposure can be either self-controlled (i.e., patients decide for themselves when to enter a more difficult situation), or controlled by the therapist. The most successful programs are those carried out in vivo, during a long uninterrupted period of time (prolonged), and in which escape and avoidance of the situation are prevented (Emmelkamp, 1994, 2004). If anxious patients escape the situation that they fear, anxiety usually will subside. This escape behavior, however, will reinforce the anxiety and hence lead to further avoidance and escape behavior in the future. Therefore, in exposure programs, it is often necessary to deal with this escape behavior by response prevention, which means that the patients are no longer allowed to perform escape behavior.

Exposure in vivo is well documented in numerous randomized controlled clinical trials (see reviews and meta-analyses by Craske & Barlow, 2008; Emmelkamp, 1994, 2004; van Balkom, Nauta, & Bakker, 1995; van Balkom et al., 1997). Results of these reviews and meta-analyses are usually consistent indicating that exposure in vivo has a substantial effect size for agoraphobic symptoms. A total of 60–80% of all treated agoraphobics benefit significantly from exposure. Thus, exposure has become the gold standard treatment of agoraphobic patients.

Although prolonged exposure has been found to be superior to short exposure, this does not mean that having the opportunity to escape during exposure in vivo has detrimental effects as once thought (Craske, 1999). A treatment procedure where patients are allowed to escape the situation but have to reenter it again and again is as effective as prolonged exposure in vivo (Emmelkamp, 1982). This form of treatment can be conducted as a self-help program (Emmelkamp, 1982). Self-help exposure treatments for PD/agoraphobia can be done through a self-help book or a computer (Emmelkamp, 2005; Schneider, Mataix-Cols, Marks, & Bachofen, 2005). Although exposure therapies can be conducted as self-help programs either with instructions by a live therapist, by a computer, or by phone, there is some evidence that therapist guidance may lead to superior results (Williams & Zane, 1989). Further, self-help treatments are less effective for more severe patients and patients with comorbidity (Hecker, Losee, Roberson-Nay, & Maki, 2004).

Exposure in vivo not only leads to a reduction of anxiety and avoidance, but also to a reduction of panic attacks (Lelliott, Marks, Monteiro, Tsakiris, & Noshirvani, 1987; Michelson, Mavissakalian, & Marchione, 1988; Telch, Agras, Tayloor, Roth, & Gallen, 1985) and a reduction of negative self-statements (van Hout et al., 1994; van Hout, & Emmelkamp, 2002). The results of exposure therapy with agoraphobics are long-lasting. Follow-up reports ranging from 4 to 9 years after treatment have been published. Generally, improvements brought about by the treatment were maintained (Bakker, van Balkom, Spinhoven, Blaauw, & van Dyck, 1998; Fava et al., 2001; Gould, Otto, & Pollack, 1995; O'Sullivan & Marks, 1990). In a study by Peter, Brückner, Hand, Rohr, and Rufer (2008), a total of 40% of the patients reached a level within a normal range in 3–9 years after treatment. In two thirds of the patients, treatment outcome was stable during follow-up.

4.4.1   Exposure in Vivo Versus Cognitive Therapy

A number of studies with agoraphobics have shown that exposure in vivo is superior to cognitive therapy consisting of insight into irrational beliefs (RET) and training in incompatible positive self-statements (SIT) (Emmelkamp et al., 1978, 1986; Emmelkamp & Mersch, 1982). Current cognitive-behavioral approaches focus more directly on the panic attacks than is the case in RET and self-instructional training. A number of cognitively oriented researchers have stressed psychological factors in accounting for panic attacks (Clark, 1986; Ehlers & Margraf, 1989). In these models, it is assumed that patients misinterpret bodily sensations as a sign of a serious physical danger (e.g., a heart attack). The common element is that patients are likely to mislabel such bodily sensations and attribute them to a threatening disease and as a result may panic. Central to the cognitive conceptualization of panic is that bodily sensations are interpreted as dangerous. A positive feedback loop between physiological arousal and anxiety is postulated that leads to an ascending "spiral" ending in the full-blown panic attack.

Those formulations of panic have led to development of cognitive therapy focusing on the bodily sensations. The cognitive therapy of Clark et al. consists of explanation and discussion of the way hyperventilation induces panic, breathing exercises, interoceptive exposure, and relabeling of bodily symptoms. This package produced a substantial and rapid reduction in panic attack frequency (Clark, Salkovskis, & Chalkley, 1985; Salkovskis, Jomes, & Clark, 1986). Clark et al. (1994) compared the cognitive therapy for panic with applied relaxation and drug treatment (imipramine). All three treatments were found to be effective in reducing panic,

anxiety, and avoidance. The cognitive therapy was found to be superior to the other two treatments on 12 out of 17 measures. At a 15-month follow-up, 80% of cognitive therapy patients, 47% of applied relaxation, and 50% of imipramine patients were panic-free. Beck, Stanley, Baldwin, Deagle, and Averill (1994) found cognitive therapy more effective than relaxation and minimal contact control condition in panic patients with mild or moderate agoraphobia.

Van den Hout et al. (1994) evaluated the effects of cognitive therapy and exposure in vivo in patients with PD and agoraphobia. Half of the patients received four sessions of cognitive therapy, followed by eight sessions of cognitive therapy plus exposure. In the other condition, the first four sessions consisted of supportive therapy in order to control for therapist attention. As expected, cognitive therapy led to a reduction of panic attacks, whereas panic was not affected by supportive therapy. However, on all other measures, i.e., Fear Questionnaire, Behavioral Avoidance Test, Beck Depression Inventory and measures of FOF, and state and trait anxiety, improvement commenced *after* exposure in vivo commenced. Thus, although cognitive therapy led to a reduction in panic attacks, this did not automatically lead to an abandonment of the agoraphobic avoidance behavior. Also, Rijken, Kraaimaat, de Ruiter, and Garssen (1992), Williams and Falbo (1996), and Burke, Drummond and Johnston (1997) did not find a combination therapy more effective than exposure alone in agoraphobic patients. In contrast, two studies found cognitive therapy as effective as exposure in vivo (Bouchard, Gauthier, Laberge, French, Pelletier, & Godbout, 1996; Hoffart, 1995). However, in both studies, exposure in vivo was an essential component of the cognitive therapy, which renders the results difficult to interpret. Finally, in a study of Marchand et al. (2008), it was hypothesized that patients with moderate to severe agoraphobia receiving a combination of cognitive therapy and graded exposure in vivo would improve more than those receiving cognitive or behavioral treatment alone at 1-year follow-up. Results failed to support this hypothesis.

There is now considerable evidence that the degree of agoraphobic disability has a significant bearing on panic treatment effectiveness. In the study of Williams and Falbo (1996), 94% of low agoraphobia subjects were free of panic after treatment, while only 52% of the high agoraphobia subjects became panic-free. As noted by the authors, the findings suggest that when panic treatment research excludes people with severe agoraphobic avoidance, as it has routinely done, an overtly positive estimate of panic treatment effectiveness can result.

Taken together, there is convincing evidence that cognitive therapy dealing with misinterpretations of bodily sensations is highly effective in reducing panic attacks. However, this does not necessarily lead to a reduction of the avoidance behavior in severe agoraphobic patients. A combination of cognitive therapy and exposure in vivo is not more effective than exposure in vivo alone. Further, the role that cognitions play in cognitive therapy remains unclear (Oei, Llamas, & Devilly, 1999). Given this state of affairs, cognitive therapy (without exposure in vivo) cannot be recommended for panic patients with severe agoraphobia.

4.4.2 Interoceptive Exposure for Panic Disorder

The cognitive-behavioral treatment of PD includes interoceptive exposure, which involves inducing the feared bodily sensations associated with panic attacks through various exercises in order to reduce the fear associated with these physical sensations through habituation. These exposure exercises are designed to mimic the physiological sensations that patients experience

during panic attacks (i.e., sweating, heart palpitations, and dizziness) through assignments such as brief vigorous physical exercise, hyperventilation, and spinning.

Barlow, Craske, Cerny, and Klosko (1989) evaluated the effects of a comprehensive package consisting of exposure to interoceptive stimuli, imaginal exposure, breathing retraining, and cognitive restructuring. This package was found to be more effective than applied relaxation and no-treatment. In a second study from the same group (Klosko, Barlow, Toussinari, & Cerny, 1990), this package was found to be more effective than alprazolam and placebo. However, in a large multicenter trial (Barlow, Gorman, Shear, & Woods, 2000), this package was found to be as effective as imipramine and both active treatments were more effective than placebo. A combined treatment of CBT and imipramine was not significantly superior to CBT plus placebo. Six months after treatment discontinuation in the intent to treat analysis the response rates were 39% for CBT alone, 26.3% for CBT combined with imipramine, 19.7% for imipramine alone, and 13% for placebo.

A few studies investigated the effects of various components of a cognitive-behavioral treatment package. Craske et al. (1997) and Schmidt et al. (2000) demonstrated that interoceptive exposure is a more powerful component of CBT for PD than breathing retraining. Results of both studies revealed that breathing retraining added little to other components of the CBT intervention. Antony, Ledley, Liss, and Swinson (2006) instructed participants to complete 13 interoceptive exposure exercises and found that breathing through a very thin straw for 2 min was the most potent exposure exercise, followed by spinning around while standing for 1 min, hyperventilation for 1 min, and pressing a tongue depressor down at the back of the tongue for 30 s.

4.4.3   CBT and Comorbid Substance Abuse and Dependence

In the case of comorbid substance abuse or dependence, the task of the clinician is to determine the temporal relationship between the syndromes identified. For example, panic attacks are often associated with withdrawal syndromes. The course of the disorders can usually be established retrospectively, for example by using the Time-Line Follow-Back interview. The association between the PD/agoraphobia and the substance-use disorder is not necessarily unidirectional, but in some cases a vicious cycle exists. Research in this area is scarce and provides little in the way of clinical guidelines. Research has primarily focused on alcohol abuse and dependence. Although it has been claimed that comorbid anxiety disorders predict poor outcome of alcoholism treatment, results are inconclusive given the many methodological problems in most studies (Emmelkamp & Vedel, 2006). In cases where PD/agoraphobia precedes development of substance abuse; it has been suggested that many patients may ingest alcohol or drugs as self-medication to cope with the psychiatric symptoms. Would a combination of cognitive-behavior strategies focusing on both the PD/agoraphobia and substance abuse enhance treatment effects? Unfortunately, the results of the few studies that investigated whether dual treatments focusing both on the alcohol dependence as well as on PD/agoraphobia are more effective than treatment focusing on either disorder on its own are negative. Bowen, D'Arcy, Keegan, and Van Senthilsel (2000) evaluated whether a cognitive-behavioral treatment for PD and agoraphobia would enhance the effects of the regular alcoholism program in alcohol-dependent inpatients with comorbid PD. Unfortunately, the addition of 12 h of cognitive-behavioral therapy directed at panic and agoraphobia led neither to enhanced outcome on

drinking measures nor on mood and anxiety symptoms. In a study by Schadé et al. (2005), patients with a primary diagnosis of alcohol dependence and a comorbid anxiety disorder involving agoraphobia or social phobia were randomly assigned to an intensive psychosocial relapse-prevention program on its own, or in combination with an anxiety treatment program comprising cognitive-behavioral therapy and optional pharmacotherapy (selective serotonin reuptake inhibitors). The addition to the treatment directed at anxiety neither enhanced treatment outcome in terms of abstinence or a reduction in days of heavy drinking, nor reduced relapse. The additional therapy reduced the anxiety symptoms, but it had no significant effect on the outcome of alcohol treatment programs.

Since there is considerable evidence that substance abuse may perpetuate or exacerbate anxiety symptoms, it is therapeutically wise to wait and see what happens with the anxiety symptoms when the substance use is stopped or substantially reduced. Generally, cognitive-behavior therapy targeting the substance abuse is not only likely to result in a reduction of substance use but in a reduction of anxiety symptoms as well; so, within the perspective of a stepped-care approach, in most cases treatment should be directed at the substance abuse first (Emmelkamp & Vedel, 2006). If the anxiety symptoms remain prevalent after a period of at least 4 weeks of abstinence, there is reason to consider more detailed assessment and treatment directed toward PD/agoraphobia. If anxiety does not improve after reduction of substance abuse, adding treatment components directly addressing the anxiety disorder might be indicated.

4.4.4 Effect of Personality Disorders

Comorbid personality disorders are common in patients with anxiety disorders, with the avoidant and dependent PDs being most frequent (Emmelkamp & Kamphuis, 2007). The American Psychiatric Association (APA) practice guidelines for PD recommends psychodynamic psychotherapy for PD patients with comorbid personality disorders. No data underlie this recommendation. Although there is some evidence that some personality traits are associated with poorer outcome in CBT, there is no evidence that the presence of personality disorders per se results in poorer outcome when personality disorder diagnosis is formally established with a structured interview (Emmelkamp & Kamphuis).

4.4.5 CBT: The Role of the Therapist

There is some evidence that cognitive-behavior therapy can be applied with reduced therapist contact (Cote, Gauthier, Laberge, & Cormier, 1994), or can be conducted by competent nurse-therapists (Kingdon, Tyrer, Seivewright, Ferguson, & Murphy, 1996). Results with respect to the efficacy of bibliotherapy are inconclusive (Fanner & Urquhartt, 2008). One study found that telephone-based collaborative care for PD and generalized anxiety disorder is more effective than usual care in terms of anxiety reduction (Rollman, Belnap, & Mazumdar, 2005). Another study found that a telephone-based behavior therapy program was an effective treatment for people with PD and agoraphobia (Swinson, Fergus, Cox, & Wickwire, 1995).

More recently, a number of studies have shown that CBT can also be delivered through the Internet (Carlbring et al., 2006; Emmelkamp, 2005; Klein, Richards, & Austin, 2006). For example, in a study in Australia (Kiropoulos et al., 2008), an Internet-based CBT intervention was

compared to best-practice face-to-face CBT for people with PD with or without agoraphobia. Effects of the Internet-based CBT program were found to be comparable to those of face-to-face CBT in terms of reductions in panic attacks and avoidance behavior, depressed mood and panic-related cognitions. Participants rated both treatment conditions as equally credible and satisfying.

4.4.6 Spouse-Aided Therapy

In anxiety disorders, two different formats of spouse-aided therapy can be distinguished.

In *partner-assisted exposure* the partner accompanies the patient to each treatment session. The couple receive a treatment rational in which the focus is on exposing the patient to phobic situations. The partner can assist in making a hierarchy consisting of gradually more difficult exposure tasks. At each session, the patients are given a number of exposure homework assignments. The role of the partner is to stimulate the patient to do these exercises, help in confronting the phobic situations, accompany the patient if necessary, and reinforce the patient in mastering these exposure exercises successfully. Thus, treatment focuses on the phobia. Relationship problems, if any, are not discussed.

Other spouse-aided approaches in anxiety disorders have focused on interpersonal difficulties thought to maintain agoraphobic symptoms. These approaches include *communication training* and *partner-assisted problem solving* directed either at phobia-related conflicts or at general life stresses and problems.

In contrast to expectations derived from general systems theory, there is no evidence that exposure therapy of the patient with agoraphobia has adverse effects on the relationship or the partners' symptoms. The controlled studies in this area concur that the relationship remains stable or slightly improves, with no exacerbation of symptoms in the partner or the patient. Thus, the system-theoretic conceptualization of anxiety disorders being a symptom of more serious marital problems is not supported by the empirical evidence (Emmelkamp & Gerlsma, 1994; Marcaurelle et al., 2003).

Studies investigating the effects of spouse-aided therapy in individuals with agoraphobia led to conflicting results. Most studies have evaluated the effects of partner-assisted exposure. In two studies (Cobb et al., 1984; Emmelkamp et al., 1992), spouse-aided exposure therapy was found to be no more effective than treatment of the patient alone. In contrast, one study (Cerny, Barlow, Craske, & Himadi, 1987) found superiority for the spouse-aided exposure condition, when compared to a non-spouse group on measures of agoraphobia. However, this study has a number of methodological problems which make the results difficult to interpret. Taken together, the results of studies that have been conducted so far indicate that there is no need to include the spouse in the exposure treatment of agoraphobics.

The results of studies that evaluated the efficacy of interpersonal skills training interventions are rather mixed, so no general conclusions are allowed. Treatment focusing on general life stress rather than on relationship difficulties was found to be less effective than exposure by the patient alone. In contrast, studies that focused on relationship issues in addition to exposure led to slightly better results, especially at follow-up. Notably, this was also the case in couples who were not maritally distressed. Given the finding that criticism of the spouse may be related to relapse at follow-up, this may require specific attention to communication training in couples with a critical partner (Emmelkamp & Vedel, 2002).

4.4.7 CBT Versus Other Psychotherapies

Few studies have evaluated the effects of psychotherapies other than cognitive-behavior therapy in patients with PD with or without agoraphobia. Van den Hout et al. (1994) found cognitive therapy more effective than supportive psychotherapy in reduction of panic attacks. Further, Craske, Maidenberg, and Bystritsky (1995) found a cognitive-behavior therapy package more effective than nondirective psychotherapy. In both studies, treatment involved only four sessions. Hoffart and Martinsen (1990) compared two inpatient programs in agoraphobics: (1) psychodynamic therapy and (2) exposure plus psychodynamic therapy. Only the integrated therapy resulted in stable improvements. Given a number of methodological problems including lack of randomization and lack of behavioral measures, the results are difficult to interpret.

Teusch, Böhme, and Gatspar (1997) compared two inpatients programs: (1) client-centered therapy and (2) exposure in vivo plus client-centered therapy. Both treatment formats led to significant reductions in panic, avoidance, and depressive symptoms. The combined treatment was superior to client-centered therapy on readiness to expose oneself actively to phobic situations at discharge and at a 6-month follow-up, reduction in agoraphobia at a 3-month follow-up, and general anxiety at a 6-month follow-up. Unfortunately, an exposure only condition was not included in the design, thus precluding conclusions with respect to the additive effect of client-centered therapy to exposure in vivo.

Two studies compared cognitive therapy with another psychotherapy in patients with PD without severe agoraphobia. Beck, Sokol, Clark, Berschick, and Wright (1992) compared cognitive therapy with client-centered supportive therapy. After 8 weeks, 71% of the patients in the cognitive therapy condition were panic-free in contrast to 25% of the patients who had received nondirective therapy. Shear, Pilkonis, Cloitre, and Leon (1994) compared cognitive therapy with "nonprescriptive treatment" in patients with PD. This nonprescriptive treatment included psychodynamic elements. In this study, cognitive therapy was not found to be superior to this nonprescriptive treatment.

More recently, panic-focused psychodynamic therapy was found to be equally effective as applied relaxation in patients with PD (Milrod et al., 2007). However, subjects in panic-focused psychodynamic psychotherapy had significantly greater reduction in severity of panic symptoms. Unfortunately, panic-focused psychodynamic therapy has not been compared with the state-of-the-art CBT, which has been found consistently superior to applied relaxation (Arntz & van den Hout, 1996; Barlow et al., 1989; Beck et al., 1994; Clark et al., 1994; Craske, Brown, & Barlow, 1991).

In sum, rather few controlled studies support the effects of other psychotherapies than cognitive-behavioral therapy for PD with or without agoraphobia. Unfortunately, due to methodological problems (e.g., few sessions, concurrent inpatient treatment, lack of randomization), results with respect to the effects of alternative psychotherapies are inconclusive.

4.4.8 CBT and Pharmacotherapy

Many studies have been reported that investigated the relative contribution of cognitive-behavioral procedures and psychopharmaca, which would be difficult to discuss in any detail. Different classes of drugs have been investigated, including antidepressants (Trycyclic

Anti-Depressants [TCAs] and Selective serotonin reuptake inhibitors [SSRIs]) (high-potency) benzodiazepines, and cognitive enhancers.

Antidepressants have been demonstrated to be effective in preventing panic attacks, and improving anticipatory anxiety and avoidance behavior. In a recent meta-analysis, Furukawa, Watanabe, and Churchill (2007) investigated the relative effectiveness of CBT, antidepressants, and the combination of both treatment approaches. In the acute phase treatment, the combined therapy was superior to antidepressant pharmacotherapy or CBT. The combined therapy led to more dropouts due to side effects than CBT. After termination of the active treatment, the combined therapy was as effective as CBT and more effective than antidepressants alone. Thus, results of this meta-analysis suggest that either combined therapy or psychotherapy alone may be chosen as first-line treatment for PD with or without agoraphobia, depending on patient preference. A recent study of Marchand et al. (2008) suggest, however, that a combination of CBT and antidepressant medication is not more effective that CBT plus placebo.

High-potency benzodiazepines have been shown to display a rapid onset of antianxiety effect and have beneficial effects during the first few days of treatment and are therefore often prescribed; however, the use of benzodiazepines is associated with a number of negative side effects, including sedation, cognitive impairments, and development of dependence and tolerance. Often a rebound of panic attacks occurs during tapering off. Results of studies investigating the effects of combining CBT with benzodiazepines are mixed. Combined treatment of alprazolam and exposure or CBT results in poorer maintenance of remission of PD than CBT alone (Marks et al., 1993; Otto, Pollack, & Sabatino, 1996; Spiegel & Bruce, 1997), but can facilitate discontinuation of alprazolam therapy in patients who have been treated with alprazolam only. A recent review concluded that there is a paucity of high quality studies in this area: "Based on limited available published and unpublished data, however, the combined therapy is probably to be recommended over benzodiazepine alone for PD with agoraphobia. The combination might be superior to behavior therapy alone during the acute phase, but afterwards this trend may be reversed" (Watanabe, Churchill, & Furukawa, 2007).

A new class of drugs (cognitive enhancers) holds particular promise for the future. Examples of novel pharmacological enhancers include D-cycloserine (Vervliet, 2008), yohimbine hydrochloride (Powers, Smits, Otto, Sanders, & Emmelkamp, 2009), methylene blue (Gonzalez-Lima & Bruchey, 2004), and oxytocin (Mathew, Price, & Charney, 2008).

The most widely studied cognitive enhancer to date is D-cycloserine (DCS). DCS is a partial N-methyl-D-aspartate (NMDA) glutamate agonist. Davis et al. showed enhanced extinction in animals who were administered DCS relative to placebo (Davis, Ressler, Rothbaum, & Richardson, 2006; Falls, Miserendino, & Davis, 1992). These studies were then followed by several randomized trials in humans. Administration of DCS prior to exposure therapy enhances treatment outcome among patients with height phobia (Ressler et al., 2004), social phobia (Hofmann et al., 2006), and obsessive compulsive disorder (Kushner et al., 2007). However, no study has yet been reported on PD/agoraphobia.

Yohimbine hydrochloride is a selective alpha2-adrenergic receptor antagonist that enhances extinction learning in animals (Cain, Blouin, & Barad, 2004; Morris & Bouton, 2007). In the first study of yohimbine in humans, Powers et al. showed that yohimbine administration prior to exposure-based treatment of claustrophobic participants enhanced treatment outcome at medication-free follow-up (Powers et al., 2009). Studies are currently underway in other anxiety disorders. However, this cognitive enhancer has yet to be evaluated in patients with PD/agoraphobia.

The potential therapy-enhancing effects of methylene blue and oxytocin in human subjects should emerge shortly.

4.4.9 Benchmarking of CBT for Panic Disorder with or Without Agoraphobia

There is an ongoing debate over the extent to which results from randomized controlled trials (RCTs) of psychological treatments can be generalized to routine clinical practice. Questions that have to be addressed are whether (a) patients and therapists in RCTs are truly representative of those seen in clinical practice; and (b) whether manualized treatment is used in routine practice (Powers & Emmelkamp, 2009). In RCTs, so called efficacy studies, often a relatively homogeneous sample of patients are recruited specifically for the study, patients are randomly assigned to treatment or control groups, and therapists are trained in a specific intervention and supervised so that they will implement the intervention in a manner consistent across therapists. In contrast, in routine clinical practice, therapists who are already working in a clinical setting with patients who are routinely referred for services are used.

A number of studies have compared the typical RCTs with the so called effectiveness studies in clinical practice in order to benchmark the treatments. In a recent review of research in this area, Hunsley and Lee (2007) found that across the adult effectiveness studies most results were comparable with the efficacy-based outcome benchmarks. With respect to the treatment of PD/agoraphobia, four of seven effectiveness trials had results comparable with the benchmark, with one study having a lower improvement rate and two having a higher improvement rate. Taken together, the results of the benchmark studies suggest that the results are generalizable to routine clinical practice, but what is the level of competency needed to implement the various assessment instruments and treatment methods discussed so far? This will be discussed below.

4.5 Mechanisms of Change

4.5.1 The Process of Exposure

Exposure is usually explained in terms of habituation. Habituation refers to a decline in fear responses, particularly the physiological responses, over repeated exposures to fear-provoking stimuli. The classical habituation theory predicts that habituation would not occur if (baseline) arousal was high. Then, arousal would further increase and lead to *sensitization* (i.e., increase in fear responses after repeated exposures to fear-provoking stimuli). However, the literature revealed that a reduction instead of a further increase in psychophysiological and subjective anxiety could be expected, for instance, during exposure to high fear-provoking stimuli (e.g., flooding therapy). Recent habituation theories have been extended to accommodate these findings. These dual-process theories describe complex interactions between habituation and sensitization, in which habituation can eventually occur after exposure to high fear-provoking stimuli (van Hout & Emmelkamp, 2002).

Several studies have provided supportive evidence for the role of habituation in exposure therapy, self-reported fear and physiological arousal showing a declining trend across exposures, consistent with habituation (van Hout, Emmelkamp, & Scholing, 1994).

4.5.2 Cognitive Change Models

The success of exposure in vivo has also been explained by the acquisition of fresh, disconfir-matory evidence, which weakens the catastrophic cognitions. From this perspective, exposure is viewed as a critical intervention through which catastrophic cognitions may be tested. This is in line with the cognitive-behavioral therapy (CBT) based on the perceived danger theory according to Beck et al. Within this model, exposure (i.e., behavioral experiments) is generally regarded as a necessity for testing the validity of dysfunctional thoughts next to other strategies such as Socratic questioning of probabilities.

Several process studies have been performed looking into the cognitive processes of exposure in vivo. In these process studies, thoughts are generally collected by means of in vivo assessment (e.g., thoughts are reported into a tape recorder) during exposure, or using thought listings (i.e., free report of all thoughts on paper) directly following exposure. In general, incon-sistent findings are reported in these process studies designed to measure the relationship between cognitive change and improvement during in vivo exposure in phobic patients (van Hout & Emmelkamp, 2002).

More consistent results were found in a process study using a short self-report question-naire to measure the frequency of thoughts during exposure in vivo. Results showed that cog-nitive change (decrease in frequency of negative self-statements) was achieved by exposure in vivo therapy. However, cognitive change per se was not related to a positive treatment outcome. The results suggested that the magnitude of the frequency ratings of negative self-statements at the start, during, and at the end of exposure therapy was the most critical factor. The most improved patients reported overall less negative thoughts (van Hout et al., 1994). Clinicians hold that cognitive avoidance during exposure is detrimental to its effects. Distraction is one of the safety measures used by phobic patients with a disorder. As predicted by the emotional processing theory of Foa and Kozak (1986), a number of studies have shown that distraction during exposure inhibits habituation, but results are inconclusive (Craske, 1999; Kamphuis & Telch, 2000; Mohlman & Zinbarg, 2000; Penfold & Page, 1999). The results of these studies are difficult to interpret due to different populations studied and distracters used.

Next, we turn to a discussion of basic and expert competencies in the treatment of PD/agoraphobia.

4.6 Basic Competencies of the Clinician

Basic competency in treating PD with or without agoraphobia should include accurate diagno-sis, comprehensive assessment, and facility with the treatment protocol.

4.6.1 Diagnosis

As in the case of any mental disorder, accurate diagnosis is the first step in professional treatment. This may be accomplished in two primary steps. First, the clinician should have a firm under-standing of the conceptual model of PD and the reasons behind the diagnostic criteria. This will only be reviewed briefly here, as it is covered earlier in the chapter. Second, the clinician should be skilled at using the tools for assessing the diagnostic criteria (semi-structured interviews).

Panic attacks were at the heart of the early models of PD. However, it became obvious that although panic attacks were necessary, they were not sufficient to explain the maintenance of PD. For example, some treatments (psychological and pharmacological) readily eliminate the occurrence of panic attacks, and yet these patients often continue to report significant impairment. In addition, panic attacks and anxiety sensitivity are common in all anxiety disorders (Taylor et al., 1992). As mentioned earlier, approximately 50% of the general population report experiencing an unexpected panic attack at some point in their lives. What appears to truly differentiate PD patients from those who have had panic attacks but not the disorder is the development of panic-related apprehension. Thus, the current DSM-IV-TR still includes more than one unexpected panic attack as the first criterion, but it goes on to emphasize there must be a month or more of panic-related apprehension defined by three categories including: (1) fear of future attacks, (2) fear of the consequences of attacks, and (3) several types of avoidance behavior. The feared consequences are further broken into physical, social, loss of control, or functional impairment categories. Panic-related apprehension will be discussed further below as part of the assessment section, but the clinician should be aware of each category even during the diagnostic interview. Once the clinician determines that the patient has had more than one unexpected panic attack and a month or more of panic-related apprehension, differential diagnosis may arise. Comorbidity is common in PD and basic competency should include the ability to accurately differentiate panic and related disorders. Key questions the clinician should be able to answer include: (1) if the patient never had a panic attack again, would they still have anxiety? (2) if they meet the criteria for multiple disorders which one is primary (earliest onset)? and (3) which disorder is principal (causes the most impairment)? It is important to remember that disorder onset occurs only when symptoms significantly interfere with life and activities. Therefore, the date of PD onset is when the panic-related apprehension began to cause significant impairment – not at the time of the first panic attack. Once the clinician masters the model of PD, then semi-structured interviews and measures can guide the assessment process.

4.6.2 Assessment

The assessment of PD can guide treatment planning and monitor outcome. The process should be viewed as an ongoing activity throughout treatment. A competent clinician should be skilled with both diagnostic and subject distress measures. The most common and accurate diagnostic tools include the Structured Clinical Interview for DSM-IV Disorders – SCID (First, Spitzer, & Gibbon, 1994), the Composite International Diagnostic Interview – CIDI (WHO, 1997), the Mini-International Neuropsychiatric Interview – MINI (Sheehan et al., 1998), and the Anxiety Disorders Interview Schedule Adult Version – ADIS-IV (Brown, DiNardo, & Barlow, 2004). These interviews are the most common diagnostic tools used in expert PD treatment and research centers. Although these instruments may guide the diagnostic process, they should not replace the ability of the clinician to know the reason behind each question. Basic competency will be demonstrated by striking a balance between delivering the questions in a reliable manner while also using targeted probing questions as needed. The ability of the clinician to accurately diagnose patient may be accessed through close supervision particularly on the first couple of cases.

Once the diagnosis is made, the clinician should be able to determine the severity and maintaining factors of each case. The competent clinician should be able to use these measures to focus treatment. Again, tools are available to guide this assessment that was covered above. Severity of PD is most often measured with the PD Severity Scale – PDSS (Shear et al., 1997). This interviewer-administered scale was modeled after the Yale Brown Obsessive Compulsive Scale for Obsessive Compulsive Disorder (OCD). Competency with the PDSS should be measured by interrater reliability. As mentioned earlier, anxiety sensitivity appears to mediate treatment response to CBT (Smits et al., 2004). Therefore, it is crucial to measure anxiety sensitivity throughout treatment. The most common measure for anxiety sensitivity is the Anxiety Sensitivity Index – ASI (Peterson & Reiss, 1987). In addition, the Panic Appraisal Inventory may be used to further assess treatment targets (Telch, 1987). The panic appraisal inventory includes three subscales that assess: (a) anticipated panic, (b) perceived consequences of panic, and (c) perceived self-efficacy in coping with panic. The perceived consequences subscale can be particularly useful in assessing which consequences the patient fears the most. This scale shows the relative distribution of threat associated with physical, social, and loss of control consequences. The therapist should also be familiar with the Beck Depression Inventory – BDI (Beck, Ward, Mendelson, Mock, & Erbaugh, 1961). In particular, the clinician should regularly monitor items two and nine as they are associated with suicide risk. Finally, interoceptive assessment should guide the application of interoceptive exposure. This assessment should take place later during treatment and thus will be discussed below.

In addition to administration and scoring, the clinician should be able to interpret the scores. Basic competency should include knowledge of the norms for people with PD and for healthy controls. Basic competency also includes the ability of the clinician to incorporate the findings of these measures into informed treatment decisions.

Basic competency in the treatment of PD should also include an awareness of the treatment of PD NIH consensus statement (NIH, 1991, 1992, 1993). Experts from around the world converged to create a consensus statement on all that was known at that time about the proper treatment of PD. As this statement is now almost 20 years old, the conclusions are out of date but clinicians should still be aware of the major findings. The NIH (1991) consensus panel stated:

▶ Panic disorder is a distinct condition with a specific presentation, course, and positive family history and for which there are effective pharmacologic and cognitive-behavioral treatments. Treatment that fails to produce benefit within 6–8 weeks should be reassessed. Patients with panic disorder often have one or more comorbid conditions that require careful assessment and treatment. The most critical research needs are: the development of reliable, valid, and standard measures of assessment and outcome; the identification of optimal choices and structuring of treatments designed to meet the varying individual needs of patients; and the implementation of basic research to define the nature of the disorder. Barriers to treatment include awareness, accessibility, and affordability. An aggressive educational campaign to increase awareness of these issues should be mounted for clinicians, patients and their families, the media, and the general public.

The statement was general but emphasized the time-limited nature of effective treatments. In 1998, there was another international consensus group charged with the goal of providing

primary care clinicians with recommendations in the treatment of PD (Ballenger et al., 1998). Again, as the statement is over 10 years old now, the findings are out of date. In addition, the statement focused on pharmacotherapy. They recommended using SSRIs as first-line treatment for a period of 12–24 months. They went on to suggest a slow taper over 4–6 months when discontinuing medication. Basic competencies should also include awareness of pharmacologic strategies to deal with PD, covered briefly above. Clinicians should be informed about the pros and cons of antidepressant medication and high-potency benzodiazepines in the treatment of PD.

4.6.3 Treatment

After diagnosis and assessment, the first step in treatment is psychoeducation. Competence in psychoeducation delivery should include broad and deep knowledge of PD. This phase is primarily didactic and is crucial for building rapport. The material for psychoeducation is available in any treatment manual, but the clinician should be able to deliver the information from memory, assisted by only an outline. This will increase the credibility of the therapist and the treatment. Although this phase is primarily didactic, a skilled therapist will follow each knowledge piece with brief solicitation from the patient on how it relates to them.

Second, the therapist initiates self-monitoring. Various forms may be used but most include daily monitoring of anxiety, panic, and associated specific threat forecasts. The best way for a therapist to become skilled at initiating self-monitoring is to try it themselves. Therapists should try monitoring themselves for at least 1 week prior to trying this with a patient. Therapists should go over these forms with patients in each session and demonstrate that intervention is tied to these ongoing assessments. Also during this phase, many manuals include breathing retraining. However, this may be omitted (Schmidt et al., 2000).

Third, the therapist should be able to conduct interoceptive assessment and associated exposures. The therapist should be able to complete each of the interoceptive tasks themselves without any anxiety prior to conducting this assessment with a patient. Next, the therapist should be able to tolerate making the patient anxious during the assessment and subsequent repeated exposures. The therapist should be skilled with the full spectrum of interoceptive exposure techniques including: head shaking, spinning, push ups, stair climbing, running in place, gag reflex, breath holding, straw breathing, head between the legs, hyperventilation, CO_2 inhalations, caffeine challenges, niacin challenges, and yohimbine challenges. To demonstrate competence, a clinician should either conduct interoceptive or in vivo exposure in every session once psychoeducation has ended. In addition, the clinician should demonstrate competent exposure execution. In short, exposure should be conducted in vivo when possible in a graduated fashion (to reduce dropouts). Long massed continuous exposures are preferred over short interrupted spaced trials. Finally, attention to what is learned is critical. Although massed exposures may be preferable for acute outcome, spaced exposures may reduce relapse. Therefore, an expanding spaced schedule may be optimal (Rowe & Craske, 1998; Tsao & Craske, 2000).

Fourth, in vivo exposure is initiated to address avoidance behavior. These exercises are most effective when the therapist conducts the exposure with the patient at first. The therapist should expect to leave the therapy office for these exposures and may need to work with their clinical setting to obtain the necessary approval to do so. Effective PD treatment is very active, and a competent therapist should demonstrate willingness to get out of the office with the patient when indicated.

Fifth, all of these steps should be supplemented with attention to fading of the use of safety behaviors. Safety behaviors include actions (mental or physical) that the patient engages in to prevent feared outcomes. Safety behaviors are also often referred to as safety signals or conditioned inhibitors in the translational research literature. If the threats are false alarms (as in the case of PD), safety behaviors have the effect of reducing anxiety in the short run but maintaining fear in the long run. If the threat is a true alarm, then obviously the safety behavior should not be eliminated. Examples of safety behaviors include carrying water, cell phones, defibrillators, medications, the presence of another person, wearing a seat belt, and mentally counting to avoid thinking of something (Barlow, 1988). All types of avoidance may also be considered safety behaviors, but the reverse is not true. As can be seen, safety behaviors are not necessarily good or bad. The important questions are: (a) why is the patient engaging in the behavior? and (b) if the behavior is to prevent a feared outcome, is the outcome a true or false alarm? For example, wearing a seat belt would be considered an adaptive safety behavior, whereas, carrying a defibrillator may be maladaptive for a physically healthy panic patient with cardiac concerns. Studies show that the use or even availability of safety behaviors during treatment may lead to poorer outcome when later tested without availability of the safety aids (Powers, Smits, & Telch, 2004). Conversely, asking patients to refrain from safety behaviors leads to superior outcome (Salkovskis, 1991; Wells et al., 1995). It is important to note that the use of safety behaviors during treatment is not necessarily contraindicated. In fact, if a patient will only engage in exposure with the use of a safety aid then it may be required to proceed. In this case, the safety behavior may be faded later in treatment so that the patient learns unambiguous safety. If the patient believes that he or she was safe during treatment *because* of the safety behavior then this attribution may put the patient at risk for relapse (Powers, Smits, Whitley, Bystritsky, & Telch, 2008).

Once the didactic phase of the treatment is complete, the therapist should be able to check off each of the following sessions: (a) inquiry about homework from last session, (b) going through the threat forecast forms since the last session, (c) conducting in-session interoceptive or in vivo exposure or stating a valid reason why not, and (d) assigning homework. To assess competence a supervisor should review recording from the beginning sessions (to determine competence in delivery of the rational and psychoeducation) and several recordings of later sessions with the above checklist.

4.7   Expert Clinical Competencies

It is difficult to firmly differentiate basic from expert competencies in the treatment of PD. The developmental trajectory of a clinician working with PD is surely more accurately described as a continuum. However, the portion of the continuum allocated to the expert clinician includes state-of-the-art treatment from burgeoning research. Therapists who may be described as experts should be knowledgeable and skilled at psychological and pharmacological augmentation strategies along with the ability to work with complex presentations. Most current augmentation strategies are the result of recent advances in translational research (Craske, Hermans, & Vansteenwegen, 2006; Craske et al., 2008). Early models of mechanisms of change in anxiety disorder treatment emphasized fear activation followed by fear reduction. For example, emotional processing theory suggests that for effective treatment: (a) the fear structure must be activated, and (b) evidence that is not consistent with the fear structure must be available and processed (Foa & Kozak, 1986; Foa & McNally, 1996; Rachman, 1980). The theory

suggests that fear structure activation is indexed by self-reported fear and psychophysiology. The processing of incompatible information is then theoretically indexed by within and between trial habituation. However, studies show initial fear activation (Foa et al., 1983) and within trial habituation (Kozak, Foa, & Steketee, 1988) is not always associated with better outcome. In fact, studies show that CBT is effective even when exposure trials are terminated at the point at which anxiety reaches a high level – given further exposures are conducted (Emmelkamp & Mersch, 1982; Rachman, Craske, Tallman, & Solyom, 1986). More recent theories on mechanisms of change emphasize developments in laboratory models of fear acquisition and extinction.

From a translational research perspective, we may view extinction of conditioned fears as a laboratory model of exposure-based treatment of anxiety disorders (Bouton, Mineka, & Barlow, 2001; Craske et al., 2006; Davey, 1987, 1997; Eelen, Hermans, & Baeyens, 2001; Mineka, 1985). Translational research shows that extinction learning is an active process of new learning. Safety learning inhibits fear learning rather than erasing it as once thought (Bouton, 1993). Both fear and safety learning are then in competition. When confronted with the feared stimulus, this competition is resolved in favor of the memory which matches the current context best. Relevant contexts include both internal and external stimuli (therapist presence/absence, location, time, drug state, etc.). In a clinical setting, this means that what is learned in the therapy context may not entirely translate to other contexts after treatment is over. This reemergence of fear in different contexts after exposure treatment comes in several forms including spontaneous recovery, renewal, reinstatement, and rapid reacquisition. First, time may be considered a context. Thus, it is possible to observe a return of conditioned responding after extinction simply with the passage of time. This circumstance is called spontaneous recovery (Baum, 1988). Second, renewal is when the subject is presented with the extinguished Conditioned Stimulus (CS) in any context other than the extinction context and conditioned responding returns (Bouton). Third, reinstatement is observed when conditioned responding reemerges in response to an unsignaled Unconditioned Stimulus (US) (Rescorla & Heth, 1975). Finally, rapid reacquisition occurs when the CS–US relationship is learned faster after acquisition and extinction trials than in naive subjects who never learned the CS–US relationship (Ricker & Bouton, 1996). With these findings in mind, several augmentation strategies have emerged. Below we outline current expert competency areas. These methods are considered state of the art. However, "state of the art" is a moving target, and thus expert clinicians should be aware of the latest developments as they emerge. For example, for some time fading safety behaviors was considered an expert competency, while now it is a mainstream skill.

4.7.1 Augmentation (Psychological)

Taking into account what has been learned from translational research, several exposure modifications should be considered.

4.7.2 Extinction in Multiple Contexts

As extinction learning appears to be context-specific, one strategy to increase the durability of treatment is to conduct exposure in multiple contexts (Chelonis, Calton, Hart, & Schachtman,

1999; Gunther, Denniston, & Miller, 1998; Vansteenwegen et al., 2007). For example, Gunther et al. (1998) found more durable extinction in rats that received extinction in three contexts compared to those that had received extinction in only one context. Similarly, in a taste aversion study with rats, Chelonis et al. (1999) found that extinction in three different contexts reduced later renewal. These findings were also then replicated with human participants. Vansteenwegen et al. (2007) found multiple context extinction superior to single context extinction among spider phobics.

4.7.3   Occasional Reinforced Extinction Trials

Another recent finding in the animal literature is that occasional reinforced trials during extinction can slow rapid reacquisition (Bouton, Woods, & Pineno, 2004). From this perspective, if there are no US presentations during extinction, and if the subject encounters even one US presentation during follow-up testing that fearful responding should return as it signals acquisition trials. Conversely, if occasional US presentations occur during extinction, then occasional encounters with the US at follow-up testing signals both acquisition and extinction resulting in less return of fearful responding. As in the case of the most recent studies, the results suggest that occasional anxiety during exposure treatment may be beneficial in long-term outcome.

4.7.4   Mental Reinstatement

Mental reinstatement refers to having a patient mentally reinstate the treatment context when encountering the fear stimulus in a novel context. In the first examination of this strategy by Mystkowski, Craske, Echiverri, and Labus (2006), 48 spider fearful participants received exposure-based treatment in one of two contexts. At a 1-week follow-up they were tested in either the same or different context. Participants were randomized to either mentally reinstate the treatment context or a neutral context. Mental reinstatement of the treatment context included instructions to "[r]emember what happened and what you learned last time, and where all of that took place." The neutral condition was instructed to "[p]lease remember all of the things that you do to get ready in the morning before leaving for school or work." Consistent with prediction, results showed that the mental reinstatement of the treatment context lead to significantly less return of fear (Mystkowski et al., 2006).

4.7.5   Fear Antagonistic Action Strategies

Telch et al. reasoned that if safety behaviors can interfere with long-term treatment efficacy, then engaging in actions in direct opposition to the fear action tendencies may enhance outcome. Indeed an initial randomized controlled trial of 88 acrophobics showed that fear antagonistic actions enhanced treatment outcome (Wolitzky & Telch, 2009). Examples of fear antagonistic action strategies include running toward the railing while conducting a height exposure on a landing, walking backward to the railing, and putting hands behind the back. Participants were randomized to exposure with oppositional actions, exposure only, psychological placebo treatment, or a wait list. The fear antagonistic action condition showed greater fear reduction

compared to the other groups at posttreatment and follow-up. In addition, the oppositional action group showed greater generalization of fear reduction to an untrained test context.

4.7.6 Eliminating External Attributions

Most patients seeking help for anxiety are already taking medication when they arrive for treatment (Roy-Byrne et al., 2002; Taylor et al., 1989). An expert clinician should be aware of the literature on combined CBT and medication treatment (Barlow et al., 2000; Gladsjo et al., 2001; Marks et al., 1993; Sharp et al., 1996). The research to date suggests a slight advantage of combined treatment and post assessments. However, this advantage is lost at follow-up. In fact, the Barlow et al. study showed that up to half of posttreatment responders who discontinued their medication relapsed within 6 months. The detrimental effects of combined treatment on medication-free follow-up are likely due to a combination of drug context (Mystkowski, Mineka, Vernon, & Zinbarg, 2003), associative (Rescorla & Wagner, 1972), and/or attributional mechanisms (Powers et al., 2008). However, continuing exposure during medication taper may prevent later relapse. Indeed studies show CBT for PD is effective during gradual benzodiazepine taper (Hegel, Lewis Ravaris, & Ahles, 1994; Otto et al., 1993; Spiegel, Bruce, Gregg, & Nuzzarello, 1994) and SSRI discontinuation (Schmidt, Wollaway-Bickel, Trakowski, Santiago, & Vasey, 2002; Whittal, Otto, & Hong, 2001).

4.7.7 Cognitive Therapy

In the USA, the main emphasis is on interoceptive exposure to deal with PDs. In a number of cases, however, interoceptive exposure does not result in the expected cognitive changes and anxiety reduction and here a more elaborate cognitive therapy may be indicated. To deal with the underlying cognitions and schemata in treatment-resistant patients with PD requires a thorough understanding of the cognitive theory of PD and an intensive training and supervision in cognitive therapy.

4.7.8 Augmentation (Pharmacological)

Although knowledge of the effects of antidepressants and high-potency benzodiazepines belong in the domain of basic clinical competency, knowledge and application of cognitive enhancers requires expert knowledge. As discussed above, there are a number of cognitive enhancers that may facilitate learning in an exposure context, D-cycloserine and Yohimbine being the most promising. Although the cognitive enhancing effects of these drugs have not yet been tested in the treatment of patients with PD and agoraphobia, results in other phobic disorders suggest that the addition of these drugs may help in treatment-resistant cases.

4.7.9 Complex Presentation

Another expert competency is knowledge and skill associated with complex clinical presentations. For example, the clinician should be able to convey the prognosis for panic patients

with comorbidity. For example, a series of studies by Tsao et al. shows reliable decreases in comorbid conditions in PD patient following treatment with CBT (Tsao, Lewin, & Craske, 1998; Tsao, Mystkowski, Zucker, & Craske, 2002; Tsao, Mystkowski, Zucker, & Craske, 2005). Similarly, comorbid personality disorders do not appear to affect the efficacy of CBT for PD (Dreessen & Arntz, 1998; Dreessen, Arntz, Luttels, & Sallaerts, 1994). In short, most PD patients will be on medication and meet criteria for at least one or the other disorder. However, treatment may proceed without much modification even with complex cases. There is evidence that complex cases may start and end higher on standardized PD measures, but the slope of improvement is not different. These data suggest that more severe cases can reach similar levels of functioning with further treatment, but in a number of instances specific expert competencies are needed.

Such expert competency includes knowledge of substance abuse and dependence and how to treat these disorders. As noted above, a substantial number of patients with PD and agoraphobia abuse substances. Substance abuse has to be adequately dealt with in order to overcome the PD and prevent relapse (Emmelkamp & Vedel, 2006).

Another expert competency is related to dealing with PD and/or agoraphobia in the context of a depressive disorder. Depressive disorders often co-occur with PD/agoraphobia and a thorough functional analysis (Emmelkamp, Bouman, & Scholing, 1993) is needed to determine whether the depression should be treated first or treatment should commence with targeting the PD first. In not too severely depressed patients, where the depressed mood is the result of the PD and agoraphobia, there is usually no need to focus the treatment on the depression: if the PD improves, the depressed mood will improve concurrently.

Finally, in a few cases PD is related to marital distress. The expert should be knowledgeable about the literature in this area, able to adequately assess the relationship between panic/agoraphobia on the one hand and the relationship distress on the other, and trained in involving the partner in treatment, either in the context of spouse-aided therapy, or in the context of communication training dealing with the presumed underlying relationship distress.

4.7.10 Cultural Issues

Finally, expert clinical competencies include appreciation for cultural issues that may be related to the presentation and maintenance of PD and agoraphobia. Explanatory models of illness refer to causal attributions of a specific episode of illness that are held by patients, their family or practitioners. Predominantly culturally shaped, these models project personal and social meaning on the illness experience, and can affect coping, treatment preferences, compliance, and therapeutic relationship. In light of the available evidence, fostering the effectiveness of mental health care requires an understanding of patients perspective through assessments of their explanatory models of illness. In a study of Ghane, Kolk, and Emmelkamp (2009), anxious patients scored higher on interpersonal, victimization, and religious/mystical causes, when interviewed by an ethnically similar interviewer, and scored higher on medical causes, when interviewed by an ethnically dissimilar interviewer. Results of this study suggest that clinicians should be aware of culture-specific panic-related beliefs. In addition, in orthodox Muslim culture, agoraphobia of females might be seen as a virtue rather than as a disorder in need of treatment. Here, it may be essential to involve the family in the treatment. Expert clinicians should be informed about the progress in culturally related issues in mental health.

Basic Competencies
Accurate diagnosis
Knowledge of the model of panic disorder
Differential diagnosis
Assessment
Diagnostic tools: SCID, MINI, CIDI, or ADIS-IV
Subjective distress measures: PDSS, ASI, PAI, BDI
Treatment
Psychoeducation
Self-monitoring
Breathing retraining
Interoceptive exposure
In vivo exposure
Safety behavior fading
Antidepressants and high-potency benzodiazepines
Expert Competencies
Augmentation (Psychological)
Extinction in multiple contexts
Occasional reinforced trials
Mental reinstatement
Fear antagonistic action strategies
Eliminating external attributions
Cognitive therapy
Augmentation (pharmacological)
D-cycloserine
Yohimbine hydrochloride
Methylene blue
Oxytocin
Complex presentation (comorbidity)
Cultural influences

4.8   Transition from Basic Competence to Expertise

There is no consensus on the correct process of attaining basic competence and transitioning to expertise in the treatment of PD. There are surely multiple paths to similar proficiency. The best path is most influenced by the context of the learner. For example, a clinician finishing internship in clinical psychology graduate school is most appropriate for a postdoctoral program where the proper training is provided. Next, we briefly outline such training assuming the

learner in this case is a seasoned clinician interested in reaching basic and/or expert competence in the treatment of PD/agoraphobia.

The most common model used to lead existing therapists to basic competency and then on expert competency is called the "Watch one, Do one, Teach one" method. The specific execution of the method varies from training site to training site. The first step is for the therapist to read a general treatment-oriented chapter such as chapter 1 in the Barlow's *Clinical Handbook of Psychological Disorders* (Barlow, 2008). Next, the therapist should read through the protocol manual they plan to use such as *Mastery of your Anxiety and Panic* (Barlow & Craske, 2007). After becoming familiar with these materials, the therapist should consider attending a workshop that covers the treatment. In our experience this takes a minimum of 1 full day and preferably would span 2–4 days. The workshop should cover the etiology and epidemiology of the disorder, research on maintaining factors, empirically supported treatments, and efficacy of data. The workshop should also include a session-by-session section complete with demonstrations or videotaped examples. After the workshop the therapist should find a way to either sit in on a couple of therapy cases or watch such therapy cases on video. At this point the therapist should be ready for their own first panic patient. The sessions should be videotaped for the purpose of supervision. The therapist and supervisor should be able to talk in person or by conference call once a week to go over the most recent session. To reach basic competence each therapist should see four complete patients under close supervision with adequate ratings of adherence (asked about homework, went over threat forecast forms, conducted exposure, assigned homework). Of these four patients at least two should have moderate to severe agoraphobia.

Expert competence usually comes with further experience with patients and training in how to train other therapists. This can be accomplished in the same manner. The therapist can attend a workshop on how to train and supervise others in the treatment and then be supervised in their supervision. In addition, to become an expert it is tantamount to keep up with the research literature in PD and agoraphobia.

4.9   Summary

This chapter has summarized the literature on assessment, maintenance, treatment, and mechanisms of change in treatment of patients with PD with or without agoraphobia. Knowledge of the burgeoning literature in this area is relevant for the development of basic and expert clinical competencies in PD/agoraphobia. The clinician should first be familiar with the diagnostic criteria for PD and agoraphobia. Knowledge of structured clinical interviews is needed to be able to formalize the diagnosis. Knowledge of self-report measures, behavioral assessment, and self-monitoring is needed to assess the quality and severity of PD and agoraphobia and evaluate progress of treatment. Further, basic competency also requires knowledge on which factors are involved in the maintenance of these disorders. In addition, basic clinical competencies should entail knowledge about psychoeducation and evidence-based protocols for conducting interoceptive exposure and exposure in vivo outside the therapist office. Expert clinical competencies may entail advanced understanding and skills of applying psychological and pharmacological procedures to augment exposure therapy, skills in enactment of cognitive therapy and couple therapy, knowledge and skills to deal with PD and agoraphobia in cases with comorbid disorders (e.g., substance abuse/dependence and depression) as well sensitivity to anxiety-related cultural factors.

5 Obsessive Compulsive Disorder

Martin E. Franklin · Sophia Talbott

Abstract: The development of basic competence and the progression from basic to expert competence in delivering cognitive behavioral therapy (CBT) for obsessive compulsive disorder (OCD) is a complex endeavor that has rarely been the focus of discussion in the literature despite the obvious importance of the topic. In this chapter we endeavored to develop a basic set of therapist skills that range from: 1) comprehensive and yet focused assessment of core symptoms; 2) differential diagnosis from disorders that overlap OCD; 3) clinical management of the common comoridities likely to be encountered; 4) providing a clear rationale for the treatment procedures that flow logically from a neurobehavioral framework; 5) conveying the current state of the treatment literature and its implications for treatment choice; and 6) developing reliance on the conceptual model of OCD to inform treatment progression. The movement from basic competence to expert delivery of CBT for OCD requires continuing education and monitoring of the extant literature, treating a sufficiently high volume of cases to master the heterogeneity of OCD presentation, and therapists' willingness to acknowledge what they do not yet know and persistence in seeking out professional opportunities to bridge the gaps in their knowledge.

5.1 Overview

In keeping with the spirit with which this book is intended, our purpose in writing this chapter is to provide a sufficiently detailed description of obsessive compulsive disorder (OCD) and its treatment, so that practicing psychologists can learn about what in our view constitutes the requisite and the expert competence in assessing and treating this condition with cognitive-behavioral theory (CBT). OCD is a complex disorder that is associated with significant morbidity, comorbidity, and functional impairment across the developmental spectrum, and there are important subtleties to its evaluation and treatment that may not be immediately apparent to the novice practitioner. That said, there is a recent evidence from a relatively large case series conducted in middle Norway indicating that treatment outcomes achieved by master's-level clinicians without any prior expertise with pediatric OCD were both statistically and clinically meaningful. Interestingly, these outcomes were also comparable to what has been achieved in the context of tightly controled randomized studies of CBT conducted in the academic context under conditions that emphasized internal validity (Valderhaug, Larsson, Gotestam, & Piacentini, 2007). This is an encouraging news indeed, indicating that substantive and durable treatment outcomes can be achieved in community clinical settings with youths suffering from OCD. The study included supervision by psychologists who were knowledgeable about OCD and its treatment; these psychologists had access to one of the world's leading experts in the application of CBT to children and adolescents, Dr. John Piacentini at UCLA, and thus the generalizability of this

study's findings to treatment that does not include these key procedural elements remains to be explored. What is clear, though, is that clarifying what constitutes competent and expert delivery of CBT for OCD is a valuable and worthwhile endeavor, one which we aim to pursue here.

By way of brief review, the DSM-IV Text Revision (DSM-IV TR; American Psychiatric Association, 2000) defines OCD by the presence of recurrent obsessions and/or compulsions that interfere substantially with daily functioning. Obsessions are "persistent ideas, thoughts, impulses, or images that are experienced as intrusive and inappropriate and cause marked anxiety or distress" (p. 457). Common obsessions are repeated thoughts about contamination, causing harm to others, and doubting whether one locked the front door. Compulsions are "repetitive behaviors or mental acts the goal of which is to prevent or reduce anxiety or distress" (p. 457). Common compulsions include hand washing, checking, and counting. In order to warrant diagnosis and separate OCD from the virtually ubiquitous occasional unwanted thought and repetitive behavior reported by most individuals who are asked, obsessions and/or compulsions must be found to be of sufficient severity to cause marked distress, be time-consuming, and interfere with daily functioning. If another Axis I disorder is present, the obsessions and compulsions cannot be restricted to the content of that disorder (e.g., preoccupation with food in the presence of eating disorders).

Development of OCD is typically gradual, but acute onset has been reported in some cases. In some cases of pediatric OCD, onset is very sudden (e.g., overnight) and associated with strep infection; treatment of the infection is associated with the substantial reduction of symptoms, but recurrence of infection is again associated with symptom exacerbation (Swedo et al., 1998). This unusual presentation appears to be more common in males than females, and has come to be known as Pediatric Autoimmune Neuropsychiatric Disorders (PANDAS); when dramatic symptom onset is described, it is important that clinicians query families of pediatric OCD sufferers about strep throat infections, colds, or other illnesses in the weeks and months prior to a dramatic symptom onset. PANDAS treatment would include a round of antibiotics to treat the infection as well as the usual, empirically supported treatments for OCD that are recommended for non-PANDAS OCD (Storch et al., 2008). No research has examined strep-related onset of OCD in adults.

As is the case with many mental health problems, individuals with OCD often suffer for years before seeking treatment. Moreover, when treatment is sought, it is often difficult to access the psychosocial treatment of choice, CBT involving exposure and response prevention (EX/RP). A comprehensive review of pharmacotherapy for OCD is beyond the scope of our chapter (Franklin & Simpson, 2005). It may suffice for our purposes here though to say that while large, multisite randomized studies clearly indicate that medications that affect the serotonergic neurotransmitter system (e.g., selective serotonin reuptake inhibitors, the tricyclic antidepressant clomipramine) are efficacious for OCD for children, adolescents, and adults, their effects are far from universal or complete, and side effects prevent some patients from reaching doses likely to be efficacious. As is discussed in detail below, CBT involving EX/RP has been found to be consistently superior to various control conditions and comparable to active pharmacotherapy in some studies and superior in others; it also appears that while combined treatment afforded some advantages over monotherapy in some studies (Hohagen et al., 1998; Pediatric OCD Treatment Study Team, 2004), there are also large studies that have failed to detect such an advantage (Foa et al., 2005).

5.2 Recognition of Symptoms and Their Assessment

Individuals suffering from OCD experience intrusive, unwanted thoughts or images that generate marked distress. These obsessions are coupled with repetitive behaviors or mental acts known as compulsions, which are performed in an attempt to reduce obsessional distress and/or to prevent the occurrence of dreaded yet unrealistic outcomes (e.g., contracting HIV through casual contact). Proper recognition of these symptoms is essential for effective treatment. The goal of assessment of the OCD symptoms, specifically, is to identify specific cues that trigger the distress, avoidance behaviors, and rituals. The evaluator also needs to explore key aspects of the patients' beliefs about OCD (e.g., the degree to which the individual views the obsessions and compulsions as senseless) and their perceived consequences of refraining from rituals and avoidance. Below we discuss our approach to this evaluation of OCD in depth.

5.2.1 OCD Symptom Topography and Severity

Treatment of OCD should always begin with at least two sessions of symptom assessment and psychoeducation. In our view, this should include (1) a comprehensive evaluation of current and past OCD symptoms; (2) a review of current OCD symptom severity and associated functional impairment; and (3) an evaluation of comorbid psychopathology. The strengths of the individuals and their family should also be considered, as well as their current knowledge of OCD and its treatment, their treatment histories, and readiness to engage in a treatment that is designed specifically to be challenging. There are many self-report and clinician-administered instruments that can be used to guide assessment; we will not review these in depth here. In our clinic and in multisite clinical trials, we ask patients and/or families, depending on the age and emotional maturity of the patient since OCD can affect people across the developmental spectrum, to complete the most relevant self-report measures prior to the intake visit, and then the intake clinician reviews these materials prior to the meeting with the patient. Prominent comorbidities or other problem areas revealed through responses to these measures can then be targeted in greater detail at intake through the use of structured or semi-structured diagnostic interviews (e.g., Anxiety Disorders Interview Schedule (ADIS) or Anxiety Disorders Interview Schedule for Children (ADIS-C)). It is then crucial to document past and current OCD symptoms and current symptom severity, which we do via the clinician-administered Yale Brown Obsessive Compulsive Scale (Goodman et al., 1989a, b) or Children's Yale Brown Obsessive Compulsive Scale (CY-BOCS) (Scahill et al., 1997), again depending on the developmental level of the patient. The clinician should be aware of the implications of the Y-BOCS and CY-BOCS symptom severity score, which ranges from 0–40 (higher scores indicating greater severity); a cut score of 16 is usually sufficiently severe to warrant inclusion in treatment studies, and scores of 30 or greater are considered especially severe. This information can be used to inform treatment decisions such as CBT session frequency.

Prior to initiating the formal assessment, the evaluator should define obsessions and compulsions, using specific examples, if the patient is having difficulty in grasping the key concepts. We also let patients know about the prevalence, nature, and treatment of OCD, which may increase their willingness to disclose specific symptoms once the semi-structured interview

begins. Psychoeducation is incorporated liberally throughout the assessment, since asking the patient a series of questions about OCD symptoms may provide an opportunity to inform the patient about the nature of the disorder or to correct misinformation that he or she may have about what constitutes OCD and appropriate treatment.

5.2.2 Differential Diagnosis

The high comorbidity of OCD with other disorders, as well as the similarity between the criteria for OCD and other DSM-IV disorders, can pose diagnostic quandaries. Below, we review some of the more common diagnostic difficulties likely to confront clinicians and provide recommendations for making these difficult diagnostic judgments. For the novice clinician who is about to conduct an intake that was scheduled for OCD specifically, it is important to resist the urge to place the round peg in the square hole. Some of the conditions discussed below have formal similarity to OCD, yet misdiagnosis could lead to inadequate treatment. We encourage our clinicians to be mindful of the possibility that the information provided to the telephone screener who scheduled the intake after a very brief assessment may or may not reflect the clinical nuances of the case, and that they should remain open to the possibility that OCD is not the primary diagnosis or the proper diagnosis at all.

Obsessions Versus Depressive Rumination. The distinction between obsessions and ruminations rests primarily on thought content and on the patient's reported responses to such thoughts. Unlike obsessions, ruminations are typically pessimistic ideas about the self or the world, and content frequently shifts. Additionally, individuals who are ruminating tend not to make attempts to suppress their ruminations in the same way that individuals with OCD try to suppress obsessions with rituals or avoidance. When depression and OCD co-occur, both phenomena may be present but only obsessions should be targeted with exposure exercises. We have also found clinically that the generally pessimistic presentation of depressed patients can undermine hopefulness about improving during EX/RP, and thus these beliefs may require therapeutic intervention even though they are not obsessional per se.

Other Anxiety Disorders. OCD often co-occurs with other anxiety disorders and diagnostic criteria are sometimes similar among anxiety disorders, but the symptoms associated with each diagnosis can usually be distinguished. For example, the excessive worries characteristic of generalized anxiety disorder (GAD) may appear similar to OCD but, unlike obsessions, worries are excessive concerns about real life circumstances and are often experienced by the individual as appropriate (ego syntonic). In contrast, obsessive thinking is more likely to be unrealistic or magical and obsessions are usually experienced by the individual as inappropriate (ego dystonic). Distinguishing between OCD and GAD is most relevant when the patient exhibits no obvious compulsions, but individuals with obsessions yet no compulsions comprise only about 2% of those diagnosed with OCD (Foa et al., 1995). Hence, the clinician should be sure to query specifically about what the patient does when his or her worries occur, and should examine whether compulsions follow. Exposure to feared thoughts and situations without sufficient education about the importance of refraining from compulsions could lead to compromised outcomes, so the importance of making a detailed query of "what happens after the obsession occurs?" cannot be overstated.

In the absence of overt rituals, symptoms of specific phobias can also appear similar to OCD. For example, OCD involving excessive fears of causing harm to others and specific phobia can each result in persistent fear of driving over bridges. However, unlike an individual with this subtype of OCD, a person with a specific phobic will often feel immediate relief after exiting the bridge on those rare occasions when crossing the bridge cannot be avoided. In contrast, the individual with OCD who fears having caused a fatal accident while driving over a bridge will likely become even more anxious once he or she has exited the bridge, driven largely by the fact that he or she can no longer check to see if such an accident has occurred. Such individuals may then drive over the bridge repeatedly searching for evidence of the crime they might have committed, which provides temporary reassurance about the previous crossing but then may also give rise to having caused another accident while distracted by the checking behavior. Both individuals would report fear of driving over bridges, but the markedly different consequences of doing so and the compulsions in the latter case would clearly influence case conceptualization and treatment. For the phobic patient repeated trips over the bridge would be indicated, whereas for the OCD patient a single trip over the bridge during times perceived to be risky followed by refraining from subsequent trips that serve a checking function would be the proper route to take in CBT.

Tourette's Syndrome and Tic Disorders. In order to differentiate the stereotyped motor behaviors that characterize Tourette's Syndrome and tic disorders from compulsions, the functional relationship between these behaviors and any obsessive thoughts must be examined. Motor tics are generally experienced as involuntary and are not aimed at neutralizing distress brought about by obsessions. There is no conventional way of differentiating them from "pure" compulsions, but OCD with "pure" compulsions is extremely rare (Foa et al., 1995). As noted above, there appears to be a high rate of comorbidity between OCD and tic disorders (Pauls, Towbin, Leckman, Zahner, & Cohen, 1986); thus, both disorders may be present simultaneously in a given patient. Interestingly, recent research indicated that tics were similarly responsive to an exposure plus response prevention protocol when compared in a randomized study to habit reversal training where a competing response is used to substitute for the tic; this finding suggests that the conceptual model underlying the treatment of tics might require modification (Verdellen, Keijsers, Cath, & Hoogduin, 2004). Clearly, though, an emphasis on imaginal exposure to obsessional content would be prominent in an individual who engages in repetitive tapping behavior to prevent a specific dreaded outcome (e.g., death of child in an accident), whereas one who reported that a very formally similar tapping behavior was engaged in to reduce discomfort associated with premonitory urges (Woods, Piacentini, & Himle, 2005) would be unlikely to benefit from imaginal exposure.

Delusional Disorder and Schizophrenia. Individuals with OCD may present obsessions of delusional intensity (Kozak & Foa, 1994). Approximately 5% of OCD patients report complete conviction that their obsessions and compulsions are realistic, with an additional 20% reporting strong but not fixed conviction. Therefore, it is important to consider the diagnosis of OCD "with poor insight" even if these beliefs are very strongly held. The differentiation of delusional disorder from OCD can depend on the presence of compulsions in OCD (Eisen et al., 1998). In OCD, obsessions of delusional intensity are usually accompanied by compulsions.

It is also important to recognize that the content of obsessions in OCD may be quite bizarre, as in the delusions of schizophrenia, but bizarreness in and of itself does not preclude a diagnosis of OCD. For example, one patient seen at our center was fearful that small bits of her "essence" would be forever lost if she passed too close to public trash cans. This patient did not

report any other symptoms of formal thought disorder, such as loose associations, hallucinations, flat or grossly inappropriate affect, and thought insertion or projection. Following a course of EX/RP that focused on exercises designed to expose the patient to the loss of her "essence" (e.g., driving by the city dump), the patient's OCD symptoms were substantially reduced. On occasion patients do meet diagnostic criteria for both OCD and schizophrenia, and a dual diagnosis is appropriate under these circumstances. Importantly, EX/RP should proceed with such patients only if the associated treatment exercises do not cause exacerbations of the comorbid thought disorder symptoms.

5.2.2.1 Comorbidities

OCD commonly co-occurs with other symptoms and complaints such as depression, anxiety, phobic avoidance, and excessive worry (Karno, Golding, Sorenson, & Burnam, 1988; Rasmussen & Tsuang, 1986; Tynes, White, & Steketee, 1990). Epidemiological studies found that about 30% of individuals with OCD also met criteria for a major depressive episode (Karno et al., 1988); sleep disturbances have been found in approximately 40% of the people with OCD. Presence of depression with OCD is important in that some studies have suggested that severe depression in particular is associated with poorer CBT outcomes (Abramowitz & Foa, 2000; Steketee, Grayson, & Foa, 1987), although the mechanism by which depression affects outcome remains unclear.

Comorbidity of OCD with other anxiety disorders also appears to be substantial. Rasmussen and Tsuang (1986) reported that in a sample of OCD patients, the lifetime incidence of simple phobia was about 30%; for social phobia, 20%; and for panic disorder, 15%. A relationship of OCD with eating disorders has also been reported. About 10% of women with OCD had a history of anorexia nervosa (Kasvikis, Tsakiris, Marks, Basaglu, & Nashirvani, 1986), and over 33% of bulimics had a history of OCD (Hudson, Pope, & Yurgelun-Todd, 1987; Laessle, Kittl, Fichter, Wittchen, & Pirke, 1987).

Disorders, such as Tourette's syndrome and other tic disorders, also appear to be related to OCD. Some 20–30% of individuals with OCD reported a current or past history of tics (Pauls et al., 1986). Estimates of the comorbidity of Tourette's and OCD range from 36% to 52% (Leckman & Chittenden, 1990; Pauls et al., 1986). Also, 5–7% of OCD patients are thought to suffer from Tourette's syndrome (Rasmussen & Eisen, 1989).

The key point for the clinician to consider here is not simply to assess for the presence of comorbidity but rather to consider its treatment implications. Comorbidity is present in many if not most cases but, if the OCD is primary, then CBT targeting OCD may ensue and will likely prove effective regardless; there is also some evidence that targeting OCD in such cases can result in reductions of the nontargeted comorbid symptoms (Franklin, Abramowitz, Bux, Zoellner, & Feeny, 2002; Franklin, Abramowitz, Kozak, Levitt, & Foa, 2000). The ADIS allows the clinician to rate the severity of each diagnosis and thus make the assessment of primary diagnosis more formally; however, there is also the matter of cause and consequence to consider when making the decision as to which disorder to address. For example, patients with severe OCD and comorbid depression often report that their depression is linked to the dysfunction caused by OCD; hence, reducing OCD ought to result in a "two birds with one stone" effect. For patients who report histories of comorbid symptoms that do not appear to be functionally linked to OCD, the decision to treat OCD must be considered carefully. There are occasions when we evaluate patients in our OCD program, determine that they do indeed have

sufficient symptoms to warrant an OCD diagnosis, yet we refer for treatment of the secondary condition because we have made the determination that the OCD treatment might be compromised if the comorbid condition is not addressed first. For example, a patient with comorbid panic disorder who has difficulty traveling to the clinic for appointments might need to have the panic symptoms addressed first before the OCD treatment could be conducted without significant interruption. We encourage all clinicians to consider the data they have gathered in the evaluation process before making a judgment as to whether to recommend treatment of OCD. If they decide this is not in the patient's best interest, conveying this clearly and sensitively will also be imperative in encouraging patients to follow the clinical advice given. Less-experienced clinicians may certainly wish to consult at this important stage of the treatment process, lest they begin a treatment that may not prove effective.

5.2.3 Maintenance Factors

Much research in the past 2 decades has been devoted to examining neurobiological, neuro-chemical, genetic, and environmental factors associated with OCD. Collective findings from these studies indicate that OCD is multi-determined and that the interactions among these factors are extremely complex. That said, factors associated with etiology may or may not be the factors associated with maintenance, and the treatment outcome literature suggests that interventions that have targeted maintaining factors such as serotonin reuptake dysfunction, negative reinforcement, and dysfunctional cognition have proven to be efficacious in reducing OCD symptoms. For our purposes here, we will concentrate our review on psychological processes, although we recognize that there are biological substrates both discovered and undiscovered that underlie many of the factors we discuss below.

5.2.4 Negative Reinforcement and Two-Factor Theory

As we described above, compulsions or rituals are repetitive behaviors performed intentionally to prevent or alleviate discomfort brought about by obsessions. Mowrer's two-factor theory (1939, 1960) has been brought to bear in explaining the maintenance of OCD via the process of negative reinforcement: obsessions give rise to anxiety or distress, individuals engage in compulsions or other forms of avoidance behavior to reduce this distress, and it works, even if only eventually and temporarily. Reduction of obsessional distress provides negative reinforcement for the compulsions, i.e., the individual learns that when such distress arises again, compulsions are likely to provide relief, which then increases urges to engage in such behavior when confronted with obsessional distress down the line, which further strengthens these relationships. Accordingly, in order to maximize treatment efficacy, ritualistic behaviors, even seemingly minor ones, should be prevented. Therefore, the therapist must be able to recognize overt and covert rituals as well as more subtle forms of avoidance.

Active rituals, like passive avoidance, may be explicit (e.g., prolonged washing, repeated checks of the door, and ordering of objects) and/or subtle (e.g., wiping hands on pant legs, blinking, replacing "bad" thoughts with "good" thoughts). Because individuals with OCD may not be sufficiently well versed in the nature of compulsions nor willing completely to report on subtle compulsions lest the therapist suggest refraining from them, it is imperative for the

therapist to recognize when such forms of OCD behavior are being engaged in, and to address these key treatment issues immediately.

Naturally, individuals with OCD often attempt to avoid anxiety-provoking situations. Most passive avoidance strategies are fairly obvious (e.g., not entering public rest rooms, not preparing meals, and not taking out the trash). However, the therapist also needs to be attentive to subtle forms of avoidance such as carrying money in one's pockets to avoid opening a wallet, wearing slip-on shoes to avoid touching laces, and using drinking straws to avoid contact with a glass or a can. These kinds of avoidance behaviors might be so ingrained in a patient as to have escaped his or her attention, so querying the patient about such behaviors must be done collaboratively and in the spirit of the treatment itself, rather than confrontationally.

Although compulsive rituals are intended to reduce the distress associated with obsessions, patients sometimes report that the performance of these rituals is averse in itself. When certain compulsions become averse, some patients decrease the time they spend performing the ritual by increasing avoidance behaviors or by substituting other less time-consuming rituals. In some cases, seemingly "new" rituals may develop during the course of treatment to fill the function of those previously identified and prevented. It is important to recognize such substitutions because, even if they are less time-consuming and functionally impairing, they too serve the same negative reinforcing function described by Mowrer as did the more elaborate ritual, and thus also need to be addressed in treatment with ritual prevention. Therapists must remain alert to such shifts in ritualistic behaviors, and help patients to become alert to the possibility of such shifts as well.

5.2.5 Threat Cues

Threat cues may be either tangible objects in the environment or thoughts, images, or impulses that the person experiences. Most OCD sufferers experience fear in reaction to specific environmental cues (objects, persons, or situations); however, each patient will have his or her own unique threat cues. For example, individuals who fear contamination from toilets may differ as to whether all toilets are feared or only those open to the public. One patient may fear only the toilet itself, whereas another patient also fears bathroom floors, doorknobs, and faucets. The therapist needs to gather specific information about cues that elicit the patient's distress in order to identify the basic sources of the fear.

Anxiety and distress may also be generated by images, impulses, or abstract thoughts that the individual finds disturbing, shameful, or disgusting. Examples of such cues include impulses to stab one's child, thoughts of one's spouse injured in an accident, or images of engaging in sexual acts with religious figures. Clearly, internal threat cues may be triggered by external situations such as the sight of a knife triggering the obsession of stabbing one's child. Some patients may get distressed when experiencing certain bodily sensations, such as minor aches and pains triggering the fear of having cancer.

Identification of the basic source is important for planning the treatment program, since confronting that source will be essential for successful behavioral treatment of OCD. It is important that the therapist conducts a thorough investigation of objects, situations, and places that evoke obsessional distress for the patient at the time of presentation and at onset. Such information will help identify the source of the distress and the basic fear troubling the patient.

In many cases, patients may be reluctant to express their obsessive thoughts, either because they are ashamed of themselves or because they fear that expressing them will make the consequence more likely to occur. As with external cues, it is necessary for the therapist to recognize internal fear cues in order to understand the underlining fears.

5.2.6 Feared Consequences

Many obsessive-compulsives are afraid that something terrible will happen if they fail to perform their rituals. Some patients have clearly defined negative consequences (e.g., "I will burn in hell for all eternity if I don't neutralize this blasphemous image"), whereas others have only a vague notion of a negative consequence (e.g., bad luck). Others do not fear catastrophes at all, but report instead that they cannot tolerate the emotional distress they experience if they do not perform rituals. Data from the DSM-IV field trial indicated that approximately two thirds of OCD patients could clearly identify consequences that would follow from refraining from rituals other than emotional distress, whereas the remainder could report no such consequences (Foa et al., 1995). It is important to identify the specific details of the patient's feared consequences in order to plan an effective treatment program, since these consequences must be directly targeted in exposure and ritual prevention exercises.

5.2.7 Cognitive Factors

Salkovskis' (1985) influential cognitive analysis of OCD suggested that an exaggerated sense of responsibility and self-blame are the central themes in the obsessive-compulsive's belief system. Neutralization, in the form of behavioral or cognitive compulsions, can be understood as an attempt to reduce this sense of responsibility and prevent blame. In addition, frequently occurring thoughts regarding unacceptable actions may be perceived as equivalent to the actions themselves, so, for example, even if the person has not actually engaged in unacceptable behavior, the mere thought of doing so is equivalent to having actually done so. More specifically, Salkovskis proposed that five dysfunctional assumptions characterize obsessive-compulsives and differentiate them from persons without OCD: (1) having a thought about an action is like performing the action; (2) failing to prevent (or failing to try to prevent) harm to self or others is the same as having caused the harm in the first place; (3) responsibility is not attenuated by other factors (e.g., low probability of occurrence); (4) not neutralizing when an intrusion has occurred is similar or equivalent to seeking or wanting the harm involved in that intrusion to actually happen; (5) one should (and can) exercise control over one's thoughts(p. 579). From this work and from other cognitive conceptualizations of OCD has grown a more cognitively oriented treatment approach that aims to test and thus disconfirm mistaken OCD-related beliefs. Just as behaviorally oriented therapies often involve discussions of OCD beliefs, many of these cognitive protocols involve behavioral experiments (i.e., exposures), the point of which is to provide information that weakens this belief system, which in turn will allow patients to more successfully refrain from rituals and other forms of avoidance. Some theorists and most therapists have blended the more behavioral approaches such as two-factor theory with the contemporary views of the central role of cognition in anxiety and OCD, and emphasize that the goal of exposure is to provide disconfirmatory evidence to weaken the fear structure

(Foa & Kozak, 1985, 1986). In our hands, there is often a Socratic discussion of OCD-relevant beliefs between the therapist and the patient, yet these discussions are likely to be taking place in anticipation of an exposure, during an exposure, or after having completed an exposure. "What do you make of the fact that you had a large butcher knife in your dominant hand, were intentionally having thoughts of cutting my throat and watching me bleed out here in my office, I had my back turned to you so I couldn't prevent your assault, and yet I'm not dead yet?," is not an uncommon thread of discussion in our work with OCD patients with fears of harming others.

5.2.8   Evidence-Based Treatment Approaches

In the last 2 decades, we have witnessed a tremendous increase in the number and methodological sophistication of clinical trials designed to examine the efficacy of treatments for OCD. Indeed, development and empirical evaluation of treatments in both psychotherapy and pharmacotherapy now provide a robust evidence base for the treatment of OCD, and more recently has spanned the developmental spectrum as well. The following section will describe the approaches with the most empirical support and summarize the evidence for the efficacy of these treatments.

5.2.9   Exposure and Ritual Prevention

Since Meyer's (1966) initial positive report of the efficacy of EX/RP, many subsequent studies have indicated that most treatment completers make and maintain clinically significant gains. Randomized controlled trials (RCTs) have indicated that EX/RP is superior to a variety of control treatments, including placebo medication (Marks, Stern, Mawson, Cobb, & McDonald, 1980), relaxation (Fals-Stewart, Marks, & Schafer, 1993), and anxiety management training (Lindsay, Crino, & Andrews, 1997). Moreover, it also appears that the treatment gains following EX/RP are quite durable: Foa and Kozak (1996) reported that in 16 studies that included long-term outcome data ($N = 376$; mean follow-up interval of 29 months), 76% of completers still met treatment responder criteria. Several studies have now indicated that these encouraging findings for EX/RP are not limited to highly selected RCT samples (Franklin, Abramowitz, Kozak, Levitt, & Foa, 2000; Rothbaum & Shahar, 2000; Valderhaug et al., 2007; Warren & Thomas, 2001). Below we summarize the literature on the ingredients that comprise EX/RP in order to help clinicians decide which EX/RP components are most essential.

Exposure Versus Ritual Prevention Versus EX/RP. Foa, Steketee, Grayson, Turner, and Latimer (1984) randomly assigned patients with washing rituals to intensive treatment (15 daily 2 h sessions conducted over 3 weeks) by (1) exposure only (EX), (2) ritual prevention only (RP), or (3) their combination (EX/RP). On average, patients in each condition were found to be improved at both posttreatment and follow-up, but EX/RP was consistently superior to the single-component treatments. These findings clearly suggest that exposure and ritual prevention should be implemented concurrently; treatments that do not include both components yield inferior outcome. Therapists can convey this information to patients who are struggling with one of these two components of the treatment in an effort to encourage them to refrain from rituals more consistently or be more aggressive in planning and seeking out opportunities to do intentional exposures during and between sessions.

Addition of Imaginal Exposure. Several studies have indicated that treatment involving imaginal exposure plus in vivo exposure and ritual prevention was superior at follow-up to an in vivo exposure plus ritual prevention program that did not include imaginal exposure (Foa, Steketee, Turner, & Fischer, 1980; Steketee, Foa, & Grayson, 1982). However, some studies have failed to replicate this finding (de Araujo, Ito, Marks, & Deale, 1995). In our clinical work, we have found imaginal exposure useful for patients who report that disastrous consequences will result if they refrain from rituals. Because many of these consequences cannot be readily translated into in vivo exposure exercises (e.g., turning into another person by touching his or her belongings), imaginal exposure allows the patient an opportunity to confront these feared thoughts and images. Addition of imagery to in vivo exposure may also prevent the use of cognitive avoidance strategies by those who try intentionally not to consider the consequences of exposure while confronting feared situations in vivo. In sum, although the data do not show that imaginal exposure is essential for achieving good acute outcomes, it may enhance long-term maintenance of gains and can be used adjunctively for patients with disastrous consequences. For patients who only report extreme distress as a consequence to refraining from rituals and avoidance behaviors, imaginal exposure may be superfluous.

Gradual Versus Abrupt Exposures. Although group differences in OCD symptom reduction were not found for patients who confronted the most distressing situations from the start of therapy and those who confronted less distressing situations first, yet patients preferred the more gradual approach (Hodgson, Rachman, & Marks, 1972); we still recommend that therapists conduct this treatment hierarchically. Patient engagement in treatment is essential in EX/RP, and thus situations of mild to moderate difficulty are confronted first, followed by several intermediate steps before the most distressing exposures are accomplished. It is important that the therapist emphasizes that exposure will proceed at a pace that is acceptable to the patient, and that no exposure will ever be attempted without the patient's prior approval. This approach should not be confused with setting a low bar for climbing the stimulus hierarchy, however: indeed, it is preferable to confront the highest item on the treatment hierarchy as soon as feasible (e.g., within the first week of intensive treatment) to allow for sufficient time to repeat these difficult exposures over the latter sessions.

Duration of Exposure. Duration of exposure was once believed to be important for outcome in that prolonged continuous exposure was found more effective than short interrupted exposure (Rabavilas, Boulougouris, & Perissaki, 1976). Indeed, reduction in anxiety (habituation) across sessions has been associated with improvement following exposure-based treatments for OCD and for PTSD (Jaycox, Foa, & Morral, 1998; Kozak, Foa, & Steketee, 1988; van Minnen & Hagenaars, 2002). However, there are several studies that have not found a strong relationship between within-session habituation and fear and symptom reduction (Jaycox et al., 1998; Kozak et al., 1988; Mathews, Johnston, Shaw, & Gelder, 1974; Rowe & Craske, 1998). Foa, Huppert, and Cahill (2006) suggested that this observation is not inconsistent with emotional processing theory because the proposed mechanism underlying symptom reduction is the modification of the relevant erroneous associations through disconfirming information, not through habituation per se. Accordingly, therapists should be clear to instruct patients that they should attempt to persist with exposure until the associated anxiety is substantially reduced, the more important factor in achieving good outcome is repeating the same exposures so as to promote reduction of associated anxiety over time. OCD patients might be particularly vulnerable to fears of ending exposures "too soon" and hence doing the treatment incorrectly, so this new instruction might help encourage patients

to go about their business without ritualizing or avoiding regardless of whether anxiety still lingers on from an exposure task.

Session Frequency. Intensive exposure therapy typically involves daily sessions over the course of approximately 1 month, but good outcomes have also been found with more widely spaced sessions (Abramowitz, Foa, & Franklin, 2003; de Araujo et al., 1995; Franklin et al., 1998). A recent RCT in pediatric OCD found no difference between intensive and weekly treatment (Storch et al., 2008). Clinically, we recommend that therapists take motivational factors, developmental level of the patient, psychiatric comorbidity, need for a faster response, and cost into account when determining session frequency. Less frequent sessions may be sufficient for highly motivated patients with mild to moderate OCD symptoms who readily understand the importance of daily exposure homework exercises, whereas patients with very severe symptoms or who are experiencing difficulty completing EX/RP tasks between sessions might benefit more from a more intensive visit schedule.

5.2.10 Efficacy of EX/RP, Pharmacotherapy, and Their Combination

Although numerous RCTs have found that serotonergic antidepressants are superior to placebo in reducing OCD symptoms, few have directly compared the relative or combined efficacy of antidepressant medications and EX/RP. Unfortunately, several of those studies included complex designs that make it difficult to draw clear conclusions about relative and combined efficacy (Marks et al., 1980, 1988). Cottraux, Mollard, and Bouvard (1990) compared fluvoxamine (FLV) with anti-exposure instructions, FLV plus weekly EX/RP, and pill placebo (PBO) plus EX/RP, and found FLV plus EX/RP and FLV plus anti-exposure instructions superior to PBO plus EX/RP; there was a trend towards an advantage for combined treatment but it failed to reach significance. Hohagen et al. (1998) compared EX/RP plus FLV to EX/RP plus PBO and found that both groups improved significantly and comparably on compulsions, but that the patients who received EX/RP plus FLV were significantly better at posttreatment on obsessions than those who received EX/RP plus PBO. Subanalyses indicated that patients who suffered from secondary depression also fared better if they were receiving EX/RP plus FLV.

The relative and combined efficacy of clomipramine (CMI) and intensive EX/RP was examined in a multicenter, randomized, controlled study conducted at our center and at Columbia University. Findings with treatment-completer data as well as intent-to-treat data indicated that at posttreatment the active treatments appear superior to placebo, EX/RP appears superior to CMI, and the combination of the two treatments does not appear superior to EX/RP alone (Foa et al., 2005); relapse was more evident following treatment discontinuation in the CMI group than in either of the treatments that included intensive EX/RP (EX/RP, EX/RP plus CMI; Simpson et al., 2004). However, the Penn-Columbia study design may not have optimally promoted an additive effect for CMI because the intensive portion of the EX/RP program was largely completed before patients reached their maximum dose of CMI. In addition, combined treatment effects may be more evident when intensive EX/RP is not used (Foa, Franklin, & Moser, 2002). Of note, an additive effect for combined treatment was found in a recent study in pediatric OCD conducted at Penn, Duke, and Brown in which CBT was conducted weekly rather than intensively (Pediatric OCD Treatment Study Team, 2004), although site effects emerged in that trial indicating that the CBT monotherapy effect at Penn was very large and thus no additive effect for combined treatment was found at this site.

In summary, methodological issues in the studies that have been conducted and a general lack of large head-to-head trials precludes confident conclusions about the relative and combined efficacy of serotonergic medications and EX/RP. The absence of conclusive findings notwithstanding, many experts continue to advocate combined procedures as the treatment of choice for OCD (Greist, 1992). In clinical practice, it is common to see patients for EX/RP treatment who are taking Serotonin Reuptake Inhibitors (SRIs) concurrently. In uncontrolled examinations of EX/RP treatment outcome for adults (Franklin et al., 2002) and youth (Franklin et al., 1998; Piacentini, Bergmann, Jacobs, McCracken, & Kretchman, 2002) treated in OCD outpatient clinics, no posttreatment differences in OCD symptom severity were detected between patients who received EX/RP alone versus those who were on SRI medication when receiving EX/RP. Thus, therapists can feel some confidence that the extant literature support two key conclusions: (1) concomitant pharmacotherapy is not required for every patient to benefit substantially from EX/RP and (2) concomitant pharmacotherapy does not appear to inhibit EX/RP treatment response.

5.2.11 Cognitive Therapy (Treatments Targeting Antecedents Cognitions)

Early studies of cognitive therapies for OCD found few differences between standard behavioral treatments and behavioral treatments augmented with cognitive techniques (e.g., Emmelkamp & Beens, 1991; Emmelkamp, Visser, & Hoekstra, 1988). However, advances in cognitive conceptualizations of OCD were followed by the development of more efficacious and durable cognitive treatments. Freeston et al. (1997) found a cognitive-behavioral intervention efficacious compared to a wait-list control group for patients with "pure" obsessions. Several other studies (Cottraux et al., 2001; McLean et al., 2001; Vogel, Stiles, & Götestam, 2004; Whittal, Throdarson, & McLean, 2005) have suggested equivalent results for cognitive therapy and EX/RP, respectively, although procedural overlap between the two conditions in these studies precludes confident conclusions. Together with data from studies attesting to the utility of cognitively oriented approaches for OCD-related conditions such as hypochondriasis (Barsky & Ahern, 2004; Warwick, Clark, Cobb, & Salkovskis, 1996), cognitive therapies hold promise for the treatment of OCD, and might be an efficacious potential alternative to EX/RP.

5.2.12 Mechanisms of Change Underlying the Intervention

The etiology of OCD remains a source of wide speculation and a host of neuroanotomical, neurochemical, and psychological theories, and the neurobiology of the obsessional process and changes in glucose metabolism in implicated brain regions following EX/RP has already been established (Baxter et al., 1992). That said, the factors associated with etiology may or may not be the factors associated with maintenance, and it is highly unlikely that a single cause, genetic or otherwise, will ever be found for a disorder so complex and heterogeneous. Nevertheless, Mowrer's two-factor theory (1960) explains maintenance of pathology in OCD by suggesting that intrusive, spontaneous, and involuntary obsessions give rise to anxiety, and that compulsions are executed responses designed specifically to reduce it. An analogous application in chronic tic disorders (CTDs) has also been posited: in the case of CTDs, the

unpleasant premonitory urges are also intrusive, unwanted, and involuntary, and clearly have their origins in neurobiological dysfunction (Mink, 2001). Thus, the obsessions in OCD and the premonitory urges in CTDs are both unwanted, neurobiologically mediated events associated with negative affect or discomfort. That said, completion of the compulsions or tics themselves can be considered according to two-factor theory to be semi-volitional, in that they are both executed responses designed to reduce obsessional distress or unpleasant premonitory sensations (Bliss, 1980; Leckman, Walker, & Cohen, 1993). Accordingly, exposure to the situations that provoke obsessions or premonitory urges without engaging in the compulsion or tic to negatively reinforce (reduce) that urge will eliminate the negative reinforcing effects of the intentional behavior, and thus eventually reduce the frequency and intensity of these thoughts or sensations. Notably, the efficacy of EX/RP for OCD is well established (Abramowitz, Whiteside, & Deacon, 2005; Barrett et al., 2008); moreover, habituation to urges to engage in compulsions occurs over time, and subsequent reductions in the frequency and intensity of obsessions and urges to ritualize are consistently observed (Himle & Franklin, in press). Empirical study of this theoretical approach and the behavioral procedures emanating from this theory is relatively new in CTDs, but there is now empirical evidence for EX/RP's efficacy for CTDs (Hoogduin, Verdellen, & Cath, 1997; Verdellen et al., 2004). Perhaps more importantly on theoretical grounds, several studies now also indicate that premonitory urges habituate over time when patients refrain from engaging in tics despite having intentionally promoted tic urges (Hoogduin et al., 1997; Verdellen et al., 2008). As mentioned above, our clinical presentation and practice includes attention to OCD-relevant dysfunctional beliefs, but fundamentally it is our view that exposure provides the optimal context to change these mistaken beliefs, and thus we emphasize it throughout our work with OCD patients.

5.3 Basic Competencies of the Clinician

In our view, basic competencies for a clinician treating OCD include: (1) providing a proper diagnosis; (2) conducting a comprehensive assessment blended with accurate and psychoeducation; (3) leading an empirically grounded discussion of treatment alternatives; and if treatment with EX/RP is ultimately selected, (4) delivering hierarchy-driven exposure plus ritual prevention in a manner that reflects knowledge of the complexities of this treatment and this disorder, with consistent reliance upon the core theoretical model that underlies treatment when treatment does not proceed smoothly. Development of these basic competencies will likely be hastened via regular access to expertise in the disorder; organizations such as the Obsessive Compulsive Foundation, the Association for Behavioral and Cognitive Therapies, and the Anxiety Disorders Association of America facilitate such access through their regular training institutes and workshops. The lead author's development of these basic competencies was jump started by ready access to one of the world's foremost authorities on CBT for OCD, Dr. Michael Kozak, as his first clinical supervisor during internship. The best substitute for experience is the experience of others, after all, and all better when the other whose experiences are being accessed has a wealth of information to share and the wisdom to know how to share it without demoralizing or humiliating the therapist in training.

Diagnosis. As reviewed above, DSM-IV TR defines OCD by the presence of recurrent obsessions and/or compulsions that interfere substantially with daily functioning; there is a

time criterion for OCD (>1 h of obsessions and compulsions per day) that is designed to assist the clinician in not diagnosing subclinical cases. However, this time criterion was not generated empirically and should not be adhered to rigidly (e.g., if the patient has 30 min total per day of obsessions and/or compulsions yet is highly avoidant of situations likely to trigger obsessional distress or urges to ritualize). Obsessions are "persistent ideas, thoughts, impulses, or images that are experienced as intrusive and inappropriate and cause marked anxiety or distress" (p. 457). What they are not, however, is positively valenced. For example, the first author once conducted a consultation on a case of a teenage boy whose symptoms were being conceptualized as OCD, yet seemed to focus primarily on his great enthusiasm for the local hockey team, which his parents and the referring clinician described as "obsessional." A comprehensive discussion revealed that the boy's focus on the sport that he loved was motivated in part by his feelings of general incompetence at an academically challenging high school; importantly, his thoughts about his hockey team were not experienced as intrusive and did not cause anxiety or distress, except when he was being criticized by his parents for caring more about hockey than about his studies. There are no positive obsessions, and when the description of "obsessional" content has a clear positive valence to it (e.g., fantasizing intentionally about murder rather than experiencing intrusive, unwanted thoughts of harming another person intentionally) then the interviewer should clarify this important distinction and concentrate on procuring an accurate diagnosis of some other condition if appropriate.

It is important for the clinician to keep in mind that obsessions give rise to anxiety, and are unintentional, whereas compulsions are "repetitive behaviors or mental acts, the goal of which is to prevent or reduce anxiety or distress" (p. 457). Again, the competent clinician needs to discern that repetitive behaviors are indeed serving this neutralizing function, are taking up more than a trivial amount of time, and are being conducted in a rigid manner or according to some set rules. Passive avoidance behavior, though often prominent in OCD, does not in and of itself constitute compulsion; so, becoming anxious in a social situation or in the presence of unpleasant physical sensations and responding to these distressing thoughts or feelings by leaving the situation does not meet this criterion, and thus other diagnoses might be more appropriate. The competent clinician should ask the patient to review the most recent experiences of obsessional distress and then ask, "So when that thought entered your mind, did you do anything to get rid of it or to try to make it less distressing for you?" This allows the clinician to define compulsions by their function, and evaluate whether mental rituals are present that the patient would not necessarily view as compulsive in the classic sense of the term. Many of our patients will quickly tell us that they do not have washing rituals, as if to say that they do not have compulsions since these are perceived to be the most common if not the quintessential compulsive behaviors. The competent clinician is searching for evidence of the "OCD tennis match" that so often characterizes the subjective experience of these patients: OCD serves (e.g., unwanted obsessional thought about harm befalling a loved one), the patient returns serve (e.g., replacing this intrusive thought with an image of the loved one safe at home), OCD returns the return of serve (e.g., "How can you be SURE that she's safe?"), which is then returned again by the patient (e.g., repeating the safe image again while calling the loved one's cellphone to check with them directly), and so on. Once this pattern is identified, the clinician can then determine whether there are other content areas that conform to this same pattern, cause distress, and interfere with functioning. With this search completed and the differential and comorbid diagnoses surveyed, the clinician would be well on his or her way to providing a proper diagnosis of OCD.

Assessment and Psychoeducation. The competent clinician conducts the assessment using the various interviews and questionnaires described above, but with an overarching goal of establishing for the patient both the "tree level" (e.g., specific obsessions and functionally associated compulsions) and "forest level" (e.g., overarching principles that define the disorder and help patients develop the ability to predict what OCD will do) patterns of OCD. The demonstration of basic competence must include both of these elements, since the heterogeneity of OCD requires that the patient quickly develops a working knowledge of what constitutes an obsession, what constitutes a compulsion, how obsessions are negatively reinforced by compulsions, which provide relief in the short-run but perpetuates the frequency and intensity of obsessions in the long-run. This information can be provided directly (e.g., "First I'm going to ask you about the obsessions, the thoughts that give rise to anxiety, and then about compulsions, which are the behaviors or mental acts you engage in intentionally to reduce the obsessional distress or to decrease the likelihood that something bad really happens") but should also be asked about via example (e.g., "And if you were to suddenly develop a fear of blue carpets and have to neutralize that fear by touching a metal object, which of those would be defined as an obsession and which as a compulsion?") so as to quickly teach the basic elements of OCD psychopathology before having to consider the treatment implications of this functional relationship, which will come later on in the discussion of treatment alternatives.

Another important task that arises in assessing OCD patients and providing basic information for them in preparation for the discussion of treatment alternatives is the chronicling of current functional impairment. OCD patients are often highly fearful and they exhibit a range of insight into the senselessness of their obsessions and compulsions; insight is compromised when confronted with fear-evoking stimuli, too, which means it is very important to have at the ready a clear list of functional difficulties that the patient is experiencing as a result of OCD. In pediatric OCD, there is a formal measure designed specifically for this purpose (Piacentini, Peris, Bergman, & Chang, 2007); with adults, the clinician should be sure to survey interpersonal difficulties arising due to OCD, the effects of avoidance on attainment of personal and professional goals, quality of life assessment, and so on. This information is vital when the patient has to make a decision about whether to enter into a treatment that is designed intentionally to be distressing (EX/RP) or, if already participating in that treatment, having to decide about whether to proceed with particularly anxiety-evoking exercises. The competent clinician needs to frame those discussions with the implications of not moving forward for the patient's benefit (e.g., "Remember how you said you thought your marriage would be much stronger if you were able to refrain from asking your wife for reassurance?") rather than simply reiterating the theoretical framework of EX/RP (e.g.,"Treatment outcome will be compromised if you don't proceed in refraining from your reassurance seeking"). Optimally both tacks will be taken by the clinician in an artful manner – in fact there is now quite a bit of interest in OCD research about the inclusion of Motivational Interviewing techniques in the context of delivering this treatment (Simpson, Zuckoff, Page, Franklin, & Foa, 2008).

Discussing Treatment Alternatives. Basic competence in leading a discussion of treatment alternatives starts with a working knowledge of the extant pharmacotherapy and psychotherapy outcome literatures. This is important since OCD patients are known for their own working knowledge of this literature, and a clinician who wishes to establish his or her expertise and competence in this area must have a good working understanding of what this literature tells us about what to expect from the various therapies. Overstatement of the likelihood of success in EX/RP without an explicit acknowledgment of the difficulties inherent in doing this

form of therapy is a place where inexperienced clinicians can sometimes run aground. It is reasonable to say from the literature reviewed above that we should expect that approximately 75–85% of patients who complete EX/RP will respond to treatment, response is likely to be substantial but not complete, most who make gains will likely maintain them, and the better patients do in the short-run (acute treatment) the better they will do in the long-run (long-term outcomes). It also appears that combining EX/RP with pharmacotherapies of established efficacy (e.g., serotonin reuptake inhibitors) will at the very least not compromise outcome and, especially perhaps if the EX/RP is conducted weekly, could enhance outcome. Factors associated with attenuated outcome such as concomitant depression, poor insight, etc., should also be discussed up front by the clinician, especially with those patients who exhibit these risk factors.

Discussion of treatment alternatives should not end with only the treatment that the clinician is offering, either. Patients should be provided with the pros and cons of each of the empirically supported regimens, as well as with a clear statement that the absence of evidence for a particular regimen is not the same thing as evidence that it does not work. Evidence from randomized controlled trials provides a more educated guess about any given patient's outcomes, but does not guarantee them one way or the other. Some treatments require less effort, time, up front costs, and intentional confrontation with anxiety-evoking situations, and thus the clinician should be sensitive to the patient's state of mind and should not oversell any particular treatment, since ultimately it is the patient who will make this choice in the end.

Conducting Treatment. Although a detailed description of basic competence in delivering EX/RP from beginning to end is precluded by space considerations, there are some key elements that must be done correctly if treatment has any chance of working. First, the treatment should be collaborative in nature, but guided by the clinician's understanding of the theoretical model, the manual's guidance, and his or her working knowledge of the patient as well. Treatment must begin with a clear plan, and in our view a sufficiently detailed hierarchy of situations likely to evoke a little, some, a lot, and a great deal of distress across the key obsessional themes is needed. We have a motto in our work that "OCD is like Hawaii" in that there is typically a big island of greatest concern but often several smaller ones, each of which can be subdivided into low, medium, and high anxiety at least. Teasing out obsessional themes, associated rituals, and the areas of greatest anxiety and functional impairment will dictate where treatment should begin. We preach "taking one island at a time" and "doing the best you can in the meantime" with obsessional themes that have yet to be targeted: for example, if a patient has obsessional fears of contamination as well as fears of losing important items and of harm befalling loved ones, we would encourage the development of three separate hierarchies, each broken down in this manner. The competent clinician will ask the patient to participate in exposures in session and to complete assignments related to the themes addressed in session, with clear instructions in the theoretical rationale for ritual prevention as well as practical advice as to how best to refrain from ritualizing when anxiety is high. The beginning clinician needs to walk the fine line between acknowledging the difficulty of completing exposure tasks with enthusiastic support for efforts, even when those efforts are only partially successful, along with emphasis on moving towards "behaving as if you don't have OCD." We expect partial success in the beginning of treatment, yet if we settle for partial improvements without complete response prevention we run the risk of compromising treatment outcome since OCD is still being "fed" via negative reinforcement. Along this road lies the task, among the most difficult

lessons for the beginning clinician, to make patients aware of the psychological consequences of their choices rather than to make the choices for them. Adopting this stance will assist the clinician in not taking too much responsibility for the patient's choices, which will prevent subsequent desperate efforts for the clinician to "make them do it"; such efforts are often counterproductive, and can compromise alliance with little tangible payoff in terms of symptom reduction. A very long time ago, the lead author was particularly frustrated with a patient's partial compliance with ritual prevention and was expressing this in a supervision meeting. Dr. Kozak, the clinical supervisor, responded to the diatribe by suggesting that "You appear to be confused about something here – do you think this treatment is about you, or about the patient's own choices?" What followed were constructive suggestions as to how best to help the patients marshal their own emotional resources and social support to help the patient do what needed to be done, rather than to increase the pressure, sharpen the rational arguments, and fine tune the level of vitriol the novice therapist thought would be needed to accomplish this important task. With clarity improved, the therapy proceeded much more smoothly from that point on.

5.4   Expert Competencies of the Clinician

The old adage of "watch one, do one, teach one" in our view simply does not do justice to the treatment of OCD, in part because with wide symptom heterogeneity under the broad diagnostic umbrella there is no true quintessential case of OCD from which to generalize. Most studies of OCD psychopathology suggest at least 5–6 clusters of distinct OCD patient profiles, with additional variability along the continuum of obsessional theme, associated rituals, degree of passive avoidance, level of insight, comorbid symptoms, and the developmental continuum, which makes it extremely difficult to transfer knowledge from one subcluster to the next without a wealth of clinical exposure. One way to get the kind of exposure necessary is to have the novice therapist who wishes to move beyond that point in his or her own professional development conduct initial intakes for new patients; in the case of the first author, approximately 1–2 new patient intakes for the first 3 years of practice in the clinic allowed for development of a broader perspective of how OCD manifests. Treating a subset of these patients then provided further opportunity to hone the craft of delivering treatment, developing a flexible clinical style that is nevertheless deeply rooted in empirical and theoretical soil.

Making Reliable Predictions. In our view, the expert clinician must have such a thorough understanding of the theoretical model and its specific application in individual patients – both forest and trees, as it were – that he or she can assist patients in anticipating what OCD symptoms are likely to arise next. Making reliable predictions about what OCD will do next is a surefire way to garner the patient's faith in the therapist and in his or her understanding of the disorder, and that faith can then be translated into confidence that the chosen exercises are being devised in collaboration with someone who knows the disorder extremely well. It was well into the first author's career focusing on OCD and its treatment when a young patient delivered a compliment that underscores what we view here as the goal for developing expert competency: after the author had asked a question in an intake about what the patient's OCD would require of her next after she had washed her hands and yet had to turn off the contaminated bathroom faucet with a now decontaminated hand, the patient whispered to the therapist so her parents could not hear, "Are you one of us?" Perception that the clinician

has truly mastered OCD and can anticipate its next several moves will go a long way toward developing the trust necessary for him or her to move forward with an inherently difficult regimen.

Keeping the Complex Simple. "Let it go, don't make it go," is what the first author has used as a seven-word summary of the many volumes written to describe EX/RP. Establishing the core concepts in OCD first is crucial to be able to then boil it all down to its most basic elements. Obsessions give rise to anxiety, compulsions reduce it, passive avoidance is a way to prevent one's OCD from being triggered in the first place, and rituals and avoidance serve the same function, which is to placate OCD in the short-run yet strengthen it in the long-run. Treatment, then, hinges on changing the maintenance factor, i.e., removing OCD's main source of fuel, which is rituals and avoidance. Patients need to understand each and every one of their own symptoms using this conceptual model, and often the expert clinician will encourage patients to stretch even beyond their own current symptoms to be able to classify obsessions, compulsions, passive avoidance behaviors, and their likely functions for symptoms that they had once and have now faded, even for symptoms that they have never had. Knowledge is power, and the patients must be sufficiently knowledgeable so that they can quickly recognize OCD whenever it rears its ugly head, and take the appropriate action to counteract it. The appropriate action is often no action at all, and this needs to be conveyed clearly to patients: anything that is done in the service of reducing obsessional distress in the moment will perpetuate OCD, so the focus goes instead towards going about one's business, directly confronting the anxiety rather than running away from it. When a therapist develops confidence in this conceptual model he or she is empowered to convey this clearly to patients, which improves patient confidence in the efficacy of the treatment procedures, even when anxiety persists or gets worse immediately because of the steadfast refusal to fix it. Every possible scenario of OCD can be put through this basic conceptualization, which robs OCD of the power to overwhelm patients with "new" symptoms. "There are no new symptoms – only new disguises" is one way of making this point clearly, and getting patients to understand this can encourage them to use the treatment procedures that flow from the conceptual model more confidently and more quickly, which in turn will reduce the amount of compulsions that get "missed" and thus contribute to obsessional frequency and intensity down the line.

"I once knew a kid who …." Decades worth of experience treating OCD provides a bank full of clinical vignettes that can be drawn upon to help underscore key points during the treatment. Provided of course that these vignettes are delivered in a HIPAA-compliant fashion, patients are often better able to relate to, and benefit from, the stories of those who have been through what they are currently going through, and so the clinician should make ample use of these opportunities in treatment. These clinical tales are often at their most useful at "stuck points" in treatment, such as when patients are declining to move forward with difficult exposures, unwilling to confront the most threatening items on the hierarchy. Those of us who have treated thousands of OCD patients over the years can readily recall those who were unable to clear this important hurdle, as well as many if not most of our patients who were successful in reclaiming their lives from OCD despite very high levels of anxiety. An expert therapist will be able to weave in the clinical vignettes seamlessly in an effort to move the treatment forward, and will be able to judge whether the story should have a happy or unhappy ending depending on where the patient is at present with respect to motivation, readiness to change, and confidence in the conceptual model and in the treatment procedures that flow directly from it.

"The best way out is through." Expert therapists are likely to be more comfortable in delivering the bad news of OCD treatment, that it will require a great deal of effort, that there are times when that effort will not seem to be worthwhile, and that OCD is a formidable foe indeed that will not relent easily. Those with a great deal of clinical experience are perhaps more willing to embrace the possibility of failure, which allows them to be more direct with patients in providing expectations about treatment course and progress, regardless of its valence. The experts we have encountered seem less comfortable with overselling the treatment, since having set up unrealistic expectations up front to encourage a patient to try EX/RP may well backfire when the patient is progressing to the most difficult exposures on his or her hierarchy. Embracing such difficulty with metaphors tailored to the patient's interests and learning history is also a behavior that an expert therapist is more likely to be able to engage in than a novice, and in fact seemingly off-task conversations at the beginning of the treatment (e.g., "So tell me about something you're really good at") can then be used to underscore key teaching points in treatment. For example, a young man who had played basketball extensively during his childhood and adolescence was confronting his most anxiety-provoking rung on his contamination hierarchy, which was proving to be extremely difficult during the first exposure session devoted to that item (public toilets). The therapist, sensing the patient's loss of resolve in the presence of intense, panic-like symptoms, asked the patient about his experiences of learning how to shoot a jump shot from 18 ft away from the basket. The therapist then asked the patient (who by this time was hyperventilating) to recall whether his grade school basketball coaches initiated practice with 18-ft jump shots or whether they started in closer to teach good form. "Good form first," the patient replied. The therapist then asked about whether the first opportunities in practice to shoot 18-ft jump shots were as easy as shooting from 5 ft away. "Of course not, especially when you're not being guarded!," the patient replied. The therapist then asked the patient to recall whether shooting of 18-ft jump shots, unguarded, ever got any easier, knowing full well that the patient was an accomplished point guard who had most certainly mastered this skill. "Sure it did, and then we worked up to taking them in practice with the big guys running at us full speed." Grasping the metaphor at this point, the patient said: "And I suppose that right now the anxiety is the big guy running at me full speed as I line up the shot." "Something like that," the therapist smiled and replied. The patient's next move, which he was capable of making now that the treatment procedures had been clarified in a language he readily understood and now his anxiety had been modulated at least somewhat (he was still of course sitting on a public bathroom floor), was to proclaim: "Well, we can always make a ball fake and take it straight to the rim!" which he proclaimed with enthusiasm as he touched the toilet seat directly. A less-experienced therapist might not have thought to glean this information up front nor been able to employ it at a pivotal stuck point, but rest assured that experience and good supervision will hasten such developments.

Managing Case Complexity. Some years back, our research group conducted a naturalistic study of the effects of therapist experience on EX/RP outcomes in adult outpatients with OCD, and found that the patients of clinical psychology interns and other inexperienced therapists achieved posttreatment outcomes that were comparable to those achieved by the patients of our most experienced therapists (Franklin et al., 2003). Of note, however, was the fact that cases were not assigned to therapist at random but rather by the senior-level supervisors, who made case assignments based on a host of factors including case complexity. Case complexity in OCD refers both to the complexity of the OCD symptoms themselves, but also to the comorbid

symptoms and diagnoses, treatment histories, interpersonal strengths and challenges, and family factors. In general the more complex cases were assigned to the more experienced therapists, since there are a number of key issues to be addressed in treatment that may not be attended to sufficiently when the therapist does not have a wealth of experience upon which to draw.

Data from clinical samples of OCD patients suggest that comorbidity is likely to be the rule rather than the exception, so the expert clinician must certainly assess and manage comorbidity in the context of conducting EX/RP. As we have outlined in the context of our work with trichotillomania (Franklin & Tolin, 2007), there are several potentially reasonable options to consider clinically in the presence of comorbidity: (1) continue to focus on OCD symptoms regardless; (2) attempt to incorporate some clinical procedures and devote some session time to management of comorbid symptoms but continue to focus largely on OCD; (3) shift the focus of treatment to the management of comorbidity, with an eye on returning to OCD relatively quickly; or (4) suspend OCD treatment to focus exclusively on the comorbidity, and refrain from reinitiating OCD treatment until the comorbid symptoms are under control. Successful navigation of this rather complex decision tree relies on the judgment of the clinician as well as knowledge of the extant literature: for example, a recent paper indicated that EX/RP outcomes for pediatric OCD were less robust if the patients had been diagnosed with a comorbid externalizing disorder (Storch et al., 2008), so the experienced and empirically grounded clinician would already be considering a different course of action if this were the clinical presentation up front. Considering the mechanism by which these effects could have occurred also should be expected of an expert clinician, and thus the decision in such cases to defer OCD treatment in this case would have to be delivered in a savvy manner to help families understand how these symptoms affected EX/RP outcomes and why the best course of action may be to target the externalizing disorder first. An expert clinician should have a working knowledge from the literature of which comorbid conditions are likely to attenuate with treatment of the OCD ("two birds with one stone"), which are likely to persist, and how to manage both disorders in sequence. We are also careful when assigning cases to take the patient's interpersonal style into account, since some of our more persistent patients might respond more to the firm limits that a senior expert can often provide.

5.5   Transition from Basic Competence to Expert

There may well be multiple paths that can be traversed in order to accomplish transition from basic to expert competence, but most assuredly every one of them is paved with gaining more and more clinical experience conducing EX/RP with clinically ill OCD patients. This is not to say that clinical experience alone will necessarily yield the desired outcome – indeed there are many examples in sports and music where practicing incorrectly can result in the development of bad habits that are difficult to break. However, in our view, it is essential that the clinician who wishes to achieve expert status continues to practice actively with OCD patients rather than simply relying on the cases brought into clinical supervision by trainees. Some of the key clinical decisions to be made in conducting EX/RP with OCD patients have been highlighted here, and there are many excellent and more detailed references in the form of state-of-the-art treatment manuals that can be employed in the service of helping OCD patients confront the situations and thoughts that evoke obsessional distress while simultaneously refraining from

rituals and other forms of avoidance. The clinician interested in transitioning from basic to expert competence is vigorously encouraged to find these resources, compare them, and develop a consistent approach to diagnosis, assessment, discussion of treatment alternatives, and treatment. It is also helpful to access when possible the consultation of experts, since some of the more obvious mistakes in dealing with OCD patients (e.g., arguing with them about possibilities of feared outcomes) are virtually ubiquitous and can probably be avoided without having to be experienced directly.

It is imperative to keep up on the latest developments in clinical research in order to achieve and then maintain expert status: perhaps unlike most patients, individuals with OCD and their families are notable for the degree to which they have developed at least a working knowledge of the literature, and gaps in your own knowledge will serve to reduce trust and perhaps to increase patient resistance. For example, one mother of an OCD patient at intake unfurled a very detailed notebook complete with RCT study design slides and, when the therapist completed his discussion of the outcome literature, she reviewed her copious notes and then asked, "Doctor, I noticed that you did not allude to the findings of the De Haan study – was there some reason you omitted that?" Had the therapist's answer been, "What De Haan study?," the interaction would have gone quite differently than it did, which was a perhaps somewhat overly detailed discussion of the methodological necessity of a control group to establish relative efficacy, especially early on in the development of a treatment literature. Assured by the response, the mother signed up her child for treatment with this experienced therapist.

Workshop attendance can also facilitate the transition from basic to expert competence, although it is important that the burgeoning expert signs up for trainings that are at least at the same level of current competence or, better yet, above that level. Moreover, it is important to be willing to flaunt one's ignorance at such workshops, since unwillingness to ask questions out of concern that "I should already know that," is the surest way to remain in a fledgling state. Ongoing consultation is often part of these trainings and, as highlighted by the Valderhauget al. (2007) study, even indirect access to an expert supervisor was associated with excellent and durable outcomes in a rural outpatient setting that was not an OCD clinic per se.

5.6   Summary

Assessment and treatment of OCD is both challenging and rewarding, and although the transition from basic to expert competence is an arduous journey that requires years of direct clinical work, access to knowledgeable supervisors and consultants, continued, rigorous training, and the willingness to keep up with a literature that seems to be growing exponentially, it is nevertheless a sojourn well worth undertaking for a host of reasons. First, amount of suffering evident in patients with OCD is immeasurable, and quality of life in these patients is often severely compromised. Second, the empirical evidence clearly indicates that we have treatments that are effective in reducing symptoms and alleviating OCD-related dysfunction; these treatments are neither universally nor completely effective, but it is clear that completing EX/RP either alone or in combination with pharmacotherapy is associated with substantive and lasting benefits for most patients. Third, OCD is more common than previously believed, and there is a great need for practitioners who know the disorder well who can implement EX/RP in accordance with the theoretical model upon which it is founded. Fourth, OCD patients and

families who believe they were understood and treated well are often excellent sources of subsequent referral. In concert with grateful referral sources who are pleased to see their most challenging OCD cases get and stay better, it is realistic to build an OCD subspecialty practice expeditiously.

The work in developing expertise in OCD and its treatment over the past 2 decades has been extremely satisfying, and will continue to be so. In many ways, the subjective experience has been best captured in a quotation attributed to the late and legendary Philadelphia Phillies' broadcaster Harry Kalas, who was asked why after over 40 years of broadcasting baseball games he still loved his work so much: "Because every single day you come to the ballpark you can expect to see something that you have never seen before." OCD's heterogeneity and the many clinical nuances that have to be navigated to deliver effective EX/RP provide that very same sense of wonder even after doing so for a very long time. That said, returning again and again to the theoretical model upon which treatment rests allows the clinician a way to understand all of these new observations and to put them in a context for patients that will help them to understand them well too. It is this knowledge, as well as the support of a therapist who knows the disorder as well as one can without actually suffering from it, that assists even the most severe patients in doing what needs to be done to reduce the deleterious effects of OCD and thereby reclaim their lives.

6 Post-Traumatic Stress Disorder

Daniel F. Gros · Peter W. Tuerk · Matthew Yoder · Ron Acierno

Abstract: From its initial definition and frequent revisions in the Diagnostic and Statistical Manual of Mental Disorders, assessing and treating posttraumatic stress disorder (PTSD) has presented many challenges to clinicians and researchers alike. However, through advances in cognitive and behavioral theory and practice, a number of evidence-based assessments (EBAs) and evidence-supported treatments (ESTs) have been developed to address this complex disorder. In this chapter, we briefly review the diagnostic features and EBA practices for PTSD. We also detail the mechanisms involved in the maintenance and treatment of PTSD and the EST approaches for the disorder. Finally, we outline the basic and expert clinician competencies involved in the treatment of PTSD from an evidence-based, cognitive-behavioral perspective.

6.1 Overview

In this chapter, we briefly review the diagnostic features and assessment practices for posttraumatic stress disorder (PTSD). We also detail the mechanisms involved in the maintenance and treatment of PTSD and the evidence-supported treatment (EST) approaches for the disorder. Finally, we outline the basic and expert clinician competencies involved in the treatment of PTSD from an evidence-based, cognitive-behavioral perspective.

6.1.1 Diagnostic Features

As defined by the *Diagnostic and Statistical Manual of Mental Disorders* (DSM; American Psychiatric Association, 2000), PTSD is characterized by (A) exposure to a traumatic event in which the individual experienced, witnessed, or was confronted with an event that involved the actual or threatened death or serious injury to one's self or others and the individual's response to said event which involves intense fear and helplessness. Traumatic events that commonly result in PTSD include, but are not limited to, military combat, being a victim of a violent assault or other crimes, natural or man-made disasters, motor vehicle accidents, or being diagnosed with a life-threatening illness. In addition, three symptom clusters are associated with the event, involving: (B) persistent reexperiencing of the traumatic event, including distressing recollections or dreams, acting or feelings as if the event were recurring, and intense psychological distress or physiological reactivity on exposure to cues that symbolize the event; (C) persistent avoidance of stimuli associated with the traumatic event, including avoidance of thoughts, feelings, memories, activities, places, or people that serve as reminders of the trauma, and general emotional numbing, including diminished interested in activities, feelings of detachment, restricted affect, and sense of a foreshortened future; and (D) persistent symptoms of increased arousal, including sleeping disturbance, increased irritability and anger, difficulty

concentrating, hypervigilance, and an exaggerated startle response. The symptoms must (E) present for at least 1 month and (F) result in significant impairment in social and/or occupational functioning.

6.1.2 Prevalence, Course, and Risk Factors

Although more than half of all US adults are exposed to at least one traumatic event (Kessler, Sonnega, Bromet, Hughes, & Nelson, 1995), lifetime prevalence for PTSD is estimated around 8% of the adult population (American Psychiatric Association, 2000). However, research demonstrates a dose–response relation between the severity of a traumatic event and the onset of PTSD (for review, see Friedman, Resick, & Keane, 2007), whereas prevalence of PTSD is higher among victims of more severe traumatic events (e.g., survivors of rape, childhood sexual abuse, and military combat and captivity). The course of PTSD is variable as the disorder can occur at any age, the symptoms can develop at variable time intervals after the initial traumatic event, and the symptoms can resolve within the first 3 months or persistent for longer than 12 months after the traumatic event (American Psychiatric Association, 2000). Several factors increase risk of PTSD, including pretraumatic (e.g., age, sex, previous trauma history, personal and family psychiatry history, and education level), peritraumatic (e.g., nature of the trauma, dissociation, and panic attacks), and posttraumatic factors (e.g., social support; Friedman et al., 2007).

6.2 Recognition of Symptoms and Their Assessment

Since the diagnosis was included in the DSM-III (American Psychiatric Association, 1980), psychological assessment and treatment practices for PTSD have received significant attention and frequent revision (Keane & Barlow, 2002). Due to a wide range of symptom presentations, inconsistent relations to trauma exposure (e.g., exposure does not always lead to the development of PTSD), and high rates of comorbidity with other anxiety and mood disorders, the assessment of PTSD can present a challenge to mental health professionals (Keane, Brief, Pratt, & Miller, 2007; Litz, Miller, Ruef, & McTeague, 2002). Nonetheless, a recognition among experts that exposure to potentially traumatic events actually is a normative experience (e.g., natural disasters, interpersonal violence, military conflicts) and a recognition of negative health and economic consequences associated with PTSD highlight the need for adequate assessment and treatment for the disorder (Keane et al., 2007). Fortunately, a number of evidence-based assessments (EBAs) exists that can aid clinicians to identify and investigate the symptoms of PTSD (Keane & Barlow, 2002). The focus of this section of the chapter is on present goals and practices for psychological assessment of PTSD.

6.2.1 Goals for the Assessment of PTSD

Litz et al. (2002) outlined several goals relevant to assessing PTSD symptoms. Although assigning a diagnosis of PTSD is often the primary goal of assessment, there are several other factors

to consider, which depend on the context of assessment, needs of the patient, and clinical resources. The primary goals of any assessment of PTSD are to (1) establish the presence and extent of a potentially traumatic event, and (2) complete a diagnostic assessment of PTSD symptoms. However, there may be several secondary goals to PTSD assessment, including: (3) placing a traumatic event or events in a life-span context in order to more fully understand factors that may have contributed to development and maintenance of the disorder, (4) evaluating compensation and litigation status for patients involved in the legal system, and (5) evaluating motivation and readiness for change for patients seeking treatment. Clinicians and researchers should select appropriate measures and tailor assessments to attain each of the desired goals. Descriptions of the various types of assessment instruments for PTSD symptomatology are given below.

6.2.2   Semi-Structured Diagnostic Interviews

Semi-structured clinical interviews utilize a combination of standard clinical interview procedures with focused prompts to assure consistent and valid coverage of relevant parameters for a given disorder. These interviews allow for thorough investigation of clinical presentation and routinely include components of formal batteries to assess specific diagnostic questions (Litz et al., 2002). Although less common in purely clinical settings due to time constraints and specialized training required to administer these interviews correctly, semi-structured clinical interviews can improve diagnostic accuracy and treatment planning and may be useful in hospital and social service settings (Keane & Barlow, 2002; Keane et al., 2007). There are two primary types of semi-structured interviews used to identify PTSD: semi-structured interviews that assess a wide range of symptoms of psychopathology and semi-structured interviews that solely focus on the symptoms of PTSD.

The *Structured Clinical Interview for DSM-IV* (SCID-IV; First, Spitzer, Gibbon, & Williams, 1996) and *Anxiety Disorder Interview Schedule* (ADIS; Di Nardo, Brown, & Barlow, 1994) are the two most common general semi-structured interviews used to assess PTSD and related disorders (Keane et al., 2007; Litz et al., 2002). In contrast to the semi-structured interviews that focus solely on PTSD, both the SCID and ADIS assess PTSD and several other anxiety, mood, and related disorders based upon the criteria listed in the DSM-IV. Both interviews have demonstrated excellent validity and reliability findings in the literature (for review, see Keane et al., 2007). One additional benefit of the ADIS is the inclusion of continuous ratings of frequency and intensity of distress for each disorder.

The *Clinician-Administered PTSD Scale* (CAPS; Blake et al., 1995) is the most commonly used PTSD-focused semi-structured interview (Keane et al., 2007); however, other interviews are available (*PTSD Symptom Scale Interview* [Foa, Riggs, Dancu, & Rothbaum, 1993]; *Structured Interview for PTSD* [Davidson, Smith, & Kudler, 1989]). In contrast to the SCID and ADIS, the CAPS provides a wider assessment of PTSD symptoms, including the 17 DSM-defined PTSD symptoms, symptoms of guilt and dissociation related to the traumatic experience, and the impact of one's symptoms on occupational and social functioning (Litz et al., 2002). In addition, the CAPS includes frequency and intensity ratings for each symptom, which provides continuous descriptors of symptomatology. Similar to the SCID and ADIS, the validity and reliability of the CAPS is well supported (Keane et al., 2007).

6.2.3   Self-Report Questionnaires

Several self-report questionnaires offer time- and cost-efficient ways to assess symptoms of PTSD (Orsillo, 2001). Self-report questionnaires have received widespread acceptance in the PTSD literature due to the ease with which they can be administered and scored (Keane & Barlow, 2002). The primary goals of these measures are to screen for PTSD symptoms, provide dimensional (e.g., intensity) data on symptom level, as well as to related impairment of PTSD, and track treatment progress (Litz et al., 2002). In order for a self-report measure to be considered an EBA, psychometric properties must be well researched, including evidence of test-retest reliability, internal consistency, and content, construct, and criterion-related validity (Antony & Rowa, 2005; Keane et al., 2007).

   Self-reported questionnaires vary in a number of important ways. One way in which measures differ is in their targeted symptoms. Some questionnaires, such as the *PTSD Checklist* (PCL; Weathers et al., 1993), the *Purdue PTSD Scale-Revised* (PPTSD-R; Lauterbach & Vrana, 1996), and the *PTSD Symptom Scale* (PSS-SR; Foa et al., 1993), map items directly onto DSM criteria to permit diagnostic classification using DSM algorithms and provide a continuous measure of severity (Litz et al., 2002). These measures tend to be brief with around 20 items each. Alternatively, several other measures, such as the *Minnesota Multiphasic Personality Inventory PTSD Scale* (MMPI-PTSD; Keane, Malloy, & Fairbanks, 1984) and *Mississippi Scale for PTSD* (MPTSD; Keane, Caddell, & Taylor, 1988), do not directly assess criterion-related symptoms of PTSD; rather, they assess overall symptom severity and associated impairment. Non-DSM-referenced scales tend to be more time-consuming and contain around 40 items each. Questionnaires also differ in time frame of assessment, whereas some measures assess symptoms over the past month (e.g., PCL and PPTSD-R) and others specify only the past week (e.g., *Impact of Event Scale-Revised* [IES]; Horowitz, Wilner, & Alvarez, 1979) or specify no time frame at all (e.g., MMPI-PTSD and MPTSD). Together, in combination with the psychometric properties (for review, see Orsillo, Batten, & Hammond, 2001), these characteristics may inform clinician's decisions regarding choosing an appropriate self-report measure of PTSD symptoms.

6.2.4   Psychophysiology

Psychophysiological methods of assessing PTSD have received significant attention in the literature (Keane & Barlow, 2002; Keane et al., 2007; Litz et al., 2002; Orsillo et al., 2001; Pole, 2007). Psychophysiological methods, including indices of autonomic reactivity (e.g., heart rate, blood pressure, electrodermal response) and emotional reactivity (e.g., facial electromyography), have been used to diagnose PTSD and assess treatment outcome (Keane et al., 2007). Psychophysiological assessment is well suited for PTSD because the DSM diagnostic criteria for the disorder include physiological reactivity to internal or external cues that resemble the traumatic event. However, this DSM criterion is not required for a diagnosis of PTSD and an estimated 40% of individuals with PTSD do not exhibit reactivity, which may reduce the ability of psychophysiological assessments to detect differences in some persons with PTSD (Prins, Kaloupek, & Keane, 1995). In fact, the largest and arguably most rigorous study of the psychophysiology of PTSD involving comparison of four psychophysiological indices and SCID-based PTSD diagnosis in a sample of over 1,300 veterans was successful in classifying only two

thirds of those with a current diagnosis of PTSD (Keane et al., 1998). Numerous factors may contribute to the disparity between psychophysiological and self-report indices, including general biological influences (e.g., age, sex, race, and fitness level), methodological factors and protocol demands, and the use of pharmacological agents (Keane et al., 2007; Litz et al., 2002). There also has been some research to suggest that psychophysiological methods may be useful in assessing changes during the course of treatment (Fairbank & Keane, 1982; Shalev, Orr, & Pitman, 1992). Although mostly limited to case studies, there is more optimism for these psychophysiological methods due to their ability to control for individual variability through within-subject designs (Litz et al., 2002). In summary, psychophysiological assessment of PTSD has some value as both a diagnostic tool and an assessment of treatment process, if used with support from alternative forms of assessment, such as self-report measures and structured interviews. However, due to the expense in terms of time and cost, patient burden, the expertise required to administer and interpret the findings, and the efficiency of more economical methods of assessment discussed earlier, the widespread adoption of psychophysiological indices of assessment is limited (Keane & Barlow, 2002).

6.2.5   Limitations and Future Directions

Together, these three approaches to assessment provide a comprehensive evaluation of the symptoms of PTSD; however, several issues should be taken into consideration when discussing current assessment practices. One of the primary concerns is the level of comorbidity and overlap between PTSD and other related disorders, especially depression and the other anxiety disorders (Antony & Rowa, 2005; Brown & Barlow, 2002). Although several of the semi-structured interviews provide information to address these concerns, a majority of self-report measures and psychophysiological indices does not assess comorbidity. A second concern relates to controversies surrounding the symptom clusters of PTSD and the symptoms of anxiety and depression more generally (e.g., Simms, Watson, & Doebbeling, 2002; Watson, 2005). Clinicians and researchers are exploring alternate assessment and classification systems, including expanding the role of functional impairment in assessment (Cohen & Mannarino, 2004), as well as, exploring a broader symptom-based, rather than DSM criterion-based system (Antony & Rowa, 2005).

6.3   Maintenance Factors of the Disorder or Problem

In the immediate aftermath of a traumatic event (0–48 h), the typical response is one of cognitive, emotional, and behavioral disruption. The event is fresh in memory and a majority of survivors evinces some degree of distress and impairment (Litz & Maugen, 2007). However, the posttraumatic stress literature of the past 20 years demonstrates that most people exposed to traumatic events, approximately two thirds, recover effective functioning within 3 months (Blanchard, Hickling, & Forneris, 1997; Rothbaum, Foa, Riggs, Murdock, & Walsh, 1992). Nonetheless, this leaves a significant number of people for whom the initial trauma-induced distress and impairment does not subside and PTSD develops (Kessler et al., 1995).

Most traumatic events are sudden, unpredictable, outside of the range of normal human experience, and emotionally painful. Enduring symptomatology in the individuals who develop

PTSD has been parsimoniously explained by several researchers using conditioning/learning theories (Keane & Barlow, 2002; Kilpatrick, Veronen, & Best, 1985). According to learning theory, a traumatic event (e.g., combat exposure) serves as the original stimulus that leads to an unlearned response comprising PTSD symptoms (avoidance, hyper-arousal, intrusive ideation). These responses become associated with salient stimuli (i.e., "triggers") present in an individual's internal (e.g., racing heart) and external environments (e.g., loud noises) during the time of exposure, and these stimuli begin to elicit learned anxiety responses in the future. Thus, when an individual who was exposed to a traumatic event is then exposed to one of these trigger stimuli, a negative emotional PTSD response identical or very similar to the original emotional response occurs. In order to reduce or eliminate aversiveness of this learned anxiety response, individuals will escape from, and subsequently avoid, activities, places, or people that remind them of the event, thereby reducing anxiety in the short term (in response to an escape from conditioned or learned fear stimuli) but perpetuating this maladaptive learned response in the long term (by preventing extinction of the learned response).

Alternatively, several theories of PTSD focus on the thoughts, assumptions, interpretations, and beliefs that are impacted by traumatic events (for a review, see Cahill & Foa, 2007). Under these theories, traumatic events are conceptualized as providing new, often frightening information about one's self and the world, resulting in the formation of cognitive fear structures (Foa & Kozak, 1986; Foa, Steketee, & Rothbaum, 1989). Cahill and Foa (2007) note:

▶ A fear structure becomes maladaptive or pathological when (1) associations among stimulus elements do not accurately represent the world, (2) physiological and escape/avoidance responses are evoked by harmless stimuli, (3) excessive and easily triggered response elements interfere with adaptive behavior, and (4) harmless stimulus and response elements are erroneously associated with threat meaning. (p. 62)

As such, the ways in which survivors think about the self, the world in which they live, and the meaning of events/stimuli occurring in the world are often disrupted. Thus, according to this theory, posttraumatic distress results from post-event cognitions.

Current theories regarding the enduring nature of PTSD center on avoidance. Indeed, as described earlier, avoidance is one of the three characteristic symptom clusters of PTSD. The types of avoidance that contribute to the maintenance of pathological posttraumatic stress symptoms and to PTSD itself can be organized into two groups: cognitive and behavioral factors. These two categories of avoidance are not necessarily mutually exclusive, but can often be systematically related. However, for purposes of clarity, they will be discussed separately in this section.

6.3.1   Behavioral Avoidance

Given the distress and pain associated with traumatic events, it is understandable that survivors attempt to avoid stimuli which remind them of the trauma(s). However, as learning theory describes (e.g., Mowrer, 1960), after a person is exposed to a life-threatening event, a fear-response, involving aversive sympathetic nervous system arousal, may be elicited by not just stimuli present during the event but, also through processes of higher-order conditioning and stimulus generalization, so that additional stimuli and situations that are associated with either the original traumatic event, or other salient stimuli associated with the event elicit the

fear-response (Keane, Zimering, & Caddell, 1985). For example, a victim of sexual assault may associate his or her assault with darkness and the perpetrator (i.e., stimuli present during the event); however, their fear-response may be generalized to all situations involving either nighttime, men, sexual activity, and thoughts/words associated with the rape experience. To avoid distress, the victim may avoid each of these generalized persons, places, situations, including men, sexual activity, and stimuli associated with the rape itself. This avoidance behavior naturally results in diminution of negative emotions in the very short term, in effect (negatively), reinforcing more frequent use of avoidance. However, avoidance also has the negative effect of fostering withdrawal and maintaining PTSD (Mowrer, 1960). Thus, teaching individuals to confront and remain in the presence of previously avoided situations (i.e., expose themselves to these situations) that trigger anxiety will eventually reduce symptoms of PTSD. This anxiety reduction, if structured appropriately, will be complimented by increases in natural reinforcement derived by engaging in previously rewarding activities and may reduce depression.

6.3.2 Cognitive Maintenance Factors

Given that traumatic events are distressing by definition, there is a tendency to cope with the distress of reexperiencing symptoms by attempting to avoid thinking about the event itself in much the same way as behavioral avoidance is manifest in avoiding persons, places, or situations that remind one of the traumatic event. A common response to traumatic memories described by those seeking treatment for PTSD is, "I try not to think about it." However, research demonstrates that suppressing negative trauma-related thoughts leads, paradoxically, to an increase in thought frequency (Davies & Clark, 1998; Reynolds & Wells, 1999). In fact, Shipherd and Beck (1999) found that after survivors of sexual assault with PTSD were asked to deliberately suppress their negative thoughts, they reported a significant rebound effect of negative thoughts when compared to survivors without PTSD, suggesting that active thought suppression contributed to an increase in negative thoughts.

Various prominent theories of PTSD describe the mechanism by which cognitive avoidance maintains the disorder in different ways, but active behavioral avoidance of trauma-related cognitions and reminders is incorporated into nearly all these theories. For example, schema theories (e.g., Epstein, 1985; Janoff-Bulman, 1992; McCann & Pearlman, 1990) imply that avoidance maintains PTSD by preventing resolution of the discrepancy between pre-trauma internal models (e.g., the world as a safe place) and trauma-related information (e.g., the world is a dangerous place all the time) – a process that requires cognitive processing of the new information. Emotional processing theory (Foa & Kozak, 1985) and Ehlers and Clark's (2000) cognitive theory note that cognitive avoidance prevents change in the underlying memory, or fear structures, resulting in maintenance of PTSD symptoms.

Avoidance further contributes to PTSD by preventing the survivors from being exposed to information that may challenge their posttrauma beliefs. For example, soldiers returning from combat with PTSD may have learned to associate unknown people (i.e., possible enemy combatants) with danger and therefore avoid situations involving the potential of encountering crowds of people they do not know (e.g., malls, parks, restaurants, etc.). Through behavioral avoidance of social situations, they also are prevented from encountering information incongruent with their belief that strangers are dangerous, thereby maintaining PTSD symptoms.

6.3.3 Conclusion

In short, traumatic events result in behavioral avoidance, learned fear responding to stimuli that were previously neutral, cognitive confusion, and emotional pain. Associations of trauma cues with emotional pain foster avoidance of cues. Behavioral avoidance prevents cognitive and emotional processing, adjustment of erroneous beliefs, and corrective modification of conditioned associations between a fear-response and neutral or positive stimuli. Cognitive avoidance also leads to a paradoxical increase in trauma-related intrusions. Together, these behavioral and cognitive mechanisms have been shown to contribute to the development and maintenance of PTSD; accordingly, decreasing or eliminating avoidance disrupts the maintenance of PTSD symptoms.

6.4 Mechanisms of Change Underlying the Intervention

As noted above, the typical recovery pattern seen in the majority of people following traumatic events involves modifying the emotional associations and maladaptive automatic cognitions through exposure to feared stimuli. Such exposure promotes cognitive and emotional processing of events that originally may have been experienced as confusing, sudden, or nonsensical. These learning and cognitive processes happen, to a greater or lesser degree, in everyday life through conversations with others about the event and repeated contact with trauma-related cues (e.g., taking the bus to work after the original assault happened at a similar bus stop; going to crowded but safe places such as malls). Avoidant behaviors disrupt this normative process and are thought to be responsible for the maintenance of PTSD (Cahill & Foa, 2007; Kindt, Buck, Arntz, & Soeter, 2007). Given these conceptualizations of the disorder, exposure, reconditioning, and cognitive/emotional processing are all active mechanisms of therapeutic change in symptoms of PTSD. The importance of, and the emphasis given to, each of these varies by specific treatment model; however, the treatments found to be most effective include each to some degree.

   Exposure treatment or therapy refers to the process of encountering trauma-related associations, cues, thoughts, and memories. Exposure therapy describes a treatment model generally based on learning theory concepts of extinction and habituation. Exposure also can be conceptualized as the opposite of behavioral and cognitive avoidance, which are the behaviors developed by individuals with PTSD to reduce aversiveness associated with trauma cues. Notably, nonavoidance and exposure foster relearning. As described above, traumatic events may result in pathological associations between a fear-response and external and internal stimuli or cues. Survivors are negatively reinforced (aversiveness is reduced) by avoiding these previously neutral cues. Because they avoid these stimuli, no extinction (unlearning) of the conditioned fear-response is possible, and the constellation of symptoms known as PTSD endures (Rescorla, 2001). Unlearning the fear-response (i.e., unpairing the association between a previously neutral stimulus such as a bus stop and the fear-response such as heightened anxiety) is necessary and achieved through repeated exposure to trauma-related cues (decreasing behavioral avoidance). In addition to the basic conditioning principal of extinction, these experiences also provide survivors with information and evidence that may modify learned maladaptive cognitions acquired during the traumatic event. For example, a combat veteran who associates strangers or crowds with a fear-response (and therefore avoids social situations)

will learn to "uncouple" the conditioned association between crowds and the fear-response via repeated, prolonged exposure to crowds/strangers in realistically safe settings (malls, parks, restaurants, etc.). In addition, many trauma survivors with PTSD find the physiological symptoms associated with the disorder highly distressing themselves (e.g., increased heart rate, sweating, shortness of breath, etc.). Thus, these visceral stimuli also become targets for exposure therapy (e.g., interoceptive exposure to prescribed exercise). Through repeated exposure to feared stimuli, not only is the conditioned arousal response extinguished (Keane et al., 1985; Kilpatrick et al., 1985), but the survivors also learn to tolerate their symptoms and learn that they can handle their arousal responses.

In addition to the more parsimonious learning theory described above, an alternative cognitive theory that explains the efficacy of exposure is emotional processing, which involves two basic premises (Foa & Kozak, 1985, 1986). The first premise is that PTSD indicates the presence of maladaptive fear structures in the memory of a survivor (see above section for more discussion). The second premise is that successful treatment modifies the maladaptive elements of the fear structure in such a way that information which previously elicited anxiety symptoms no longer does so. According to this theory, when a survivor is intentionally exposed to safe but feared stimuli, they encounter new information that is not compatible with the fear structure. In addition to modifying pathological conditioned responses, the new information is instructive about the probability and cost of feared consequences and disconfirms erroneous beliefs associated with the fear structure (Cahill & Foa, 2007).

Thus, most cognitive-behavioral treatment models include an exposure component which is thought to promote reconditioning and process mechanisms of change. However, the amount and type of exposure that is most beneficial to patients remain controversial and therapies involving only a minimum of "reliving" the trauma have been found to be effective (Ehlers et al., 2003; Ehlers, Clark, Hackmann, McManus, & Fennell, 2005; Harvey, Bryant, & Tarrier, 2003). In addition, some research has suggested that it is not only exposure-based physiological activation and reconditioning that is responsible for fear reduction (Kamphuis & Telch, 2000; Lang & Craske, 2000), but rather, repeated nonreinforced exposure to feared stimuli results in a completely new memory being formed (Rescorla, 2001). Following this line of thinking, the formation of new memories associated with cognitive change leads to fear reduction (Kindt et al., 2007), but the likelihood of this happening independent of behavioral exposure is low.

Despite the questions remaining surrounding the optimal amounts of exposure or the underlying cognitive mechanisms of impact, the role of exposure to trauma-related cues and stimuli in PTSD symptom change and extinction is well established (Domjan, 2003; Resick, Monson, & Gutner, 2007). As such, exposure and the resulting cognitive/emotional processing and reconditioning are considered primary mechanisms of change in PTSD.

6.5   Evidence-Supported Treatment Approaches

Based upon the guidelines developed by the Division 12 Task Force on Promotion and Dissemination of Psychological Procedures (1995; Chambless et al., 1996) and the American Psychological Association Task Force on Psychological Intervention (1995), Chambless and Hollon (1998) outlined a definition for ESTs. These criteria are repeatedly discussed throughout the literature and, thus, are described in brief here. The five criteria are: (1) EST must be

compared with a control group or alternative treatment in a randomized control trial (RCT) in which the EST is statistically superior to the comparison group; (2) studies of the EST must include a treatment manual, a population with reliable and valid inclusion criteria, reliable and valid outcome assessment measures, and appropriate data analysis; (3) EST must be superior to the comparison treatment in at least two independent research settings with the majority of studies supporting its efficacy. If only one study is available, in the absence of conflicting evidence, the label of "possibly efficacious" is assigned. The label of "efficacious and specific" is used if the EST is shown to be superior to an alternative treatment, including pill or psychological placebo, in at least two independent research settings.

Similar guidelines have been adopted for PTSD treatments (Foa & Meadows, 1997; Harvey et al., 2003). The ESTs for PTSD include exposure therapy (Foa, Rothbaum, Riggs, & Murdock, 1991; Rothbaum & Foa, 1992), eye movement desensitization and reprocessing (EMDR; Shapiro, 1989, 1995), stress inoculation therapy (SIT; Kilpatrick & Amick, 1985; Kilpatrick, Veronen, & Resick, 1982), cognitive therapy or cognitive processing therapy (CPT; Resick, 1992; Resick & Schnicke, 1992, 1993), and various pharmacological agents (for review, see Friedman & Davidson, 2007). The descriptions for each of the treatments are provided below.

6.5.1 Evidence-Supported Treatments

Exposure Therapy. Exposure therapy is the most thoroughly investigated form of treatment for PTSD and is found in several different variations, including systematic desensitization, flooding, prolonged exposure, or implosive therapy (Keane & Barlow, 2002). Importantly, most of the effective types of treatment for PTSD involve an exposure therapy component, including EMDR, SIT, and CPT. Exposure therapy techniques involve confronting (in realistically safe environments) one's feared persons, places, situations, and/or memories through in vivo exposure and imaginal exposure (Keane & Barlow, 2002; Resick & Calhoun, 2001). Evidence supports the efficacy of exposure therapy alone (Foa et al., 1999; Ironson, Freund, Strauss, & Williams, 2002; Marks, Lovell, Noshirvani, Livanou, & Thrasher, 1998; Resick, Nishith, Weaver, Astin, & Feuer, 2002) and in combination with other treatments (Foa et al., 1999; Lee, Gavriel, Drummond, Richards, & Greenwald, 2002; Marks et al., 1998) in comparison to wait-list control. Comparisons studies demonstrate that exposure therapy also is more efficacious than several active treatments, including SIT (Foa et al., 1991, 1999) and relaxation therapy (Taylor et al., 2003). In fact, dismantling studies that have been conducted to determine active ingredients responsible for PTSD treatment gains demonstrate that exposure in isolation is as effective as several variations of combination treatments (Foa et al., 2005; Paunovic & Öst, 2001).

Eye Movement Desensitization and Reprocessing. Eye movement desensitization and reprocessing is a controversial, but effective, treatment developed through personal observation rather than an empirical procedure (Keane & Barlow, 2002; Resick & Calhoun, 2001). The premise of EMDR is that troubling thoughts and imagines can be resolved through lateral eye movements. Thus, the basic EMDR protocol for PTSD involves: (1) visualizing the traumatic memory (i.e., imaginal exposure); (2) rehearsing the negative cognitions (i.e., cognitive exposure); (3) focusing on the physical symptoms of the anxiety (i.e., visceral exposure); and (4) engaging in bilateral eye movements by following the clinician's finger back and forth for 24 repetitions (Resick & Calhoun, 2001). The controversy centers over whether or not the

eye-movements are actually necessary or add anything to the efficacy of the treatment. Although the majority of the early research was limited to case studies and noncontrolled studies (Resick & Calhoun, 2001), more recent investigations repeatedly have demonstrated the efficacy of the EMDR in patients with PTSD (for review, see Resick et al., 2007). In fact, several studies have found no differences on similar outcome measures between the efficacy of EMDR and exposure therapy at posttreatment and follow-up (e.g., Ironson et al., 2002; Lee et al., 2002; Power et al., 2002; Rothbaum, Astin, & Marsteller, 2005). However, studies of EMDR with and without the eye movements demonstrated equal effectiveness (Boudewyns & Hyer, 1996; Devilly, Spence, & Rapee, 1998; Pittman, Orr, Altman, & Longpre, 1996), suggesting that the active mechanism of EMDR is the exposure to, and perhaps the "processing" of, traumatic memories, rather than the bilateral eye movements (Keane & Barlow, 2002; Resick & Calhoun, 2001). As such, the treatment adds little to existing behavioral and cognitive treatments. In commenting on EMDR in light of these findings, McNally (1999) noted "what is effective in EMDR is not new, and what is new is not effective" (p. 619).

Stress Inoculation Therapy. Stress inoculation therapy (Kilpatrick & Amick, 1985; Kilpatrick et al., 1982) was one of the first comprehensive treatments for PTSD (Resick & Calhoun, 2001). SIT emphasizes an individually tailored treatment program to instruct patients in a set of coping skills which in turn facilitate mastery over their fears. SIT contains multiple treatment components, including psychoeducation, muscle relaxation, breathing control, covert modeling, role playing, thought stopping, and guided self-dialogue. Several studies have supported the efficacy of SIT when compared to a wait-list control group (Foa et al., 1991, 1999); however, as described earlier, SIT and SIT with exposure appear to perform worse than exposure-alone (Foa et al., 1999), perhaps because of the fewer overall exposure trials and less overall focus on therapeutic exposure in SIT.

Cognitive Therapy. Based upon the information-processing theory of PTSD (Foa & Kozak, 1986; Foa et al., 1989), CPT was specifically designed to combine components from exposure-based treatment of PTSD with cognitive components from standard cognitive therapy (Resick & Calhoun, 2001). The cognitive components of CPT target the conflicting beliefs and meanings attributed to the traumatic event and expectations about the future. The exposure component involves creating an exposure narrative of the sensory memories, thoughts, and feelings during the traumatic event and reading the narrative daily throughout treatment. Several studies support CPT's efficacy over wait-list control groups (Chard, 2005; Monson et al., 2006; Resick & Schnicke, 1992) and show CPT to be equally efficacious as prolonged exposure (Resick et al., 2002). It is difficult to determine, however, based on existing studies, whether CPT would remain as efficacious as prolonged exposure if its exposure components were removed.

Pharmacotherapy. Several antidepressants appear useful in treating PTSD. These agents include selective serotonin reuptake inhibitors (SSRIs; Brady et al., 2000; Davidson et al., 2001; Marshall, Beebe, Oldham, & Zaninelli, 2001; Tucker et al., 2001), tricyclic antidepressants (TCAs; Davidson et al., 1990; Kosten, Frank, Dan, McDougle, & Giller, 1991), monoamine oxidase inhibitors (Kosten et al., 1991; Neal, Shapland, & Fox, 1997), and several other antidepressant agents including nefazodone (Saygin, Sungur, Sabol, & Cetinkaya, 2002), mirtazapine (Davidson et al., 2003), and venlafaxine (Davidson et al., 2006). Several other types of medications also have shown promise in the treatment of PTSD, including antiadrenergic agents, anticonvulsant agents, partial N-methyl-D-aspartic acid (NMDA) agonists, gamma-Aminobutyric acid-ergic (GABA-ergic) agonists, and atypical antipsychotics; however, more research is needed

to determine their efficacy (Friedman & Davidson, 2007). In general, although several concerns still exist regarding the generalizability to different populations and the maintenance of treatment effects after the discontinuation of the medication (Friedman & Davidson), SSRIs are considered the pharmacological treatment of choice based upon mounting support for their efficacy in the literature and their relatively mild side effects (American Psychiatry Association, 2004; Davidson et al., 2005). Note, however, that pharmacologically based improvements in PTSD symptomatology, while statistically significant and reliability reported, rarely result in complete, or even nearly complete symptom amelioration (Albucher & Liberzon, 2002).

6.5.2   Selecting Which Treatment to Use

Based on the findings presented above, there are numerous psychosocial and pharmacological treatment options for PTSD. Although it may appear that some of the active treatments outperform others in direct comparison studies and meta-analytic investigations (e.g., Bisson et al., 2007; Foa et al., 1999; Taylor et al., 2003), the small number of comparison studies combined with variations in samples, measures, and treatment procedures between studies suggest that any conclusions may be a result of numerous confounds (Benish, Imel, & Wampold, 2008; Shadish & Sweeny, 1991). In fact, in the majority of treatment studies, the comparison therapies were not intended to be actively therapeutic (e.g., supportive therapy), which, similar to placebo-controlled studies with medications, may artificially inflate the benefits of the active treatments (Benish et al., 2008). In order to address these concerns, Benish et al. completed a meta-analysis of only bona fide psychosocial treatments and found no evidence of outcome differences in PTSD symptoms or any other outcome variable, suggesting that previously reported differences among treatments may be accounted for by methodological differences. Alternatively, the centrality of the exposure component to most existing treatments may indicate that this is the "active ingredient" in effective interventions for the disorder. Given these possibilities and their implications regarding the lack of importance of specific treatment components (i.e., other than exposure), treatment choice among the ESTs should be based upon other factors, including clinician experience and preference and, most importantly, the "fit" between a particular intervention and a particular patient. For example, a cognitively advanced patient may feel well matched to CPT; whereas, a very highly motivated patient with moderate-to low-anxiety sensitivity may prefer prolonged exposure. Such matching of patient preferences to intervention characteristics may well enhance patient satisfaction and adherence (Benish et al., 2008). However, notwithstanding these potentially useful treatment components, clinicians should not lose sight of the central importance of exposure in any intervention for PTSD.

6.5.3   Limitations and Future Directions

Although several ESTs are available, a number of questions still exist regarding how best to treat patients with PTSD. In order to address these questions, future directions for the PTSD literature include: increasing the number of methodologically sound RCTs, comparison studies of active treatments, and dismantling studies to determine which components are most important to the treatment of PTSD (Benish et al., 2008; Resick et al., 2007); examining each of the ESTs in a wide range of at-risk populations including victims of interpersonal violence,

disasters, military combat personnel, and emergency service responders (Harvey et al., 2003); increasing the amount of research on the prevention of PTSD and the treatment of acute posttraumatic reactions (Friedman & Davidson, 2007; Litz & Maguen, 2007); broadening current ESTs for PTSD to treat comorbid conditions such as substance abuse and/or depression (Resick et al., 2007); disseminating the ESTs to increase treatment access for patients with PTSD (Resick et al., 2007); and, risk, recovery, and resiliency studies, including genetic studies, to determine what types of individuals are most likely to develop PTSD, recover, or never experience symptoms in order to refine treatment strategies and to direct them to those at greatest risk. Together, these future directions may aid in improving the ESTs for PTSD and the quality of care of patients with PTSD.

6.5.3.1 Basic Competencies of the Clinician

Mastery of the clinical competencies of psychotherapy is vital to administering any and all forms of psychosocial treatments effectively (Sumerall, Lopez, & Oehlert, 2000; Zaro, Barach, Nedelman, & Dreiblatt, 1977). Thus, a number of education and training programs have developed competency-based training models, including the National Council of Schools and Programs of Professional Psychology (Peterson, Peterson, Abrams, & Stricker, 1997), scientist-practitioner clinical psychologists (Belar, 1992), counseling psychologists (Stoltenberg et al., 2000), and the Association of Directors of Psychology Training Clinics (Hatcher & Dudley Lassiter, 2006). In fact, a separate section on competence was added to the American Psychological Association's *Ethical Principles of Psychologists and Code of Conduct* (American Psychological Association, 2002). Together, these events demonstrate an escalating interest in competency-based education, training, and credentialing in psychology (Kaslow, 2004; Sumerall et al., 2000).

Competence is defined as "the habitual and judicious use of communications, knowledge, technical skills, clinical reasoning, emotions, values, and reflection in daily practice for the benefit of the individual and community being served" (Epstein & Hundert, 2002, p. 227). More specific to psychotherapeutic competencies, there is a set of core (or basic) and specialty (or expert) competencies that is required to be an effective therapist (Kaslow, 2004). As outlined by Spruill et al. (2004), the basic competencies include: intervention planning (i.e., integration of theory, research and practice, assessment, case formulation, and selection of the best strategy for intervention); intervention implementation (i.e., execution of the treatment plan, management of special situations, termination skills, working with and within various care systems, general case-management abilities, and self-care); and intervention evaluation (i.e., performance appraisal/self-evaluation skills and effective use of supervision and consultation). The expert competencies go a step further by building upon the core competencies through the application of advanced practices that require specialized knowledge, skills, and attitudes (Kaslow, 2004).

In the sections that follow, we adapt these notions of basic and expert competencies to the treatment of PTSD. As described earlier, most effective behavioral interventions for PTSD involve a form of exposure therapy (Resick et al., 2007). Thus, the competencies described below pertain to the skills needed to administer efficacious exposure therapy to patients with PTSD. As treatment protocols of exposure-oriented therapies are available elsewhere (e.g., Foa, Hembree, & Rothbaum, 2007; Foa & Rothbaum, 1998), these sections will focus on the

competencies involved in successfully employing these treatments, rather than step-by-step descriptions of treatment procedures and/or scripts of sample dialogues.

Similar to the standard clinical competencies, the basic skills in employing effective exposure therapy with patients with PTSD involve both specific and nonspecific therapeutic factors. Nonspecific factors involve relationship building skills, including warmth, empathy, reflective listening, and positive regard (Lejuez & Hopko, 2006; Strupp & Hadley, 1979). Specific factors refer to the particular intervention-based techniques that target, disrupt, or otherwise change maladaptive or pathological processes. Research on these factors has demonstrated a link between the nonspecific factors (Orlinsky, Ronnestad, &Willutski, 2004) and specific factors (Bemish et al., 2008) with treatment outcome across a variety of treatment modalities. Based upon the PTSD treatment literature (Foa et al., 2007), we selected three primary competencies to discuss: building a therapeutic relationship, conveying the rationale for treatment, and encouraging treatment adherence.

Relationship Building. Similar to most forms of psychotherapy, a strong therapeutic alliance is a critical component to the efficacious treatment of PTSD (Foa et al., 2007). Thus, a number of skills are needed to promote the development of a trusting therapist–patient relationship. However, as detailed below, some of these skills must be adapted to the specific needs of patients with PTSD. These skills include acknowledging a patient's decision to enter treatment, remaining nonjudgmental, restricting one's own expressions of affect, incorporating a patient's experiences into the descriptions of treatment, and being confident and collaborative in one's approach to treatment. Together, these competencies of relationship building will promote a trusting therapeutic alliance with patients with PTSD.

When initially developing a relationship with a patient, the therapist should acknowledge and support a patient's decision for entering into the therapeutic process. This initial step toward getting help can be a major turning point in a patient's well-being and psychological health and deserves the therapist's attention and positive reinforcement in light of the fact that simply presenting for treatment initially can be highly aversive. In addition, several types of PTSD patients (e.g., victims of sexual assault and active military personnel) may have been discouraged or made to feel guilty about seeking treatment. Thus, therapists must align themselves with the patient to support his or her efforts for treatment. Checks of motivation and frequent use of positive reinforcement should be maintained throughout the treatment experience, especially during transitions in treatment procedures and periods of increased avoidance (Foa et al., 2007).

A second component of relationship building involves the ability to be nonjudgmental and comfortable with the details of a patient's traumatic experiences. In particular, a therapist must be able to communicate with a patient without expressing verbal or nonverbal affect indicative of shock, disgust, incredulousness, anger, or sadness. Although this competency may seem straightforward, a combination of basic socialized responses and clinical training to both empathize and express sympathy can present subtle, though important, obstacles to developing this competency. It is very important that therapists allow their patients the space to describe their experiences and emotions by limiting their own expressions of sympathy or empathy, at least during the initial recounting of the story. Normal and natural displays of sympathy upon hearing a traumatic story, such as empathetically wincing or offering hasty condolences are not only unhelpful, but often can also be counterproductive. Therapists should strive for a balance by not overtly expressing high levels of empathy considered normal in other forms of therapy, but also not acting cold or indifferent to the patient's emotional recount of their traumatic

event. However, once a desirable balance is found, open communication with the patient will promote a healthy therapeutic relationship.

There are several reasons for therapists to restrict their immediate expressions of affect or empathy. First, when a therapist avoids expressing overt signals of distress, they model hearing about an awful traumatic event without experiencing overt distressing emotions, challenging a patient's common intrinsic assumption that traumatic events are inexorably related to uncontrollable negative emotions. Second, as traumatic events often are reexperienced in jagged, disorganized, and tangled packets of memories and emotions (Foa & Kozak, 1991), it is often difficult to guess correctly which details of the trauma are related to which emotions. By automatically empathizing with assumed emotions, a therapist risks misunderstanding and invalidation. A third reason for limiting the reactive flow of verbal and nonverbal affect or empathy is that it may promote the projection of thoughts and feelings belonging to the therapist onto the patient. This expression of emotions by a therapist, sometimes labeled countertransference, is associated with a negative impact on behavioral treatment outcomes (Ellis, 2001).

Another component of relationship building involves the retention and use of a patient's own descriptions of their fears in the therapeutic examples of psychoeducation and treatment rationale. For example, a therapist may choose to demonstrate the connection between a patient's specific set of avoidant behaviors (e.g., avoiding crowded areas) and the negative impact on their social or occupational functioning (e.g., cannot retain a fulltime job). This skill can accomplish several goals for developing a trusting therapeutic relationship. First and foremost, the use of a patient's own example of fears and symptoms demonstrates to the patients that they are heard and understood. Second, the incorporation of their descriptions into the therapeutic examples may promote greater understanding of the rationale for treatment. Finally, this act of adaptation to the psychoeducation and treatment rationale demonstrates that the therapist is tailoring treatment to the patient's individual needs.

A fourth component of relationship building with patients with PTSD involves the ability to instill hope in patients and confidence in the treatment modality through a flexible and collaborative therapeutic process. PTSD treatment often requires a large emotional commitment due to its anxiety-provoking nature. Thus, it is possible that there may be little positive reinforcement for a patient to continue treatment prior to the recognition of symptom reductions. During this period, several extrinsic reinforcers may be motivating a patient to remain in treatment, including support from family and friends and the patient's initial relationship with the therapist; however, these factors may not be long lasting if the patient does not believe that the treatment will work. In order to instill hope and confidence in the patient, a therapist must be able to sell themselves and the therapy by demonstrating their own knowledge and expertise about PTSD and its treatment. In addition, a therapist also must be collaborative with a patient's individual goals and needs to encourage their active participation while monitoring and adapting to the patient's anxiety and urges to avoid. Accordingly, a basic competency for all forms of exposure therapy is the capacity to instill confidence in patient's ability to get better. Together, these practices may aid in the development of hope and confidence in the patient and a strong therapeutic alliance with the therapist, likely improving treatment adherence, attendance, and homework completion.

Conveying the Treatment Model. A second basic competency of employing exposure-oriented therapies is the therapist's ability to clearly, effectively, and convincingly convey the

treatment model to patients with varying levels of sophistication. Although most effective behavioral treatments for PTSD involve talking about, dealing with, or imagining the traumatic event, the vast majority of exposure exercises take place outside of the treatment center and outside the eyesight of the therapist (Foa et al., 2007). Accordingly, it is imperative to the success of treatment that a patient understands and appreciates the benefits associated with exposure and, thus, be willing to engage in these activities on their own. This may be particularly challenging in patients with PTSD due to their reliance on avoidance as a method to reduce anxiety and distress (Friedman et al., 2007). Much of the treatment rationale must be presented through early psychoeducation about the disorder and the treatment for the disorder.

Psychoeducation about the symptoms and treatments of PTSD can be challenging to deliver due to the complexity of the disorder. Some common psychoeducation topics include a basic explanation of the origins of intrusive memories and nightmares, the fight or flight response, thought suppression, and explanation of the role of negative reinforcement in escape and avoidant behaviors. Therapists should be well versed in, and comfortable with, using several explanations and metaphors to be effective in conveying the information to patients. In addition, as described earlier, it is helpful to incorporate the patient's own symptoms and experiences into the psychoeducation to improve understanding of the descriptions. The primary goals of psychoeducation are to present a convincing rationale for treatment and have the patient buy into the treatment procedures. These goals can be accomplished by remaining thoroughly grounded in the conceptual model and theory underlying exposure therapy (Foa et al., 2007). The addition of research findings and the therapist's own experiences administering exposure therapy may aid in the process. Finally, as an example of these concepts, Foa et al. recommend telling patients, "that we will push them outside of their comfort zone but not outside of their safety zone" (p. 33). Together, these practices should increase the patient's understanding of the rationale for treatment and further develop the therapeutic alliance and, likely, decrease the treatment attrition.

Encouraging Treatment Adherence. A third basic competency of employing exposure-oriented therapies is encouraging treatment adherence through the control of patient avoidance. Treating PTSD effectively is analogous to treating avoidance effectively. This sentiment cannot be overstated. Although attrition rates for exposure-based and nonexposure-based treatments are similar (Hembree et al., 2003), roughly 20–30% of all patients with PTSD end treatment prematurely. Thus, specific techniques should be used to help reduce attrition rates and avoidance and increase the likelihood of successful treatment.

One technique to improve treatment adherence is to help patients plan for anticipated avoidance. Engage the patient in direct discussions regarding the notion of the avoidance of treatment. Preparing for common avoidance reactions (e.g., I did not sleep well the night before), especially early on in the treatment process, can help patients to overcome their avoidance and attend treatment regularly. For less cognitively sophisticated patients or adolescents, it can be productive to create a name for their avoidance (e.g., "Avoiding John" or "Mr. Avoider") to externalize the symptoms and promote greater awareness of their avoidant tendencies.

A second technique to reduce in-session avoidance is to help patients to identify their side-tracking techniques. More specifically, patients may arrive to therapy motivated to talk about the "emergency of the week," rather than the assigned homework and prescribed in session exercises. Although these attempts are often sincere, they also are powerful avoidant strategies.

One approach to prevent these distractions may be to outline the agenda at the beginning of each session and allocate a brief period for discussion of the past week's events (e.g., 5 min). In addition, another strategy may be to ask at the beginning of each session, "how was your homework?" rather than, "how was your week?" to orient the patient to an agenda item, rather than a distraction.

A third technique to reduce patient avoidance is to make reminder calls for appointments and homework assignments prior to the upcoming session. These reminder calls may help patients to stay oriented toward nonavoidance and provide opportunities for additional positive reinforcement from the therapist. Although potentially time-consuming, reminder phone calls, especially early on in treatment, can help to reduce patient avoidance of treatment sessions and homework assignments, thus, improving the likelihood of efficacious treatment.

6.5.3.2 Expert Competencies of the Clinician

Given the development of basic competencies in treating PTSD, therapists continuing to treat PTSD naturally may gravitate toward expert competencies. These expert competencies build upon basic competencies through the application of advanced practices that require specialized knowledge, skills, and attitudes of the targeted population and specific treatment procedures (Kaslow, 2004). Many EST protocols include room for flexibility to allow for the individual expression of expert therapist competencies within the therapeutic framework (Foa et al., 2007; Kendall, Chu, & Gifford, 1998; Lejuez & Hopko, 2006). Detailed below are three techniques that we have deemed as expert competencies necessary to the treatment of PTSD, including treating co-occurring conditions, using creativity and flexibility in the development of exposure exercises, and crisis management.

Treating Co-occurring Conditions. Similar to patients with other anxiety disorders and depression, patients with PTSD frequently present with comorbid or co-occurring conditions, including high rates of major depressive episodes (48%; 49%), specific phobias (31%; 29%), social phobia (28%; 28%), alcohol abuse/dependence (52%; 28%), drug abuse/dependence (36%; 27%), and generalized anxiety disorder (17%; 15%) in men and women, respectively (Kessler et al., 1995). Thus, one expert competency in the treatment of PTSD involves the incorporation of additional skills and resources from the other EST modalities. These additions to standard EST practices for PTSD may aid in addressing the complex needs of patients with comorbid conditions. For example, some patients with PTSD may be particularly sensitive to the somatic symptoms associated with PTSD or related anxiety disorder. If these sensitivities result in additional distress or avoidance, it may be beneficial to incorporate aspects of interoceptive exposure exercises (Barlow, Craske, Cerny, & Klosko, 1989). These exercises incorporate physical activities, like jogging-in-place or spinning in a chair, to expose patients to the physiological symptoms of anxiety in a safe environment while encouraging habituation and the extinction of these fears. Additional treatments, including exposure with response prevention for obsessive thoughts and compulsive behaviors (Foa & Wilson, 1991), motivational interviewing for substance use disorders (Miller & Rollnick, 2002), and behavioral activation for depression (Lejuez, Hopko, Lepage, Hopko, & McNeil, 2001), may expand the scope of treatment and improve treatment outcome. The ability to identify broader behavioral concepts and appropriately intervene can be more important than closely following any specific treatment

protocol, especially if these changes address the needs of the patient. These practices depend on the use of therapist creativity, flexibility, and ability to create an individual treatment plan for the patient (Kendall et al., 1998). While these and other adjunctive treatment techniques can be helpful, one must take care to provide such interventions in addition to, and not at the expense of, time devoted to exposure-oriented techniques (Foa, Rothbaum, & Furr, 2003). Preliminary research on the treatment of comorbid PTSD and panic disorder and PTSD and substance use disorders has demonstrated promising findings (for review, see Resick et al., 2007).

Using Creativity in Conducting Exposure Exercises. Another expert competency in the treatment of PTSD involves the use of creativity in designing exposure exercises. Creative practices can be applied to both in vivo and imaginal exposure exercises as long as the therapist adheres to the recommended guidelines for exposures. As outlined by Antony and Swinson (2000), the guidelines for conducting an exposure involve: practicing exposures in a planned, structured, and predictable fashion; presenting the exposures at a gradual pace; practicing exposures without subtle avoidance strategies; rating patient levels of fear during the exposure; attempting not to fight the fear during an exposure exercise; practicing exposure exercises frequently and close together; practicing exposure exercises long enough to experience a significant decrease in anxiety; using cognitive coping strategies to counter anxious automatic thoughts during exposure practice; and expecting to feel uncomfortable during the exposure. However, these guidelines provide room for interpretation of, and flexibility in, the exposure practices.

Several examples of uses of creativity in exposures are as follows. In vivo exposures may include the use of actors, props, or technology to increase the level of realism of the exposure exercise. For example, recent developments in virtual reality (VR) exposure practices have demonstrated promising results in patients with PTSD (for review, see Welch & Rothbaum, 2007). These VR simulations include accurate visual, auditory, and even tactile and olfactory cues from the initial traumatic event (e.g., driving armored convoy through Iraq). Creativity also can be adapted to imaginal exposure exercises to help patients to experience their memories in a vivid and sensory-rich manner. All five of the senses should be used in exposure exercises to promote the development of movie-like imagery of the traumatic memories, including cues for the sights, sounds, tastes, smells, and physical sensations. Being creative and vivid with questioning also sends a message to the patient that mastery of all aspects of the memory is vital to, and attainable in, the treatment of PTSD. These creative exercises should carry over into the patient's behavioral homework assignments. The use of audio/video clips, images, driving routes, times of day, or even the weather conditions may help create opportunities to alter and adapt exposure practices to individual patient needs.

Crisis Management. Given the presentation of patients with severe PTSD and the nature of exposure therapy, crisis management skills frequently are needed to maintain order in session and keep the focus on the treatment of PTSD (Foa et al., 2007). Sources of potential crises include comorbid conditions and related suicidality (e.g., depression, substance use, borderline personality disorder), multiple life stressors that lead to chaotic lifestyles and interfere with the development of healthy coping strategies (e.g., social, familial, or financial troubles), and over-engagement or excessive emotional distress elicited by an exposure exercise (e.g., dissociative symptoms or emotionally overwhelmed). Several techniques should be used for crisis management. First, if a patient is over-engaging in an exposure exercise, the exposure procedures should be reversed to reduce immediate distress, but maintain the focus of treatment. For example, in imaginal exposure, a patient may describe the exposure scene in the past tense,

rather than the present tense, or keep their eyes open, rather than closed, to slightly reduce the engagement of the exposure exercise and reduce the associated distress. Second, if comorbid conditions or additional problem areas are identified during the initial assessment, frequent reassessments should be conducted throughout the treatment to monitor progress (e.g., amount of alcohol consumption). If the additional problems are deemed an immediate risk to the safety of the patient, PTSD treatment should be postponed. However, if no imminent risk is identified, treatment should continue in order to improve the anxiety and distress associated with PTSD and, hopefully, also positively impact the comorbid condition (Foa et al., 2007). Once again, the focus of treatment should remain on improving PTSD; however, crisis management skills are a vital expert competency in the treatment of PTSD.

6.5.3.3 Transition from Basic Competence to Expert Competence

Competency-based education focuses on the development of the therapist into an independent, ethical, and effective clinician in a specific, specialty area of psychotherapy (Kaslow, 2004). These goals typically are predetermined and clearly outlined by a governing body or professional society; however, these requirements should not be limited to the acquisition of specified competencies, rather these qualities should emphasize the ability to adapt to change, exhibit sound judgment in challenging situations with conflicting values and ethical issues, generate new knowledge, and continue to learn and improve performance (Fraser & Greenhalgh, 2001).

When these training issues are related to the transition from the basic to expert competencies, several important considerations must be evaluated, including therapist experience, supervision and collaboration opportunities, and the availability of, and exposure to, an eclectic mix of patients and presenting problems. As in any competency-based education, training should be developmentally informed, thereby incorporating increasingly more complicated experiences (Kaslow, 2004). For example, many of the basic competencies can be accomplished through initial assessment interviews with patients with PTSD. Within each interview, a therapist may practice relationship building and conveying the treatment model in a safe, less-intimidating setting. Once mastered in an assessment setting, new treatment patients with uncomplicated presentations of PTSD should be assigned, allowing the therapist to master each of the basic competencies within a treatment setting. Once again, after mastery is accomplished, patients with complicated presentations of PTSD (e.g., patients with comorbid disorders, patients with extreme distress, and patients with severe avoidance) should be assigned to practice the expert competencies. In cases where therapists have minimal prior patient contact, PTSD vignettes should be used to role play therapeutic interactions and practice exposure exercises. Of course, each of these steps should be supervised by an expert in the field of PTSD treatment and occur within a respectful and facilitative learning environment to ensure that acceptable levels of knowledge and skills are developed (Kaslow, 2004).

6.5.3.4 Conclusion

Together, these basic and expert competencies represent a set of skills necessary for the efficacious treatment of PTSD. Although similar to the standard practices for beginning and expert

therapists (Kaslow, 2004), these practices are modified to recognize the specific challenges of working with patients with PTSD. Thus, each competency requires additional attention, training, and supervision to achieve mastery.

6.6   Summary

From its initial definition and frequent revisions in the DSM, the assessment and treatment of PTSD has presented many challenges to clinicians and researchers alike. However, through advances in cognitive and behavioral theory and practice (e.g., Cahill & Foa, 2007; Foa & Kozak, 1986), a number of ESTs has been developed to successfully treat PTSD (Resick et al., 2007). Although the precise mechanisms of change are still uncertain (Benish et al., 2008), both basic- and expert-level clinician competencies, including developing a trusting relationship with appropriate empathy and reflective listening, delivering therapeutic techniques like exposure comfortably and confidently, and applying creativity and flexibility to meet the patient's needs, are common requirements for each of the ESTs. In combination with supervision and collaboration with other experts and awareness of the ever-changing literature, evidence-supported therapeutic practices can be administered competently and effectively to patients with PTSD and related disorders.

7 Social Anxiety Disorder

Timothy M. Emge · Debra A. Hope

Abstract: Social anxiety disorder is a common and debilitating disorder, often leading to complications such as depression, substance abuse and increased suicide risk. During the past two decades, research on the cognitive, behavioral, interpersonal and physiological aspects of social anxiety and subsequent theoretical models have greatly increased our understanding of the nature and maintaining factors for social anxiety disorder. Well-validated assessment procedures including self-report, interview and behavioral measures, are now available. Therapeutic exposure, typically combined with cognitive interventions, is the most established evidence-based treatment. Comparisons of psychosocial treatment to pharmacotherapy and some promising innovative treatment approaches are discussed as well. Emerging work on mechanisms of change suggest that changes in judgments about the probability and costs of negative outcomes are key to clinical change. Competencies for clinicians include expertise with basic cognitive and behavioral therapies, therapeutic exposure and adaptations for the unique characteristics of social anxiety disorder. Especially important is the impact of socially anxious individuals' fears in interpersonal relationships on the therapeutic relationship. Expert competencies include treatment of more severe cases, overcoming extreme social isolation, complex presentations and social anxiety disorder that presents within the context of serious mental illness. Working in a multicultural context, particularly with language differences and sexual minorities are also discussed. Transition to expert competency relies on traditional educational venues, written material and utilizing expert consultation that is available on electronic venues.

7.1 Overview

Social anxiety, an experience of fear in interpersonal or performance situations, may occur commonly for many people, especially in novel or personally important situations, such as a wedding. However, for most people, the fear is transient and does not significantly interfere with functioning. Individuals who frequently experience high levels of social anxiety and either extreme distress or avoidance of social/performance situations may warrant the diagnosis of social phobia, also known as social anxiety disorder (American Psychiatric Association, 2001, DSM-IV-TR).[1]

Research into social anxiety disorder, which was once one of the least-studied anxiety disorders (Liebowitz, Gorman, Fyer, & Klein, 1985), has increased dramatically over the last 20 years with new insight into its etiology, theoretical framework, and effective treatments. While social anxiety disorder was once considered rarely incapacitating (DSM-III-R; American Psychiatric Association, 1987), it is now known to be associated with impairments extending

---

[1] The DSM-IV-TR includes *social anxiety disorder* as an alternative name for *social phobia* in order to underscore its pervasiveness and high level of impairment, as well as to indicate that it is conceptually different from other phobias. In line with this reasoning, this chapter will use the term *social anxiety disorder* when describing clinically significant anxiety in social or performance situations.

beyond social concerns. An early study by Turner, Beidel, Dancu, and Keys (1986) found that high percentages of individuals with social anxiety disorder reported that their functioning in academics and occupation had been hindered by their social anxiety. In comparison with the general population, individuals with social anxiety disorder report significantly more impairment in social functioning and general mental health (Simon et al., 2002). In comparing across anxiety disorders, quality of life is similar for obsessive-compulsive disorder, panic, and social anxiety disorder. As expected, however, social anxiety disorder is associated with more negative ratings for both social and leisure activities (Lochner et al., 2003).

Of individuals diagnosed with social anxiety disorder, 37.2% are found to meet criteria for diagnosis of major depressive disorder and 23.9% meet criteria for alcohol dependence, the only two psychiatric disorders more common than social anxiety disorder (Magee, Eaton, Wittchen, McGonagle, & Kessler, 1996). Longitudinal studies have investigated whether social anxiety disorder acts as a risk factor or develops later as a consequence of depression and alcoholism. In a 10-year, four-wave study in Munich, social anxiety disorder was found to be a stable risk factor for development of future depression, independent of age and gender (Beesdo et al., 2007). In another longitudinal study within the Oregon Adolescent Depression Project (Buckner et al., 2008), individuals with social anxiety disorder and no substance disorders at baseline had 4.5 greater odds of developing alcohol dependence and 6.5 greater odds of developing cannabis dependence, after controlling for age, depression, and other anxiety disorders. This heightened risk was not found with other anxiety disorders or mood disorders.

Approximately 12% of individuals with social anxiety disorder have a history of suicide attempts (Cox, Direnfeld, Swinson, & Norton, 1994). Similar to investigations of comorbidity, data from the 3-year Netherlands Mental Health Survey and Incidence Study (Sareen et al., 2005) were used to determine if the presence of anxiety disorders at baseline increased an individual's rate of suicidal ideation or suicide attempts. After controlling for age, gender, marital status, and Axis I diagnoses including other anxiety disorders, and drug use/abuse, individuals with social anxiety disorder were 2.5 times more likely to have suicidal ideation than individuals without mood or anxiety disorders, though no increase in risk of suicide attempts was found. In a female twin study, Nelson et al. (2000) also concluded that when social anxiety disorder is comorbid with major depressive disorder, there is a substantial elevation in risk of developing alcohol dependence as well as elevation in the risk of suicide-related symptoms.

Social anxiety disorder is the most common anxiety disorder and the third most common psychiatric disorder (Kessler, 1994; Ruscio et al., 2008). Lifetime prevalence estimates vary depending on the breadth of situations assessed as well as the criteria for determining how excessive the fear or avoidance must be to meet criteria (for a full review see Heimberg & Becker, 2002). The most recent National Comorbidity study replication found a lifetime prevalence of about 12% and 12-month prevalence of 7.1% (Ruscio et al., 2008). There appear to be two peaks in the age of onset – before the age of five (individuals who do not remember a time without symptoms) and another between the ages of 11 and 15 (Schneier, Johnson, Hornig, & Liebowitz, 1992). A full 80% of individuals meeting criteria for social anxiety disorder report a date of onset before the age of 20 (Stein & Stein, 2008). While prevalence studies estimate that women outnumber men with a ratio 3:2 (Kessler, McGonagle, Zhao, & Nelson, 1994), treatment studies typically estimate either no gender differences or men outnumber women, suggesting that men are overrepresented in treatment-seeking samples, possibly due to gendered role demands.

Many individuals with social anxiety disorder are not identified by health care professionals and/or do not receive treatment. In a study involving patients who presented with another psychiatric diagnosis to primary care physicians, almost 25% met screening criteria for social

anxiety disorder that was not diagnosed by their physician (Den Boer & Dunner, 1999). In another study, as many as 97% of the individuals with social anxiety disorder were never identified as meeting diagnostic criteria by their primary care physician (Vermani, 2007). Despite well-established treatments discussed below, estimates of how many individuals meeting criteria utilize treatment ranges from 19% in the general population (Schneier, Johnson et al., 1992) to 50% in primary care settings (Gross et al., 2005). In a community-based clinic, only half to two thirds of clients meeting criteria for social anxiety disorder reported their socially anxious symptoms as being the primary reason for seeking therapy (Zimmerman & Mattia, 2000). Despite the high rate of occurrence and significant negative effects of social anxiety disorder, the amount of time individuals experience significant distress before seeking treatment is, on average, 20 years (Davidson, Hughes, George, & Blazer, 1993; Turner et al., 1986). Given this, social anxiety disorder appears to be a chronic disorder with the potential to disrupt social functioning for decades.

7.1.1   Review of Symptoms/Assessment

Symptoms of social anxiety disorder can be conceptualized as revolving around three core domains: cognition, physiological symptoms, and behavioral responses. *Cognitions*: when individuals with social anxiety disorder are compared to nonanxious controls, they report more negative thoughts and fewer positive thoughts (Dodge, Hope, Heimberg, & Becker, 1988; Glass & Furlong, 1990; Turner et al., 1986), they predict a greater likelihood of negative events occurring (Foa, Franklin, Perry, & Herbert, 1996; Lucock & Salkovskis, 1988), and they have unrealistically high standards for their performance in social situations (Lundh & Öst, 1996). Thoughts that may occur during anxiety-provoking situations include, but are not limited to, concerns about the opinions of others, the experience of anxiety itself, and anticipation of poor performance and negative outcomes (Hope, Burns, Hayes, Herbert, & Warner, in press). As will be described further below, social anxiety disorder is also characterized by attentional biases towards cues of social threat (e.g., Hope, Rapee, Heimberg, & Dombeck, 1990) and interpretation biases (e.g., Amir, Foa, & Coles, 1998). *Physiological symptoms* are similar to those seen in other anxiety disorders, including rapid heart rate and muscle tension. When compared to nonanxious controls, socially anxious individuals tend to interpret these sensations as more visible and indicative of extreme anxiety (Roth, Antony, & Swinson, 2001). *Behavioral responses* include behavioral avoidance of feared situations, anxiety symptoms within the situation, such as rapid speech, and safety behaviors. Safety behaviors (Clark & Wells, 1995), are defined as maladaptive coping behaviors that individuals use while in feared situations to reduce anxiety, and include strategies such as limiting eye contact or rushing through oral presentations before feared consequences can occur.

Tremendous progress has been made in the last 20 years in the assessment of social anxiety disorder. A range of strategies and instruments has been developed including client self-report questionnaires, clinician-administered questionnaires and diagnostic interviews, and behavioral assessment. Each will be discussed in turn, with some key examples.

Self-report Measures. Self-report measures range from quick diagnostic screening instruments to extended assessments of anxiety and avoidance across situations to constructs thought to be core to the disorder. The Mini Social Phobia Inventory (Mini-SPIN; Connor, Kobak, Churchill, Katzelnick, & Davidson, 2001) is a three-item self-report diagnostic screening tool that is highly sensitive to detecting the presence of social anxiety disorder and can be readily employed in clinicians' offices. Several self-report questionnaires have been routinely used in

research to assess overall anxiety or avoidance and can be used in clinical practice. The Social Interaction Anxiety Scale (SIAS) and the Social Phobia Scale (SPS) were developed by Mattick and Clarke (1998) to assess the extent and specific types of fears associated with social anxiety disorder. High scores on the SIAS are associated with a greater number of feared social situations, while high scores on the SPS are associated with a greater number of feared performance situations (Brown et al., 1997). Scores on these scales are stable in untreated samples and sensitive to clinical change during treatment. The Social Phobia and Anxiety Inventory (SPAI; Turner, Beidel, Dancu, & Stanley, 1989) assesses social anxiety across a range of situations and is one of the few measures initially developed and validated on a clinical sample. The Brief Fear of Negative Evaluation (BFNE; Leary, 1983) assesses an individual's sensitivity to criticism by others, a central construct within social anxiety disorder (Collins, Westra, Dozois, & Stewart, 2005; Wells et al., 1995). Treatment-induced changes in fear of negative evaluation have been found to be one of the best predictors of long-term symptom reduction (Mattick, Peters, & Clarke, 1989). The BFNE, though subject to some criticism based on its factor structure (Rodebaugh, Woods et al., 2004) and high correlation with the Beck Depression Inventory (Saluck, Herbert, Rheingold, & Harwell, 2000), remains an important tool in assessing long-term treatment outcome. The recently developed Social Anxiety Session Change Index (SASCI; Hayes, Miller, Hope, Heimberg, & Juster, 2008) is a four-item measure designed to be used in routine clinical practice and treatment process research to track session-by-session changes across treatment for key aspects of the diagnostic criteria for social anxiety disorder. Preliminary psychometric data are promising (Hayes et al., 2008).

Clinician-Administered Measures. The Liebowitz Social Anxiety Scale (LSAS; Liebowitz, 1988) measures both fear and avoidance levels in 11 social and 13 performance-based situations, and is highly sensitive to diverse presentations. This measure has good psychometric properties and has also shown to be sensitive to treatment effects (Heimberg & Holaway, 1999). Although originally developed to be administered by a clinician, the LSAS has also been adapted as a self-report measure (LSAS-SR) which shows psychometric properties similar to the original version (Baker, Heinrichs, Kim, & Hofmann, 2002; Fresco et al., 2001; Oakman, Van Ameringen, Mancini, & Farvolden, 2003).

Although popular diagnostic interviews such as the Structured Clinical Interview for DSM-IV Axis I Disorders (SCID-I; First, Spitzer, Gibbon, & Williams, 1997) and the Mini International Neuropsychiatric Instrument (MINI; Sheehan et al., 1997, 1998) contain sections for social anxiety disorder, the most detailed diagnostic instrument is the Anxiety Disorders Interview Schedule for DSM-IV (ADIS-IV; Brown, DiNardo, & Barlow, 2004). The ADIS-IV has high construct and discriminant validity for social anxiety disorder (Brown, DiNardo, Lehman, & Campbell, 2001). The ADIS-IV is ideal for discriminating among anxiety and mood disorders but its lengthy administration time makes it difficult to use routinely in some settings.

Behavioral Assessment. Behavioral assessment of social anxiety disorder typically involves sampling the individual's behavior in feared social situations via direct observation, often of a role-played interaction or performance (McNeil, Ries, & Turk, 1995). Given the well-established biases in self-reports of their own social behavior (Norton & Hope, 2001; Rapee & Lim, 1992; Stopa & Clark, 1993), a behavioral assessment allows the therapist to make an accurate appraisal of the client's performance, visibility of anxiety symptoms, and use of safety behaviors. Behavioral assessment tests can thus be used to either disconfirm negative biases or identify whether a client has a performance/skills deficit or notably obvious anxiety symptom that should be addressed in treatment. As with the other assessment strategies described above,

behavior assessments can be readministered to assess for any reduction in anxiety and improvement in performance during and after treatment. Additional measures such as subjective anxiety ratings and ambulatory physiological data (typically heart rate) can also be taken during behavioral assessments in order to provide information in more modalities.

7.2 Maintenance Factors

Within current conceptual frameworks of social anxiety disorder, there are several factors that are thought to contribute to its chronic nature. The first factor involves safety behaviors, defined above as maladaptive coping behaviors the individual uses to reduce anxiety in anxiety-provoking situations. Examples of safety behaviors include avoiding eye contact to reduce anxiety and participating in a social interaction but avoiding the most distressing parts of it, such as talking only to friends at a party. Safety behaviors are thought to maintain chronic social anxiety disorder by preventing the individual from fully engaging in situations so that they miss the opportunity to learn that their feared outcomes do not typically occur. Since these behaviors are highly effective at reducing experienced anxiety in the short term, socially anxious individuals tend to use them more often and in more environments than nonanxious individuals (McManus, Sacadura, & Clark, 2008).

Second, characteristic biases in attention and interpretation of key social stimuli are cognitive aspects of social anxiety that are thought to help maintain the disorder. Individuals with social anxiety have been found to show increased vigilance towards their own physiological signs of anxiety and performance during stressful situations (Asmundson & Stein, 1994). It is thought that when faced with threatening situations, socially anxious individuals respond by increasing their self-focused attention, away from outside information that may serve to disconfirm their fears (Clark & Wells, 1995; Kimbrel, 2008). At the same time, they maintain vigilance to outside information that confirms their fears. Basic attentional biases toward threat-relevant stimuli, in which individual's attention is drawn to information indicating the presence of negative evaluation, has been found using threat-relevant stimuli in Stroop, dot probe, inattentional biases paradigms, and more naturalistic settings involving the detection of negative evaluation (Hope et al., 1990; Lee & Telch, 2008; MacLeod, Mathews, & Tata, 1986; Mathews & MacLeod, 1985; Veljaca & Rapee, 1998). Other biases exaggerate the likelihood of negative outcomes and overestimate the social cost, if negative outcomes do occur (Amir et al., 1998).

It is important to note that most social interactions do not naturally elicit explicit feedback on performance. Rather, there are ambiguous social cues, such as eye contact, facial expressions, and speed/tone of speech that are interpreted by nonanxious individuals in a culturally appropriate way. Individuals with social anxiety tend to interpret any ambiguous social cue as negatively valenced (Amir et al., 1998; Brendle & Wenzel, 2004) and also catastrophize stimuli that are marginally negative in nature (Stopa & Clark, 2000). When asked to evaluate their own performance, self-ratings are found to be more negative than fellow participant and blind observer's ratings (Alden & Wallace, 1995; Rapee & Hayman, 1996; Stopa & Clark, 1993). Finally, when asked to interpret signs of anxiety during a social task, individuals with high social anxiety interpret their own sensations as indicative of extreme anxiety, though this is not seen when they interpret other's signs of anxiety (Roth et al., 2001).

Safety behaviors and cognitive biases prevent socially anxious individuals from fully engaging in social interactions and prevent accurate processing of social stimuli. Negative predictions

are reinforced as being accurate, increasing future anxiety about the situation (Kashdan & Roberts, 2007; Riskind & Williams, 2006). It is hypothesized that performance may actually be negatively affected in this situation since most cognitive resources are focused on the self instead of the task itself (Clark & Wells, 1995; Rapee & Heimberg, 1997; Rodebaugh, Holaway, & Heimberg, 2004).

The final maintenance factor suggested by Clark and Wells (1995) involves the tendency of socially anxious individuals to ruminate about past and future threatening events. Here, they suggest that since the memories related to feeling highly anxious should be strongly encoded, individuals will find memories of past failures to be particularly salient just before encountering a feared situation. These will then prime individuals to increase their self-focused attention at the potential cost of performance, while looking for confirmatory evidence that the situation is indeed threatening. However, a general memory bias in social anxiety disorder has not been consistently found in the past (Cloitre, Cancienne, Heimberg, Holt, & Liebowitz, 1995; Foa, Gilboa-Schechtman, Amir, & Freshman, 2000; Rapee, McCallum, Melville, Ravenscroft, & Rodney, 1994).

The above processes are also reflected in emotional processing theory of anxiety disorders (Foa, Huppert, & Cahill, 2006; see also Foa & Kozak, 1986). Here, social anxiety is thought to occur when maladaptive fear structures are created that associate stimuli, reactions, and cognitions in a dysfunctional manner. For example, the stimuli can include any event that could be interpreted as having negative social evaluative connotations, such as perceptions of their own anxiety or an audience member yawning. These stimuli become associated with verbal, physical, or behavioral responses, such as rapid speech, more anxiety-related sensations, and avoidance behaviors. As these associations form, two additional cognitive biases occur: an overestimation of the probability of negative evaluation (e.g., I will be laughed at) and exaggerated cost that would follow poor performance (e.g., my boss will fire me). As will be discussed later, change in cost biases have been associated with successful treatment (Foa et al., 1996).

7.3 Evidence-Based Treatment Approaches

Despite the chronic course and high degree of impairment seen in social anxiety disorder, several treatments have been found to be effective in clinical and community studies. Approaches that have shown some evidence of efficacy include a variety of cognitive-behavioral treatments, such as therapeutic exposure, cognitive therapy, applied relaxation, and social skills training, as well as pharmacological interventions including monoamine oxidase inhibitors (MAOIs), selective-serotonin reuptake inhibitors (SSRIs), anxiolytics, and beta-blockers. Of psychological treatments, exposure-based treatments remain the most studied, so they will be the primary focus of this review.

7.3.1 Exposure-Based Interventions

Exposure therapy, effective in other anxiety disorders (Barlow & Beck, 1984), is based on the concept that fear of social situations is maintained by repeated avoidance of these situations. This is disrupted when individuals with social anxiety disorder are instructed to approach feared situations and remain in them until experienced anxiety symptoms decrease.

By experiencing a reduction and eventual absence of anxiety in feared situations, anticipatory anxiety and avoidance decreases as well. Given the prominence of cognitive basis in social anxiety disorder discussed above, early treatment researchers hypothesized that adding a cognitive component to treatment should produce beneficial treatment gains (Butler, 1985). The cognitive component typically targets distorted cognitions regarding feared situations and replaces them with adaptive cognitions, based on Beck's model (Beck & Emery, 1985).

One of the most studied combined cognitive and exposure treatments is Heimberg's cognitive-behavioral group therapy for social anxiety disorder (CBGT; Heimberg & Becker, 2002). Heimberg, Becker, Goldfinger, and Vermilyea (1985) showed CBGT, comprised of imaginal exposure, performance-based exposure during session, cognitive restructuring, and homework involving exposures practiced in group, resulted in significant reduction in several measures of anxiety, which were maintained 6 months later for a majority of participants. In comparing CBGT to a credible attention control group involving education and support, Heimberg, Dodge, Hope, Kennedy, and Zollo, Becker (1990) found that, though both groups improved significantly on multiple measures, the CBGT group improved more on several measures as well as being rated as more improved 6 months later. This difference was attributed to continued improvement on positive and negative self-statements and may reflect continued use of coping strategies learned in CBGT. At follow-ups conducted between 4 and 6 years posttreatment, gains made by individuals who completed CBGT show good stability, with anxiety ratings by the individuals, independent raters, and behavior test judges being closer to nonanxious controls than those who completed the control condition (Heimberg, Salzman, Holt, & Blendell, 1993). In a large study of 133 individuals randomly assigned to CBGT, phenelzine (an MAOI), a pill placebo, or a credible control (educational-supportive group therapy), both CBGT and phenelzine had higher proportions of responders at the end of treatment than the two control conditions, though they were not significantly different from each other (Heimberg et al., 1998).

Although the group format was originally thought to be important to provide opportunities to practice exposures, other studies showed group and individual therapy had similar efficacy (Lucas & Telch, 1993). The primary advantage of group therapy is cost-effectiveness (Scholing & Emmelkamp, 1993). However, many nonresearch settings have insufficient client flow for group treatment, so CBGT was adapted to an individual format (Hope, Heimberg, Juster, & Turk, 2004). In a comparison of the individual treatment based on the manual (Hope, Heimberg, & Turk, 2006; Hope et al., 2004) to wait-list controls, individual cognitive-behavioral therapy (CBT) showed large treatment effects that were maintained at 3-month follow-ups (Ledley et al., in press).

Rodebaugh, Holaway, and Heimberg (2004) identified five meta-analyses (Chambless & Hope, 1996; Fedoroff & Taylor, 2001; Feske & Chambless, 1995; Gould, Buckminster, Pollack, Otto, & Yap, 1997; Taylor, 1996) that examined the effect sizes of cognitive-behavioral treatment for social anxiety, defined as including cognitive restructuring with and without exposure, social skills training, and/or applied relaxation. In these studies, moderate to large controlled effect sizes were found when CBT was compared to wait-list controls. Similarly, moderate to large uncontrolled effect sizes were found when comparing active treatments. Furthermore, treatment gains were maintained at follow-up assessments, between 2 and 12 months following treatment completion. No differences were found between the individual and group treatment (Fedoroff & Taylor, 2001; Gould et al., 1997; Taylor, 1996). There is some evidence that some versions of CBT without exposure, including social skills training, cognitive restructuring, or applied relaxation, result in nonsignificantly smaller effect sizes when

compared to cognitive restructuring combined with exposure (Fedoroff & Taylor, 2001; Gould et al., 1997; Taylor, 1996). Rodebaugh et al. (2004) point out that the nonsignificant differences may be due to insufficient power in these comparison studies.

From these studies it becomes clear that CBT, whether as an individual or a group treatment, is an effective treatment for social anxiety disorder. Since dismantling studies of CBT indicate that exposures are the most important part of CBT (Hope, Heimberg, & Bruch, 1995), it becomes necessary to ask whether the added cognitive restructuring is useful. Evidence from clinical studies is inconsistent. Earlier studies by Mattick and Peters (1988) and Mattick, Peters, and Clarke (1989) indicate that cognitive restructuring, when used with exposure, is associated with more improvement on measures of irrational beliefs and negative self-evaluation, the most improvement on behavioral assessments, and the improvement of social phobic symptoms at follow-up. Meta-analyses, however, do not consistently show CBT to be superior to exposure-alone therapy (Fedoroff & Taylor, 2001; Feske & Chambless, 1995; Gould et al., 1997) though Taylor (1996) indicated that, while CBT was not significantly different from exposure only or social skills training, it did tend to show the largest effect size. The general consensus is that exposure is a key aspect of treatment for social anxiety disorder and likely the most potent aspect of the combined treatment packages.

7.3.2 Cognitive Therapy

One promising newer treatment that emphasizes cognitive interventions rather than exposure is Clark's cognitive therapy for social anxiety disorder (Clark, 1997, 2001). This treatment focuses on disrupting factors that serve to maintain social anxiety by helping clients to understand which behaviors serve to maintain social anxiety, evaluate their performance while dropping these safety behaviors during behavior experiments, reduce self-monitoring, and shift their attentional focus to the external environment. Cognitive restructuring is also used in order to address dysfunctional cognitions that occur both during behavior experiments and during anticipatory rumination (Clark, 1997). Clark et al. (2003) compared this cognitive therapy to SSRI fluoxetine plus self-exposure to approximate routine practice of physicians in the UK, and with placebo plus self-exposure. Assessments at pretreatment, mid-treatment, posttreatment, after three booster sessions, and at 12-months posttreatments included an independent ADIS-IV (Brown, DiNardo, & Barlow, 2004) assessment and six self-report measures. At mid-treatment, cognitive therapy was more effective than both the medication plus self-exposure group and the placebo plus self-exposure group, which were not significantly different from each other. At posttreatment, this pattern was seen again. Additionally, both the cognitive therapy and the medication groups showed significant improvement on all measures, while the placebo group showed improvement only on the composite and six of the seven individual measures. At the end of the booster sessions, cognitive therapy was still superior to the medication group on four of the seven measures, with no loss of treatment effects, while the medication group improved on three measures. At 12-month follow-up, cognitive therapy was again superior to the medication group on four measures, but neither group showed any further treatment gains or loss of established gains. Clark et al. (2003) compared the same cognitive therapy to an exposure plus applied relaxation condition and to a wait-list control group. At posttreatment, both active treatments were superior to the wait-list control

on all measures and behavior tests, and showed significant treatment gains when compared to pretreatment assessments. Additionally, cognitive therapy was found to be superior to exposure plus applied relaxation. At 3-month follow-up, cognitive therapy was superior to the exposure condition on all measures of social anxiety, while at 1-year follow-up this was only seen in five of the seven measures. However, during this follow-up period, 44% of the exposure group sought out additional treatment, compared with 6% of the cognitive therapy group. This cognitive therapy has also been compared to a 3-week intensive group format and a treatment as usual condition (Mörtberg, Clark, Sundin, & Wistedt, 2007). Here, all treatments produced significant reductions in symptoms of social anxiety, and the original cognitive therapy format outperformed the intensive 3-week format and treatment as usual condition, which consisted of some type of antidepressant or benzodiazepine. It is interesting to note that the intensive group produced treatment gains equivalent to 12 months of medication in only 3 weeks.

Although Clark's cognitive therapy includes some therapeutic exposure, the focus differs from the typical combined exposure and cognitive restructuring treatment in that exposures are used as behavioral experiments in service of the cognitive work rather than being a primary mode of treatment. The treatment also emphasizes some specific video feedback that has some empirical support on its own (Harvey, Clark, Ehlers, & Rapee, 2000). Clark's cognitive therapy is promising with large effect sizes. However, there is less evidence that its sophisticated procedures are transportable to other research or clinical settings. In contrast, more traditional cognitive therapy and exposure packages have been successfully demonstrated in numerous locations.

7.4   Exposure Plus Social Skills Training

Similar to the reasoning for dismantling CBT, there is also interest in determining whether adding treatment components would increase the effectiveness of CBT. Since there is evidence that some individuals with social anxiety disorder have deficiencies in social skills and/or anxiety-induced inhibition of social functioning (Hopko, McNeil, Zvolensky, & Eifert, 2001), adding a social skills training (SST) is a theoretically valid addition to exposure-based treatment (Baker & Edelmann, 2002; Stopa & Clark, 1993). SST involves teaching individuals how to effectively use socially appropriate verbal and nonverbal language in interpersonal communication. It has shown to be effective for individuals with high levels of social anxiety (Trower, Yardley, Bryant, & Shaw; 1978) as well as when combined with exposure for social anxiety disorder. (Turner, Beidel, & Cooley-Quille, 1995; Turner, Beidel, Cooley, Woody, & Messer, 1994). Furthermore, 2-year follow-ups show continual improvement (Turner, Beidel, & Cooley-Quille, 1995). To evaluate effectiveness of SST within a CBT framework, Herbert et al. (2005) integrated a psychoeducational component regarding speech content, paralinguistic features of appropriate speech, and nonverbal behavior within Heimberg's original CBGT. Specific target behaviors were chosen for each participant and were practiced within, and outside of, session. In order to allow for adequate time for exposures within session, cognitive restructuring was reduced by approximately 5 min per exposure. Results indicate that the SST integrated CBT treatment was significantly more effective than CBT without SST as well as having a larger effect size than previous studies of CBGT.

7.4.1 **Pharmacotherapy**

In addition to psychological interventions that have been shown to be efficacious in the treatment of social anxiety disorder, there are a number of studies investigating pharmacological treatments as well. In the study discussed above that compared phenelzine to CBGT, a pill placebo, and a credible psychotherapy control group, Heimberg et al. (1998) found that while phenelzine achieved a higher response rate at mid-treatment, the two active treatments were not significantly different at 12 weeks. Furthermore, Liebowitz et al. (1999) found that at follow-up, 50% of the phenelzine responders had relapsed, compared to 17% of the CBGT group. This indicates that while phenelzine may reduce symptoms faster than CBGT, these gains are not maintained once treatment is withdrawn.

A meta-analysis of 24 studies comparing either CBT or pharmacological treatments to control conditions found that treatment effect sizes were not significantly different from each other, 0.74 for CBT and 0.62 for pharmacological, though the lack of follow-up data in many studies prevents comparison of the maintenance of treatment gains between CBGT and medication (Gould et al., 1997). More recent meta-analyses have also found SSRI's to be more effective than placebo at reducing symptoms of social anxiety (Fedoroff & Taylor, 2001; Hedges, Brown, Godfey, & Larcher, 2007). Finally, beta-blockers, though widely used for performance anxiety, have shown little to no effect in the treatment of social anxiety (Turner, Beidel, & Jacob, 1994).

Combining CBT with pharmacological treatment, though useful for certain other disorders (e.g., depression; TADS team, 2007), is only a valid approach if the combination yields greater effects than either treatment alone. It is also possible that combining pharmacological treatment with CBT may inhibit mechanisms of treatment during CBT, since clients may be unable to reach peak anxiety levels during exposures (Otto, Smits, & Reese, 2005). In a meta-analysis comparing CBT, pharmacological treatment, and combination treatment, Foa, Franklin, and Moser (2002) concluded that not only was there insufficient research conducted in this area, but that the studies that had been conducted showed combining treatment modalities conferred neither an advantage nor a disadvantage. In a more recent study, Davidson et al. (2004) conducted a randomized, double-blind, placebo-controlled study comparing comprehensive cognitive-behavioral therapy (CCBT; a combination of exposure, cognitive restructuring, and social skills training) to CCBT with placebo, CCBT with fluoxetine, fluoxetine alone, and to placebo alone. Again, all active treatments were found to be more effective than placebo at posttreatment, but were not significantly different from each other.

Very recent research has begun in the use of the memory enhancer d-cycloserine (DCS) to augment the effectiveness of exposure. This is based on animal studies indicating DCS functions to aid in the consolidation process of learning (Davis, Ressler, Rothbaum, & Richardson, 2006), though it does not do so by increasing experienced anxiety (Bailey, Papadopoulos, Lingford-Hughes, & Nutt, 2007). Hofmann (2007) discusses the biological and psychological mechanisms thought to be affected during exposure therapy and the effect of DCS on these systems. By administering this drug prior to exposure therapy, Hofmann et al. (2006) and Guastella et al. (2008) provide evidence that DCS augments the effectiveness of exposure for social anxiety disorder. Though these results require further replication and comparison to traditional CBT in social anxiety disorder, they represent a promising new direction for improving the treatment efficacy of current therapies.

7.5   Mechanisms of Change Underlying the Interventions

Despite the fact that therapeutic exposure has long been used with anxiety disorders in general with an early emphasis on conditioning models (Mower, 1947), little is known about what learning principles might underlie the treatment. In their review of treatment mechanisms for social anxiety disorder, Heimberg and colleagues (Rodebaugh et al., 2004) conclude that individuals may learn new associations but that old learning does not disappear, based on Bouton's work (Bouton, 2002; Bouton & King, 1986).

Cognitive models of social anxiety disorder highlight a specific pattern of interactions between cognitive biases, physical sensations, and behavioral responses in the maintenance of social anxiety. Rapee and Heimberg (1997) described a model in which socially anxious individuals, who expect negative evaluation from others and perceive this evaluation as highly important, shift their attentional resources away from the task at hand and instead focus on both their mental representations of their performance and on any signs of negative evaluation in their environment. This shift both increases the probability of detecting any signs of anxiety or negative evaluation while increasing the possibility of diminished task performance due to a lack of focus. Their perceptions of their own performance and the evaluations from others also typically include cognitive biases described above. Anxiety results when their perceptions of their performance fall short of what they think their audience expect in the given situation. Probability biases, such that socially anxious individuals expect they will fail more often than nonanxious controls, coupled with a high degree of importance on successfully completing the task, result in anticipatory anxiety as well (Foa & Kozak, 1986). Safety behaviors, such as avoidance or distraction, are often used to temporarily reduce anxiety in the short-term while acting to maintain the disorder in the long-term.

Specific components of current psychological treatments are aimed to target specific maintenance factors in order to interrupt the cyclical nature of the above model. Within CBT, cognitive restructuring serves to address, challenge, and correct probability biases, cost biases, and dysfunctional core beliefs that are present when threatening situations are encountered. The end results are realistic evaluations of several elements of threatening situations, including competency of performance, likelihood of others noticing anxiety symptoms, the likely outcome if failure occurs, and less global dysfunctional core beliefs. Exposure, during which an individual's anxiety levels rise to a peak during stressful tasks and then allowed to decrease over time without safety behaviors or avoidance, is thought to function by moderating the cost biases associated with the task. Using Foa and Kozak's (1986) theory of emotional processing, exposures conducted in this manner act to first activate fear structures by inducing anxiety symptoms in feared situations. As anxiety symptoms decrease naturally, the individual is able to reevaluate the cost of remaining in the feared situation in an adaptive way. Exposure also acts to introduce contrary evidence to fear structures, such that an individual must incorporate a reduction of anxiety into associations with feared situations, thereby breaking the strong association of fear and the situation itself.

These theoretical accounts of the mechanisms of change have only recently become the focus of study. Several studies have found that changes in judgment biases are related to treatment outcome. Foa et al. (1996) and Hofmann (2004) both found that reductions in cost bias (high cost if feared social outcomes occur) were related to treatment outcome. In contrast, reduction in probability bias (likelihood of feared outcomes) accounted for clinical change in McManus et al. (2000). Change in cost bias was unrelated to outcome after accounting for

probability bias in McManus et al. In the most sophisticated study to date, Smits, Rosenfield, McDonald, and Telch (2006) examined within and across session change in cost and probability bias in a three-session intensive exposure-based treatment of public speaking anxiety. Their analyses clearly showed reduction in probability bias is the most likely treatment mechanisms.

7.6 Basic Competencies of the Clinician

None of the research on psychosocial treatment of social anxiety disorder has examined what type or level of therapist training is necessary to achieve good outcomes. Nor has research focused on therapist characteristics, background, or experience that might be ideal. However, in 2 decades of conducting these interventions and training therapists with various backgrounds, there are numerous key points of competence that we have identified. The discussion of competencies makes some assumptions that are important to identify first.

One assumption made in the discussion of competencies is that the therapist has general competency in cognitive-behavioral interventions. Although what this might specifically mean could fill a volume on its own, in general it is assumed that the following are true:

(a) The therapist is able to conceptualize cases from a cognitive-behavioral perspective (Persons, 2008).
(b) The therapeutic relationship is collaborative (Beck, 1995).
(c) The therapist is able to engage in fundamentals of cognitive-behavioral therapy such as effectively using homework (Tompkins, 2004), self-monitoring, and psychoeducation.
(d) The therapist monitors the client's progress and adapts the treatment as needed to maximizes outcomes (Persons, 2008).

The second assumption is that the therapist has general competency in psychological interventions including skills such as establishing rapport, conducting a clinical interview, managing session time, making a proper diagnosis, etc. Again, a full discussion of these competencies is beyond the scope of this chapter.

7.6.1 Exposure and Cognitive Restructuring

As was apparent in the review above, the fundamental component of the psychosocial interventions with the most scientific support is therapeutic exposure. Various sources describe how to conduct exposure for treatment of social anxiety disorder (Heimberg & Becker, 2002; Hope et al., 2004, 2006; Turner, Beidel, & Cooley-Quille, 1997). Therefore, the first basic competency is the ability to conduct exposures, including developing a hierarchy and adapting the exposures as needed based on individual client needs. In most of the research protocols, the exposure is graduated and includes both role-played or in-session exposures and in vivo exposure.

Most of the psychosocial interventions with strong scientific support also include a cognitive therapy component, typically identification and rational analysis of dysfunctional thoughts based on the work of Beck (e.g., Beck & Emery, 1985). The second basic competency is the ability to integrate cognitive restructuring with therapeutic exposure. Therapeutic exposure

provides an excellent opportunity for cognitive restructuring by activating the anxiety-related cognition and providing an opportunity to gather disconfirming information to challenge irrational cognition. Thus, the second basic competency is to capitalize on the reciprocal process of anxiety-eliciting exposure and cognitive intervention.

These first two competencies reflect the basic treatment components. The following basic competencies include aspects of treatment in which the psychopathology of social anxiety disorder interacts with treatment to create unique challenges.

7.6.2 Managing the Therapeutic Alliance

The therapeutic relationship is an interpersonal relationship, albeit with certain legal and ethical obligations due to its unique nature. Clients with social anxiety have a disorder that specifically impairs interpersonal relationships, adding additional challenges to psychotherapy. Individuals with social anxiety disorder are, by definition, highly fearful about interpersonal evaluation. This can play out in the therapeutic alliance in a number of ways. First, socially anxious individuals are hypersensitive to cues of negative evaluation and, as noted above, are prone to negatively misinterpret minor negative or even neutral cues (Clark & Wells, 1995) from the therapist. For example, a therapist's inquiries over whether a client read assigned psychoeducational material may be perceived as criticism by a socially anxious client when a nonanxious client would understand that the therapist is simply trying to ascertain what material needs to be reviewed in session. Furthermore, because fear of negative evaluation often limits assertiveness (Holt, Heimberg, Hope, & Liebowitz, 1992), the clients would be unlikely to defend themselves against perceived, but unintended, criticism.

It is impossible for a therapist to guard against all possible triggers of negative evaluation fears with socially anxious clients and it would probably not be therapeutic to do so anyway. However, one does not want this fear to lead to behavioral avoidance of the therapy sessions. One basic competency is for the therapist to have heightened awareness of how he or she will be perceived by the client and to closely monitor the therapeutic alliance for ruptures. Heightened attention to nonverbal communication and mismatches between the client's verbal and nonverbal behavior will help therapist detect when their messages are poorly received.

If a client's fear of negative evaluation is evoked by the therapist unintentionally, then it can typically just be handled within the treatment model. Rather than simply offering reassurance, the therapist can gently help the client evaluate the evidence that a negative evaluation was intended by the therapist or that the client did something wrong, or at least something that was important. This can be an emotionally intense discussion for clients so it should not occur frequently and should end with the therapist confirming that the more benign explanations that were generated are what were intended. The benefit of such a discussion can quickly spiral downward if the client then perceives another error for their original misperception, so normalizing their reaction (e.g., "This sort of thing often happens as we work our way through this treatment.") can help draw the discussion to a close.

Certainly every therapist–client pairing is unique and each pair will find their own way of working together. However, a general approach that is gentle and collaborative often works

well. Irreverence and humor that might be ideal with certain clients is unlikely to be effective with socially anxious individuals.

7.6.3 Tolerating Client's Affect and Identifying Avoidance Strategies

A basic skill in training for mental health professionals is to tolerate client's experience and expression of negative affect in the session. Exposure-based treatments for anxiety disorders, including social anxiety disorder, demand this skill because the goal of treatment is to induce anxiety via therapeutic exposure. Inexperienced therapists may understand this intellectually but then accept as true a client's irrational cognition that anxiety is bad and that they will not be able to tolerate experiencing it. A basic tenet of exposure-based treatment is that anxiety will rise, plateau, and then habituate, if one fully engages with the feared stimuli. Therapists need to trust this as well and allow clients to fully experience their anxiety, without distracting them or interrupting the experience. The key is to pick exposure situations on a graduated basis so that the anxiety is not overwhelming and then join the client in tolerating the anxiety evoked by the exposure. An inexperience therapist who is not confident in their skills with exposure-based therapy may well have higher anxiety than their clients during the first exposure sessions they conduct. Such therapists should use the cognitive restructuring skills to address their own dysfunctional thoughts about conducting exposure.

Because the motivation to avoid or escape feared situations is so strong, clients will often use subtle and not so subtle methods of avoiding the experience of anxiety in session. Therapists who are uncomfortable with client's affect may collude in this pattern of behavior. However, clients can also be very subtle with avoidance and the therapist must be able to distinguish avoidance behavior from other events. When facing an impending exposure, clients may suddenly have other issues that are more pressing than their social anxiety, they may start asking questions about the treatment procedures, or they may schedule themselves, so they may have to leave the session early. An astute therapist can identify avoidance when it occurs and gently confront it.

7.6.4 Effective Psychoeducation

Psychoeducation about the nature of social anxiety, explaining the rationale of treatment and helping the client develop anxiety management skills such as cognitive restructuring all require a teaching component in cognitive-behavioral therapy. Reading materials and worksheets can help communicate this information and many clients will be able to get the primary information through at-home reading. However, these materials are most effective, if they can be shared in an interactive fashion so that the client understands how the concepts apply to themselves. Beginning therapists often have difficulty covering psychoeducational material without lecturing to clients. Socially anxious clients may find therapy itself an anxiety-provoking experience and encourage a lecture by taking on a passive role in psychoeducational sessions. A more skilled therapist can review the material interactively, especially if the client has done some background reading or self-monitoring ahead of time. Ideally, a discussion can develop in which the therapist highlights the primary topics with the client offering personal examples. A skilled therapist may also be able to draw the material out of the client to illustrate key points, and then just provide some vocabulary to describe the experience or put the client's experience in a conceptual model.

7.6.5   Knowledgeable About Social Anxiety Disorder

As with any presenting problem, there is no substitute for the therapist having basic knowledge of the psychopathology literature for social anxiety disorder. Even 20 years ago, most therapists knew very little about the disorder. Research was so lacking that in 1985 Liebowitz et al. called social anxiety the "neglected anxiety disorder" (Liebowitz et al., 1985). Clearly, that is no longer the case. However, clinicians who were trained more than 20 years ago may not have had much exposure to the psychopathology and treatment literature for social anxiety disorder, unless they have pursued continuing education on the topic. There is a number of reasons that knowledge of psychopathology literature is helpful in treatment. First, making an accurate diagnosis requires knowledge of the diagnostic criteria with a mental representation of a prototypical case to guide diagnostic decision making. Second, understanding the common cognitive biases will keep the clinician from being misled by a socially anxious individual's distorted evaluations of their own and others' behavior in social interactions. Third, understanding maintaining factors in the disorder such as behavioral avoidance and safety behaviors will alert the clinician to needed treatment targets as well as client activities that might sabotage treatment.

7.6.6   Conducting Treatment with Clients with Concurrent Pharmacotherapy

Many clients who come for psychosocial interventions do so, in part, because pharmacotherapy is problematic or yielding partial remission of their social anxiety. Others may start, or consider starting, a pharmacological intervention in the course of treatment. All of these types of cases present challenges to a clinician conducting cognitive-behavioral therapy for social anxiety disorder. Treatment outcome studies typically eliminate individuals who are already taking medication or require that medications and their dosages be stabilized for the course of the clinical trial. Such restrictions are usually not part of a nonresearch practice, leaving limited empirical data on CBT concurrent with a changing medication regime.

Given that the research literature reviewed above suggests CBT and certain medications are similarly effective for social anxiety disorder and there is no evidence of added benefit of combined CBT and pharmacological treatment, then best practice would suggest it is prudent to initiate one treatment, determine whether it is helpful and then add the other treatment only if necessary. Whether the first-line treatment is CBT or medication depends upon the availability of the treatments, the client's inclination and any factors which may contraindicate one of the treatments (e.g., medical problems may contraindicate medication; low motivation may contraindicate CBT). (See Rodebaugh and Heimberg (2005) for a further discussion of combined treatment).

For clients receiving concurrent medication and CBT, a number of areas of therapist competency is important. If the person conducting the CBT is not the prescribing physician, then it is essential that the CBT therapist coordinate treatment with the prescribing physician. The lack of assertiveness common in social anxiety (Holt, Heimberg, Hope, & Liebowitz, 1992) likely means that a therapist cannot depend upon a client to communicate between different providers, especially early in treatment. A normal course of CBT means that anxiety levels will increase as the individual reduces avoidance. This could be misinterpreted as deterioration by a prescriber, prompting a change or increase in medication at a crucial point in therapy. Similarly, other providers may work at cross-purposes inadvertently. For example, avoidance

behavior may be recommended as a coping strategy when the CBT therapist is encouraging a client to face their fears.

Another important competency is managing client's attributions for change. The cognitive biases in social anxiety may mean that a client attributes all change to medication and none to their own efforts, despite clear evidence to the contrary. Cognitive interventions can be used to address such distorted thinking (Beck, 1995).

7.6.7 Treatment with LGB Populations

Members of the lesbian, gay, and bisexual community (LGB) have been found to exhibit higher levels of fear of negative evaluation and social interaction anxiety than the general population (Pachankis, & Goldfried, 2006). Coupled with above average utilization rates of psychotherapy (Liddle, 1996; Morgan, 1992; Bradford & Ryan, 1988), therapists should expect to see LGB clients at some point in their career. While recommendations for general competencies in conducting therapy with LGB clients can be found elsewhere (Pachankis & Goldfried, 2004; Walsh & Hope, in press), there are several competencies specific to social phobia. First, in terms of diagnosis, it is important to determine the basis of the fear of social/performance situations the client is reporting. For instance, a client who is afraid of public speaking because others will think signs of anxiety are indicative of failure/inadequacy is very different from a client who is afraid of public speaking because the audience will make assumptions about their sexuality. If the latter is the case, a diagnosis of social phobia should not be given if the client does not recognize the fear as unreasonable or excessive. For example, if LGB clients are afraid that job loss will result from revealing their sexual orientation, the therapist should keep in mind that this may be a very real consequence, occurring in many places with no legal recourse as there is no federal nondiscrimination in employment protection based on sexual orientation (Human Rights Campaign, 2009). This suggests the implementation of a modified treatment approach, such that cognitive restructuring focuses on identifying the actual versus perceived likelihood of these consequences and examining the evidence to contradict negative automatic thoughts (e.g., will absolutely no one like you if they find out you are gay?). Throughout this, the therapist should recognize that there is the possibility that some fears, such as familial estrangement or hate-crime victimization, may be wholly justified and even adaptive in nature. If the fears are found to be particularly adaptive, then challenging them may be detrimental to the client.

7.7 Expert Competencies

7.7.1 Comorbid Disorders

Social anxiety often occurs in the context of another disorder. Studies show 56.7% of individuals who seek treatment for social anxiety also meet diagnostic criteria for another disorder (Magee et al., 1996). Often additional diagnoses are anxiety disorders but social anxiety disorder may also be present with individuals with serious mental illness such as bipolar disorder or a psychotic disorder. In these latter cases, appropriate treatment for the primary disorder must occur first. However, once an individual is stabilized, it may be important to treat social anxiety to facilitate participation with treatment programs and improve long-term social functioning.

These cases require the clinician to have expertise with the best cognitive-behavioral treatments for bipolar disorder or psychotic disorders as well as expertise in treating social anxiety in order to blend the intervention into an effective hybrid.

There are several ways in which exposure and cognitive restructuring for social anxiety disorder must be adapted. First, exposures must be conducted in such a way that they are not unduly stressful to trigger a relapse in symptoms of the primary disorder. This can be done by progressing more slowly or adding some coping skills or medication to help moderate the anxiety response. Second, the therapist must to able to distinguish cognitive symptoms that are a function of the primary disorder, not the social anxiety. For example, with an individual with schizophrenia, this may include disentangling thoughts that are part of a paranoid delusion from socially anxious thoughts about negative evaluation by others. Third, the therapist must be able to adjust the pace of treatment to suit the client's level of functioning. Many clients with serious mental illness have cognitive deficits that will necessitate streamlining or spending more time on psychoeducational material or coping strategies.

7.7.2 Avoidant Personality Disorder

There has been substantial controversy over the years about the relationship between avoidance personality disorder (APD) and social anxiety disorder. Evidence suggests that individuals who meet DSM criteria for both disorders have more severe symptoms than individuals with only social anxiety disorder, but that the trajectory of change in cognitive-behavioral treatments is similar (Herbert, Hope, & Bellack, 1992). This suggests that treatment may need to be longer for these comorbid cases. Our clinical experience suggests that individuals with APD may be more likely to react with anger, the "fight" aspect of the "fight or flight response," when challenged to face their fears. Such anger can be disruptive to the therapeutic alliance but can be processed much as one would process attempts to avoid facing fears in standard exposure treatments.

7.7.3 Ethnic Minority Clients and Language Differences

While there has been little research regarding the effectiveness of exposure treatment for social anxiety disorder in the North American ethnic minority groups per se, there is some evidence that certain minority groups delay treatment for mental health problems in general, including social anxiety (Bui & Takeuchi, 1992; Hsu & Alden, 2008; Zhang, Snowden, & Sue, 1998). A full discussion of multicultural competency is beyond the scope of this chapter but cultural variations in social behavior should be considered in diagnosis and treatment. One consideration that should be noted is that frequency and presentation of nonverbal skills often vary depending on the client's cultural background and level of acculturation. For this reason, certain behaviors (e.g., avoidance of eye contact, unassertive posturing, etc.) should not necessarily be noted as symptoms of social anxiety disorder. Instead, they should be considered within the larger framework of the client's cultural background. Similarly, verbal and nonverbal behavior that is elicited or encouraged in exposure should be culturally appropriate otherwise the client's heightened anxiety may be a functional alarm of a violation of cultural norms.

In an increasingly interconnected and diverse world, it is not uncommon for a therapist to be working with a client who does not share the same primary language. Usually therapy is conducted in the therapist's primary language and it is expected that the client will be sufficiently fluent to benefit from the services. Subtleties of language that emerge in cognitive restructuring can be a challenge for nonnative speakers. The therapist must take care to insure that communication is clear and accurate. Treatment usually involves written records for homework for exposure and cognitive restructuring. Although some clients resist the idea at first, we have typically had clients do this work in their primary language and then translate as needed for the therapist in session. Working in the primary language is especially important later in treatment when cognitive interventions may be focusing on core beliefs and processing historical events and/or key familial messages that underlie dysfunctional expectations and standards of behavior. Issues about language with a client must be handled with sensitivity and reference to the case formulation as confidence in the language of the majority culture and/or handling prejudice and discrimination may also be aspects of the individual's social anxiety.

7.7.4 Client Has a Noticeable Impairment

Most individuals who seek treatment for social anxiety greatly overestimate their deficits in social situations (Norton & Hope, 2001). However, occasionally an individual seeks treatment due to heightened anxiety and self-consciousness about an impairment that is readily visible to others and may actually lead to some negative social evaluation. Such impairments may include stuttering, disfigurement, or physical impairments such as a limp or cognitive disability following a traumatic brain injury. In such cases, treatment as usual must include helping the individual make a realistic assessment of social impact of the impairment. Therapeutic exposures to a range of possible reactions by others are needed so that the client has a clear coping plan for likely scenarios. Cognitive interventions will likely also focus on giving the impairment a functional and realistic weight in the client's overall self-evaluation, rather than having the impairment as a primary defining feature of his or her self-identity.

7.7.5 Client Has Severe and Noticeable Physiological Symptoms of Anxiety

Individuals with social anxiety disorder are concerned that their anxiety will be visible to others (Hope et al., in press; Clark & Wells, 1995), but typically symptoms are not as visible as feared. Occasionally, individuals who present for treatment have highly apparent symptoms such as blushing, sweating, or tremor (Bögels, 2006). Any physical causes for such symptoms should be evaluated and treated first. Treatment in these cases must be two-pronged. First, treatment as usual should proceed with the hope that decreased anxiety will result in less frequent or less intense symptoms. Second, the symptom can be handled as described above for noticeable impairments. With symptoms which may change over time, the intervention should also include realistic assessment of the likely occurrence of the symptom, its visibility and likely

reactions by others if it does occur. If a symptom persists, then the clinician should investigate whether there are specific interventions for that particular symptom such as task concentration training for blushing (Bögels, 2001). The sources discussed below for transition to expert competency can be used for such searches.

7.7.6 Rapid Treatment

In research protocols, psychosocial treatment for social anxiety involves 12–16 weekly sessions. There is no research on whether this is ideal scheduling or duration for the treatment and occasionally individuals present for treatment who need to progress much more quickly due to an upcoming event. Certainly, sessions can be scheduled more frequently and the exposures can be tightly focused on the key upcoming event. Given the data reviewed above indicating that exposure is the most important element in combined treatment packages, rapid treatment should focus primarily on exposure with limited cognitive interventions. It is also possible to engage the client in the most challenging exposures sooner, rather than the traditional graduated approach. Flooding was a common approach in early exposure-based treatment for anxiety disorders (Barlow, 2001), but was largely abandoned because it is so difficult to tolerate. There is no known research on flooding as an intervention for social anxiety disorder. However, data with other disorders suggest no reason it would not be effective. Flooding exposures must be carefully calibrated so that the client does not escape and refuse to reengage, leading to possible iatrogenic effects. Before engaging in any rapid treatment plan for social anxiety for a specific upcoming event, therapists should also evaluate whether medication alone or combined with the rapid treatment should be considered. For anxiety in an infrequent event, especially in the absence of other clinically significant social anxiety, evaluation for an anxiolytic medication that can be taken only for the event itself may be the most efficient treatment option.

7.7.7 Lack of Social Network for In Vivo Exposures

Individuals with more severe social anxiety disorder or who have other comorbid diagnoses may have avoided social interactions for such a long time that they have a very limited social network. Such individuals may live alone, be unemployed or work at job that require little social interaction and have few friends or acquaintances. It will be difficult for them to overcome their social anxiety if they have little opportunity to practice. Therapists treating such cases will need to have extensive knowledge of specific local resources for potential friendships or dating partners. As many individuals with several social anxieties also experience economic hardship (Schneier, Hornig, Liebowitz, & Weissman, 1992), it is important that these resources include many that have little cost. Examples include volunteer positions, welcoming religious groups, adult education classes, and groups with a specific focus such as single parents or a shared cultural heritage. Certainly, the client can and should pursue the opportunities on their own, but therapy is greatly facilitated if the therapist can direct him or her towards an experience that is likely to be welcoming and successful.

7.7.8 Exposure Failure

Despite a therapist's best efforts, occasionally a therapeutic exposure will not go as planned and could be considered a failure in some way. A failed exposure would occur when the client refuses to engage in the exposure or escapes early, the client experiences confirmation that their worst fears are true or the client has an experience that has some significant social cost such as the loss of a relationship. It is the therapist's responsibility to choose exposures of appropriate difficulty and to direct therapy in a manner that limits the likelihood of negative consequences for the client. If an in-session exposure takes an unexpected turn in a nontherapeutic direction, the therapist needs to end or redirect the exposure as skillfully as possible. Any escape or avoidance should be addressed immediately and the client should be helped to enter a less threatening situation as soon as possible to avoid setting up a pattern of avoidance. The more avoided situation should be faced later. Very often aversive experiences for the client can be handled in cognitive restructuring by honestly agreeing that the experience was aversive, but then highlighting either the low probability of such an event happening again or the coping resources that the client can or did use.

7.7.9 Panic Attacks

Approximately 57% (Jack, Heimberg, & Menin, 1999) individuals with social anxiety disorder experience panic attacks in social situations. Most often these panic attacks do not require special intervention as the primary fear is of negative evaluation by others, not catastrophic misinterpretation of the symptoms as is found in panic disorder (Hofmann & Barlow, 2004). However, if comorbid panic disorder is present or the panic symptoms are especially bothersome, then techniques to manage the symptoms such as diaphragmatic breathing or cognitive therapy directed at the interpretation of the symptoms (Barlow & Craske, 2006) may be warranted. A full-blown case of panic disorder may require separate treatment that should be conducted before or after the treatment for social anxiety, depending upon the relative severity and specific needs of the case.

7.7.10 Cognitive Deficits that Interfere with Cognitive Therapy

Cognitive restructuring requires verbal proficiency and the ability to engage in logical analyses of the assumptions underlying key cognitions. At the most advanced level, it requires seeing common themes across multiple situations and the ability to engage in a self-regulation process to systematically think differently in the midst of anxiety-provoking situations. Many individuals who seek treatment for social anxiety do not have these skills due to limited intelligence, a traumatic brain injury, or other cognitive impairment. Such difficulties become readily apparent during the initial sessions when cognitive restructuring skills are introduced. An expert therapist should recognize what, if any, aspects of the cognitive work will be useful and rely more heavily on the exposure component of treatment. In many cases, the early cognitive work will yield a generic coping statement that can be used to help the client motivate themselves to engage in exposure without extensive analyses of negative thoughts in each specific situation.

7.8   Transitioning from Basic Competencies to Expert

Basic competency in cognitive-behavioral treatment for social anxiety disorder can be achieved via a combination of resources. These include reading books, chapters, and journal articles, practicing implementing treatment manuals and attending clinical workshops. Ideally, a novice clinician would also obtain clinical supervision by an expert in treatment of social anxiety. Learning the specific intervention is probably best achieved by first treating straightforward cases of no more than moderate severity without significant comorbid disorders. However, an expert clinician in one disorder (e.g., schizophrenia) is likely to develop skills in treating social anxiety as a secondary problem concurrent with that disorder.

Published reports of treatment studies are almost always based on adherence to a written treatment protocol. Although average clinicians outside of a research setting likely adapts such protocols to their own style and setting, our experience in training novice clinicians suggests that there is a benefit to learning the protocols as written first. Treatment protocols reflect a treatment program that has been carefully developed by experts in the disorder and was designed to maximize treatment outcome, as best as possible given current state of knowledge. Clinicians who wish to match the outcomes achieved in published studies should strive to conduct a similar treatment. Once the clinician has achieved proficiency in the treatment as it was designed, then experimentation with local adaptations can be attempted, carefully collecting data on client progress and satisfaction to determine whether the adaptations actually improve outcomes. If a clinician follows this process and finds useful adaptations, then there are several practice-oriented journals such as *Cognitive and Behavioral Practice* that welcome publication of such findings.

If clinical supervision or consultation is not available, then a clinician working in a more isolated situation could practice following one of the established treatment protocols, carefully tracking client progress with commonly used measures of social anxiety and comparing progress to published data, especially the numerous published case material (Chambless & Hope, 1996). These case reports tend to provide ongoing individual data, rather than just pretreatment and posttreatment group means.

If a novice clinician is having difficulty implementing treatment or is not achieving the expected client outcomes, then there are several resources available. First, the clinician could explore whether there are colleagues in the geographical area who have expertise in treatment of social anxiety disorder who might be available for formal or informal consultation. Local professional organizations often have referral lists that include areas of competence. National organizations such as Association for Behavioral and Cognitive Therapy (ABCT) and Anxiety Disorders Association of American (ADAA) have web-based referral systems that could be used to locate a local expert. Second, a clinician could post questions to relevant listservs to seek consultation. ABCT, for example, has a members' listserv that includes frequent discussions of clinical issues. This strategy broadens the available consultants well beyond the local geographic area. Third, a clinician could use one of the above strategies to find an established expert in a particular treatment who would have information on available training. Most developers for treatment programs conduct workshops as part of their dissemination efforts.

As a clinician gains more experience treating social anxiety, then it is time to move to more complex cases. All of the strategies and resources mentioned above can be used to develop this higher level of expertise. In fact, listsevs are frequently used by even expert clinicians to consult

on complex cases, especially when there is a need to design an idiosyncratic exposure situation. Ongoing assessment of client progress will help the clinician determine whether treatment is working as intended and provide feedback on what does and does not work, leading to further refinement of skills.

The transition from novice to expert in the treatment of social anxiety is likely to be facilitated if that clinician is treating a variety of anxiety disorder cases using the best evidence-based treatments. There are many similarities across the anxiety disorders, as noted by contemporary theories emphasizing the commonalities (Barlow, 2001). Indeed, there are some efforts to develop treatments that would span the disorders rather than a separate protocol for each anxiety disorder (Allen, McHugh, & Barlow, 2008; Norton & Hope, 2005). Although such cross-disorder protocols are not the first-line treatments, a quick perusal of established cognitive-behavioral interventions indicates that all include therapeutic exposure, anxiety management techniques (often cognitive restructuring), and strategies to overcome avoidance behavior. Thus, it seems likely that experience gained from treating panic disorder or obsessive-compulsive disorder, for example, is likely to generalize to treatment of social anxiety disorder.

7.9   Summary

Social anxiety disorder is a common, chronic anxiety disorder, starting early in life and often leading to significant impairment in functioning. The last quarter century of research has resulted in a good understanding of the psychopathology of the disorder and leads to the development of several effective treatments. More recently, theoretical and empirical work has started to disentangle the effects of psychosocial treatments in order to better understand some of the mechanisms of change. A clinician seeking to become competent in treating social anxiety disorder can draw upon a number of resources including published treatment manuals, a significant body of clinical literature and access to experienced providers via professional associations and the web. Because social anxiety impairs the interpersonal relationships, it presents some unique challenges to therapists. We have tried to describe those challenges and offer suggestions for overcoming them. Because cultural factors play a large role in social exchanges, cultural competency is particularly important, as described above. Social anxiety disorder occurs at a broad range of severity and comorbidly with serious mental illness, which can offer interesting and rewarding challenges for expert providers as well.

8 Schizophrenia

Jennifer D. Gottlieb · Kim T. Mueser

Abstract: Despite the often grave consequences of schizophrenia, in recent years several types of treatments have gained empirical support as helpful interventions to ease symptoms and improve functioning, including some antipsychotic medications, supported employment, assertive community treatment, integrated treatment for dual disorders, cognitive-behavioral therapy, family psychoeducation, illness management and recovery, cognitive remediation, and social skills training. The successes of these interventions have created evidence-based hope that schizophrenia is a condition that is manageable, treatable, and from which recovery is a very realistic possibility.

In this chapter, the authors first provide a summary of the elements of the aforementioned empirically-supported interventions for schizophrenia, and then discuss important basic skills that clinicians must develop in order to provide practical and effective treatment for this population, which include the adoption of a recovery and strengths-based, shared decision-making philosophy, knowledge about specific symptoms and impairment related to schizophrenia, solid assessment skills, the ability to elicit the client's natural supports, engage with the family, and interact well with an interdisciplinary treatment team. Additional basic skills in motivational enhancement, cognitive-behavioral therapy techniques, and the delivery of psychoeducation are also highlighted. Specific expert competencies are detailed, and the authors posit that skill in these interventions can significantly improve client outcomes, Strategies and resources for clinicians to gain expertise in specific treatments of interest for this disorder are discussed.

Finding opportunities for real-world practice and delivery of these practical and evidence-based treatments, coupled with ongoing supervision and consultation with a trained clinician, can have a tremendous effect on clinicians' abilities to deliver these important interventions, while conferring significant benefits to clients with schizophrenia over time.

8.1 Overview

Schizophrenia is a severe mental illness characterized by psychosis, apathy and social withdrawal, and cognitive impairment which results in problems functioning at work, in school, parenting, self-care and independent living, and interpersonal relationships. Schizoaffective disorder and schizophreniform disorder along with schizophrenia are often grouped together as schizophrenia-spectrum disorders. Diagnostic criteria for these three disorders are similar, genetic studies suggest shared vulnerability to all of them, and the same treatments are effective. Although we refer to schizophrenia in this chapter, the same information is applicable to the other disorders.

Schizophrenia is one of the most disabling psychiatric disorders and its treatment requires a disproportionate share of mental health services. For example, people with schizophrenia

occupy approximately 25% of all psychiatric hospital beds (Terkelsen & Menikoff, 1995) and, due to the episodic nature of the disorder, account for approximately one half or 50% of the inpatient admissions (Geller, 1992). The combined economic and social costs of schizophrenia place it among the world's top ten causes for disability-adjusted life years (Murray & Lopez, 1996), accounting for an estimated 2.3% of all burdens in developed countries, and 0.8% in developing economies (U.S. Institute of Medicine, 2001).

Schizophrenia usually has an onset in late adolescence or early adulthood, usually between the ages of 18 and 35. However, schizophrenia can also develop later in life, even after the age of 50, with a similar clinical presentation and psychosocial impairment (Howard, Almeida, & Levy, 1994; Howard et al., 1997). It is extremely rare for schizophrenia to develop before adolescence, and when it does, it is considered a different disorder (Cottone & Kumra, 2008).

The course of schizophrenia is usually an episodic one, with severity of symptoms fluctuating over time, and inpatient treatment is sometimes necessary for acute exacerbations when symptoms present a danger to the person or others. Most people who develop schizophrenia continue to experience symptoms and psychosocial impairments throughout their adult lives. However, longitudinal studies of the long-term course of schizophrenia have shown that a significant proportion of people experiences either partial or complete remission of the illness later in life (Harding, Brooks, Ashikaga, Strauss, & Breier, 1987a, b; Harrison et al., 2001; Tsuang & Winokur, 1975). Recognition that the long-term course of schizophrenia is not always chronic, as well as the fact that people with the disorder are capable of leading worthwhile and rewarding lives, has led to the concept of recovery being redefined from remission of symptoms to the experience of personal growth and development of meaning in life despite having the disorder (Anthony, 1993; Davidson, Tondora, Lawless, O'Connell, & Rowe, 2009; Ralph & Corrigan, 2005).

The annual incidence of schizophrenia is 0.2–0.4 per 1,000, with lifetime prevalence (risk) of approximately 1% (Jablensky, 1997). Incidence of schizophrenia is the same across genders, although women tend to have a later age of onset than men (Murray & Van Os, 1998), and a more benign course of illness, including fewer hospitalizations and better social functioning (Angermeyer, Kuhn, & Goldstein, 1990). The later age of onset in women is associated with higher attainment of pre-illness social role functioning, which confers a better outcome (Häfner, 2000).

Significant variations in the prevalence and incidence of schizophrenia across different countries and cultural groups have been reported (U.S. Institute of Medicine, 2001). However, these differences are minimized when stricter diagnostic criteria for schizophrenia are used (Jablensky, 1997). Research by the World Health Organization across multiple countries indicates that the clinical syndrome of schizophrenia is similar across a wide range of cultures and countries, including developed and developing nations (Jablensky et al., 1992; World Health Organization, 1979).

Both genetic and environmental factors appear to play a role in the etiology of schizophrenia. Rates of schizophrenia are higher among relatives of those with schizophrenia than in the general population. Adoption and twin studies have shown that this increased risk is genetic, with a tenfold increase in risk associated with the presence of an affected first-degree family member. This genetic risk increases with each affected relative, to nearly 50% when both parents are affected (McGuffin, Owen, & Farmer, 1996), and 60–84% when a monozygotic twin is affected (Cardno et al., 1999). The genetic transmission does not appear

to follow simple Mendelian single-gene inheritance patterns. More likely, there are multiple susceptibility genes, each with small effect and acting in concert with epigenetic and environmental factors.

Environmental risks for schizophrenia include biological and psychosocial factors. Risk for development of schizophrenia is increased by pre/perinatal events including maternal influenza, rubella, malnutrition, diabetes mellitus, smoking during pregnancy, and obstetric complications (Susser & Lin, 1992; Takei et al., 1996; Thomas et al., 2001). Obstetric complications associated with hypoxia are particularly related to increased risk for development of schizophrenia, with risk perhaps mediated by excitotoxic effects of hypoxia on the fetal neonatal brain (Cannon, Jones, & Murray, 2002). It has been suggested that, because most cases of obstetric complications do not lead to schizophrenia, such complications interact with genetic vulnerability to increase risk of schizophrenia (Cannon et al., 2000). However, it is not yet known whether high frequency of obstetric complications in schizophrenia is the result of abnormal brain development associated with genetic vulnerability, or an additive environmental factor toward the development of schizophrenia.

Several sociodemographic factors are associated with increased risk of schizophrenia (van Os & Marcelis, 1998). Poverty and lower social class have long been linked to higher rates of schizophrenia (Bruce, Takeuchi, & Leaf, 1991). Individuals born in urban areas are more likely to develop schizophrenia than those in rural areas (Peen & Dekker, 1997). Although incidence of schizophrenia is similar across different racial/ethnic groups (Jablensky, 1999), increased rates are present in some ethnic minority populations, such as second generation Afro-Caribbeans in the UK (Boydell et al., 2001), Dutch Antillean and Surinamese immigrants in Holland (Selten, Slaets, & Kahn, 1997), and African-Americans (Rabkin, 1979). These differences may reflect the stressful effects of being an ethnic minority in a social environment, which may increase vulnerability to schizophrenia in biologically predisposed individuals, as hypothesized in the *stress-vulnerability model* (Nuechterlein & Dawson, 1984; Zubin & Spring, 1977) and discussed later in this chapter.

8.2   Recognition of Symptoms and Their Assessment

Schizophrenia is characterized by three broad types of symptoms: psychotic symptoms, negative symptoms, and cognitive impairment (Liddle, 1987). *Psychotic symptoms* involve loss of contact with reality, including false beliefs (*delusions*), perceptual experiences not shared by others (*hallucinations*), or bizarre behaviors. A variety of different types of hallucinations occur in schizophrenia, including auditory, visual, olfactory, gustatory, or tactile hallucinations, with auditory hallucinations most common. Common delusions in schizophrenia include persecutory delusions, delusions of control (e.g., the belief that others can interfere with one's thoughts), grandiose delusions (e.g., the belief that one is Jesus Christ), and somatic delusions (e.g., the belief that one's brain is rotting away). The presence and severity of psychotic symptoms tend to be episodic over time.

Negative symptoms are defined by the diminution or absence of basic emotional and behavioral processes. Common negative symptoms include *blunted affect* (e.g., immobile facial expression, monotonous voice tone), *anhedonia* (lack of pleasure), *avolition* or *apathy* (diminished ability to initiate and follow through on plans), and *alogia* (reduced quantity or content

of speech). Negative symptoms are more pervasive and fluctuate less over time than psychotic symptoms (Fenton & McGlashan, 1991), and are strongly associated with poor psychosocial functioning (Sayers, Curran, & Mueser, 1996). Because it is less readily apparent to others that negative symptoms are manifestations of a psychiatric illness, people are often perceived by relatives and others to be lazy and willfully unengaged in bettering their lives (Weisman, Nuechterlein, Goldstein, & Snyder, 1998).

Cognitive impairment in schizophrenia includes problems in *attention* and *concentration, psychomotor speed, learning and memory*, and *executive functions* (e.g., abstract thinking, problem-solving). A decline in cognitive abilities compared to premorbid functioning is present in most individuals with schizophrenia, with cognitive functioning after onset of the illness relatively stable over time (Heaton et al., 1994). Despite such decline, some clients' cognitive functioning is in the normal range. Similar to negative symptoms, cognitive impairment is strongly associated with functional impairment (McGurk & Mueser, 2004; Mueser, 2000).

Impaired role functioning and significant changes in personal behavior are also included as diagnostic criteria for schizophrenia. Problems in these areas include reduced ability to work, attend school, parent, have close relationships, take care of oneself, and enjoy one's leisure time, with difficulties often emerging several years before psychotic symptoms (Häfner, Löffler, Maurer, Hambrecht, & an der Heiden, 1999). Impairment in functioning can be profound, resulting in the need for disability entitlements and assistance in getting basic living needs met, such as housing, medical care, food, and clothing. Improving functioning remains the single most important challenge for the management of schizophrenia. Impairment in functioning tends to be relatively stable over time in schizophrenia, with some improvements over the long-term course of the disorder (Harding & Keller, 1998).

In addition to symptoms and impaired role functioning, schizophrenia affects many other areas of living. People are at increased risk for alcohol and drug problems (Kavanagh et al., 2004), infectious diseases (e.g., hepatitis C, HIV infection) (Rosenberg et al., 2001), violent victimization (Bebbington et al., 2004) and posttraumatic stress disorder (Mueser, Rosenberg, Goodman, & Trumbetta, 2002), housing instability and homelessness (Susser, Struening, & Conover, 1989), smoking-related and other illnesses (de Leon et al., 1995), and negative emotions, such as anxiety (Huppert & Smith, 2001), depression (Addington, Addington, & Patten, 1998), and hostility (Bartels, Drake, Wallach, & Freeman, 1991). The net result of exposure to these risks is a sharply increased rate of premature mortality (Miller, Paschall, & Svendsen, 2006), due mainly to diseases (Brown, 1997), but also including an increased risk of suicide, estimated to be about 5% (Inskip, Harris, & Barraclough, 1998).

The two major diagnostic systems for schizophrenia in common use are the *Tenth Revision of the International Classification of Diseases* (ICD-10) (World Health Organization, 1992) and the *Diagnostic and Statistical Manual, Fourth Edition* (DSM-IV) (American Psychiatric Association, 1994). Both systems objectively define symptoms and characteristic impairments of schizophrenia in a similar fashion, and have improved the reliability of diagnostic assessments over more subjectively based approaches. The major differences between systems are the DSM-IV requirements of social or occupational dysfunction (not included in ICD-10) and the 6-month duration of illness (versus 1 month for ICD-10), resulting in a somewhat narrower definition of the disorder in DSM-IV. Reliability of diagnoses between the two systems is high (Peralta & Cuesta, 2003). The stability of diagnosis over time is

moderate, with most variability immediately following onset of the disorder (Häfner & an der Heiden, 2003).

The gold standard for establishing the diagnosis of schizophrenia is the Structured Clinical Interview for DSM-IV (First, Spitzer, Gibbon, & Williams, 1996). A wide range of standardized instruments has been developed for the assessment of symptoms and psychosocial functioning in schizophrenia. The most reliable measures are semi-structured interviews that systematically probe for specific symptoms or areas of functioning. Commonly used measures for assessment of symptoms include the Brief Psychiatric Rating Scale (Lukoff, Nuechterlein, & Ventura, 1986), the Positive and Negative Syndrome Scale (Kay, Opler, & Fiszbein, 1987), the Scale for the Assessment of Negative Symptoms (Andreasen, 1984a), and the Scale for the Assessment of Positive Symptoms (Andreasen, 1984b). Reliable and valid measures of psychosocial functioning include the Social Adjustment Scale II (Schooler, Hogarty, & Weissman, 1979), the Social Functioning Scale (Birchwood, Smith, Cochrane, Wetton, & Copestake, 1990), the Social-Adaptive Functioning Evaluation (Harvey et al., 1997), the Life Skills Profile (Rosen, Hadzi-Pavlovic, & Parker, 1989), and the Quality of Life Scale (Heinrichs, Hanlon, & Carpenter, 1984). Overall psychiatric and psychosocial functioning are often summarized using the Global Assessment of Functioning scale (Niv, Cohen, Sullivan, & Young, 2007), which provides a behaviorally anchored rating ranging from 1 (low) to 100 (high).

8.3 Maintenance Factors of the Disorder

A wide range of different factors can contribute to the maintenance or exacerbation of symptoms of schizophrenia, and the functional impairments that characterize the disorder. The stress-vulnerability model provides a useful heuristic for understanding factors that can influence the course of the disorder, and identifying potential strategies for improving long-term outcomes (Liberman et al., 1986; Nuechterlein & Dawson, 1984; Zubin & Spring, 1977). According to this model, schizophrenia is caused by an underlying *psychobiological vulnerability*, determined early in life by a combination of genetic and early environmental (e.g., perinatal effects) influences. Once the psychobiological vulnerability is established, onset of the illness and its course, including relapses, is determined by the dynamic interplay of several biological and psychosocial factors. Among the biological factors that influence the course of schizophrenia, antipsychotic medication and substance abuse are the most critical. *Antipsychotic medications* can reduce psychobiological vulnerability, thereby decreasing symptom severity and sensitivity to relapses. *Substance abuse*, on the other hand, can increase psychobiological vulnerability, leading to worse symptoms and more relapses.

There are several psychosocial factors that also influence the severity and course of schizophrenia. *Stress* can impinge on psychobiological vulnerability, worsening symptoms and triggering relapses. Indeed, as previously described, environmental stress may also play a role in precipitating the onset of schizophrenia in some individuals who are psychobiologically vulnerable, but would not have otherwise developed the disorder. However, stress alone does not necessarily lead to symptom exacerbation. Rather, the effects of stress are influenced by two other psychosocial factors, including coping skills and social support.

Coping skills include the ability to handle challenging and potentially stressful circumstances (e.g., problem-solving and social skills) in order to either remove the stressor itself or to reduce its noxious effects. For example, social skills for handling conflict situations, problem-solving, and relaxation are different types of coping skills that can enable people with schizophrenia to handle the stresses of daily living without experiencing symptom relapses. *Social support* can also reduce the negative effects of stress on psychobiological vulnerability by facilitating more effective coping by the client, and independently removing stresses on the client.

In addition to the factors identified in the stress-vulnerability model that can maintain or exacerbate symptoms and functional impairments in schizophrenia, several other important factors should be noted that can influence the course of the disorder. One such factor is social stigma regarding mental illness in general, and schizophrenia in particular. People in the general public often endorse a wide range of inaccurate, stigmatizing beliefs about schizophrenia (e.g., people with the illness are often violent, are unable to work or parent, cannot take care of themselves, have multiple personalities), which can be fueled by distorted media accounts of people with mental illness (Wahl, 1995, 2003). These stigmatizing attitudes can lead to a loss of opportunities that promote adaptive functioning in the community (e.g., work, school, housing), as well as social exclusion that forms a barrier to rewarding relationships and leisure activities (Corrigan, 2005). Negative and inaccurate stereotypes about schizophrenia are not limited to the general public, but are also held by individuals with the illness themselves (i.e., self-stigma) and their family members (MacInnes & Lewis, 2008). The net result of this stigma can be demoralization, poor self-esteem, and lack of self-efficacy when people with the illness believe they in fact lack worth (Barham, 1984), and therefore do not invest the effort in changing their lives.

Another factor that can inadvertently maintain symptoms and disability in people with schizophrenia is social reinforcement of the "sick role" of the "mental patient" (Goffman, 1961). This role assumes that people with a mental illness are helpless victims of circumstances beyond their control, are not capable of functioning well, and must forever be reliant upon others for getting their needs met. Endorsement of such beliefs among mental health professionals, family members, and the general public naturally leads to a paternalistic attitude toward people with a mental illness in which their lives are managed by others, and their hopes and expectations are minimized in favor of accepting the status quo. These attitudes maintain clients' dependence upon others and prevent them from taking steps to gain greater control over their lives.

A final problem that can maintain disability, which is related to reinforcing the "sick role," is the outdated assumption that people with schizophrenia are incapable of playing an active role in their own treatment (Davidson, 2005). As a result of this assumption, clients are often not engaged and involved in their own treatment planning, they fail to follow through on treatment recommendations (Raskin, 1985; Weiden, Mott, & Curcio, 1995), and they may react to perceived coercion on the part of clinicians by doing the opposite (Moore, Sellwood, & Stirling, 2000). There is a growing recognition that people with schizophrenia are actively involved in coping with their illness (Breier & Strauss, 1983), and like individuals with chronic physical illness (Newman, Steed, & Mulligan, 2004), can collaborate with professionals in treatment planning, and can learn self-management strategies for minimizing illness-related impairments (Mueser et al., 2002).

8.4   Evidence-Based Treatment Approaches

With development, implementation, and empirical evaluation of several pharmacological and psychosocial interventions, the previously held notion that schizophrenia is an intractable, untreatable disease without hope of recovery has fortunately been debunked over the years. To date, there is a variety of evidence-based approaches that have demonstrated efficacy in aiding recovery from schizophrenia – providing psychotic symptom relief, enhanced community tenure, improved social and family functioning, employment skills, cognitive improvements, and reduced substance use. In this section, we provide a brief description of eight treatment approaches that have strong empirical support based on multiple randomized controlled trials. Interventions for schizophrenia tend to focus on specific domains of functioning, and therefore the selection of which treatments are necessary for a given client is made based on that individual's needs.

8.4.1   Pharmacological Treatment

Antipsychotic medications are a mainstay in the treatment of schizophrenia. Prior to discovery of antipsychotics in the 1950s, and their widespread use in subsequent years, the vast majority of people with schizophrenia spent most of their adult lives in institutions (Johnson, 1990). Antipsychotic medications played an important role in the deinstitutionalization of people with schizophrenia and other severe mental illness by providing a potent tool for reducing or eliminating some of the most disturbing and disruptive symptoms of the illness: hallucinations, delusions, and bizarre behavior. These medications are effective at both reducing severity of psychotic symptoms and preventing relapses of psychotic symptoms that frequently require acute inpatient treatment (Schatzberg, Cole, & DeBattista, 2007). For most people with schizophrenia, antipsychotic medications play an important role in treatment, and facilitate their ability to participate in other interventions aimed at further improving their functioning.

Although antipsychotics are effective at reducing psychotic symptoms, their impact on negative symptoms is negligible. Similarly, antipsychotics do not tend to have potent effects on reducing cognitive impairment that is characteristic of the illness. These are important limitations given the preponderance of evidence showing that psychosocial functioning in schizophrenia is more strongly correlated with negative symptoms (Pogue-Geile, 1989) and cognitive impairment (Green, Kern, Braff, & Mintz, 2000) than psychotic symptoms, and they underscore the role of psychiatric rehabilitation methods in improving functional outcomes. Finally, antipsychotic medications produce a range of problematic side effects, such as increased weight, increased vulnerability to diabetes, and sedation. Extensive research is underway and aimed at both developing more effective antipsychotics that have fewer and more benign side effects.

A wide range of other medications is also frequently used in the treatment of schizophrenia. The most commonly used adjunctive medications include mood stabilizers, antidepressant medications, and benzodiazepines. However, the evidence base supporting adjunctive medications for schizophrenia is slim (Arey & Marder, 2008). Many people with schizophrenia are prescribed multiple medications, including more than one medication in a class as well as different classes of medication, although there is limited empirical support for this form of "polypharmacy" (Stahl, 1999).

8.4.2 Supported Employment

Unemployment is particularly common in people with schizophrenia (Mueser, Salyers, & Mueser, 2001). However, most clients express an interest in work (Mueser et al., 2001; Rogers, Walsh, Masotta, & Danley, 1991), and evidence suggests that clients who return to work experience a modest reduction in symptoms and increased life satisfaction (Bell, Milstein, & Lysaker, 1993; Bond et al., 2001). Supported employment is designed to help clients get and keep competitive jobs paying competitive wages in the community, working alongside nondisabled individuals. Supported employment programs for persons with severe mental illness operate on a "zero-exclusion" criterion basis, with the stated desire to work as the only criterion for enrollment in a program. Clients are not excluded due to symptom severity, clinician-perceived "lack of readiness to work," or substance abuse problems.

The Individual Placement and Support model (IPS) (Becker & Drake, 1993, 2003) is the most widely studied model of supported employment program. The IPS model is based on several core principles, including: (1) integration of vocational and clinical services, (2) rapid search for jobs and no prevocational training, (3) attention to client preferences, (4) provision of ongoing, time-unlimited supports to facilitate job retention or transition to other jobs, and (5) counseling to inform clients about the impact of working on their disability income and insurance. Compared to other vocational programs, which often require extensive prevocational training, work readiness assessments, time-limited transitional jobs, or sheltered work supported employment focuses on helping clients obtain permanent *competitive* employment as soon as possible, with the job search usually beginning within a few weeks of the client enrolling in the program.

Significant research has accumulated on the effects of supported employment for severe mental illness over the past 15 years. Four studies have tested effectiveness of converting traditional day treatment programs into supported employment programs (Bailey, Ricketts, Becker, Xie, & Drake, 1998; Becker et al., 2001; Drake, Becker, Biesanz, Wyzik, & Torrey, 1996; Drake et al., 1994). Compared to sites that did not make the transition, the newly converted sites saw significant increases in the percentage of clients who were working competitive jobs. Furthermore, a total of 16 randomized controlled trials has demonstrated moderate to strong effects when comparing the impact of supported employment to other models of vocational rehabilitation on competitive employment outcomes (Bond, Drake, & Becker, 2008).

8.4.3 Assertive Community Treatment (ACT)

Assertive Community Treatment (ACT) is an intensive community-based, integrated treatment approach for individuals with schizophrenia who have difficulty staying connected to standard outpatient treatment modalities (e.g., attending psychopharmacology appointments, participating in therapy groups) and who are at high risk of relapse and psychiatric hospitalization. The ACT program, developed in the 1970s as a response to the host of problems related to the deinstitutionalization process that began in the 1960s, takes a multidisciplinary, holistic approach to treatment (Stein & Santos, 1998). Clients are provided medication management, housing assistance, help in getting basic daily living needs met, financial entitlements and money management support, counseling, and crisis management

by a team of multidisciplinary treatment providers. What is most unique about the ACT program compared to traditional case management is the intensity of treatment (with clinician/client ratios of 1:10 in ACT compared to 1:25 or more in traditional case management), the provision of most services in the community rather than at the clinic, and the sharing of caseloads across a multidisciplinary team of clinicians who assume round-the-clock coverage for clients.

ACT functions such that all team members are in frequent contact with every client and are in direct communication with each other regarding clients' needs on a very regular basis. Most ACT teams are comprised of a psychiatrist, nurse, social worker, at least one case manager and rehabilitation counselor, and ideally a substance abuse counselor as well. As a result of the team approach and reduced caseload, clinicians can provide a degree of continuity of care and individualized attention that most other services cannot. ACT services take place in the community, with staff members conducting frequent home visits, rather than insisting that clients come to the mental health clinic for appointments. A rule of thumb for client contact is that 80% or more of the appointments take place in the home or other community setting (Bond, Drake, Mueser, & Latimer, 2001). This allows for in vivo progress: clinicians can more effectively help clients solve everyday problems, like organizing their home or increasing medication adherence, in the natural environment than they can by simply talking about the problems in an office.

The ACT model has been widely tested, with over 30 randomized controlled trials evaluating its effectiveness (Bond et al., 2001). Research findings demonstrate that clients who participate in ACT programs have fewer psychiatric hospitalizations, reduced symptom severity, more stabilized community housing, and improved quality of life. However, in addition to successful levels of client engagement (1-year retention rates in mental health services were 84% for ACT clients compared to 54% for treatment-as-usual clients) (Bond, Clark, & Drake, 1995), evaluation of consumer satisfaction (although less thoroughly investigated) suggests that clients and their families were significantly more satisfied with ACT than with other types of services (Bond et al.).

8.4.4 Integrated Treatment for Dual Disorders

Substance use disorders are widely recognized as the most common comorbid conditions in individuals with severe mental illness, with rates of lifetime abuse about 50%, and between 20% and 40% with current abuse problems (Mueser, Bellack, & Blanchard, 1992). Substance abuse in individuals with schizophrenia contributes to a wide range of negative outcomes, including elevated suicide risk, exacerbation of psychotic symptoms and more frequent hospitalizations, homelessness, violence, and increased risk for contracting infections like HIV (Drake, Mercer-McFadden, Mueser, McHugo, & Bond, 1998). Due to their unfortunately unique set of intermingling "dual-diagnosis" symptoms, clients with schizophrenia tend to do poorly in both traditional mental health programs and substance use treatment services – exclusion, early discharge, and drop-out from such programs are common, as are poor outcomes (Ridgely, Goldman, & Willenbring, 1990). As a result, there have been substantial efforts to develop effective interventions for this population. These types of integrated treatments accept clients with varying levels of motivation to change their substance use behaviors and/or manage their mental illness, and, in keeping with the well-supported stages of change model (Prochaska & DiClemente, 1984), meet each client "where they are" on that continuum.

The hallmark feature of these interventions is that the same clinician provides both mental health and substance abuse treatment, and takes responsibility for working to seamlessly integrate interventions so that they are meaningful for the clients. This blending necessitates a consistent philosophy about, and approach toward, the two problems (Drake, Mueser, Brunette, & McHugo, 2004), and high-quality clinical skills to help clients effectively manage these entangled illnesses. Of paramount importance in integrated treatment is the need to tailor the specific interventions to the client's stage of recovery. The stages of change concept has been proposed as a way of understanding the different motivational states all (or most) people progress through when changing health-related behaviors (Prochaska & DiClemente, 1984): *precontemplation* (the person is not thinking about change), *contemplation* (the person is thinking about change), *preparation* (the person is making plans to change), *action* (the person is making changes), and *maintenance* (the person is maintaining change), and has since been adapted to better represent the discrete steps people with a dual disorder progress through when addressing their disorders in the context of treatment (Osher & Kofoed, 1989). For example, a client may acknowledge the deleterious effects of untreated psychiatric symptoms and will be interested in actively working on that problem, yet simultaneously be reluctant to talk about his use of marijuana or alcohol. In these cases, the clinician needs to address the specific problems the client wants to work on, while respectfully and nonjudgmentally exploring the client's substance use while providing basic information about the effects of substances on psychotic symptoms.

Multiple controlled trials have been conducted to evaluate the impact of integrated dual disorder treatment programs (Drake et al., 2004; Drake, O'Neal, & Wallach, 2008; Kavanagh & Mueser, 2007). These studies have evaluated the effects of individual psychotherapy, intensive outpatient rehabilitation, contingency management, group counseling, family intervention, care management, legal interventions, or residential treatment. Overall, research indicates that integrated treatments for dual disorders are effective and superior to nonintegrated treatments, with the most prominent achievement on the reduction of problematic substance use. In particular, contingency management-based programs and group counseling interventions enjoyed the strongest empirical support.

8.4.5 Cognitive-Behavioral Therapy (CBT) for Psychotic Symptoms

Despite substantial advances in the effectiveness of antipsychotic medications over the past few decades (see *Antipsychotic Medications* above), many individuals with schizophrenia continue to suffer from persistent psychotic symptoms. Nevertheless, the notion that CBT is contraindicated for psychotic clients prevailed for several years and was underscored by assumptions that they lacked reasoning skills or that their cognitive deficits were too severe to participate meaningfully in CBT. However, CBT has gained both rapid popularity and empirical support in the past 15 years, and is becoming a more commonly used adjunct to medication management.

CBT is structured, goal-oriented, and relatively short-term (ranging from approximately 4–24 sessions, often with additional booster sessions as needed). After a treatment engagement period, the establishment of the rationale for the Cognitive Model (the interrelationship between thoughts, emotions, and behaviors) and the development of a "problem list" with the client (e.g., "I'm afraid that terrorists are out to get me and I am not safe," "I may get kicked out of my apartment because I yell at the voices to get them to stop," "I don't have any friends"), therapy goals can be created and systematically addressed.

For individuals who experience significant functional impairments due to delusional beliefs and/or hallucinations, a major goal of CBT is the reduction of the impact of positive symptoms, accomplished through a variety of strategies including the development of alternative explanations for symptoms coupled with a "normalizing rationale" (Kingdon & Turkington, 1991). Also taught in CBT is the skill of evaluating evidence to support (and refute) unusual thoughts or beliefs about hallucinations in conjunction with subsequent cognitive restructuring and activities involving the gathering of additional evidence through "behavioral experiments." Depending on the client's problems and goals, later sessions can also focus on other areas, such as addressing negative symptoms, social skills training, relapse prevention, or medication adherence (Fowler, Garety, & Kuipers, 1995).

There are more randomized controlled trials for CBT than for any other individual psychotherapeutic intervention for psychosis (Martindale, Mueser, Kuipers, Sensky, & Green, 2003), and results from these studies suggest moderate to large effect sizes for psychotic symptom change at the end of treatment as well as overall maintenance of therapeutic gains at follow-up (Gould, Mueser, Bolton, Mays, & Goff, 2001; Zimmermann, Favrod, Trieu, & Pomini, 2005). Reduction of the severity of distress caused by hallucinations and delusions has certainly been the most robust finding for CBT. Most randomized controlled trials of CBT for psychosis have been conducted in the UK, and the intervention is more widely available and widely practiced there than in the USA. Nevertheless, modifications of traditional CBT for psychosis models have been implemented to account for limited financial resources and the particular structure of the US mental health system. For example, group CBT has begun to be evaluated as a feasible treatment modality with some promising results (Granholm et al., 2005). If CBT for psychosis is going to become more widely available in the USA, it will be crucial to develop standardized training programs for clinicians to ensure competent treatment. In the long run, it may be desirable to develop processes for certifying or credentialing clinicians in the provision of CBT to ensure high standards of care.

8.4.6 Family Psychoeducation

To address stress and burden in the family, and to reduce relapse rates, several types of family intervention have been developed and evaluated over the years for individuals with schizophrenia. The primary focus of these interventions is on teaching families about the nature of schizophrenia and its management in a respectful, collaborative manner that avoids blaming relatives (Glynn, 1993), and eschewing outdated theories that the family causes schizophrenia (Fromm-Reichman, 1948). The Schizophrenia Patient Outcomes Research Team (PORT; (Lehman & Steinwachs, 1998) has strongly recommended family psychoeducation programs for clients who have ongoing contact with their families, and has also highlighted that these interventions should not be limited to families where high levels of stress or interpersonal conflicts are present.

The nature, content, duration, and modality of psychosocial family interventions for schizophrenia vary from brief educational lectures (Smith & Birchwood, 1987) and psychoeducational groups (Leff et al., 1990) for relatives to more intensive single-family (Hogarty et al., 1991) and multifamily group therapy (McFarlane, Lukens, et al., 1995) interventions, lasting anywhere from 2 months to 2 years. The most effective programs provide education about symptoms of schizophrenia, strategies for more effective communication and solving problems, crisis

management approaches, and the provision of emotional support. Clients with schizophrenia are routinely included in most or all family sessions. Most purely educational models utilize easy to understand handouts and present information in a nonjudgmental manner, tailored to the particular issues of the individual family. In more intensive (and often longer duration) types of family interventions, such as behavioral family therapy or management (Falloon et al., 1988; Mueser & Glynn, 1999), communication and problem-solving skills are taught using the principles of social leaning, combined with the presentation of information about schizophrenia.

Overall, evidence for efficacy of family interventions for schizophrenia suggests that inclusion of relatives in psychosocial treatment reduces relapse and rehospitalization rates by at least 20% (Pitschel-Walz, Leucht, Bäuml, Kissling, & Engel, 2001). Other findings across different trials of family intervention demonstrate improvement in knowledge about schizophrenia (McGill, Falloon, Boyd, & Wood-Siverio, 1983), better treatment compliance (McFarlane, Link, Dushay, Marchal, & Crilly, 1995), reduced tension and improved family quality of life (Zastowny, Lehman, Cole, & Kane, 1992), and improved patient social and vocational adjustment (Bäuml, Kissling, & Pitschel-Walz, 1996). Duration of family psychoeducation appears to be important. Shorter-term psychoeducational programs demonstrate limited impact on the course and severity of the disorder (Pitschel-Walz et al., 2001), whereas interventions lasting greater than 6 months tend to reduce relapse and readmission over 2 years or longer (Dixon et al., 2001; Pitschel-Walz et al., 2001). Both single and multifamily group approaches are effective at reducing relapses and rehospitalizations (Baucom, Shoham, Mueser, Daiuto, & Stickle, 1998), with each modality having advantages and disadvantages. For example, it may be easier to engage families for clients with a first episode of psychosis in single-family treatment approaches (Montero et al., 2001), while multifamily interventions may provide more opportunities for social support and vicarious learning (Glynn, Cohen, Dixon, & Niv, 2006).

While the majority of family interventions has been created and implemented by professionals, the National Alliance for the Mentally Ill (NAMI) has developed trained peer family member-led groups that combine elements of education, skills training, and emotional support and are focused on increasing family well-being (Pickett-Schenk et al., 2006). Despite the strong empirical support of family psychoeducation, the PORT study found that only 31% of their sample of clients treated for schizophrenia reported that their family even received information about the illness (Lehman & Steinwachs, 1998), let alone formal family psychosocial treatment of any kind. In addition to limited access to services, many have noted that families decline participation in family interventions at a surprisingly high rate (Barrowclough et al., 1999; Leavey et al., 2004). New evidence suggests that active recruitment and strong initial engagement of the client and his/her family members play a crucial role in the acceptance and provision of family services (Murray-Swank, Dixon, & Stewart, 2007). Of great importance for the future of family-based psychoeducation for schizophrenia is improved dissemination to families of what the interventions actually involve, targeted at debunking long-held pejorative myths about family treatments for severe mental illness. This may improve interest in, acceptance of, and funding for, empirically supported family programs.

8.4.7   Illness Management and Recovery (IMR)

The notion that clients with schizophrenia are capable of learning how to better manage their illness has led to the development of a range of interventions designed to teach basic

self-management skills. One program, Illness Management and Recovery (IMR) (Gingerich & Mueser, 2005a), has recently been developed and was designed to explicitly incorporate specific empirically supported practices for illness self-management into a single cohesive program. Unlike some of the other interventions discussed in this chapter, which are geared toward specific subpopulations of clients with psychotic disorders (e.g., those who are at very high-risk for relapse or who have persistent distressing psychotic symptoms, or who struggle with substance abuse), IMR was designed to be appropriate for practically all individuals with severe mental illness and diagnoses of schizophrenia, schizoaffective disorder, major depression, or bipolar disorder. The basic rationale underlying the IMR program is that any person with a severe mental illness can learn how to better manage one's own mental illness in the service of setting and pursuing personally meaningful, functional goals.

The core components of the IMR program include five treatment strategies based on a review of the research that has direct relevance to improve management of severe mental illness. *Psychoeducation* is aimed at improving knowledge about mental illness, such as information about the stress-vulnerability model of schizophrenia, common symptoms, and facts about medication and other treatment strategies. *Medication-adherence strategies* include motivational interviewing (examining the role that antipsychotics may play in personal goal attainment), cognitive (evaluating the accuracy of beliefs about the use of medication), and/or behavioral (utilizing behavioral tailoring to incorporate medication into the daily routine) approaches designed to increase adherence to antipsychotics and reduce nonadherence-related relapses (Buchanan, 1992). *Relapse prevention* training involves helping clients identify specific triggers and early warning signs of relapses, and developing a plan to respond to those triggers (e.g., call case manager, arrange meeting with doctor to consider increase in medication dosage) in order to prevent relapses or minimize their severity. *Coping skills training* involves teaching clients skills for managing stress and dealing with persistent symptoms such as hallucinations, anxiety, or depression. Finally, the IMR program incorporates *social skills training* as a strategy for increasing social support, which has been shown to buffer the negative effects of stress and contribute to a better course of illness (Bebbington & Kuipers, 1992; Norman et al., 2005).

In a comprehensive review of illness self-management studies, Mueser et al. (2002) identified 40 randomized controlled trials evaluating either specific components of illness self-management or comprehensive programs. This review indicated that studies of purely psychoeducational methods significantly improve clients' knowledge about mental illness, but do not affect their medication adherence, reduce relapse, or improve functioning (Macpherson, Jerrom, & Hughes, 1996). Medication adherence programs focused more on cognitive-behavioral techniques like behavioral tailoring tend to greatly affect the degree to which clients take medication as prescribed (Cramer & Rosenheck, 1999). All of the programs addressing relapse prevention planning have demonstrated decreases in relapse or rehospitalization (Herz et al., 2000). Symptom severity reduced considerably in the studies where cognitive-behavioral-based techniques were utilized to increase clients' coping skills (Lecomte et al., 1999).

The feasibility and clinical promise of the standardized IMR program have been demonstrated (Mueser et al., 2006), as has the ability to implement the program with high fidelity across multiple community mental health centers (McHugo et al., 2007). In addition, two randomized controlled trials have indicated that the participation in IMR improves illness self-management, including outcomes such as symptom severity (Hasson-Ohayon, Roe, & Kravetz, 2007; Levitt et al., in press).

8.4.8 Cognitive Remediation

Cognitive impairment has long been recognized as a cardinal feature of schizophrenia that affects most people with the illness (Harvey, Green, Keefe, & Velligan, 2004; Heaton et al., 1994). Cognitive functioning is strongly related to psychosocial adjustment in areas such as work, social relationships, and capacity for independent living (Green et al., 2000; McGurk & Mueser, 2004), but is not affected by pharmacological treatment. For these reasons, cognitive functioning has been identified as a suitable target for psychosocial intervention (Nuechterlein, Robbins, & Einat, 2005).

Cognitive remediation strategies designed to improve cognitive functioning in schizophrenia were first adapted from approaches developed for traumatic brain injury (Benedict, 1989; Butler & Namerow, 1988). These methods often employ individual computer training exercises that target and practice specific cognitive skills (e.g., attention, psychomotor speed, memory), although some utilize paper-and-pencil tasks or training of attention during other learning activities, such as during social skills training (Silverstein et al., 2005). Training periods typically range from 3 to 6 months, although some programs extend up to 1 year or more (Hogarty et al., 2004). While an emphasis of cognitive remediation is on improving cognitive functioning, some programs also teach compensatory strategies for minimizing the effects of persistent cognitive difficulties (Krabbendam & Aleman, 2003; McGurk, Mueser, & Pascaris, 2005). Some programs also provide group practice exercises.

Several reviews of cognitive remediation have been published over the past decade (Krabbendam & Aleman, 2003; Kurtz, Moberg, Gur, & Gur, 2001; McGurk, Twamley, Sitzer, McHugo, & Mueser, 2007; Twamley, Jeste, & Bellack, 2003). The most recent review was a meta-analysis (McGurk et al., 2007), which found that cognitive remediation improved both cognitive and psychosocial functioning and had a modest impact on symptomatology. How-ever, of even greater importance is that the impact of cognitive remediation in these studies was moderated by the provision of adjunctive psychiatric rehabilitation; that is, studies which provided cognitive remediation in addition to a specific psychiatric rehabilitation program found significantly greater improvements in psychosocial functioning than studies that compared providing cognitive remediation alone to usual services. Thus, cognitive remediation is an effective approach to improving psychosocial outcomes, but only when it is combined with other rehabilitation methods.

8.4.9 Social Skills Training

Poor social skills has been recognized as a core characteristic of schizophrenia from its first conceptualization as a disorder (Kraepelin, 1919/1971). Among people with schizophrenia, better social skills are associated with female gender (Mueser, Bellack, Morrison, & Wade, 1990; Usall, Haro, Ochoa, Marquez, & Araya, 2002), better cognitive functioning (Addington & Addington, 2000; Mueser, Blanchard, & Bellack, 1995; Penn, Mueser, Spaulding, Hope, & Reed, 1995), lower levels of negative symptoms (Jackson et al., 1989; Patterson, Moscona, McKibbin, Davidson, & Jeste, 2001), and better social functioning (Bellack, Morrison, Wixted, & Mueser, 1990; Bellack, Sayers, Mueser, & Bennett, 1994). Specific social skills are related to, but distinguishable from, global social competence (Appelo et al., 1992).

Social skills training was developed as a systematic approach to teaching more effective interpersonal skills to people with schizophrenia. Typically, these programs involve the use of

cognitive-behavioral techniques grounded in learning theory (e.g., coaching. prompting, modeling, chaining, positive reinforcement) to improve specific components of social skills (Bellack, Mueser, Gingerich, & Agresta, 2004; Liberman, DeRisi, & Mueser, 1989). Sessions are most often provided in groups, although it can also be provided on an individual basis, over a time-limited period of time. Therapeutic goals can address a broad range of areas, such as improving assertiveness skills, emotion recognition, family communication patterns, or conversational skills.

The research on social skills training for schizophrenia has been frequently reviewed over the past 2 decades, with generally favorable conclusions (Benton & Schroeder, 1990; Corrigan, 1991; Dilk & Bond, 1996; Heinssen, Liberman, & Kopelowicz, 2000; Wallace, 1998; Wallace et al., 1980). In the most recent meta-analysis, social skills training was found to have a large impact on skills knowledge, moderate effects on social skill performance and psychosocial functioning, and a somewhat smaller effect on the severity of negative symptoms (Kurtz & Mueser, 2008). This review confirms the important role of social skills training at improving social functioning in schizophrenia. More recent efforts in this area have also begun to focus on improving social cognition (Penn et al., 2005), or the ability of clients to make accurate social judgments about other people's thoughts, feelings, and intentions, a skill in which many people with schizophrenia have significant impairments.

8.5 Mechanisms of Change Underlying Treatment

Schizophrenia is a complex illness that affects thought processes, mood, behavior, and a broad range of functioning. Given its complexity, it is no surprise that multiple treatments are usually required to reduced symptoms and improve psychosocial adjustment, with the specific combination of services tailored to the individual and his or her circumstances. The particular mechanisms underlying treatment-related change depend on the targeted area of change and the nature of the specific intervention. Targets of intervention can be broadly divided into two types, including reducing symptoms and preventing relapses, and improving psychosocial functioning. The stress-vulnerability model provides a framework for understanding the mechanisms underlying treatments aimed at reducing symptoms, whereas the mechanisms underlying psychiatric rehabilitation are thought to be responsible for improvements in interventions that target functioning.

According to the stress-vulnerability model, interactions among four different factors influence the course and severity of symptoms in schizophrenia. Thus, a change in any one of these factors can be expected to improve the symptomatic course of the illness, including reduced psychobiological vulnerability, reduced stress, increased coping skills, and increased social support, with more robust improvements occurring when multiple factors are changed. Some interventions target a single factor, whereas others target more than one factor. Two types of intervention are most critical for reducing psychobiological vulnerability: psychotropic medications (mainly antipsychotics) and substance abuse treatments aimed at reducing or eliminating drug and alcohol abuse.

A variety of strategies can be used to reduce effects of stress impinging on vulnerability and precipitating relapses. For example, tense and critical family relationships can create a stressful home environment that has been linked to increased vulnerability to relapses (Butzlaff & Hooley, 1998), whereas family psychoeducation was developed in order to educate families

about the nature of schizophrenia and its treatment, and to teach more effective and less stressful ways of solving problems and resolving conflicts (Mueser & Glynn, 1999). Another example is training in relapse prevention skills, which involves teaching clients how to identify and either reduce or more effectively manage stressful situations that have precipitated relapses in the past, as well as monitoring early warning signs of relapse and formulating a plan for responding to the emergence of those signs (Herz et al., 2000).

Many strategies have been developed that are aimed at increasing coping skills for managing stress. For example, stress management techniques (e.g., exercises involving breathing retraining, pleasant imagery, positive self-talk, muscular relaxation) can be taught to clients to reduce the negative effects of stress (Gingerich & Mueser, 2005a). Social skills and problem-solving training can be used to teach more effective skills for reducing interpersonal conflict (Bellack et al., 2004). Similarly, a variety of strategies can be used to increase social support. For example, family psychoeducation is aimed at both reducing stress in the family and at increasing social support for the client's involvement in treatment and progress toward personal goals. Social skills training is often used to help clients develop more rewarding and supportive social relationships.

Psychiatric rehabilitation methods can be conceptualized as improving psychosocial functioning through two different mechanisms: improved competence and enhanced environmental supports for adaptive behavior (Corrigan, Mueser, Bond, Drake, & Solomon, 2008). Some interventions work through both mechanisms, whereas others operate primarily by changing just one. For example, social skills training is used to teach a wide range of skills to facilitate better social relationships, improved self-care and independent living skills, greater involvement in leisure activities, and better performance at work, school, or parenting (Liberman, 2007). Supported employment, on the other hand, involves providing environmental supports aimed at helping clients who want to work to find and keep competitive jobs in the community (Becker & Drake, 2003).

A final mechanism underlying changes in both symptoms and functioning is the individual's personal sense of agency, self-efficacy, and self-esteem. Most interventions for schizophrenia require some engagement and involvement of the client by treatment providers, and thus developing a working alliance is of primary importance (Priebe & Gruyters, 1993). A therapeutic relationship between the client and clinician requires active collaboration between the two individuals, and instilling hope and belief in the client that change is both possible and within his or her capability. This can be most effectively achieved by respecting the client's autonomy and right to make personal decisions, minimizing the use of coercive interventions, and promoting shared decision-making between the client and treatment providers (Deegan & Drake, 2006; Fenton, 2003).

8.6   Basic Competencies of the Clinician

When working with people with schizophrenia, there are some important basic skills, or competencies, that clinicians must develop in order to provide practical and effective treatment. Due to the often debilitating nature of this disorder and its resulting functional impairment, clinicians need these basic competencies to succeed in the provision of a recovery-based set of interventions. These skills are outlined below.

8.6.1 Knowledge About Schizophrenia, Empirically Supported Treatments, and Entitlements, and How to Access such Services

Not only is it important for clinicians to be knowledgeable about manifestation of symptoms of this disorder, but they should also be well-versed in the stress-vulnerability model of onset and relapse of schizophrenia. Basic command of the literature on rates of detrimental substance use (20–40%) consequences of co-occurring disorders (e.g., psychotic symptom exacerbation, increased violence), and risk factors for suicidal behavior in people with schizophrenia (e.g., substance use, illness insight) is crucial when treating these clients. Clinicians should also be aware of which treatments work for people with serious mental illness (e.g., cognitive-behavioral therapy for psychotic symptoms, integrated treatment for co-occurring disorders, supported employment, etc.) and which interventions do not confer notable benefit (e.g., psychodynamic therapy).

Case-management skills are particularly crucial when working with individuals with schizophrenia, perhaps more so than with other psychiatric disorders. Clinicians need to have an understanding of available social service entitlements and services for their clients, such as Social Security benefits, supported housing, and subsidies for reduced transportation fees, as well as how to help clients access them.

8.6.2 Ability to Effectively Assess Psychopathology, Functioning, and Strengths/Supports

When conducting initial and ongoing assessments with clients with schizophrenia, the clinician must be knowledgeable about particular areas into which to probe. It is crucial to ask a client about depression and anxiety, suicidal ideation, substance abuse, as these are frequently co-occurring problems in this population. Trauma history and posttraumatic stress symptoms, while often undetected and untreated in those with schizophrenia, occur at alarmingly high rates (43–98% have reported at least one lifetime traumatic event) (Mueser et al., 1998), and account for a great deal of additional morbidity, such as more severe psychotic symptoms and higher service utilization (Read & Argyle, 1999).

Practitioners working with those with psychosis need to know not only the importance of gathering information, but also how to effectively gather that information. For example, interviewing a client about existence of delusions or paranoid ideation can be a delicate matter – one's goal is to learn about the client's beliefs while neither colluding in the delusion nor dismissing it as false. Other unique clinical skills particular to working with this population include managing clients' paranoia toward the assessor and/or treatment team, distilling the content of thought-disordered speech, and gathering important data despite the barrier of negative symptoms that may affect the interview.

Throughout treatment, clinicians need to effectively monitor client progress and outcomes. Knowing the risk factors in this population (as described above), practitioners should have a consistent system of monitoring changes in these areas, utilizing both standardized measures (such as the Beck Depression Inventory, BDI; Beck, Steer, & Brown, 1996) and frequent "check-in." Progress toward clients' functional goals should also be assessed regularly and discussed with frequency.

8.6.3   Ability to Develop a Strong Working Alliance with People Who Have Schizophrenia

Bordin (1976) described the necessity for developing a strong client–therapist agreement on treatment tasks and treatment goals, as well as fostering a strong therapeutic bond. While this triad has been demonstrated to be important in the therapeutic relationship regardless of particular psychiatric condition, it becomes particularly critical when working with individuals with schizophrenia.

Often overlooked when treating individuals with serious mental illness is the client's perspective on his or her own treatment goals. Perhaps because a client may have pervasive psychotic symptoms or pronounced negative symptoms, the treatment team and family members may not take the necessary time to distill the client's opinion, and the end result is a set of goals on which others think the client "should" work. For instance, relatives and the treatment team may push the client to work on socializing. Upon further discussion, however, the clinician determines that the client is satisfied with his degree of social connectedness, but what he really wants is to find employment.

This collaborative goal-setting approach is crucial, and without it, treatment will likely not move forward. In addition, clinicians should make sure that they are consistently practicing reflective listening about topics important to the client (even if the content is difficult to understand or delusional), "meeting the client where he or she is at" (e.g., not pushing smoking cessation if the client does not yet have healthy, meaningful activities to replace smoking), addressing clients' immediate concerns and needs (such as housing problems, or sadness about the death of a friend), and of course, having and conveying a sense of respect for the client and his or her difficulties and goals.

8.6.4   Ability to Adopt a Recovery-Focused, Strengths-Based Philosophy Toward Treatment

Traditionally, goal-setting in the treatment of schizophrenia has been focused on the reduction or elimination of "deficits," such as psychotic symptoms, inappropriate behavior, or social withdrawal. This overemphasis on deficits in individuals who have already experienced significant setbacks in their lives can worsen self-esteem and contribute to further demoralization. Taking a strengths-based and resiliency-focused approach to treatment planning helps individuals and family members become more aware of, and feel good about, their personal positive attributes, how they have previously used these abilities to cope with life challenges and achieve goals, and how these attributes can be further utilized to achieve individual and shared goals. Thus, focusing on strengths and resiliency not only makes people feel better about themselves and their efforts, but also identifies tools that can be used to achieve goals.

This approach is reflected in the growing popularity of strengths-based case management (Rapp & Goscha, 2006) and highlights the following principles: (1) people with schizophrenia can recover, reclaim, and transform their lives; (2) the focus is on individual strengths rather than pathology exclusively; (3) the community is viewed as an oasis of resources; (4) the client is the director of the helping process; (5) a primary setting for the work is in the community; and (6) the clinician–client relationship is primary and essential.

Not only is it the clinicians' responsibility to know the newest literature on recovery from schizophrenia and take this strengths-based approach to their work with those with

schizophrenia (Davidson et al., 2009), but it is also important that they are able to convey the hope inherent in the recovery vision to clients themselves, their concerned family members, and, as needed, other members of a client's treatment team who may not have yet adopted this philosophy themselves (Deegan, 1996, September).

8.6.5   Ability to Take a Person-Centered Planning/Shared-Decision-Making Approach to Treatment

A shared decision-making approach is predicated on the assumption that all clients (and family members) need critical information to make informed decisions, but that ultimately it is the client's decision that determines the chosen treatment (Deegan & Drake, 2006). In the medical field, shared decision-making is defined as a collaborative *process* between a client and clinician to share information, perspectives, and responsibility for decisions, when there is no clearly optimal treatment (as is unfortunately often the case with schizophrenia) (Charles, Gafni, & Whelan, 1999). The process is systematic, based on providing information about the likely or possible outcomes related to the decision in question (including outcomes of the various treatment alternatives), clarifying the client's values and goals, and exploring their social support network. The client and clinician are partners, each contributing his or her own specialized knowledge and experience to making the decision, in contrast to traditional hierarchical decision-making in which clients are expected to passively follow the "doctor's orders."

Effective shared decision-making dictates that the clinician be able to: (1) provide evidence-based information (and clinical experience with this condition) regarding possible treatment options and their effects; (2) elicit client perspectives, values, and individual goals; and, (3) use clinical skill in reaching a decision/treatment plan that is mutually agreeable and reasonable to both parties (Towle & Godolphin, 1999).

This approach can improve the ability of clients, for example, to use antipsychotic medication effectively by involving them in the decision to take medication, which demonstrates respect for the client and appreciates the individuality of the recovery process, and highlights the notion that there are multiple pathways to recovery. Involving and respecting the ability and right of the clients to make their own treatment decisions help in recognizing the reality of where the choice lies, and avoid jeopardizing the therapeutic relationship by either ignoring the clients' desires or using coercion (as described in the section "Ability to Develop a Strong Working Alliance with People Who Have Schizophrenia" above).

8.6.6   Ability to Work Effectively with Natural Supports (such as Family Members) of the Person with Schizophrenia

Natural supports are nonmental health professionals who by virtue of their relationship and regular contact with the client may be in a position to help that person manage his or her psychiatric illness or make progress toward personal goals (Rapp & Goscha, 2006), such as family members, friends, employers, self-help group members, and other members of a community organization. In the absence of collaboration with these individuals, some natural supports may inadvertently undermine the client's treatment (e.g., discouraging medication adherence because they do not understand its role in treatment; encouraging alcohol

consumption at parties) or progress toward goals (e.g., discouraging returning to school or work because of fear that stress will provoke a relapse). Further, because of their contact with clients in everyday settings, natural supports are often in an ideal position to support illness self-management behaviors and steps toward goals. In addition, since many people with schizophrenia have cognitive impairments that can interfere with practicing skills related to illness self-management, job performance, or social/self-care skills in the natural environment, engaging and collaborating with natural supports can facilitate the acquisition of new skills (Tauber, Wallace, & Lecomte, 2000). Finally, work with natural supports also aims to help individuals repair relationships with family members or friends that may have been damaged during or after an episode of psychosis, in order to delay or prevent a potential loss of supportive relationships.

Given the importance of natural supports, it is crucial for clinicians to be aware of and understand these potential benefits. Moreover, clinicians need to develop the clinical skills necessary to effectively engage family members and other supports (Murray-Swank et al., 2007). This engagement generally includes (but is not limited to): (1) the provision of a clear and accurate description of the symptoms, course, treatment, and prognosis of schizophrenia and the community resources to access; (2) the ability to answer questions about the disorder and instill a recovery-based philosophy; (3) involvement of the natural supports in treatment planning as appropriate; and (4) the conveyance of an empathy and respect for the natural support persons and their important role in the client's life. When engaging natural supports (especially family members) in the client's treatment, it is critical for the clinician to do so while maintaining appropriate therapeutic boundaries with these individuals, as well as upholding appropriate client–family member boundaries by respecting the client's right to confidentiality and autonomy.

8.6.7   Motivational Enhancement Skills

Motivational enhancement strategies are widely used in psychiatric rehabilitation approaches aimed at improving illness self-management skills (Gingerich & Mueser, 2005a), substance abuse (Bellack, Bennet, & Gearon, 2007; Mueser, Noordsy, Drake, & Fox, 2003), and goal-setting and treatment planning (Corrigan, McCracken, & Holmes, 2001), and thus they have broad applicability throughout work with this population. Problems sustaining motivation to follow through on desired plans and goals, for example, are one of the defining negative symptoms of schizophrenia ("avolition").

While a wide range of strategies falls under the rubric of motivational enhancement (see section "Expert Competencies" below for a more detailed description of motivational interviewing interventions), clinicians working with individuals with schizophrenia should be competent in engaging the client in a variety of motivational enhancement-based exercises in the service of progress toward treatment goal attainment. These basic skills include first understanding and "meeting the client where he or she is at" in regard to behavioral change, and helping the client weigh the "pros" and "cons" of a contemplated change in behavior (e.g., taking medication, using drugs and alcohol). Clinicians should make concerted effort to help clients break down large goals into smaller and more manageable steps (e.g., saying "hello" to other clients at mental health clinic, then joining a new group, then inviting someone to go out for coffee as small steps toward a larger goal of "expanding social network"). Clinicians also need

to have skills to effectively explore with clients how behavior change can facilitate progress toward goals and to aid clients in reframing past challenges and setbacks as opportunities to identify personal strengths and survival skills (Mueser et al., 2003).

8.6.8   Understanding and Skill at Using Basic Cognitive-Behavioral Therapy Skills with Clients with Schizophrenia

A broad range of cognitive-behavioral therapy (CBT) approaches has been developed over the past several decades for a variety of psychiatric conditions. Basic efficacious CBT approaches with relevance to persons with psychosis include social skills training (e.g., conversational skills, job interviewing, substance refusal), training in relaxation skills to manage anxiety and paranoia, coping strategies for managing persistent symptoms (e.g., hallucinations, negative symptoms), problem-solving and self-monitoring (e.g., to modify smoking, eating, or substance use behaviors), and behavioral tailoring to incorporate medication into one's routine and increase medication adherence (Gingerich & Mueser, 2005a).

In addition to competence in CBT skills for this population, clinicians need to adopt and effectively convey the "spirit of CBT" which emphasizes a highly collaborative client–therapist relationship; the interrelationship among feelings, thoughts, and behavior; the value of weekly out-of-session homework skills practice to increase skill generalization; and the importance of reinforcement in shaping client motivation and progress toward goals. (See "Expert Competencies" section below for a description of more advanced CBT techniques.)

8.6.9   Skills for Providing Psychoeducation to Clients

Psychoeducation is providing information about psychiatric disorders and their treatment to clients and family members using a variety of teaching strategies designed to maximize comprehension and relevance of the material to their lives (Anderson, Reiss, & Hogarty, 1986; Ascher-Svanum & Krause, 1991). Common psychoeducational teaching strategies include presenting information didactically, using information handouts, asking questions to check understanding, eliciting examples and experiences of individuals related to the material, adopting the language of the person(s) to facilitate understanding, and avoiding conflict by seeking common ground when there are disagreements on topics such as diagnosis, symptoms, treatment experiences, or the explanatory model for understanding psychosis.

Psychoeducation is critical in the treatment of schizophrenia, particularly soon after the development of the illness, because clients and families often know little about the disorder or its treatment. Clients and their relatives need to understand the principles of treatment and the various treatment and rehabilitation options available in order to participate in the informed, shared decision-making that is the backbone of effective treatment of schizophrenia. Abundant evidence shows that people with psychiatric disorders can learn and retain such information (Lincoln, Wilhelma, & Nestoriuca, 2007; Mueser et al., 2002). Clinicians need to ensure that psychoeducational skills training addresses skills of specific interest to the client, and that it is culturally sensitive to the individual's ethnic and cultural background (Corrigan & Holmes, 1994; Lefley, 1987).

8.6.10 Ability to Collaborate Effectively with an Interdisciplinary Treatment Team

Treatment of schizophrenia does not occur in a vacuum, and in the most common outpatient community mental health clinic treatment model, several people from varying disciplines are involved. A typical treatment team may consist of any combination of the following professionals: psychiatrist, case manager, nurse, group home staff, supported employment staff, individual therapist, and group therapist. In addition, as described above, natural supports often play a prominent role in the treatment of those with this disorder.

The variety of disciplines represented in the composition of these treatment teams naturally indicates that the members typically differ in their educational backgrounds, training models, and treatment foci. As a result, clinicians working on these teams must develop skills to communicate effectively with the treatment team, and despite any differences in these areas, be able to maintain a professional and workable relationship for the benefit of the client.

Good interpersonal and assertiveness skills are not only crucial for the clinician in this situation, but also for the client. Clinicians should work with their clients with schizophrenia and help them learn these same skills so that they can improve communications with their other treatment providers (e.g., making an appropriate request to a psychiatrist for a medication adjustment). This can be achieved through modeling and step-by-step social skills training involving role-plays, corrective feedback, and in vivo practice in the client's immediate environment.

8.6.11 Ability to Access Expert Consultation

As with any clinical practice with any population, it is critical for clinicians to know when to seek supervision and consultation from other professionals. While work with individuals with schizophrenia can be incredibly rewarding, it can also be very challenging. Many aspects of the disorder – ranging from hallucinations and delusions to thought disorder and communication deficits, cognitive impairment, negative symptoms, co-occurring substance use, concomitant depression and suicidality, and functional impairment – can be complex to assess and treat. Therefore, clinicians must commit to consistently seeking out new research on effective treatments, attending workshops and trainings on empirically supported interventions for serious mental illness, and keeping close contact with the treatment team and the client's natural supports in order to monitor progress toward goals.

8.7   Expert Competencies of the Clinician

While the aforementioned basic competencies are skills that all clinicians who work with people with schizophrenia should have, it is helpful to have expertise in a few key areas in order to really enhance positive client outcomes. However, as the technology of psychiatric rehabilitation has blossomed in recent years (Corrigan et al., 2008), it is no longer feasible for any one clinician to have expertise in every area or competency. Furthermore, as the most typical setting for schizophrenia treatment is the multidisciplinary treatment team approach, it is possible that among all the members of the team, these expert competencies will be well represented.

Many of the expert competencies that are described below are skills that cut across the variety of the evidence-based treatments currently available for schizophrenia.

8.7.1 Ability to Deliver Group Interventions

Group psychotherapy is a cost-effective treatment model at most inpatient units, partial hospital programs, and outpatient community mental health clinics, and, therefore, is often the intervention mode of choice at these treatment centers. In schizophrenia treatment, the group model serves to create a social network for an often marginalized group of people and also allows for in vivo practice of targeted interpersonal skills.

In addition to developing proficiency in particular evidence-based group interventions for schizophrenia, such as social skills training, teaching illness self-management, and CBT for psychosis, clinicians should develop the ability to deliver these manualized treatments with skillful flexibility. This entails striking a balance between adhering to the manual content and individualizing the specifics of the intervention to meet the needs of the group members. For example, in a group where over half of the participants have reported high levels of distress related to hearing voices, skilled clinicians will spend extra time on the "coping with auditory hallucinations" module within a CBT curriculum.

Group work in schizophrenia also offers some unique challenges. Due to attention deficits, social impairment, and negative symptoms, it is critical for clinicians to develop useful strategies for engaging and motivating participation and interclient interaction in group sessions. Paranoia and delusional ideation about the group leader, other group members, and even the treatment manual content must be met with gentle reassurance on the clinician's part, coupled with the skillful use of cognitive-behavioral evidence testing to challenge these maladaptive, distressing beliefs.

8.7.2 Ability to Provide Empirically Supported Family Psychoeducation

Every clinician who does work in schizophrenia must be able to effectively communicate with and educate family members about this disorder and its treatment (see section on "Ability to Work Effectively with Natural Supports (such as Family Members) of the Person with Schizophrenia" above). However, many families require more attention and a deeper level of skill-building to improve relationships and client outcomes. In many families, the stress and strain of emotionally and financially supporting a relative with a serious mental illness, coupled with the client's own sense of demoralization and self-inefficacy can create a difficult family environment (Hatfield & Lefley, 1987).

Clinicians who develop proficiency in evidence-based family interventions, such as multifamily group therapy (see "Evidence-Based Treatment Approaches" section above), can substantially influence the family climate and in turn, significantly impact client outcomes. For example, in behavioral family therapy (Falloon, Boyd, & McGill, 1984; Mueser & Glynn, 1999), clinicians help clients and their relatives identify and work toward both individual goals (e.g., client wants to reduce substance use, mother wants to take better care of her physical health, and father wants to manage work stress more effectively) and family-based goals (e.g., the family wants to increase frequency of pleasant activities done together and decrease shouting during

disagreements). Then, information is provided to the family about the nature of schizophrenia and its treatment, followed by training in communication skills and teaching a structured approach to collaboratively solving problems. These skills are taught in the context of helping the family work together toward achieving these goals.

8.7.3　Ability to Provide Effective Longer-Term Intervention for Co-occurring Disorders and Ability to Provide Effective Motivational Interviewing Interventions

Given the high prevalence of co-occurring substance use disorders in this population and the resultant morbidity this creates, we have outlined some basic skills that all clinicians should have in order to approach this common problem (see section on "Motivational Enhancement Skills" above). Developing expertise in the treatment of co-occurring disorders is a much needed and much valued skill. In addition to the basic skills described above in the "Motivational Enhancement Skills" section (providing psychoeducation, "meeting the client where he or she is," discussing pros and cons of use), clinicians can provide clients with a longer-term and more detailed intervention replete with a variety of skills to create more enduring changes in substance use behaviors. An expert level of intervention would include clinician training in, and implementation of, the following: a clear understanding and appropriate work within a client's current "stage of change," the teaching and practice of substance refusal skills, the development of the discrepancy between client goals and behavior, review and discussion of the decisional balance for and against substance use versus abstinence, exploration about and skills-based preparation for high-risk situations, and provision of detailed relapse prevention planning (Mueser et al., 2003).

Related to the provision of useful co-occurring disorders interventions is the use of motivational interviewing to illicit changes in other behaviors (in addition to problematic substance use), such as weight loss, medication nonadherence, and smoking cessation. While under the umbrella of a motivational enhancement style (see section on "Motivational Enhancement Skills"), expertise in motivational interviewing "proper" entails use of a more comprehensive set of techniques which includes expressing empathy for the client's predicament, developing the discrepancy between current behavior and personal goals, "rolling with resistance" from the client, support of client self-efficacy, and instillation of hope that positive and lasting change is possible.

8.7.4　Skilled Provision of CBT for Psychosis and Other Difficulties Related to Schizophrenia

As mentioned above, it is important for clinicians working with people with psychosis to understand and utilize a broad range of CBT approaches as well as convey the CBT "spirit." Clinicians who master these more basic skills (social skills training, relaxation skills training, coping skills development, problem-solving, etc.), may go on to develop expertise in this intervention by gaining training and experience in the more "cognitive" aspects of this treatment.

The current cognitive model of psychosis suggests that inaccurate, maladaptive, and unhelpful beliefs are at the heart of a variety of symptoms that afflict those with schizophrenia,

including delusions, negative symptoms, and the distress caused by hallucinations (Beck, Rector, Stolar, & Grant, 2009). In this population, these types of beliefs may also be responsible for the maintenance of depressive symptoms, anxiety, trauma-related symptoms (PTSD), and self-stigma. In order to help clients with these problems, clinicians must first learn and be able to teach to clients the cognitive model of psychotic symptoms. They must gain proficiency in understanding and then conveying the skill of cognitive restructuring, as well as learn to detect, elicit, and help modify maladaptive core beliefs. Development of this expertise can provide tremendous service to clients with schizophrenia, reduce their distress, and increase goal attainment.

8.7.5 Ability to Provide Supported Employment to Clients with Schizophrenia Who Want to Work

Supported employment research has demonstrated that individuals with serious mental illness are able to successfully obtain and maintain work in competitive jobs (Bond, 2004). Clinicians working with people with schizophrenia must adopt this belief and convey this to their clients, their clients' families, and other treatment providers as needed. Basic clinician competency around client employment involves providing support for client work, discussing work history, aiding in the identification of potential job leads, and problem-solving around obstacles to obtaining work. For those clients who already have jobs, clinicians should be adept at helping clients troubleshoot and problem-solve difficulties that may develop at work. Collaboration with the psychiatrist may be necessary to help simplify client medication regimens to help clients keep up with medicine while on the job.

Many of these aforementioned interventions can be provided in the clinic. However, clients often need more in vivo support in order to get and keep jobs employment and be able to successfully maintain their jobs. In these cases, clinicians with expertise in supported employment (Becker & Drake, 2003) can help their clients by providing a more hands-on "fieldwork" experience. Supported employment clinicians provide in-person job development via holding frequent meetings with the clients' employers, as well as providing follow-along support and coaching throughout the employment experience. Clinicians with expertise in this area can significantly aid job retention and therefore the enhancement of the client's quality of life.

8.7.6 Expertise in Cognitive Remediation Interventions

Clinicians who work with people with schizophrenia must have an understanding of the nature and consequences of cognitive impairment that many with this disorder possess. Basic competency in recognizing common deficits (e.g., attention, concentration, abstraction, etc.) and how those deficits impact the work with the clinician and the daily life of the client is crucial. Clinicians must also develop skills to help clients learn strategies to compensate for, or even minimize, these deficits (such as teaching about list making, daily routines, rehearsal, over-learning, and attention-shaping) (McGurk & Mueser, 2006).

As described in the "Evidence-Based Treatment" section above, cognitive remediation is composed of a specific set of interventions designed to train clients to improve their

neurocognition in key areas such as attention and mental flexibility, in the hopes that these improved skills will generalize to improvements in daily living. Research supports the benefits of cognitive remediation, but only when it is provided in combination with other psychosocial rehabilitation approaches, such as social skills training or vocational rehabilitation (McGurk et al., 2007). Cognitive remediation needs to be implemented and evaluated by trained staff using computerized technology that has been shown to improve cognitive functioning in schizophrenia. Furthermore, it needs to be provided in the context of a focused effort on improving a specific area of psychosocial functioning, in a coordinated fashion with other rehabilitation methods. Development of expertise in cognitive remediation involves specific training and access to training technology which can provide substantial benefits to clients in terms of day-to-day skills mastery, success in employment, and general quality of life.

8.8 Transition from Basic Competence to Expert Competence

Perhaps due to the complex nature of schizophrenia, and the many potential areas of impairment caused by this disorder (social, cognitive, vocational, etc.), numerous forms of rehabilitation have been developed and tested in recent years. As a result, a great deal is known about effective psychosocial rehabilitative treatment of this disorder, which makes for a hopeful and exciting time in the field of intervention for serious mental illness. As previously mentioned, there are too many evidence-based practices in the treatment of schizophrenia for any clinician to become a master of every one (i.e., social skills training, CBT for psychosis, family psychoeducation, integrated treatment for dual disorders, cognitive remediation, illness management and recovery). Rather, most professionals tend to develop expertise in a few specific areas.

There is no consensus about what constitutes an "expert" in these treatment areas. Compared to the treatment of other psychiatric disorders (such as depression and anxiety), specific programs to certify clinicians' mastery of particular interventions for schizophrenia have not been established in the USA. As yet, the term "expert" has not been defined. Furthermore, for many years the psychosocial rehabilitation of schizophrenia was not viewed as possible in clinical psychology (Mueser & Noordsy, 2005), and even now many graduate training programs still do not offer courses and training opportunities in these interventions. Only now are some universities starting to integrate coursework and training in empirically supported treatments for serious mental illness into their curricula, and still, on a very limited basis (Spaulding et al., in press).

Nevertheless, there are several ways to pursue meaningful training in these specific interventions and move toward expertise. These strategies are outlined below.

8.8.1 Learn the Literature

Do a comprehensive literature search on the intervention of interest, and work toward staying abreast of new articles and findings on the subject. There are several good books written on most of these interventions, some of which are theoretical in nature and provide an excellent background overview of the treatment (see Table 8.1).

🔹 **Table 8.1**

Resources for training in psychosocial interventions for schizophrenia

Books and Treatment Manuals
Supported Employment Becker & Drake (2003) Swanson, Becker, Drake, & Merrens (2008)
Assertive Community Treatment (ACT) Allness & Knoedler (1998) Stein & Santos (1998)
Integrated Treatment for Dual Disorders Bellack et al. (2007) Mueser et al. (2003)
Cognitive Behavioral Therapy (CBT) for Psychosis Beck et al. (2009) Kingdon & Turkington (2004) Morrison, Renton, Dunn, Williams, & Bentall (2004) Wright, Turkington, Kingdon, & Basco (2009)
Family Psychoeducation Anderson et al. (1986) Barrowclough & Tarrier (1992) McFarlane (2002) Mueser & Glynn (1999)
Illness Management and Recovery (IMR) Gingerich & Mueser (2004) Gingerich & Mueser (2005b)
Cognitive Remediation Brenner, Roder, Hodel, Kienzle, Reed, & Liberman (1994) Wykes & Reeder (2005)
Social Skills Training Bellack et al. (2004) Liberman et al. (1989)
General Psychiatric Rehabilitation Anthony, Cohen, Farkas, & Gagne (2002) Corrigan et al. (2008) King, Lloyd, & Meehan (2007) Liberman (2008) Pratt, Gill, Barrett, & Roberts (2007)

8.8.2   Read Relevant Treatment Manuals and Books

There are now some published treatment manuals for different interventions which walk clinicians through the treatment in a step-by-step fashion, providing detailed descriptions of each session, means to troubleshoot obstacles that may arise with clients, and reproducible handouts and worksheets (see ❯ Table 8.1).

■ **Table 8.2**

Conferences, meetings and professional organizations with special interest in psychosocial interventions for schizophrenia

• American Psychological Association (APA) www.apa.org
• Association for Behavioral and Cognitive Therapies (ABCT) www.abct.org
• Schizophrenia and Other Serious Mental Disorders Special Interest Group (Affiliated with ABCT) www.schizophreniasig.com
• International Association for Cognitive Psychotherapy (IACP) www.the-iacp.com
• US Psychiatric Rehabilitation Association (USPRA) www.uspra.org

8.8.3 Attend Specialty Conferences and Meetings

An excellent way to deepen understanding about the theory behind and the application of a particular intervention for schizophrenia is to attend a conference that hosts many researchers and practitioners in the field. For instance, the Association for Behavioral and Cognitive Therapies and the US Psychiatric Rehabilitation Association both hold annual meetings that are generally well represented by professionals working with individuals with serious mental illness.

At such meetings, in addition to learning about new findings in the field, one can attend presentations often given by the developers of the actual intervention of interest, and even have the opportunity to interact with these professionals and ask questions. See ❯ Table 8.2 for additional conferences.

8.8.4 Seek Out Workshops and Other Specialized Training Opportunities

While the number of psychology graduate programs offering courses in empirically supported interventions for schizophrenia remains fairly small, it is worthwhile to search for courses or seminars of interest at local universities with masters or doctoral programs in clinical psychology, social work, or counseling psychology, or within psychiatry, psychology, or social work departments of university-affiliated medical centers.

At some conferences, half- or full-day workshops are often available to provide training in interventions such as CBT for psychosis and family psychoeducation.

8.8.5 Connect with Other Expert Practitioners and/or a Mentor in the Field

In reading books and manuals about these interventions of interest, expert professionals can be readily identified. Attending conferences, meetings, courses, and workshops provide excellent opportunities to connect with these experts. Because the field of psychosocial intervention in schizophrenia is still relatively small, most researchers and practitioners are quite amenable to interacting with clinicians interested in learning more about a

particular treatment. Finding an expert mentor is a terrific way to build expertise and be exposed to new opportunities for training.

8.8.6   Volunteer Time and Obtain Ongoing Supervision

Once one has participated in some of the aforementioned suggested activities, the next step toward expert competence is hands-on training and supervision. To gain expert competence in family psychoeducation, for example, seek out a clinician who provides this intervention and volunteer to co-lead some family sessions with him or her.

Ongoing supervision and consultation is key. If there is opportunity to provide treatment in a particular area, such as develop and run a social skills training group, or provide individual integrated dual disorders treatment, seek out ongoing appropriate supervision. This should involve initial treatment planning and case conceptualization, and weekly or biweekly phone consultation with the expert supervisor. Video or audiotaping treatment sessions (with clients' consent, of course) is ideal, as both clinician and consultant can review sessions and discuss techniques in detail.

8.8.7   Monitor Client Progress and Outcomes

An important way to evaluate one's own path to expert competence in a particular intervention is, of course, to monitor how the client is responding to the delivery of the treatment. For example, do family members receiving behavioral family therapy report reduced stress at home? Are the members of the social skills training group completing weekly homework worksheets? Has the client with alcohol dependence and schizoaffective disorder reduced his number of drinks per day? Frequent assessment of clients' progress – via both informal and formal measurement – can be an excellent gauge of clinician skill.

In addition, it is crucial to monitor the clinician's gains as well. This is often accomplished through specific treatment fidelity measures, best completed by the supervisor or consultant. Areas for improvement can be readily identified and strategies to increase adherence and proficiency discussed.

8.9   Summary

Schizophrenia, characterized by psychotic symptoms, negative symptoms, and cognitive deficits, can be one of the most debilitating psychiatric illnesses, resulting in significant impairment in social and occupational functioning. In addition, those with schizophrenia also often suffer from trauma and PTSD, co-occurring substance use disorders, and an increased risk for serious health conditions (e.g., HIV) and suicide.

Despite the often grave consequences of this disorder, in recent years several types of treatments have gained empirical support as helpful interventions to ease symptoms and improve functioning, including some antipsychotic medications, supported employment, assertive community treatment, integrated treatment for dual disorders, cognitive-behavioral therapy, family psychoeducation, illness management and recovery, cognitive remediation, and social

skills training. The successes of these interventions have created evidence-based hope that schizophrenia is a condition that is manageable, treatable, and from which recovery is a very realistic possibility.

For clinicians who work with people with schizophrenia, there are some important basic skills that must be developed in order to provide practical and effective treatment. These competencies include the adoption of a recovery and strengths-based, shared decision-making philosophy which is the cornerstone for the development of a strong working alliance with individuals with schizophrenia. Clinicians ought to have knowledge about several aspects of the disorder, solid assessment skills, and the ability to elicit the natural supports of the client, interact well with an interdisciplinary treatment team, and seek appropriate consultation. Additional basic skills in motivational enhancement, cognitive-behavioral therapy techniques, and the delivery of psychoeducation should be developed as well.

Exactly what constitutes "expertise" in the treatment of schizophrenia has not yet been standardized and it is quite rare for one individual to be a master of all of the empirically supported interventions for schizophrenia. However, there are some important expert competencies that when mastered, can significantly improve client outcomes, among these: provision of effective group interventions, family psychoeducation and/or behavioral family therapy, longer-term integrated treatment for dual disorders and standardized motivational interviewing, cognitive-behavioral therapy, supported employment, and cognitive remediation.

As discussed in this chapter, transition from a basic level of competence to an expert level of competence in the treatment of schizophrenia in all areas of intervention is generally not a realistic goal, nor available training-wise. Nevertheless, there are a variety of ways to gain expertise in these areas. Reading up on treatments of interest, seeking out available courses and workshops, and connecting with other experts in the field are excellent initial steps toward expertise in a particular intervention. Finding opportunities for real-world practice and delivery of these interventions, coupled with ongoing supervision and consultation with a trained clinician, can have a tremendous effect on clinicians' abilities to deliver these important interventions, while conferring significant benefits to clients with schizophrenia over time.

9 Borderline Personality Disorder

Darcy C. Norling · Soonie Kim

Abstract: Borderline Personality Disorder (BPD) is a devastating and stigmatizing disorder. Many therapists refuse to treat this population due to the severe pathology involved. BPD patients' extreme emotional and behavioral dysregulation including anger directed at the therapist and impulsive, life threatening behavior can be tremendously taxing on the therapist, not to mention heighten their ethical and legal risk. Dialectical Behavioral Therapy (DBT), a psychosocial treatment that combines cognitive-behavioral theory and methods with eastern meditative principles and practices, has changed this picture significantly. Several randomized clinical trials have demonstrated DBT to be the most hopeful and helpful of any new therapy available for people with BPD. As icing on the cake, it also provides a very stimulating and rewarding experience for the therapist. As such, many therapists are clamoring to learn the treatment. Although there is a wealth of information that describes the treatment itself, very little has been written regarding the necessary steps to provide it well. In this chapter we offer guidelines on how to achieve competency in DBT and further discuss how to move from beginning to expert status. The information presented has been gleaned over the last 15 years; from both formal training in DBT as well as personal experience providing full fidelity DBT "in the trenches".

9.1 Overview

Borderline Personality Disorder (BPD) is a debilitating disorder characterized by emotional and behavioral instability. The diagnosis of BPD is a chronic condition that traditionally has not responded well to standard community-based outpatient and inpatient treatment. Further, BPD is a stigmatized disorder resulting in negative attitudes and apprehension with regard to providing treatment (Lequesne & Hersh, 2004; Paris, 2005). One of the most challenging aspects is the fact that many clients with BPD engage in suicidal behavior. This fact greatly increases the anxiety of therapists, as they worry about the legal and ethical dilemmas that accompany suicide.

In addition, many clients with BPD struggle to control their anger and experience high amounts of conflict within their relationships. Anger is often turned toward the therapist, creating increased emotional vulnerability in the therapist and consequently leading to high burn-out rates.

With the creation of Dialectical Behavioral Therapy, however, many of these concerns have been alleviated. Marsha Linehan has transformed the way in which individuals conceptualize and treat BPD, which in turn has resulted in less burn out for therapists and more successful treatment outcomes.

Linehan and her colleagues have conducted many research studies which have resulted in less judgmental and more specific characteristics of BPD. These characteristics fall into the five

following areas of dysregulation: (1) emotional, (2) interpersonal, (3) cognitive, (4) behavioral, and (5) self (Linehan, 1993a).

9.1.1   Emotional Dysregulation

Emotional dysregulation refers to rapidly changing and intense emotions. Many researchers feel emotion dysregulation is the most significant problem for those diagnosed with BPD (Linehan, 1993a). They are extremely sensitive (even minor disturbances set them off), easily reactive (quick to jump to extremes), and have a difficult time returning to their baseline (Linehan). Anger and frustration are particular emotions that many individuals diagnosed with BPD struggle with. It is not uncommon for them to become physically or verbally aggressive when feeling angry.

9.1.2   Interpersonal Dysregulation

Many individuals diagnosed with BPD have extreme difficulty within relationships, often experiencing high amounts of conflict. The relationships of those diagnosed with BPD are likely to be unstable and rapidly changing from infatuation and joy to being filled with rage, anger, and hatred. In addition, individuals diagnosed with BPD generally fear being left alone and are likely to misinterpret cues as evidence of rejection or impending abandonment. When they sense a relationship is coming to an end, they often become panicked and filled with anxiety. They are likely to experience catastrophic thoughts, such as fearing they will "never find someone else" or that "they will be alone forever" and will often engage in extreme and risky behaviors (e.g., attempt suicide, become aggressive, self-harm) to avoid being left alone.

9.1.3   Cognitive Dysregulation

Many individuals diagnosed with BPD experience unhelpful and problematic thoughts and/or a disconnection from reality during times of extreme stress. They are likely to experience paranoid or negative thinking. For example, they may believe that they are being negatively evaluated or judged or fear that someone is intentionally trying to cause them harm. They often display "extreme" thinking or "black or white" thinking in which they only see their interpretation of the event. In addition, individuals diagnosed with BPD have periods of dissociation (tuning out, numbing out, "foggy state"), especially when they are under extreme stress. Dissociation often serves as a way to distract or cope with the negative emotion or event they are currently experiencing.

9.1.4   Behavioral Dysregulation

Individuals with BPD often engage in risky and impulsive behaviors that result in harm to themselves or to others. Such behaviors may include sexual promiscuity, spending sprees, substance abuse, and rage outbursts. In addition, recurrent suicidal behavior, gestures, threats,

or self-mutilating behavior are quite common. Such behavior is one of the primary reasons therapists experience great trepidation about working with this population.

9.1.5 Self-Dysregulation

Individuals diagnosed with BPD often report a lack of knowing one's self and feeling empty inside. They often express they do not know who they are or what they want out of life. The state of emptiness is extremely unsettling and uncomfortable. They may describe this feeling as having a "deep hole inside" or as a "void." The experience of not knowing one's self often results in such individuals behaving differently based on the situation or the context of the interaction.

9.2 Recognition of Symptoms and Their Assessment

A primary goal of the initial assessment session is to arrive at an accurate diagnosis and plan for treatment. This can be extremely challenging when working with individuals with BPD because rarely do such clients present to treatment for help with their personality disorder. Instead, individuals with BPD and other personality disorders are likely to present for treatment due to one or more Axis I conditions. Treatments that are geared at only the Axis I disorder are often ineffective and result in the therapist concluding the presentation as atypical or referring to the client as unmotivated and/or unwilling to change (McClanahan, Kim, & Bobowick, 2003). In any event, the end result is that a potentially helpful treatment which does not produce the intended changes and therapy is ineffective and often terminated. It is therefore crucial that attention to the diagnosis of possible personality disorders occurs within a broader context of a general clinical interview (McClanahan et al., 2003).

It is helpful to remember the five areas of dysregulation (i.e., self, cognitive, behavioral, emotional, and interpersonal) when assessing for BPD. Information regarding each of these areas should be gathered from a variety of measures in order to ensure the most accurate and thorough assessment. The following are the most standard means of assessment: (1) clinical interview (using questions from structured interviews, emphasizing a detailed relationship history, and including direct observations of the client in session), (2) collateral information, and (3) self-report measures.

9.2.1 Clinical Interview

The clinical interview is likely the most widely used method for gathering information and can provide valuable information. During the clinical interview, it is critical that specific details be gathered regarding past behavioral and psychiatric experiences. It is especially important to inquire about the individual's past experiences in therapy and relationships. Other areas to address include: work/school history, substance use, self-harm and suicidal behaviors, hospitalizations, childhood history, developmental concerns, traumatic experiences, legal history, and other impulsive/compulsive behaviors (e.g., spending money, eating, sexual behavior).

Using a structured diagnostic interview (or parts of one) can assist in gathering pertinent information to make an accurate diagnosis. The Structured Clinical Interview for DSM-IV Axis II (SCID-II; First, Gibbon, Spitzer, Williams, & Benjamin, 1997) is one such structured interview that can be used. It asks a variety of questions that screen for the areas of dysregulation associated with BPD. In addition, the Suicide Attempt Self-Injury Interview (Linehan, Comtois, Brown, Heard, & Wagner, 2006) is used to measure detailed information regarding recent non-suicidal self-injury and suicidal behavior. Examples of outcome variables include: frequency of self-injury and suicidal behaviors, medical risk of such behaviors, and impulsivity.

As noted earlier, the clinical interview should focus a great deal on past relationships. The following list provides examples of relationship descriptions that may be suggestive of BPD: moving quickly from extremes between idealization to intense devaluation, relationships with high conflict that may end impulsively and quickly, discussion of feared rejection by others, and impulsive behaviors done to avoid abandonment.

During the clinical interview, it is also useful to observe in-session behavior. For example, how does the client respond to feeling frustrated or angry? Although in-session behavior will definitely be important to observe, it is likely that during an initial assessment phase, the individual may not display overt symptoms of BPD. In fact, depending on their current stress level, they are likely to present as quite pleasant, socially adept, and appropriate in session. This is a primary reason why this disorder is easily missed early in treatment and why it is necessary to gather collateral information.

9.2.2 Collateral Information

Gathering releases in order to communicate with past treatment providers is a crucial task during the initial assessment and is especially true when working with clients who may be diagnosed with BPD. As discussed earlier, such individuals often display "extreme" thinking and may have skewed interpretations of situations. It is challenging to gather accurate information during the initial assessment phase due to these problematic thought patterns. Past providers can provide a great deal of pertinent information regarding the client's history. It may also be helpful to gather information from other sources, such as family members, friends, and employers.

9.2.3 Self-Report Measures

Self-report measures can also be very helpful when diagnosing and treating an individual diagnosed with BPD. Linehan utilizes a great number of self-report measures in her research clinic to assess for a variety of factors. For example, the Reasons for Living Inventory (Linehan, Goodstein, Nielson, & Chiles, 1983) is used to assess a client's expectations for living or killing oneself and the importance of a variety of reasons for living. The Borderline Symptom List (Bohus et al., 2007) is used to assist in diagnosing BPD. Such measures can help a clinician to determine the diagnosis, suicidal risk, specific treatment targets, and also assist in measuring changes throughout the treatment.

In addition to self-report measures geared specifically for BPD, we also recommend a general measure of emotional and behavioral distress, such as the Outcome Questionnaire

(OQ-45.2, Lambert et al., 1996), which is given to clients during the initial assessment phase and throughout treatment. The three areas of functioning accessed are: symptom distress (e.g., how a person feels inside), interpersonal relations (e.g., how a person gets along with significant others), and social role (e.g., how a person is doing in important life tasks such as work and school, Lambert et al.). It also assesses for such risk factors as suicide and substance use. Such a measure will help to determine the client's current functioning in a variety of domains and provides an additional means of assessing for change throughout treatment.

9.3   Maintenance Factors of the Disorder

When examining the factors that maintain BPD, an important place to begin is with a discussion of the factors involved in the development of the disorder. These factors are likely to also play a role in the maintenance of the disorder. The biosocial model proposed by Linehan (1993a) provides the theory behind DBT and an explanation of how and why problematic behaviors arise. In addition, there are things individuals learn through their enviroments that contribute to the maintenance of the behavioral and emotional dysregulation evident in those diagnosed with BPD.

Biosocial Model. According to Linehan (1993a), BPD is primarily a dysfunction of the emotional regulation system that results from both a biological vulnerability and a dysfunctional environment. DBT terms this the biosocial theory, which states that BPD occurs as a result of the interaction between an individual's innate emotional vulnerability and an invalidating environment. Having a biological emotional vulnerability suggests that certain individuals are born with an increased emotional vulnerability and have difficulty regulating their emotions (Linehan). Three factors characterize someone who is emotionally vulnerable: (1) a high degree of sensitivity, (2) high reactivity, and (3) a slow return to baseline. According to the biosocial theory, this emotional vulnerability interacts with an invalidating environment.

An invalidating environment is one in which the communication of private/internal experiences is met by inconsistent, extreme, and unacceptable responses; regardless of the validity of the experience (Linehan, 1993a). An invalidating environment has three primary characteristics. First, it communicates that what you are thinking, doing, or feeling is inaccurate, inappropriate, or wrong (e.g., "You shouldn't feel sad," "There is no reason to be mad"). The invalidating environment also rejects or punishes emotional displays (e.g., "You are just trying to get attention," "Cry-baby") and often only attends when the child displays strong, emotional outbursts. Finally, the invalidating environment oversimplifies the difficulty of solving a problem (e.g., "Just get over it," "Why can't you just feel happier").

It is the transaction between the emotional vulnerability and the invalidating environment that results in the severe dysregulation exhibited by those diagnosed with BPD. For example, the emotionally reactive child who is told that her feelings are inaccurate may have difficulty trusting her own internal experience and will rely on others to determine what she "should" be feeling. Because she is always looking to the environment to know what she feels, she struggles to develop a sense of self. In addition, the emotionally sensitive child who is only attended to when she screams and yells learns that the only way to gain support is to display a huge emotional outburst. She is never taught how to label or regulate her emotions. Behaviors such as cutting, threatening suicide, overdosing on pills, and burning become the manner in which these individuals regulate their emotions. Finally, the emotionally sensitive child who is told to

"just get over it" is not able to form realistic goals and never learns how to cope with emotions. She struggles to tolerate emotional distress and therefore engages in impulsive behaviors in order to decrease the distress (in the short term) and gain support.

The extreme emotional and behavioral dysregulation displayed by individuals diagnosed with BPD impacts their ability to form and to maintain stable and strong relationships. Such relationships require a stable sense of self and an ability to regulate emotions, both of which these individuals lack. Conflict within relationships is one of the most common stressors faced by individuals diagnosed with BPD and often leads to self-harm and suicidal behavior. Further, their strong emotional reactivity and sensitivity is likely to result in continued invalidation within their relationships, which unfortunately maintains the problems mentioned above.

Models of Learning. What an individual learns through life experiences increases or decreases the likelihood of problematic behaviors continuing. There are three primary modes of learning: modeling, operant conditioning, and respondent conditioning. Modeling involves watching another individual's behavior and then attempting to replicate what was observed. For example, a child watches his or her mother use a spoon to eat and then takes a spoon and attempts to mimic her behavior. Another example would be a child who watches his or her father behave violently toward the family and then begins to behave aggressively toward his or her toys.

Operant conditioning is learning through consequences. Whatever occurs immediately following the behavior either increases or decreases the likelihood that the behavior will occur again. Positive factors, such as praise and money, increase the likelihood of behavior continuing and negative factors, such as punishment or shame, decrease the likelihood of the behavior continuing. For example, a child works hard in school in order to earn a prize (e.g., cell phone). The prize serves as a positive reinforcer and increases the likelihood that the hard work in school will continue.

Finally, respondent conditioning is learning through association. Learning occurs when a natural, automatic response is paired with a neutral cue, to the point that the cue automatically produces the response. For example, a child is repeatedly terrorized after school by a gang of kids (natural response is fear). As a result, the child develops a strong fear of school (previously neutral cue). When he or she simply looks at, or drives by, his or her school, he or she automatically feels panic (the cue of school now elicits the panic). Both operant and respondent conditioning play significant roles in the maintenance of BPD.

According to operant conditioning, behavior that is reinforced whether positively (i.e., providing a "rewarding" consequence) or negatively (i.e., removing a negative consequence) is likely to continue. A factor that greatly contributes to the maintenance of BPD is that the problematic behaviors that generally accompany this disorder work (i.e., produce positive and/or negative reinforcement), at least in the short term. Consider, for example, an individual who gets into an argument with her boyfriend during which he threatens to leave. She tells her boyfriend she is going to take pills to kill herself and her boyfriend, fearing her death, immediately calms and provides her with comfort. This individual was both positively and negatively reinforced for her behavior of threatening suicide. She was provided with comfort (positively reinforced) and the argument stopped (negative reinforcement). Both of these factors increase the likelihood that this individual will engage in similar behavior the next time she is in an argument.

This behavior often turns into a pattern quickly because the maladaptive behavior is reinforced and learning of coping skills or new behaviors does not occur. For example, suppose a

negative life event occurs (e.g., argument with a friend, losing a job) and as a result, the individual feels sad, angry, or anxious. An individual with BPD who has not learned effective coping skills may engage in some maladaptive behavior in order to regulate these emotions (e.g., self-harm, suicidal behavior). This behavior is then reinforced because she feels better, at least in the short term; however, this behavior does not teach her new ways of coping and may lead to a long-term result of increased negative life events. As a result, the next time a negative event occurs, she is likely to engage in the same maladaptive behavior.

With respondent conditioning, an association is learned and continues to effect behavior, even when it no longer makes sense. For example, a neglected child is left alone and this triggers fear. Then as an adult, being alone or even just thinking about being alone triggers fear. When this occurs, it is likely that this individual will engage in frantic efforts to avoid being left alone in order to avoid the anxiety. Because he or she takes great efforts to never be alone, he or she is not provided with the opportunity for new learning to occur. In other words, because he or she avoids being home alone, he or she does not have the opportunity to find out what would happen if he or she stayed alone, and, therefore, his or her fear continues.

9.4 Treatment Overview

Until quite recently, treatment for BPD appeared quite hopeless. Throughout the last 2 decades, however, Linehan and her colleagues have developed a treatment called Dialectical Behavioral Therapy (DBT) that is shown to be effective in treating BPD (Linehan, 1993a, b). It has the distinction of being one of the first psychosocial treatments demonstrated to be effective in a randomized clinical trial (Linehan, Armstrong, Suarez, Allmon, & Heard, 1991). Although other treatments (Bateman & Fonagy, 1999, 2001; Giesen-Bloo et al., 2006; Marziali & Munroe-Blum, 1994) have demonstrated efficacy in providing treatment for BPD, DBT currently has the most empirical support and is thought of as the primary treatment for the disorder (Linehan & Dexter-Mazza, 2008). Because the purpose of this chapter is not to present a thorough description of the treatment, only a concise overview of the treatment will be provided. For a complete explanation of DBT, please refer to Marsha Linehan's main text (1993a) and accompanying skills manual on DBT (1993b). This section will briefly cover the following aspects of the treatment: (1) research to date, (2) differences between DBT and CBT, (3) secondary targets, (4) stages of treatment, (5) functions of treatment, and (6) treatment strategies.

9.4.1 Research to Date

DBT has been evaluated in six randomized control trials conducted across three independent research teams (Koons et al., 2001; Linehan et al., 1991, 1999, 2002, 2006; Linehan, Heard, & Armstrong, 1993; Linehan, Tutek, Heard, & Armstrong, 1994; Verheul et al., 2003). The results have shown DBT to be an effective evidenced-based treatment for BPD (Linehan & Dexter-Mazza, 2008). Participants treated with DBT demonstrated significantly greater reductions in suicide attempts, intentional self-injury, and suicidal ideation (Koons et al., 2001; Linehan et al., 1991, 1999, 2002; Verheul et al., 2003). In the original study of recurrently suicidal patients with BPD, participants treated with DBT were significantly less likely than those receiving treatment as usual to attempt suicide or engage in nonsuicidal self-injurious behavior, were

less likely to drop out of treatment, had fewer inpatient psychiatric days per participant, and improved more on scores of global and social adjustment (Linehan & Dexter-Mazza, 2008).

9.4.2   Differences Between DBT and CBT

DBT was developed out of cognitive-behavioral treatment for BPD. According to Linehan (1993a), DBT differs from CBT in four primary ways: (1) the focus on acceptance and validation of behavior as it is at the moment, (2) the emphasis on treating therapy-interfering behaviors, (3) the emphasis on the therapeutic relationship as an essential tool for change, and (4) the focus on the dialectical process. The theoretical orientation originates from three fundamental theories: behavioral principles, Zen philosophy, and dialectics. Behavioral change strategies are met with acceptance of the client and are balanced within a dialectical framework (Linehan & Dexter-Mazza, 2008). Although DBT is grounded in behavioral principles, its strategies and techniques pull from a variety of other orientations, including psychodynamic, client-centered, and cognitive therapy.

9.4.3   Secondary Targets

As noted earlier, DBT views BPD as primarily an emotion regulation problem which stems from the interaction of an individual's biological emotional vulnerability and an invalidating environment. The combination of emotional vulnerability with an invalidating environment presents many dilemmas for individuals diagnosed with BPD (Linehan, 1993a). These dilemmas impact both the therapist and the client's emotions and behaviors and are considered secondary targets within DBT. There are six primary behaviors that are dichotomized into a set of three polar-opposite behaviors. The first behavior is emotion vulnerability (e.g., the sense of being out of control, emotional sensitivity) and self-invalidation (e.g., hate toward oneself) (Linehan). The second behavior is active passivity (e.g., approaching problems helplessly) and apparent competency (e.g., appearing competent and able to cope). The final behavior is the unrelenting crisis (e.g., perpetual crisis) and inhibited grieving (e.g., avoiding extreme and painful emotions).

These patterns of behavior help to maintain the severe behavioral dysregulation. Treatment involves confronting the behavioral extremes and then forming a synthesis of these behaviors.

9.4.4   Treatment Stages

DBT is divided into five treatment stages with accompanying treatment goals. Clients can enter at any stage based on their current level of functioning. First, a pretreatment stage is spent orienting the client to treatment and eliciting commitment to work toward specified goals. In Stage 1 of treatment, the primary goal is on gaining behavioral control. In the first stage, there are four main targets: decreasing life-threatening behaviors (e.g., self-harm, suicide attempts, serious suicidal intent), decreasing therapy-interfering behaviors of both the client (e.g., showing up late, not completing homework) and the therapist (e.g., reinforcing dysfunctional

behavior, not returning phone calls), decreasing quality of life-interfering behaviors (e.g., major depressive episodes, substance use, eating disordered behavior), and increasing behavioral skills (e.g., emotion regulation, distress tolerance, interpersonal effectiveness, self-management, and mindfulness). All research to date has focused on this first stage of treatment (Linehan & Dexter-Mazza, 2008).

The second phase is aimed at moving a client from quiet desperation, which is defined as a place of extreme emotional pain in the presence of control of action (Linehan et al., 1999), to nontraumatic emotional experiencing. Goals in this stage are the following: accepting the facts of earlier traumatic events, reducing self-blame associated with traumatic experiences, reducing the oscillating denial and intrusive responses, and reducing dialectical tensions regarding placement of blame for the trauma (Linehan & Dexter-Mazza, 2008).

The third stage is geared at resolving problems in living and increasing self-respect and moving toward a place of ordinary happiness and unhappiness. The targets are for the client to gain independence and to trust in one's own feelings and responses. Finally, the fourth stage is aimed at reducing the feeling of incompleteness and developing the capacity for sustained contentment. The goal is for the client to gain expanded awareness and spiritual fulfillment.

9.4.5   Treatment Functions

DBT treatment is structured around the five primary functions of the treatment (Linehan, 1993a). The first function is to enhance behavioral capabilities by expanding the individual's knowledge of skillful behavior. This is accomplished through a weekly skills group. Skills acquisition within an individual therapy session is extremely difficult because of the need to address the high number of crisis behaviors and provide ample attention to the other target behaviors. There are four skill modules (i.e., mindfulness, distress tolerance, emotion regulation, and interpersonal effectiveness) taught on a rotating, ongoing basis over the course of 6 months. Linehan's program requires client's to participate in a 1-year skills training, which entails repeating each of the skill modules.

The second function is to increase the client's motivation to change by reducing reinforcement for ineffective behaviors and high probability responses that interfere with effective behaviors. This is accomplished primarily through weekly individual therapy. The third function is to ensure that new behaviors generalize from the therapeutic to the natural environment. Telephone coaching serves to meet this function. Telephone coaching also follows a target hierarchy to: (1) provide emergency crisis intervention and break the link between suicidal behavior and therapist attention; (2) provide coaching of skills; and (3) provide an opportunity for the client to repair the therapeutic relationship (Linehan & Dexter-Mazzo, 2008).

The fourth function is to enhance motivation and capabilities of the therapist. This is accomplished through the team consultation meeting. DBT believes that it is crucial to spend a great deal of time focusing on the therapist's experience and behavior within a session. The team consultation is a therapy for the therapist and serves to treat burnout and promote adherence to the model. Every therapist is required to be on a consultation team. The fifth function is to structure the environment so that effective, rather than dysfunctional, behaviors are reinforced. This is accomplished through ancillary care services, including consultation to the client, environmental intervention, and team consultation.

9.4.6   Treatment Strategies

DBT utilizes five sets of treatment strategies: (1) dialectical strategies; (2) core strategies; (3) stylistic strategies; (4) case management strategies, and (5) integrated strategies. Within any given treatment session, a combination of these techniques is used. Some may be used more frequently than others, based on the needs of the client. A brief overview of the first three will be provided.

The dialectical strategies encompass all aspects of DBT treatment. These strategies inform the entire treatment. The strategies have evolved out of a dialectical philosophical position that views reality as a wholistic process in a state of constant change (Linehan, 1993a). The primary dialectic within DBT is acceptance and change. This balance is demonstrated within all interactions with the client by utilizing various treatment strategies.

Validation and problem-solving strategies make up the core of DBT. Validation strategies target acceptance. These strategies communicate an understanding of the client's thoughts, emotions, and behaviors in the current context. The problem-solving strategies, on the other hand, target change. The therapist engages the client in analyzing his or her own behavior, committing to change, and taking steps to change the behavior (Linehan, 1993a).

Finally, stylistic strategies refer to the style and the form of therapist communication. These strategies provide guidelines for how the therapist implements other treatment strategies. Style has to do with tone, edge, intensity, speed, and responsiveness. There are two primary communication styles with DBT: reciprocal and irreverent. The reciprocal style suggests responsiveness, self-disclosure, warmth, and genuineness (Linehan, 1993a). The irreverent style is unhallowed, impertinent, and incongruous (Linehan). These two styles represent poles of a dialectical stance and must be balanced.

9.5   Mechanisms of Change Underlying the Intervention

DBT aims to change or interrupt the maintenance factors associated with BPD. According to Linehan (1993a), the therapist aims to create a validating, rather than a blaming, environment in which he or she impedes or extinguishes ineffective behaviors, drags skillful behaviors out of the client, and attempts to make the skillful behaviors very reinforcing so that the skillful behaviors replace the ineffective behaviors. We believe these are some of the most critical factors in creating this change: (1) the therapeutic relationship, (2) thinking dialectically, and (3) properly assessing why the behavior is occurring.

9.5.1   Therapeutic Relationship

The therapeutic relationship is one of the most important tools for change. Establishing a strong relationship from the beginning is crucial. The relationship between the therapist and the patient is often the strongest reinforcer for individuals diagnosed with BPD. Utilizing the stylistic strategy of radical genuineness is the key to establishing a strong relationship with a client. This involves taking a stance of equality with a client and participating in a real relationship.

It is important to address upfront and early in the relationship that the therapeutic relationship may be (and likely will be) negatively affected through the course of treatment and what each party agrees to do, if this should occur. For example, a client may become angry at his or her therapist for showing up late to session or a therapist may feel burnt-out due to a client paging many times throughout the night. How will the client and therapist handle their emotions? Will they simply avoid the issue or will the problem be handled directly? Deciding how such things will be addressed and then following through on these commitments are crucial steps in maintaining a strong relationship.

9.5.2 Thinking Dialectically

Assisting the client in behaving more dialectically is an overriding and pervasive target within DBT. The goal is to help clients to think and behave in a more balanced manner. Clients are encouraged to see reality as complex and multifaceted, with no absolute truth. Teaching clients to be comfortable with inconsistency and contradictory thoughts and helping them to integrate such polarities into a synthesis will assist clients in changing the "all or nothing" or "black and white" thinking patterns that are common with individuals diagnosed with BPD (Linehan, 1993a). Therapists must try to reinforce both a dialectical style of thinking and approaching problems and challenge nondialectical thinking and behaving (Linehan).

As noted earlier, the dialectic of acceptance and change represents the central dialectic in DBT. Effectively balancing of these two extremes is crucial for change to occur. The therapist must move back and forth between these two poles. The goal is to move the client slightly off balance so that his or her behavioral, emotional, and cognitive rigidity is difficult to maintain (Linehan, 1993a). The therapist must be alert and move with certainty and wholeheartedness. Linehan compares the use of dialectics in a relationship to ballroom dancing. The therapist must meet the client where he or she is. According to Linehan, the initial goal of the therapist is to move the client slightly off balance, with a hand guiding the movement so that eventually he or she will relax and be moved by the music.

9.5.3 Assessing the Problem

There are a variety of factors that result in, and maintain, a client's ineffective behavior. It is important to assess the "cause" or the "why" in order to produce beneficial change. Without a proper assessment (done through a thorough behavioral analysis), it is challenging to know how to intervene. If we simply guess what is maintaining/causing the behavior, it is likely that the treatment will be very ineffective and perhaps, even damaging to the client. Think of the analogy of putting diesel fuel into a car that runs on unleaded gas to clarify this idea. There are generally four primary reasons for a client to not act skillfully: (1) skill deficit, (2) contingencies or consequences, (3) strong emotions, and (4) unhelpful thoughts.

A client may not have the "tools in the toolbox." In other words, if a client does not have the knowledge or the understanding of the skill, then teaching the client these skills is a crucial first step. After all, how is a client expected to behave skillfully when he or she is unaware of what constitutes a skillful behavior? The skills or abilities taught in the DBT group sessions serve to

address this concern. These skills specifically target the areas of dysregulation associated with BPD. Through learning these skills, the clients are better able to behave effectively.

If the client has the skills, then what is getting in the way of her acting skillfully? Sometimes "using the tools is not as reinforcing as not using the tools." In other words, it may be more reinforcing (at least in the short term) to not act skillfully. For example, recall the client who got into a fight with her boyfriend and threatened to commit suicide in an attempt to get him to not end the relationship. When the boyfriend decided to stay in the relationship, the client was reinforced and learned that acting impulsively, rather than skillfully, is the way to get what she wants.

Contingency strategies must be put into place. Factors must be constructed to make it more rewarding to use the skills than to act impulsively. These strategies often change behavior through operant conditioning. For example, in order to strengthen an effective behavior (e.g., calling for coaching), you add a reinforcer (e.g., praise) and remove an aversive consequence (e.g., distress decreases). In order to weaken or suppress a dysfunctional behavior (e.g., cutting), you withhold a reinforcer (e.g., limit contact with therapist after behavior has occurred) and maintain or add an aversive consequence (e.g., no contact with therapist for 24 h). These principles will shape the desired behavior.

Sometimes the problem is that the client is "too upset to find/use the right tool." Strong emotions may get in the way of skill use. As noted earlier, Linehan (1993a) conceptualizes BPD as primarily a deficit in regulating emotions. Individuals with BPD have intense, rapidly changing emotions that result in a difficulty in demonstrating skillful behavior. Further, past traumatic events result in many individuals diagnosed with BPD experiencing unresolved, intrusive emotional reactions associated with stress. Some of the common symptoms of BPD may be directly related to these ongoing emotional responses. For these reasons, exposure to emotions (with response prevention) is often a necessary ingredient in the treatment. Such exercises allow for opportunities to practice coping with strong emotions skillfully.

Finally, another factor that inhibits skillful behavior is "figuring that the tools won't work." Thoughts often impact a client's ability to act skillfully. As noted earlier, extreme thinking is a common characteristic of individuals diagnosed with BPD. Addressing these problematic thoughts can be done through cognitive restructuring techniques. This may help clients to understand what factors contribute to such thinking, how they can know when to trust themselves, and what they can do to modify their extreme beliefs. Self-invalidation (which is also a secondary target in DBT) is another example of how negative beliefs can get in the way of behaving effectively. Modeling validation to clients and having them practice stating self-validating statements in therapy (behavioral rehearsal) can help to modify such thinking.

9.6   Basic Competency

The University of Washington is currently working on establishing formal criteria so that clinicians can become credentialed in DBT and programs can become accredited; however, these criteria are still a work in progress. Included in this endeavor will be the development and dissemination of adherence measures that will make it easier to know if what people are calling DBT is, in fact, really DBT. Although the following information is certainly not "the path to DBT enlightenment," it does serve as a compilation of ideas based on our experience over

several years developing and maintaining a full-fidelity DBT program; a journey that has involved training and supervising many DBT therapists along the way.

Webster's Dictionary defines competence as having "suitable or sufficient skill" and being "adequate but not exceptional." What does a therapist need to know to be adequate at providing DBT? What skills and abilities does a competent DBT therapist possess? It is our experience that the initial DBT learning curve is a steep one requiring knowledge and skill across a number of areas (see Linehan's text 1993a and accompanying skills training manual 1993b for elaboration). At the very least, however, we believe a competent DBT clinician should know the following: (1) the biosocial model, (2) the fundamentals of validation, (3) the function of treatment components and how to structure them, and (4) the dialectics.

9.6.1   The Biosocial Model

According to Linehan (1993a), the purpose of a theoretical model is to offer a shorthand way to think about clients, which guides us in creating a new therapy for each client. The biosocial model of DBT provides a way to conceptualize and solve problems according to the models of learning (operant and respondent) and a tool to do so (functional analysis). Thus, it is essential for a competent DBT clinician to know how to conduct a behavior chain including accurately identifying and defining the appropriate behavior to target, what questions to ask to garner information about links in the chain that led up to, and followed, the target behavior, and how to use this information to develop causal hypotheses and possible solutions. With regard to solutions, a competent DBT therapist should also be grounded in CBT, as many of the interventions proposed in DBT are born out of this approach (e.g., psychoeducational skills training, cognitive restructuring, exposure therapy, and contingency management techniques).

9.6.2   The Fundamentals of Validation

The change-based stance in DBT of problem-solving is balanced with one of acceptance, and the core strategy in this area is validation. Basically, validation communicates to the client that his or her responses are real, make sense, and are understandable within his or her life context or current situation. The competent DBT therapist should know when and how to use validation strategically as a way to de-escalate emotions and foster cooperative interaction, provide balance when pushing for change, as reinforcement for clinical progress, and strengthen the therapeutic relationship.

9.6.3   The Function of Treatment Components and How to Structure Them

A competent DBT clinician knows how to begin treatment (i.e., conduct a thorough assessment, orient to treatment, and develop initial treatment targets and build commitment toward working on them), as well as how to structure individual sessions, conduct a skills training group, and respond to telephone consultation calls. Across all components, doing adequate DBT requires knowing your role (e.g., primary duties and responsibilities), given the particular

service you are providing, and being able to identify the appropriate treatment stage and target when interacting with your clients.

Put simply, individual therapy functions to inhibit clients' "bad behavior" (usually effective in the short term but not over the long run) and drag out the good (new, more skillful behavior). Attending to the structure of individual sessions involves mastering many basic skills (e.g., knowing how to open and close a session, review diary cards and homework, as well as how to recognize and treat therapy-interfering behavior as it occurs in session). Working toward mastery can take some time, however, as many DBT therapists have experience in struggling to obtain consistently completed diary cards from their clients. However, this seemingly minute element of DBT cannot be sacrificed for several reasons: (1) self-monitoring is a pivotal skill for clients to learn as part of a self-management program, (2) completing a diary card sets a precedent for clients doing work outside treatment, and (3) the information contained on the card helps set an initial agenda for the session and keep the clinician on track.

The function of group skills training is skills acquisition or teaching new behavior. Regarding structure, a competent DBT clinician should know how to open and close a group, conduct a mindfulness practice, as well as how to teach skills in an active and engaging way. Needless to say, managing a group of individuals who are emotionally and interpersonally sensitive can be a challenging endeavor. This, combined with having a wealth of material to cover in a limited time frame, complicates the process even more. For example, the group leader can easily get sidetracked with one or more members who want to process their "crisis d'jour" in group. To address this situation, the competent DBT therapist is adept at a wide variety of interventions, for example, properly orienting the group ahead of time as to how situations like this will be handled including the rationale for doing so, gracefully weaving a client's discourse into the skills topic at hand, and enlisting the individual therapist's help to shape up the client's group-interfering behavior.

Although telephone consultation serves several functions, the primary goal is to promote generalization of skillful behavior to natural contexts (i.e., to get the client to deal more effectively with problems in their outside lives; when and where they actually occur). This involves amongst many other things, knowing what strategy or skill to use given the situation, knowing what to do when a client responds repeatedly with "yes, but" and "nothing works" during a coaching call, following the 24 h rule to prevent inadvertently reinforcing self-harm behavior with therapist attention, and knowing how to identify and treat inappropriate calls (e.g., too many "supportive connection" calls after hours).

9.6.4 Dialectics

A dialectical world view has three primary characteristics: the principle of interrelatedness and wholeness, the principle of polarity, and the principle of continuous change (Linehan, 1993a). The competent DBT clinician should have an understanding of how these characteristics manifest themselves in treatment and the therapeutic relationship. For example, failing to adopt a dialectical stance of acceptance and change is one of the most common mistakes beginning clinicians make in DBT, which is often a primary factor underlying therapeutic impasses and reason for early termination. Clients who are pushed too hard for change are likely to feel overwhelmed, misunderstood, and perceive their therapist as cold and uncaring. This invariably

leads to the client requesting (or demanding as the case may be) a change in therapists or dropping out of treatment altogether. On the other hand, a therapist who underestimates client capabilities, fragilizes his or her client, or overdoes for the clients runs the risk of fostering "active passivity" in their client (i.e., being overly dependent on their therapist to solve even the smallest of problems). This, in turn, is a major contributing factor to therapist burnout and is contrary to good outcomes for client and therapist alike.

Working with the population for which DBT was designed can be a challenging endeavor and so some have said "takes a certain type of person." Although anyone can learn DBT strategies and skills, some individuals seem to have an easier time than others. Many aspects of DBT are distinctly different than traditional therapy and therapists who come with a preconceived notion of what therapy should look like, whether by personal experience or previous training, may have greater difficulty with reaching competence. For example, self-disclosure, of either personal experience or involving a reaction to the client, is a strategy in DBT. However, many traditional therapies caution, if not prohibit, therapists from engaging in such disclosure. In addition, the active and directive style of a DBT therapist may be perceived as domineering and controlling for clinicians trained in a more "neutral" and "unfolding" approach.

With regard to style, in any given interaction with a client the competent DBT therapist strives to balance a reciprocal with irreverent communication, unwavering centeredness with compassionate flexibility, and nurturing assistance with benevolent demanding. In our experience, beginning DBT therapists seem prone to one style or the other and much of the supervision involves increasing their comfort level with, and ability to engage in, the opposing style. It is the strategic balance of both styles that allows the therapist to push the patient forward with one hand and support them with the other and flexibility and timing are the keys.

Most beginning DBT therapists seem more comfortable with reciprocal communication (i.e., a therapist style that is warm, caring, and supportive), as opposed to irreverence (i.e., a style that is matter-of-fact, offbeat, straightforward and at times, even playful). It is important for a competent DBT therapist to be able to do both equally well, as each has its use for achieving certain client goals.

Unwavering centeredness is the notion of believing in oneself, the therapy, and the client (Linehan, 1993a). It is being able to tolerate the pain or discomfort of what needs to be done in the short term, in order to get clients better over the long run. Compassionate flexibility, on the other hand, refers to the contrasting quality of being able to take in new information about the client and modify a previously held position. Needless to say, because DBT is a complex treatment, it is likely that the therapist will make many mistakes. The competent DBT therapist must be willing to acknowledge these mistakes, validate the client's experience, and do what is necessary to rectify negative outcomes.

Finally, nurturing assistance includes teaching, coaching, strengthening, and aiding the patient. Heightened awareness in this process is critical as without it, the therapist may miss subtle reactions to things done and said in therapy, by them or other group members. The provision of nurturing assistance is skillfully balanced with benevolent demanding; the therapist's recognition of the client's existing capabilities, push for adaptive behavior and self-control, and refusal to come to the client's aid when he or she can handle the situation on their own. (See ❯ Table 9.1 for a session rating form that can be used to evaluate basic adherence).

◻ **Table 9.1**
Portland DBT program, PC: Therapy session rating form
Therapist:_____ Reviewer and Date of Review: _____

Please comment accordingly
1. Diary cards are used in the session
2. Therapy session focuses on appropriate stage and target of treatment
3. Therapist balances irreverent and reciprocal communication styles
4. Therapy session is focused on skills acquisition, strengthening, and generalization
5. Therapist acts as a consultant to client
6. Therapist is dialectical in session: models or uses dialectical stance/strategies
7. Therapist uses core strategy of validation (specify level 1–5)
8. Therapist uses core strategy of problem-solving: formal problem and solution analyses
9. Other comments

9.7   Expert Status

Elaborating on the qualities of a DBT expert is both an exciting and daunting task. The underlying dialectical dilemma is, on the one hand, recognizing the importance of operationally defining what constitutes an expert in DBT and on the other, knowing if it is impossible to quantify many factors in the process. Similar to the idea of two chefs in a bake-off who follow the same cake recipe to the tee, yet in the end, one turns out better then the other. How did this occur? Perhaps it was due to the mood of the chef as he or she mixed together the cake's ingredients, how each cake was presented, the perceived reputation of the chef, or something on the part of the judges. The point of this analogy is twofold. First, expertise likely does not exist in any single person but is better defined by outcomes, and second, achieving expert results is probably a culmination of a number of complex, person–environment interactions at any given moment, as well as over time. That being said, discerning what factors contribute to differential outcomes is crucial when it comes to getting better at what we do. Although difficult, if not impossible, we must try.

How, then, is an expert DBT therapist able to produce more effective clinical outcomes more efficiently than a novice one? What does he or she actually do differently? Based on our experience, the expert DBT clinician has a firmer grasp on: (1) application of DBT to themselves and their team; (2) radical genuineness; (3) mindfulness; and (4) speed, movement, and flow.

9.7.1   Application of DBT to Themselves and to Their Team

The expert DBT clinician practices "what he or she preaches." This is a manifestation of the "parallel process in action," which means that the same things we do to get clients better (in treatment), we do to get therapists better at treating their clients (in supervision). The expert DBT therapist possesses a deeper understanding of both the client and the treatment as a result of applying the treatment in their own lives; to their own behavior and in their personal

relationships. For example, being adept at regulating emotion (e.g., anxiety) allows the expert clinician to feel more comfortable in session, thereby improving their capacity for creativity, ability to work with what is happening in the room, and strategically move from principle to protocol without missing a beat. In addition, heightened ability to see things "dialectically" increases the expert clinician's awareness of the many, transacting factors that create and maintain problems. The expert is constantly asking the question "what is being left out?" with particular emphasis on his or her own contribution to the problem as well as the solution.

On a related note, many beginning DBT therapists avoid confrontation (e.g., calling a spade a spade) as clients can be quick to get angry and verbally attack when challenged or conversely, easily fall apart and engage in high-risk or crisis-generating behavior. Both instances illustrate the dynamic of the therapist being punished for doing good therapy. Nevertheless, it is critical that DBT therapists use exposure therapy on themselves, so that they can confront when necessary (e.g., going to where angels fear to tread). For example, I (Soonie) recently worked with a woman who had been fired by her last three therapists. When asked why, she stated that each therapist, in one form or another, had told her she was "just too complicated" for them to work with. Not long into our treatment the reason became apparent, from start to finish of our sessions, the client was critical and attacking. No matter what I said or did, it was the wrong thing in her eyes. After our sessions I felt beat up, or more aptly put, like I "had been run over by a Mack truck."

In order to continue working with this client I had to confront the problem behavior head on (although the thought of doing so was terrifying to say the least). Although initially my feedback provoked heightened anger on her part, over time we were able to work through the problem and our relationship (and sessions) improved dramatically. By practicing opposite to emotion action on myself (basically exposure therapy), I was able to treat my client's "in-session dysfunctional behavior" effectively.

9.7.2 Radical Genuineness

The expert DBT clinician works to be radically genuine (i.e., equal to the client and engaged in a real relationship). For example, recently I (Darcy) accepted a quick page from a client on my cell phone. I was in the car with a friend and took the page, keeping confidentiality in mind. After getting off the phone, my friend stated, "You were just so you in the phone call." Radical genuineness reduces pressure on the therapist to "stay in the role" with their client which in turn, makes for more comfortable and rewarding interactions. Radical genuineness also creates an inherently validating experience for clients who communicate equality and respect (i.e., the therapist interacts in the same way with their client as they would with a family member or friend; clients are no better or worse and are entitled to the same treatment). Finally, a radically genuine relationship between a therapist and a client approximates the real-world relationships offering the opportunity for in vivo corrective experiences.

9.7.3 Mindfulness

Mindfulness functions to help the expert DBT clinician maintain moment-to-moment awareness of both the client's behavior and his or her own throughout their interactions. This

information is then used in an intentional way to promote a good working alliance between parties and enhance client progress in reaching their goals.

Mindfulness practice also enables the expert DBT therapist to let go of judgment and expectations of what should be, radically accepting the client just as he or she is at any particular point in time. Paradoxically, acceptance of "what is" often shifts clients to change, thereby moving them that much closer toward their goals. Inhibiting judgment (the experience of badness versus goodness, the desire to hold on to what feels good and push away what does not) is a challenging skill, particularly because clients' problems often occur in the context of relationship and have a direct and negative impact on the people around them – including their therapist. In this respect, inhibiting judgment helps the therapist regulate potentially damaging emotions (e.g., anger, frustration), which can disrupt the relationship and thwart client process. Adopting a nonjudgmental stance also opens the door to seeing things more clearly and critically (i.e., without bias, so that the therapist can more accurately identify and treat the problem at hand).

An expert DBT clinician not only uses mindfulness in his or her work, but also incorporates the principles and practices into his or her daily life. Although some argue that mindfulness practice outside the work setting is necessary for even a beginning DBT clinician, in our experience many DBT therapists do not engage in such practice. We have come to believe, however, that regular and disciplined mindfulness practice is absolutely necessary to move from being competent in DBT to becoming an expert. It is the actual experiencing, fully and deeply, of what concepts like judgment and acceptance really are which proves to be essential.

9.7.4   Speed, Movement, and Flow

The expert DBT therapist is adept at thinking on their feet. He or she is able to attend to the great influx of a client's behavior as it speeds by and organize it in ways that take into account both principle (e.g., conceptualize based on models of learning) and protocol (e.g., manage the session according to the appropriate stage and target of treatment). Linehan (1993a) identifies this task as being one of the most challenging for new therapists and one of the most important to the overall progress of therapy. The expert DBT therapists' session flows in a seemingly effortless manner as they discern targets accurately, move smoothly back and forth from validating the client to pushing for change, maintain balance stylistically and all the while, and are in skillful collaboration with the client.

9.8   Transition from Basic to Expert Status

Although adherence to the model is a primary goal for any DBT clinician, adherence does not guarantee competency or expertise. Competent DBT comes with formal training and supervised practice, expert status with time, continued practice and ongoing consultation. There are three important avenues that move a DBT neophyte to competence and onward to expert: (1) formal training, (2) supervised practice, and (3) the consultation team.

◼ Table 9.2
Portland DBT program, PC: First-year training checklist

1. Sit in on group – full round covering all the skills
2. Sit in on at least two intakes followed by orientation sessions (conducted by two different therapists with one being a senior staff person)
3. Attend weekly team consultation meeting
4. Attend weekly one-to-one appointment with supervisor
5. Observe family and friends orientation workshop
6. Participate in current study groups offered at the program
7. Participate in monthly mindfulness consultation group offered at the program
8. Review all program paperwork and forms
9. Review the format and content of clinical charts
10. Watch "Getting Started" videotapes with MML (BTTG)
11. Watch "Assessing and Treating" videotapes with MML (BTTG)
12. Watch client videotapes on "Crisis Survival Strategies," "Opposite-to-Emotion Action," and "Radical Acceptance" (BTTG)
13. Attend any outside DBT trainings recommended by the supervisor (BTTG)
14. Attend in-service trainings and workshops offered by the program
15. Attend intensive or fundamentals training (BTTG)
16. Read DBT text and skills manual

9.8.1 Formal Training

It is important to expose oneself to as many formal training opportunities in DBT as possible. Coursework in DBT is now available in some graduate programs and online through independent training groups. Other training opportunities include attending formal workshops in DBT ranging from 2-day introductory sessions to 10-day intensive trainings. It is highly recommended that therapists striving to achieve expert status in DBT attend an intensive training followed by regular consultation with an expert in the field. Formal training can be accomplished in other ways such as participating in study groups where books are read and discussed and DVD training videos watched. We have created a DBT training checklist for new therapists to ensure they receive what we feel is an adequate dose of training their first year. (See ▸ Table 9.2 for an example of our agency's training list). You may also refer to *DBT in Clinical Practice: Applications Across Disorders and Agencies* (Dimeff & Koerner, 2007) for more ideas on how to provide basic training in DBT.

9.8.2 Supervised Practice

Direct experience practicing any new behavior is necessary to achieve mastery. While reading about DBT will provide a basic understanding of the treatment and guidance in how to

■ **Table 9.3**

Portland DBT program, PC: DBT supervisor interview questions

1. What is the extent and nature of their training in DBT?
2. Have they completed the 10-day intensive DBT training?
3. Have they been supervised by an expert in DBT? By whom and for how long?
4. How many clients have they treated using DBT?
5. Do they have experience in any DBT adaptations (to other problems, populations and settings)?
6. Are they part of a DBT team? Who else in on the team? How often do they meet?
7. What happens in each component of DBT? What are the goals/functions of individual therapy versus group versus phone consult?
8. How do they manage their DBT after-hour crises?
9. What is their familiarity with the research on DBT?

implement it, actual practicing is the sine qua non to providing the treatment competently. This, of course, assumes that practice is supervised and that supervisor feedback is incorporated. Supervisors are advised to monitor and evaluate their supervisees beyond "talking about treatment," for example through direct observation via sitting in on sessions, watching them through a one way mirror, and through observing videotaped sessions. We encourage that supervisors evaluate their supervisee's work for both adherence to protocols and for acting from overarching principles of dialectics, mindfulness, and models of learning. Finally, very similar to an individual session in DBT, supervision should be an active process emphasizing practice both inside the session (e.g., role-play) and out (e.g., homework). For a more extensive discussion regarding DBT supervision, see the chapter by Fruzzetti et al. (1997) in *The Handbook of Psychotherapy Supervision*.

In order to become an expert in DBT, it is essential to work with a supervisor who is an established expert himself or herself. This is no easy task as there are far more individuals seeking supervision from DBT experts than there are experts in the field. Nevertheless, it is necessary to be closely connected with a supervisor skilled in DBT and who is also grounded in the underlying theoretical principles on which the treatment is based. We have provided a list of interview questions to ask a potential DBT supervisor (see ❯ Table 9.3). Above all, be sure to check out the individual's credentials including DBT training references and/or certificates if available.

9.8.3   Consultation Team

As noted throughout this chapter, having a well-functioning consultation team is a critical factor in the ongoing development of a DBT therapist. In fact, it is a basic requirement of DBT that anyone conducting the treatment be part of a consultation team that meets regularly. Just as clients agree to abide by certain conditions of DBT (i.e., treatment agreements), the treatment team agrees to abide by a set of consultation team agreements (see ❯ Table 9.4). These agreements should be clearly communicated to the new team members before joining the group and reviewed by the team as a whole on a regular basis. Adhering

⬛ **Table 9.4**

DBT consultation team agreements (From Linehan & Dexter-Mazza, 2008)

1. *Dialectical Agreement*: We agree to accept a dialectical philosophy. There is no absolute truth. When caught between two conflicting opinions, we agree to look for the truth in both positions and to search for a synthesis by asking questions such as "What is being left out?"

2. *Consultation to the Client Agreement*: We agree that the primary goal of this group is to improve our own skills as DBT therapists, and not serve as a go-between for clients to each other. We agree to not treat clients or each other as fragile. We agree to treat other group members with the belief that others can speak on their own behalf

3. *Consistency Agreement*: Because change is a natural life occurrence, we agree to accept diversity and change as they would naturally come about. This means that we do not have to agree with each other's positions about how to respond to specific clients, nor do we have to tailor our own behavior to be consistent with everyone else's

4. *Observing Limits Agreement*: We agree to observe our own limits. As therapists and group members, we agree to not judge or criticize other members for having different limits from our own (e.g., too broad, too narrow, "just right")

5. *Phenomenological Empathy Agreement*: All things being equal, we agree to search for nonpejorative or phenomenologically empathic interpretations of our client's, our own, and other member's behavior. We agree to assume that we and our clients are trying our best and want to improve. We agree to strive to see the world through our client's eyes and through one another's eyes. We agree to practice a nonjudgmental stance with our clients and with one another

6. *Fallibility Agreement*: We agree ahead of time that we are each fallible and make mistakes. We agree that we have probably either done whatever problematic things we are being accurse of, or some part of it, so that we can let go of assuming a defensive stance to prove our virtue or competence. Because we are fallible, it is agreed that we will inevitably violate all of these agreements, and when this is done, we will rely on each other to point out the polarity and move to a synthesis

to these agreements creates an atmosphere of mutual respect and trust that is critical to learning to provide effective DBT.

The consultation team serves many functions but first and foremost it aims to improve the therapist's skill at providing DBT. The primary process by which therapists get better at doing DBT parallels clients using DBT to get themselves better, i.e., therapists practicing the treatment strategies and skills with, and on, each other. Thus, in addition to staffing client issues in the team meeting, therapists look for opportunities to apply the treatment "in vivo." For example, chain and solution analyses are regularly conducted on team members who are consistently late or not prepared for meetings. Another common scenario involves one team member experiencing increasing anger and frustration at another because their fellow team member "should know better" or "be doing things differently" than they are. This situation provides a rich opportunity for the "accuser" (i.e., frustrated team member) to practice radical acceptance and taking a nonjudgmental approach to assessing the problem with the "perpetrator" (i.e., problematic team member). Finally, in our experience, therapists (being the greatest conflict avoiders/people pleasers of them all) are notorious for fragilizing each other due to fear of anger, being disliked, or having others think poorly of them. The use of exposure to "approach not avoid" the feared stimuli or situation is warranted in order to achieve the end goal of improved skill in providing DBT.

9.9   Summary

DBT is a ground-breaking treatment shown to be effective in the treatment of BPD, a disorder that for many years was thought untreatable. Providing DBT treatment to individuals diagnosed with BPD is a complex and challenging process. It is our experience that there is a steep learning curve in understanding and delivering the treatment. There are many things to keep in mind and to balance when conducting DBT. In addition, the population for which DBT is designed further complicates factors. There is a high rate of burnout associated with working with individuals diagnosed with BPD because of their extreme emotional and behavioral dysregulation, including rage outbursts and suicidal behaviors. As a result, mastering DBT is a challenging process.

Very little is written about how to become a DBT clinician. The questions of "What differentiates a beginning-level DBT clinician from an expert DBT clinician?" and "How does someone become an expert?" have not been formally answered. This chapter is the first to address such questions. The answers included in this chapter, however, remain merely a hypothesis. At this point, from a research perspective, we do not know exactly who or what qualifies as an expert DBT clinician. Formalizing such information will hopefully lead to increased fidelity and adherence by clinicians to the DBT model and thereby result in more effective services for our clients.

10 Substance Use Disorders

David J. Kavanagh · Jason Connor · Ross Young

Abstract: Basic competencies in assessing and treating substance use disorders should be core to the training of any clinical psychologist, because of the high frequency of risky or problematic substance use in the community, and its high co-occurrence with other problems. Skills in establishing trust and a therapeutic alliance are particularly important in addiction, given the stigma and potential for legal sanctions that surround it. The knowledge and skills of all clinical practitioners should be sufficient to allow valid screening and diagnosis of substance use disorders, accurate estimation of consumption and a basic functional analysis. Practitioners should also be able to undertake brief interventions including motivational interviews, and appropriately apply generic interventions such as problem solving or goal setting to addiction. Furthermore, clinical psychologists should have an understanding of the nature, evidence base and indications for biochemical assays, pharmacotherapies and other medical treatments, and ways these can be integrated with psychological practice.

Specialists in addiction should have more sophisticated competencies in each of these areas. They need to have a detailed understating of current addiction theories and basic and applied research, be able to undertake and report on a detailed psychological assessment, and display expert competence in addiction treatment. These skills should include an ability to assess and manage complex or co-occurring problems, to adapt interventions to the needs of different groups, and to assist people who have not responded to basic treatments. They should also be able to provide consultation to others, undertake evaluations of their practice, and monitor and evaluate emerging research data in the field.

10.1 Overview

Substance use disorders (SUDs) are common, with an incidence in the general population of around 9% (excluding tobacco) – a rate similar to mood and anxiety disorders (Grant et al., 2004). Furthermore, they often have a severe impact on physical health, psychological status, and social functioning (e.g., Bush, Autry, Bush, & Autry, 2002). Together, these features highlight the importance of effective prevention and treatment responses. Clinical psychologists have contributed significantly to the development, evaluation, and implementation of interventions in this field, and assurance of their competencies has substantial potential impact on service quality.

While all psychological disorders require a multidisciplinary approach if they are to be fully understood, this is especially true for SUDs. The fact that these disorders involve ingestion of psychoactive agents requires that practitioners have a basic understanding of relevant information derived from pharmacology, neurophysiology, genetics, and general medicine. This knowledge becomes especially important for expert practitioners.

However, the need for multidisciplinary knowledge should not overshadow the importance of knowledge and skills acquired from the mainstream discipline of clinical psychology.

Despite recent developments in the basic science and pharmacotherapy of addiction, assessments and frontline treatments for substances of abuse retain strong influences from psychological theory and research. In many cases, interventions have been adapted from other problem areas (e.g., anxiety, social skills). In others, specific interventions have grown within SUDs (e.g., motivational interviewing, relapse prevention), some of which are now applied in the treatment of other disorders. This chapter discusses the evidence base for psychological responses to substance misuse and the nature of related competencies and describes key areas from other disciplines as well.

10.1.1 Key Concepts

Psychoactive substances alter the functioning of the central nervous system, so the users experience temporary changes in consciousness (including emotions, perceptions, and other cognitions). They are broadly categorized into *depressants*, *stimulants*, and *hallucinogens*. Intoxication with depressants results in acute suppression of neural activation, and depending on the neural systems involved, it is typically experienced as sedating. Depressants do not necessarily trigger or worsen a depressed mood, although some may do so (e.g., dysphoria subsequent to an episode of alcohol use). Stimulants trigger neural excitation, while perceptual changes are the key hallmark of hallucinogens. These categories should be seen as shorthand descriptions that are to some extent, simplifications. For example, some substances do not easily fit into this rubric. Cannabis has subjective effects across all three categories (Green, Kavanagh, & Young, 2003), and some effects of cocaine (typically categorized as a stimulant) involve inhibition of neural transmission (Frishman, Del Vecchio, Sanal, & Ismail, 2003). Substances often have contrasting effects over time, setting, and dosage (e.g., initial increases in pulse and blood pressure at low doses of alcohol, but reductions at higher doses).

While levels of *intoxication* generally increase with dosage, individuals show differential sensitivity to effects, and effects of a given dose may change over time, depending on their physiological state and history of use. Psychoactive substances can be seen as poisons, since overdoses can have deleterious effects (e.g., sedatives suppress respiration or heartbeat and stimulants can increase heart rate and blood pressure to the point where cardiac fibrillation or brain hemorrhage may occur). *Metabolism* of the substance protects the body to same extent from toxic accumulation, although this protection is limited by enzyme kinetics. Some metabolites can also have aversive and potentially dangerous effects. An example is acetaldehyde, the initial metabolite of alcohol (Jelski & Szmitkowski, 2008), which can produce symptoms of nausea and sympathetic nervous system arousal.

Withdrawal refers to effects of stopping or substantially reducing consumption. In general, withdrawal effects approximate the opposite of intoxication (e.g., sedation/excitation), although the full story is more complex. Repeated use triggers structural and functional neural changes: some involve *sensitization* to the presence of the substance (e.g., increased motivational salience; Robinson & Berridge, 1993); others comprise neural adaptation. The latter effects are experienced as increased *tolerance* when more of the drug is needed to have the same effect. Over time, adaptational responses become faster and stronger, and pleasure from intoxication becomes less intense and shorter in duration (Koob & Le Moal, 2008; Solomon, 1980). Use

becomes more strongly associated with relief of withdrawal ("needing") rather than hedonic "wanting" (Robinson & Berridge). Increased incentive salience and tolerance are important contributors to progressive increases in consumption that are commonly seen with psychoactive substance use, and the progressive neural adaptation underpins development of a full *withdrawal syndrome* after a history of heavy use. There is a significant classical conditioning effect, with withdrawal being more pronounced in the presence of environmental cues associated with drug administration.

Substances with a high potential for misuse have extremely pleasurable net effects of intoxication or are particularly prone to tolerance and an aversive impact from cessation. Route of administration is an important contributor to rate of uptake and distribution through the body, with injection and inhalation typically resulting in a steeper trajectory of effects than gastrointestinal use.

The rate of metabolism is also important. Substances which are rapidly metabolized into inactive metabolites and are rapidly excreted (e.g., nicotine) are associated with frequent consumption, not only because more frequent use is required to maintain the acute substance effects, but also because the salience and aversive nature of a rapidly developing withdrawal is a powerful trigger for immediate use. On the other hand, substances with a longer half life (e.g., methadone and some benzodiazepines) produce challenges for the ongoing maintenance of abstinence in the presence of a withdrawal that may extend over several weeks.

10.2   Developmental Symptoms and Their Assessment

10.2.1 Problem Features

For many people, some substance use (e.g., caffeine or alcohol) is pleasurable and nonproblematic. For others, substance use can have a severe impact on health, quality of life, and economic and social functioning (Connor, Saunders, & Feeney, 2006). *High-risk use* refers to consumption that conveys a significant risk of later problems. Some substances (e.g., cigarette smoking) have no level of consumption that is physically "safe." In other cases (e.g., alcohol), there may be benefits of low-level use, so that net health effects may be positive (Li, 2008; cf. Fillmore, Kerr, Stock-well, & Bostrom, 2006). Recommended maximum limits for alcohol vary across countries and over time: the current level in the USA is less than or equal to two drinks (28 g ethanol) a day for men and less than or equal to one drink (14 g ethanol) a day for women (United States Department of Agriculture and United States Department of Health and Human Services, 2005).

Two key substance-related disorders in the *Diagnostic and Statistical Manual of Mental Disorders*, *4th Edition* (DSM-IV) (American Psychiatric Association, 1994) are *abuse* and *dependence*. Substance abuse refers to repeated substance use, despite impairments in functioning across important interpersonal, social, and occupational domains, or recurrent use in situations that are physically hazardous. It is positioned in the context of social norms and culture. For this reason, it does not appear in *International Classification of Diseases – 10th Revision* (ICD-10) (World Health Organization, 2004), which, instead, has a diagnosis of *harmful use* (i.e., a pattern of use that is producing mental or physical harm).

Substance dependence additionally involves a pervasive, chronic cluster of psychological, behavioral, and physiological drives that maintain the condition typically associated with excessive administration. The current conceptualization of dependence relies extensively on the seminal description of the alcohol dependence syndrome by Edwards and Gross (1976). The features include withdrawal (or use to avoid it), tolerance, inability to control use (i.e., often used more than intended or over a longer period; a persistent desire or unsuccessful attempts to stop or reduce), high priority for use (i.e., substantial time obtaining, using, or recovering; other important activities stopped or reduced), and continued use despite physical or psychological harm (a feature similar to ICD-10 Harmful Use). DSM-IV requires three of the seven features to be present in a 12-month period and the presence of clinically significant impairment or distress.

While abuse was thought to be a milder form of substance use problem in DSM-IV (Feingold & Rounsaville, 1995), more recent research has cast doubt on whether most abuse criteria involve milder symptoms (Li, 2008). Substance-related problems are better described along a continuum of severity (Gillespie, Neale, Prescott, Aggen, & Kendler, 2007; Kahler & Strong, 2006), with particular features occurring at different levels of frequency of use or severity of dependence in different substances (Gillespie et al., 2007).

Key clinical psychology competencies in the addictions field should not only encompass the basic concepts summarized above, but reflect the emerging sophistication in our understanding of substance-related disorders and the potential for significant changes in diagnostic criteria over time. In the remainder of this chapter, we use the term *substance use disorder* (SUD) to embrace abuse, harmful use or dependence, and *substance misuse,* to include both SUDs and high-risk use.

Substance misuse contributes disproportionately to human morbidity and mortality, with the high prevalence and risks from tobacco and alcohol use offering a particularly heavy burden (World Health Organization, 2008). The impact of a specific substance on an individual is augmented by heightened risks of co-occurring substance misuse (Substance Abuse and Mental Health Services Administration, 2008) and other mental disorders. Approximately half of the people with an alcohol use disorder and three quarters with another drug use disorder also meet criteria for at least one other mental disorder (Kessler, McGonagle, Zhao, & Nelson, 1994). Because of their high population prevalence, depression and anxiety disorders are the most commonly co-occurring mental disorders, even though the greatest relative risk occurs in bipolar disorder and schizophrenia (Regier et al., 1990). So, one in four people with alcohol dependence carry a lifetime history of mood disorder and one in three have had an anxiety disorder (Merikangas et al., 1998). High rates of comorbidity mean that competencies for practice in SUDs should not be seen in isolation: a competent practitioner in this field should also have competence in assessment and treatment of other mental disorders and should be able to tailor assessment and treatment for people with co-occurring substance misuse (Kavanagh & Connolly, 2009a, b).

10.2.2 Assessment

Assessment should always be integrated into the therapeutic process, and this is especially important in addictive disorders. Rather than being an information-gathering exercise, assessment provides valuable lead into brief opportunistic interventions that develop awareness

and build motivation. As discussed further below, there is strong evidence supporting the efficacy of brief interventions delivered in this manner.

10.2.2.1 Establishment of Trust

Substance use problems often attract negative social responses, and the use of many substances is illegal. It is therefore not surprising that many substance users reject labels they perceive as value-laden (e.g., "alcoholic") and minimize substance-related problems, particularly when reporting them to others. Use and abstinence of specific substances can be confirmed by biochemical assays, but self-report remains the only practical way to obtain the level of detailed information that allows development of a detailed functional analysis. Before someone is willing to freely discuss their substance use and its effects, they must be assured that disclosure will not have negative consequences. Development of a nonjudgmental and warm relationship and clarity about confidentiality and use of information are particularly important when trust is initially low.

10.2.2.2 Assessment of Consumption

Intoxication and cognitive impairment can make it difficult for users to encode and recall substance use, but inaccuracy in consumption can also arise from the way in which questions are asked. Such inaccuracy may be interpreted as a consequence of "alcoholic denial," but there is little evidence to support this. Omitting questions about specific substance groups is a frequent cause of underreporting, and reports of "usual" consumption are prone to recall biases and error, particularly if there are substantial variations in usage over time. If there are stable weekly or monthly patterns, accuracy can be increased by asking about specific substances that are used each day of the week or month, and further improvements can be made by triangulation from multiple estimates (recent frequency and typical amount; weekly purchases, cost). Tracking usage often requires detailed knowledge of quantities that are actually used (e.g., drink sizes): this may entail both education and home tasks.

Use of event-cued recall of consumption on a calendar-based Timeline Followback (Sobell & Sobell, 1993) can provide detailed information about consumption over the previous 1–3 months. If the person is highly motivated, daily self-monitoring may be used over short periods. Cues and time-stamped records can be offered by using e-mails, electronic diaries, or mobile telephones, and errors due to intoxication may be reduced by tracking products (e.g., number of bottles, amount of the substance or money remaining). Self-monitoring may underestimate usual consumption by cueing self-control. While potentially problematic for assessment, this feature may be used to assist early stages of treatment (Kavanagh, Sitharthan, Spilsbury, & Vignaendra, 1999).

Where an underestimated consumption is suspected, a "bogus pipeline" effect may be used (Roese & Jamieson, 1993), where the person is informed that confirmatory evidence, such as physiological measures, can be used to check reports. While this strategy may be unavoidable when there are contingencies for reduction or abstinence, care is needed to maintain trust and rapport when it is used. It also raises broader ethical issues, and collateral reports may be used as a more pragmatic and honest means to validate self-reports. However, collateral reports also

raise ethical and pragmatic problems. Substance use may be hidden from others, and collaterals are subject to the same recall errors and biases as the client.

It is tempting to see biochemical analyses as the gold standard, although considerations of cost, limited sensitivity to small amounts or longer periods, and ambiguity of interpretation can be issues. For example, breath analyses for smoking or alcohol have practical application only to consumption over the previous few hours. Plasma thiocyanate can detect smoking over the previous 14 days, but is relatively insensitive to light smoking (Pre & Vassy, 1992). Current biomarkers of heavy alcohol use vary in sensitivity and specificity, and some are also inflated by other conditions, but a combination of markers increases accuracy (Miller & Anton, 2004). In general, assays have greater utility for outpatient assessment where the focus is on detection of abstinence versus use (rather than changes in quantity and frequency), and where the substance or a metabolite is present for a longer period (e.g., cannabis; Musshoff & Madea, 2006), or where it is captured (e.g., in hair). However, even when all of these are present, sensitivity can still sometimes be an issue (e.g., plasma provides greater sensitivity to cannabis use than hair; Musshoff & Madea). A general clinical psychologist may be expected to understand basic assays and reports (e.g., blood alcohol level, carbon monoxide, substances detected by a laboratory), but a specialist in alcohol and other drugs should be able to administer a breath test and be aware of limitations of other specific biochemical assays.

10.2.2.3 Functional Analysis

A functional analysis of substance misuse has the same elements as other problems (Wilson, Spence, & Kavanagh, 1989; chapter 9), embracing both deficits and strengths (e.g., periods of abstinence or moderation; effective coping, unaffected aspects of the person's life), examining historical and current antecedents and consequences or incentives, and covering cognitive, affective, behavioral, physiological, and social domains. Since ambivalence about consumption or engagement in treatment is often present, careful analysis of positive and negative incentives for current use and behavior change (and the accuracy of these expectancies) is particularly important.

10.2.2.4 Psychometric Measures

There are many robust psychometric instruments for screening and assessment of SUDs. It is beyond the scope of this chapter to review each of these measures. Sound summaries are provided by Dawe, Loxton, Hides, Kavanagh, and Mattick (2002) and Allen and Wilson (2003).

10.3   Maintenance Factors of Substance Misuse

While psychological, biological, cultural, and social factors contribute to the development of problematic use, there is no simple explanation for some becoming dependent, while others do not. The predominant theories for etiology of problem drinking up to the early 1960s were grounded in a disease model. On the basis of anthropological (MacAndrew & Edgerton, 1969)

and experimental (Marlatt & Rohsenow, 1980) studies, the idea that problematic substance use and anticipated effects of substances draw heavily on learned behavior has gained acceptance. While the genesis of substance use problems clearly involves genetic risk (Wong, Schumann, Wong, & Schumann, 2008), this needs to be complemented with a broader understanding of the psychological and socio-cultural processes involved in problem drinking.

In common with other problem domains, social-cognitive theory (Bandura, 1982) continues to make a significant impact on our understanding of the initiation and maintenance of addictive disorders. Bandura (1997) identified two types of expectations that have particular relevance to addictions: outcome and self-efficacy expectancies. Positive outcome expectancies of substance use develop from an early age, often vicariously, and are associated with increased risk of substance-related problems (Goldman, 1987; Young & Oei, 1993). Low self-efficacy expectancies for control of substance use are associated with increased substance use (Skutle, 1999) and relapse following treatment (Maisto, Connors, & Zywiak, 2000). Outcome and self-efficacy beliefs are typically more powerful predictors together than individually (Baldwin, Oei, & Young, 1993; Bandura, 1999).

Other psychological theories that have informed our conceptualization of substance misuse include Social Control Theory (based on family and affiliative group beliefs and supervision), Behavioral Choice Theory (based on the relative access to drug and nondrug rewards), and Stress and Coping Theory (where coping skills to face challenges without substance use are suboptimal or absent; Moos, 2008).

Identified risk factors for substance misuse support the premises of all four theories. These include: (1) social environmental adversity, such as high crime, alienation, and high population density, (2) family pathology such as parental substance misuse, family disruption, poor attachment and low parental monitoring, and (3) peer influence, such as a heavy or precocious peer substance use and delinquency and individual risks, including the presence of childhood traumatic events, conduct disorder symptoms, impulsivity, low self-esteem and mood or anxiety disorder. Risk factors are comprehensively reviewed in Armstrong and Costello (2002) and Weinberg, Rahdert, Colliver, and Glantz (1998).

10.4 Evidence-Based Treatment Approaches

There is substantial evidence on effectiveness of interventions for alcohol (Miller & Wilbourne, 2002) and tobacco use (The Clinical Practice Guideline Treating Tobacco Use and Dependence Update Panel Liaisons and Staff, 2008). Evidence to support intervention choices for many other substances is less advanced. For example, psychological intervention for benzodiazepine dependence provides incremental improvements in outcomes above gradual dose reduction alone, but there is insufficient evidence to identify effective treatment components (Parr, Kavanagh, Cahill, Mitchell, & Young, 2009).

10.4.1 Motivational and Brief Interventions

Motivational interviewing (MI) was developed by Miller (1983) for treatment of problem drinkers and further refined by Miller and Rollnick (1991) and Rollnick and Miller (1995). MI has been defined as "a client centered, directive method for enhancing intrinsic motivation to

change by exploring and resolving ambivalence" (Miller & Rollnick, 2002). Ambivalence is a common feature of clients considering making a change to problematic substance use. Key goals of MI are to avoid labeling, support self-efficacy, recognize and accept ambivalence as normal, and encourage the client's own reflection and dialog for change.

Several reviews and meta-analyses support the efficacy of MI in the treatment of most SUDs (e.g., Kaner et al., 2007; Rubak, Sandback, Lauritzen, & Christensen, 2005; Vasilaki, Hosier, & Cox, 2006), although studies on nicotine dependence show high heterogeneity and low effect sizes (Burke, Arkowitz, & Menchola, 2003; Dunn, Deroo, & Rivara, 2001). Confrontation, which is antithetical to MI, is an ineffective treatment (Miller & Wilbourne, 2002).

In the Miller and Wilbourne (2002) meta-analytic review of 361 controlled alcohol treatment trials, MI and other brief interventions had greater cumulative support than a wide range of other psychological and pharmacological treatments. Two landmark trials have compared a multi-session version of MI, motivation enhancement therapy (MET), with comparison treatments (Project MATCH Research Group, 1998; UKATT Research Team, 2005). These trials demonstrated that MET had equivalent efficacy to Cognitive-Behavioral Therapy (CBT), Twelve-Step Facilitation (TSF; Project MATCH Research Group), and Social Behavior and Network Therapy, a CBT-based treatment (UKATT Research Team, 2005, 2008), and that it achieved this benefit in substantially fewer sessions. Consistent with the model underpinning MI, outpatients who commenced at lower levels of baseline motivation and reported higher anger levels had better outcomes from MET in Project MATCH, although the former effect was restricted to the first year of follow-up (Project MATCH Research Group, 1997, 1998).

10.4.2 Twelve-Step Facilitation (TSF)

The most widely recognized TSF approach is Alcoholics Anonymous (AA). It involves self-help groups that offer ongoing mutual peer support, and promote an abstinence goal (Anonymous, 2007; Vaillant, 2005). While health practitioners do not participate in AA activities, both approaches may co-occur. Central to TSF is that participants accept that they are powerless over their substance use. Other steps involve taking greater responsibility, including restitution for past harm to others, while letting go of inner struggle. Although the core theme is to surrender to a higher power to assist with change, TSF does not support any specific religion. Other features in some countries include use of a buddy system (a "sponsor") to provide support between group meetings.

There are significant methodological challenges in assessing the efficacy of AA, since most groups do not register participants, attendance, or outcomes. Few controlled studies of self-help groups exist (Kelly, 2003), and almost exclusively these examine alcohol dependence. While there is support for the hypothesis that more AA attendance is associated with better outcomes (Emrick, 2001), this result confounds commitment to change with group exposure. While two meta-analytic studies found little support for AA in treatment of alcohol use disorders (Ferri, Amato, & Davoli, 2006; Kownacki & Shadish, 1999), trials often lack a placebo, no-treatment, or wait-list control.

To provide more rigorous tests of the relative efficacy of TSF, some studies have used an intervention that applies a TSF philosophy, without actually being an AA group. Outcomes of such trials are mixed at best (Miller & Wilbourne, 2002). Identification of patient characteristics associated with a greater impact from TSF has also had little success. In Project MATCH,

participants with a social network of heavy drinkers did better from TSF than MI, but only at the 3-year follow-up (Project MATCH Research Group, 1997, 1998).

10.4.3 Cognitive-Behavioral Therapies (CBTs)

In SUDs, cognitive therapy (Beck, 1993) is particularly applied to excessively positive substance expectancies, low self-efficacy and negative beliefs about abstinence, as well as to depressogenic or anxiety-related cognitions that may trigger dysfunctional substance use. Other common elements in CBTs for substance misuse include development of skills in predicting high-risk situations for substance use, and applying problem solving and response planning. Skills in refusing social pressure to use substances and stress management may be developed, and there is often a focus on increasing pleasurable activities and social roles that are inconsistent with substance use.

Efficacy of CBT for alcohol dependence is well established (e.g., Assanangkornchai & Srisurapanont, 2007; Berglund et al., 2003), although it appears to have similar impact to several other "active" treatments. As already discussed, Project MATCH found similar treatment outcomes between CBT, MI, and TSF (Project MATCH Research Group, 1997, 1998). The efficacy of CBT for cannabis (Denis, Lavie, Fatseas, & Auriacombe, 2006), cocaine (Knapp, Soares, Farrell, & Silva de Lima, 2007), and amphetamine misuse (Denis et al., 2006; Knapp et al., 2007; Lee & Rawson, 2008) is also receiving growing support.

10.4.4 Behavioral Therapies Based on Operant or Classical Conditioning

While behavioral approaches based on operant or classical conditioning are often employed within multicomponent CBTs, their effects can also be considered separately. The most widely studied behavioral therapies are cue exposure and contingency management.

Cue Exposure. Repeated pairing of substance use with both positive effects and environmental cues elicits conditioned responses that increase the probability of use. Cravings (or urges to use substances) are often elicited by exposure to conditioned stimuli (Carter & Tiffany, 1999). Repeated exposure to conditioned stimuli can induce habituation of craving (e.g., Kavanagh et al., 2006). Exposure to cues may be combined with cognitive therapy or skills training in resisting substance use (Monti et al., 1993), an approach that blurs distinctions between habituation-based treatment and other CBTs.

Most controlled trials have focused on alcohol. Cue exposure (CE) is typically more effective than control conditions such as relaxation training (Drummond & Glautier, 1994), but has similar efficacy to CBT (Dawe, Rees, Mattick, Sitharthan, & Heather, 2002; cf. Sitharthan, Sitharthan, Hough, & Kavanagh, 1997), and its addition to CBT may not add to efficacy (Kavanagh et al., 2006).

Contingency Management (CM). CM introduces a tangible reinforcer (e.g., money or vouchers for inpatient privileges) to increase desired behaviors such as session attendance or abstinence. Adding CM to treatment of cocaine abuse has had promising results (Stitzer & Petry, 2006), and there is a growing support with cannabis and amphetamine dependence (Carroll et al., 2006; Denis et al., 2006; Lee & Rawson, 2008).

Provision of external reinforcement creates a vulnerability to extinction of the behavior once reinforcers are withdrawn. This may be particularly problematic when there is intrinsic

motivation to participate in treatment and control consumption, since the person may reattribute their behavior to the external reinforcer (Deci, Koestner, & Ryan, 1999). If external reinforcers are used, they should be presented as an adjunct to other incentives rather than a replacement, and the primary emphasis (particularly in latter treatment sessions) needs to be on internal motivation and naturalistic rewards that are likely to continue after formal treatment ceases. Aversive therapies were popular in the 1960s and 1970s, but for ethical reasons, they are no longer in common use.

10.4.5 Couples and Family Therapy

In the past, substance misuse has often been treated as an individual problem. Recognizing social factors in substance misuse and recovery has resulted in a greater emphasis on inclusion of family members in interventions. Couples and family therapies have been found to be effective in treatment of both alcohol (O'Farrell & Fals-Stewart, 2002) and other substance misuse (Powers, Vedel, & Emmelkamp, 2008).

10.4.6 Community Reinforcement Therapy (CRT)

Although originally conceptualized as an operant approach, CRT incorporates many elements from CBTs and other case-management interventions (Azrin, 1976; Hunt & Azrin, 1973), including referral to other professionals (e.g., for legal or financial issues), TSF, pharmacotherapy, behavioral marital therapy, and development of social roles (e.g., employment) and recreational activities that are inconsistent with substance use. Later versions incorporate written contracts, tracking of high-risk situations, rehearsal of skills in resisting substance use, peer support, and sometimes CM (Secades-Villa, Garcia-Rodriguez, Higgins, Fernandez-Hermida, & Carballo, 2008). CRT has empirical support across several substances, although numbers of trials remain limited (Roozen et al., 2004; Smith, Meyers, & Miller, 2001).

One version of CRT, Community Reinforcement and Family Training (CRAFT; Meyers, Miller, Hill, & Tonigan, 1998), attempts to induce behavioral change in people who refuse treatment, by encouraging concerned family members or friends to reward instances of substance control or treatment, and withdraw reinforcement for substance misuse. While there are few trials of CRAFT, available evidence is supportive, and suggests that systematic reinforcement produces superior results to Al-Anon, which are AA-related groups for family members, with some similar aims and strategies to CRAFT (Smith et al., 2001).

10.4.7 Pharmacological Approaches

For alcohol, heroin, and nicotine dependence in particular, there are strong data to support a combined pharmacological and psychological treatment. Support for pharmacotherapy of cannabis, stimulant, and hallucinogen misuse is more limited.

Alcohol. The pharmacotherapy for alcohol dependence that has the longest history is disulfiram or antabuse, which stops the metabolism of acetaldehyde, producing sympathetic nervous system activation, nausea, vomiting, and headaches. The knowledge that this aversive

response will occur after ingestion of alcohol can assist users to maintain total abstinence. While there is some evidence that consistent, supervised use of disulfiram can improve alcohol outcomes (Fuller & Gordis, 2004; Hardt, 1992), poor adherence (Fuller & Gordis) means that it has little demonstrated effectiveness (Helig & Egli, 2006). In addition, potential physical complications from disulfiram (e.g., to a compromised cardiovascular system) have restricted its utility (Chick, 1999; Malcolm, Olive, & Lechner, 2008), and a medical assessment is required before its prescription.

More recently, naltrexone and acamprosate have been used. There is evidence of efficacy for both medications, and in particular, each may add to the effects of psychological treatment (Bouza, 2004; Feeney, Connor, Young, Tucker, & McPherson, 2006; Kranzler, 2001). Clients with severe alcohol dependence, high current consumption, a history of unsuccessful treatment and significant craving may particularly benefit from adjunctive pharmacotherapy. While often characterized as an anticraving medication, naltrexone may have its main impact on craving by reducing rewards from drinking, rather than affecting craving more directly. Consistent with this, its differential benefits are more typically seen with occasions of heavy drinking than abstinence (Pettinati et al., 2006). Both agents may also allow an indirect effect via the opportunity to benefit more from psychosocial interventions.

Nicotine. Nicotine replacement therapy doubles the chances of successfully quitting (Stead, Perera, Bullen, Mant, & Lancaster, 2008), as does bupropion (an antidepressant; Hughes, 2007). A new agent, varenicline triples the chances of quitting, compared with placebo (Cahill, 2008). Best practice for nicotine dependence currently includes one of these pharmacotherapies.

Opiates. Methadone (an opiate agonist) remains the frontline replacement therapy for opiate dependence. Typically treatment involves daily oral doses. Methadone retains the clients in treatment longer, improves functional outcomes, and reduces opiate use compared with control treatments (Mattick, Breen, Kimber, Davoli, & Breen, 2003). Buprenorphine (a partial opiate agonist) offers an alternative to methadone with similar efficacy (Mattick et al., 2003). Advantages over methadone include lower potential for abuse and reduced physical dependence. Naltrexone (an opiate antagonist) has been relatively ineffective in treating opiate dependence, primarily due to poor treatment retention (Minozzi et al., 2006). There is some empirical support for stand-alone psychological interventions for opiate dependence (Mayet, Farrell, Ferri, Amato, & Davoli, 2004), and evidence that psychological and pharmacological treatments are synergistic (Stein et al., 2004).

10.4.8 Preventive Intervention

Community-based universal prevention approaches that increase purchase cost and legal age of access to (licit) substances have been among the more effective strategies to reduce substance-related harm, particularly in young people (Stockwell, Gruenewald, Toumbourou, & Loxley, 2005). Media and social marketing campaigns have been successful in reducing tobacco use at a population level (Bala & Lesniak, 2007), but there is less evidence for other substances. The most widely studied universal prevention programs are school-based interventions. Many programs show improvements in substance use in the short term (<12 months), but data on long-term maintenance of improvements are weak (Foxcroft, Ireland, Lowe, & Breen, 2002; White & Pitts, 1998), unless the intervention has a broad skills base and is delivered over several years. Screening "at risk" populations and providing brief, opportunistic treatment does appear

to reduce consumption and decrease numbers progressing to problematic substance use (Babor & Kadden, 2005; Kaner et al., 2007). Key aspects of successful programs appear to be engagement in prosocial goals and activities, rather than education about substances and their effects.

10.5   Mechanisms of Change Underlying the Intervention

Historically, substance misuse treatment research has been more focused on "what works" than on "why it works." Identifying the mechanisms responsible for effectiveness is a tall order (Kazdin, 2006), and meeting those criteria has remained elusive in virtually all psychotherapies, including those for addictions (Longabaugh, 2007). Despite the lack of advancement of our knowledge to date, potential contributors to effects of addiction treatments have been identified. Attendance and participation in AA or other treatments frequently emerge as a predictor (Forys, McKellar, & Moos, 2007) but as noted above, they are confounded with motivation.

10.5.1 Potential Client–Therapist Mechanisms

Stage of Change. While it is not an explanatory theory, the Stages of Change (or Transtheoretical) model of Prochaska and DiClemente (1983) has been an influential summary of client preparedness in SUD treatment. There is some evidence that participants with lower motivation to change respond more effectively to MI, although the meditational effect of readiness to change has received only inconsistent support (Morgenstern & McKay, 2007).

   Therapeutic Alliance. The UKATT trial (UKATT Research Team, 2005) identified therapist–client alliance as the strongest predictor of outcome. Patients who perceive therapists as less understanding are more likely to drop out of therapy for substance misuse (Cournoyer, Brochu, Landry, & Bergeron, 2007). However, therapeutic alliance has not consistently been predictive of outcome (Long, Williams, Midgley, & Hollin, 2000).

10.5.2 Potential Social or Contextual Mechanisms

Relationship Functioning. There is evidence of marital satisfaction increasing after behavioral couple therapy for alcohol misuse, and for better alcohol outcomes after improvements in marital interaction, but as yet there is no full test of mediation (Morgenstern & McKay, 2007).

   Group Membership. It is difficult to untangle effects of AA, but commitment to AA practices is positively associated with outcome (Longabaugh et al., 2005). Social network support for abstinence has been proposed as a critical contributor to positive outcomes from AA (Longabaugh, Wirtz, Zweben, & Stout, 1998) and social support may be important across treatments, particularly for males (Moos, 2007).

10.5.3 Potential Psychological Mechanisms

Learning. While there is intuitive appeal that therapy involves learning (e.g., of new skills), there are little data on its potential mediational role. Morgenstern and Longabaugh (2000)

could find no evidence of skills mediation in CBT. When coping skills have been associated with outcome, changes in those skills have not been specific to CBT (Morgenstern & McKay, 2007). Approach-related coping is generally associated with better outcomes than avoidance coping (Moos, 2007), but both can be effective (Litt, Kadden, Cooney, & Kabela, 2003; Maisto et al., 2000). Most research on meditational effects of coping skills has examined effects of perceived coping, rather than directly observing behaviors (e.g., Litt et al., 2003). Indirect evidence that skills practice is important is provided by observations that homework completion is related to better outcomes from CBT (Carroll, Nich, & Ball, 2005), although these require replication, and as with session attendance, this factor confounds with motivation. Reinforcement expectancies have also shown promise as predictors of outcome, but further tests of their role as a treatment mechanism remain to be undertaken (Young & Oei, 1993).

Self-Efficacy. Prospective treatment-based studies have predominately examined situational confidence in the form of self-efficacy beliefs. Self-efficacy predicts relapse to heavy drinking for up to 2 years (Kavanagh, Sitharthan, & Sayer, 1996; Walton, Blow, Bingham, & Chermack, 2003). When both alcohol expectancy and self-efficacy are examined together, self-efficacy beliefs are typically stronger predictors of alcohol consumption post treatment than alcohol expectancy (Solomon & Annis, 1990). However, some studies have failed to find evidence of a predictive role of self-efficacy (McKay, Maisto, & O'Farrell, 1993; McKellar, Harris, & Moos, 2006). An incremental contribution from self-efficacy above performance achievements is most often seen in contexts where the person has information about future challenges to their coping skills, which enables them to predict their behavior control (Bandura, 1982). If they have little experience in controlling substance use, respondents may not yet know which situations will be most difficult, and if there is little change in situational challenge over time, there is less opportunity for self-efficacy to improve on predictions from past performance.

Self-efficacy is a summative subjective estimate of coping potential, and questions can also be raised about factors that maximize it. McKellar, Ilgen, Moos and Moos (2008) found the best predictor of self-efficacy to be AA attendance in the 12 months following treatment, with lesser contributions from diminished depression, avoidance coping, and social support.

10.5.4 Potential Macro- and Microenvironmental Mechanisms

Availability of Contingent Reinforcement. Alternative, nonsubstance related sources of reinforcement predict more positive outcomes (Moos, 2007), and many people with substance use problems live in environments with relatively impoverished availability and variety of reinforcers. As discussed above, both CM and CRT systematically manipulate access to a range of reinforcers, contingent on abstinence and other functional behaviors (Petry et al., 2005). Development of social roles such as employment or relationships with nonusers results in complex and sustainable "natural" reinforcers being put in place (along with other potential benefits, such as reduced exposure to temptation and acquisition of control skills).

Craving. In CE, repeated exposure to interoceptive and exteroceptive cues without ingesting the substance allows habituation of craving, in part because of the absence of pairing with pleasure or relief that is associated with substance use. As already noted, it can also be seen within an operant or skills-training paradigm, in which resistance of substance use is socially reinforced. Limitations to effectiveness of CE may in part stem from limited generalizability from clinical to natural settings, and the fact that any effective treatment involves repeated

trials of resisting substance use in the natural environment (Kavanagh et al., 2006). Modification of cognitive responses such as craving may further improve effects of exposure (Kavanagh, Andrade, & May, 2004).

10.5.4.1 Changes in CNS Receptor Density and Activity

There are profound homeostatic changes that occur over prolonged exposure to addictive substances and alter the internal environment. For example, significant reductions in D2 dopamine receptors in key reward structures, including the Nucleus Accumbens, may influence mood, craving, and associative memory, as well as having downstream effects on gamma-aminobutyric acid (GABA) and endogenous opiates (Young, Lawford, Nutting, & Noble, 2004). Indirect sensitization of dopamine neurons may also occur via changes in stress-induced glucocorticoid release (Uhart & Wand, 2009) that mirror changes in the macro-environment, and emphasize the potential importance of effective stress management. Treatment of secondary depression or dysthymia may also affect neurotransmitter activity, as may environmental selection, social functioning, and confidence. Limitations to neural recovery may occur directly (e.g., from neurotoxic effects of substances) or indirectly (e.g., via nutritional deficits or brain trauma).

10.6   Basic Competencies of the Clinician

All clinical psychologists should have a basic understanding of substance use and misuse, and be able to assess consumption, screen for SUDs, conduct a functional analysis of a SUD and offer a basic evidence-based intervention. They should be particularly adept at dealing with substance-related problems of high population prevalence (e.g., nicotine, alcohol) and low physical dependence. Given high frequencies of other co-occurring disorders in people with substance misuse, practitioners should be able to adjust assessment and intervention techniques from other problem domains to people with co-occurring disorders with high population prevalence (e.g., anxiety and depression), and to clients that are most commonly seen in their clinical practice.

10.6.1 Generalized Competencies

Formation of a Trusting Relationship. While development of *rapport and trust, listening and reflective skills, empathy, warmth, and acceptance* are general competencies across problem domains, the counter-normative nature of substance use problems and the suspicion or hostility towards addiction services that is often seen in clients make it critical that these generalized competencies are highly developed in addiction practitioners. These attributes must be genuinely expressed – that is, psychologists cannot have negative attitudes toward people with addictive disorders if they are to be effective change agents.

Generalized Skills in Assessment and Intervention. Discussion of specific competencies for substance misuse below will assume that practitioners have well-developed competencies across areas covered in Volume I, encompassing the nature, conduct, and reporting of the

following together with skills in referral and liaison with other health agents, giving and receiving effective supervision and consultation, and skills in searching and evaluating research evidence:

- *Interview-based assessments*, including standard diagnostic interviews, mental status examinations, risk assessments, and detailed functional analyses,
- *Common psychometric measures*, including tests of depression, anxiety, quality of life, and cognitive functioning, and
- *Cognitive and behavioral interventions* (e.g., cognitive therapy, problem solving, social skills training, cognitive-behavioral marital interventions, contingency management) for individuals, families, and groups.

The focus below is on application of this knowledge and skills to substance misuse.

10.6.2 Basic Knowledge

To demonstrate competency, a clinical psychologist should have a broad, basic understanding of addictions and their assessment and management, including:

- *Key concepts of substance use and misuse* (as outlined above).
- *Primary psychoactive drugs in current use and sources of information about population consumption patterns*. While the range of abused substances is large and consumption patterns are subject to rapid change, psychologists should know drug classes, basic mechanisms, and the names (including common street names) of frequently misused substances. Ready access to information to community survey data on substance use is also needed. These data can provide normative information to challenge overestimations of the frequency of heavy consumption, and alert the practitioner to emerging consumption patterns.
- *Ethanol content of common alcoholic drinks, standard drink sizes, and recommended maximum consumption limits*. Both standard drink sizes (Devos-Comby & Lange, 2008) and recommended maxima vary across different countries: clinical psychologists should be aware of local practices, and be able to calculate daily or weekly consumption of standard vendor serves of beer, wine, or spirits (excluding cocktails) in grams of ethanol.
- *Intoxication and withdrawal effects, including their duration*. This should cover commonly used substances (caffeine, alcohol, nicotine, cannabis, and in some countries, cocaine) and substance groups (meth/amphetamines/3,4-methylenedioxymethamphetamine (MDMA), opiates, hallucinogens, inhalants). It should include an understanding of the stages and primary features of discontinuation syndromes, particularly alcohol or benzodiazepine withdrawal, which carry significant risks of adverse outcomes, including death (e.g., from seizures). In contrast, heroin withdrawal, which is typically viewed as more dangerous than withdrawal from alcohol, is rarely life-threatening and resembles a severe dose of influenza.
- *Common short- and long-term risks from frequently used substances and substance groups*. These should not only involve pharmacological effects (e.g., alcoholic liver cirrhosis), but also risks from adulterated content (e.g., insoluble substances), mode of administration (e.g., infection via injection), loss of consciousness (e.g., inhalation of vomit), and associated risk behaviors (e.g., injuries, sexually transmitted diseases, nutritional deficiencies,

hypothermia). It should also involve an awareness of common social, economic, occupational and legal consequences, and related deficits in functional behavior and quality of life.

- *Features of key substance-related disorders*. In DSM-IV, this involves an understanding of criteria for substance dependence, abuse, intoxication and withdrawal, and an awareness of substance-induced disorders. Categories or criteria may significantly change in subsequent editions of DSM, and the clinical psychologist should be aware of any changes as they occur.
- *Factors associated with substance uptake and misuse*. This includes an appreciation of subgroups associated with higher rates of substance misuse, and variables correlated with uptake and maintenance of use and misuse. A basic appreciation is needed of potential determinants within the ethnic, linguistic, or subcultural groups that are most likely to be encountered by the practitioner.
- *Factors associated with positive outcomes and relapse*. Practitioners should understand factors and coping strategies associated with natural recovery. They should have a general appreciation of the following, including differences across substances (e.g., alcohol, nicotine) and client subgroups (e.g., low/high dependence, physical disorder, cognitive deficit):

  - Nature and treatment implications of harm reduction, moderation, and abstinence goals
  - Relative frequency of moderation and abstinence
  - Associations of moderation and abstinence with physical, functional, and neuropsychological outcomes

They should appreciate the distinctions between lapses and relapses, and common risk situations for lapses.

- *Cognitions, emotions, and behaviors commonly associated with risks of misuse and relapse*. These cognitions should include low self-efficacy for substance control, permissive thoughts, overly positive substance expectancies, craving, and goal violation effects. Primary affective foci are depression, anxiety, anger, while key behaviors include deficits in substance refusal and alleviation of dysphoria.
- *Theoretical models of substance misuse, relapse, and recovery*. Clinicians should appreciate the nature and evidence status of key theoretical approaches and exemplars, and their application to practice. Awareness of the Stages of Change model, its descriptive nature, and utility, are needed.
- *Strategies to assess consumption*. These include quantity–frequency measures, Timeline Followback (Sobell & Sobell, 1992), and self-monitoring.
- *Psychometric instruments in common use*. Knowledge of psychometric characteristics for measures of common addictive disorders, in the areas of screening (e.g., the Alcohol Use Disorders Identification Test; Saunders, Aasland, Babor, de la Fuente, & Grant, 1993) and degree of dependence or functional impact (e.g., Severity of Alcohol Dependence Questionnaire; Stockwell, Hodgson, Edwards, Taylor, & Rankin, 1979; Fagerstrom Tolerance Questionnaire; Tate & Schmitz, 1993).
- *Medical management*. Practitioners should have a basic awareness of withdrawal and medically supported detoxification regimes and pharmacotherapies for substance dependence.
- *Psychological interventions and their relative evidence base*. Appreciation is needed for strategies with a strong evidence base and for the lack of evidentiary support for confrontational methods. The knowledge should be sufficient to make an informed referral and know contexts where a basic generalized competency (e.g., social skills training, meditation,

relaxation training) can usefully be applied. A more detailed knowledge of brief interventions including MI and of relapse prevention (including identification of high-risk situations and related problem solving) is required.

- *Common ethical issues in addiction practice*. Substance misuse can present significant legal and ethical challenges for practitioners, especially where there are negative potential consequences of full disclosure (e.g., forensic, employment, housing), and where the clinical psychologist is an agent of the court, employer, or other authority. Awareness of common ethical issues and their resolution is required.

10.6.3 Basic Skills

10.6.3.1 Assessment

- *Accurate estimation of usual and current consumption across all psychoactive substances*. This includes self-report data on usual quantity and frequency of consumption, assessment of current consumption using a Timeline Followback, and application of self-monitoring.
- *Reliable use and valid interpretation of relevant screening instruments.*
- *Family history of substance misuse*. Clinicians should be able to identify the presence and nature of substance misuse by members of the client's immediate and extended family.
- *Personal history of substance use and misuse, and associated factors*. Clinicians should be able to construct a timeline of substance use and misuse and periods of abstinence or moderation, identifying situational contexts for changes over time, together with physical, cognitive-affective, and functional outcomes. The nature and perceived effect of past treatments or self-help involvement should be noted. They should also be able to gather a history of any co-occurring disorders, and relate episodes of those disorders to the substance use history.
- *Situational triggers and consequences of recent substance use and abstention or control*. Both perceptions or expectations and the actual nature and degree of association of triggers and consequences should be assessed. Current risk to the client and others should be covered.
- *Reliable diagnosis of SUDs, using a written standardized protocol.*
- *Preparation of appropriate reports on the above issues and communication of the results to clients, family members, and health care agents.*

10.6.3.2 Intervention

- *Effective conduct of a brief intervention*. This involves feedback of assessment information (including population data), provision of informed advice, assistance in developing a behavior change plan, and follow-up of progress.
- *Basic competence in conducting a motivational interview*. This includes the six principles of a mnemonic such as FRAMES (feedback, responsibility, advice, menu, empathy, and self-efficacy; Miller & Rollnick, 2002), and key strategies to elicit change talk (e.g., decisional balance, values exploration).
- *Application of clinical psychology interventions from other domains*. These techniques should include effective education (e.g., about standard drinks), contingency management (e.g., for abstinence), problem solving (e.g., for high-risk situations), social skills training

(e.g., for substance refusal), including effective use of modeling, cognitive therapy (e.g., for overly positive substance expectancies), CBTs for couples and families (e.g., to elicit nonintrusive social support for change, address social triggers for substance use, or reduce carer distress), and development of pleasurable or achievement-related activities and roles that are inconsistent with substance use.

10.7   Expert Competencies of the Clinician

Expert or specialist clinicians should have a higher level of knowledge, skills, and self-efficacy in all basic competencies, and be able to deal with more complex presentations or assist people who have not responded to basic interventions. They should be able to adapt their assessment and treatment approach to people of different ages, genders, or ethnic or cultural backgrounds. In addition, treatment needs to be responsive to different levels and types of substance use problems, or different maintaining factors, and to those with co-occurring physical or mental health issues. The specialist clinician should maintain a sound, current grasp of developments in addiction practice, emerging data on epidemiology, assessment and treatment, and a high level of skills in evaluating published evidence. The specialist should show creativity in the development of innovative interventions that are tailored to the needs of individuals and subgroups, while retaining consistency with existing research data and with results of a comprehensive functional assessment.

10.7.1 Specialist Knowledge

Addiction specialists should have a detailed and current understanding of:

- *Key substance-related concepts and related mechanisms* (e.g., tolerance, reinstatement).
- *The full range of psychoactive drugs in current use, and recent trends in consumption.* This knowledge should include current street names for these substances, their cost, usual dosage, and the likely nature of their active constituents.
- *Nature of intoxication and withdrawal effects of psychoactive substances in current use.* While the nonspecialist was expected to have a basic understanding of effects from very common substances and primary substance groups, specialists should have a more detailed knowledge of specific substances, appreciate key neural mechanisms in intoxication, and have a broad understanding of metabolism of commonly used drugs (e.g., alcohol) and of drug interactions.
- *Short- and long-term risks from the use of specific substances.* Particularly detailed knowledge is required about risks from substances in common use (e.g., nicotine, alcohol).
- *Features of substance-related disorders.* This knowledge should include a detailed understanding of the nature of specific symptoms of SUDs, and be sufficient to allow reliable differential diagnosis in contexts of significant cognitive impairment or comorbidity. It should cover an appreciation of the features, frequency, causation, management, and prognosis of commonly associated physical disorders (e.g., human immunodeficiency virus/acquired immune deficiency syndrome (HIV/AIDS), Wernicke–Korsakoff syndrome).

- *Factors associated with substance uptake, and with onset and maintenance of misuse.* An understanding is needed of the current status of variables associated with the onset and maintenance of substance misuse, and with relapse and recovery. This includes an understanding of the heritability of alcohol and other substance misuse, and a basic appreciation of specific genetic or other physiological hypotheses and their evidence base. A sophisticated understanding of ethnic, linguistic, or subcultural factors should be present, especially in relation to groups that are most likely to be encountered by the practitioner.
- *Factors associated with positive outcomes and relapse.* Specialists should have a detailed appreciation of processes underpinning lapses and relapses, maintained recovery, relative merits, and applications of harm reduction, moderation, and abstinence goals.
- *Cognitions, emotions and behaviors commonly associated with risk of misuse and relapse.*
- *Theories of substance misuse, relapse, and recovery.* The specialist needs a detailed knowledge of the current evidence on specific models, and their relative utility.
- *Evidence status of strategies to assess consumption, and ways to maximize accuracy.*
- *Psychometric instruments for screening, degree of dependence and functional impact of substance use, and their relative reliability, validity, and utility.*
- *Medical management.* Specialists should have a detailed appreciation of the nature, evidence base and indications for: (a) medical treatments for withdrawal and detoxification, and (b) pharmacotherapies for substance dependence. Knowledge of these interventions should include a basic appreciation of common complications or side effects and their management, and be sufficient to allow informed referral and collaboration, but not primary responsibility for their application.
- *Psychological interventions and their relative evidence base.* This knowledge should be sufficient to underpin an evidence-based application of a wide range of preventive and treatment strategies, including interventions for people with high levels of dependence or complex co-occurring problems. A particularly sophisticated knowledge of brief interventions including MI and relapse prevention is required. Specialists should also have a detailed appreciation of TSF and other self-help approaches in common use, and of potential synergies with other interventions.
- *Ethical and legal issues in addiction practice.* A sophisticated awareness of a wide range of ethical dilemmas *and* an ability to critically analyze alterative resolutions is required.

10.7.2 Specialist Skills

10.7.2.1 Assessment

- *Effective engagement of reluctant or suspicious clients in assessment.*
- *Conduct of assessments in challenging contexts (e.g., other ethnic settings, or in the presence of cognitive dysfunction or other comorbidity).*
- *Accurate estimation of usual and current consumption across all psychoactive substances.* This includes the use of multiple imputation methods (e.g., amount and frequency, cost, usual purchase amount), resolution of conflicting information from multiple sources, sensitive application of a bogus pipeline technique, reliable and valid administration of a breath analysis for carbon monoxide or alcohol, and knowledge of biological assays.

- *Appropriate selection, reliable use and valid interpretation of psychometric instruments* to screen for SUDs, and assess variables such as degree of dependence, functional impact, coping strategies, self-efficacy, substance expectancies, and social support.
- *Conduct and reporting of a detailed functional analysis, incorporating historical and current aspects*. This should include an ability to undertake assessment in the style of a motivational interview, assess the degree of contingency, disentangle aspects relating to each of multiple substances, and assess the degree of interrelationship between co-occurring disorders or other problems. An expert, evidence-based assessment of specific risks to clients and others can be given.
- *Reliable diagnosis of SUDs*. This should include a high level of reliability in the use of a standardized diagnostic interview, including the assessment of the independence of potentially comorbid disorders.
- *Preparation of reports on the above issues, and communication of the results*. This should include the ability to prepare and defend an expert forensic report and identify appropriate multidisciplinary management strategies or referrals where indicated.

10.7.2.2 Intervention

- *Expert competence in conducting a motivational interview*, including its application to subgroups in different affective states, or with varying cognitive abilities and personalities.
- *Application of clinical psychology interventions from other domains*. A high level of skills is expected, in modifying these techniques to people with SUDs, including those with severe substance dependence or co-occurring disorders, and in developing individually tailored, integrated, and multicomponent treatments, based on needs, capacities, and goals of the client, as identified in a functional analysis.
- *Expert competence in specific strategies* such as cue exposure and relapse prevention and in the integration of psychological intervention with medical or self-help approaches is needed.

10.7.2.3 Consultation and Supervision

The expert clinician is not only expected to have specialist skills in case management; but also to maintain a leadership role. In both consultation-liaison and supervision, the addiction specialist should be able to clearly communicate with practitioners from different disciplines or domains of practice and with varying levels of existing knowledge.

The nature of consultation-liaison and supervision or mentoring skills do not significantly differ from their application in other practice domains: The primary distinction here is the content that is being discussed. Consultants provide an authoritative and timely opinion on assessment and management, which is based on a sound assessment and detailed understanding of the current literature, and acknowledges its limitations (e.g., expertise, opportunity to assess the client, state of the field). Management recommendations should provide sufficient information for the other practitioner to implement them effectively, or recognize the necessity for additional training or client referral.

At times, consultation will merge into informal supervision. However, formal supervision typically involves a negotiated agreement for regular contact and a focus on practice-related work based on supervisees' needs and negotiated goals (Kavanagh, Spence, Wilson, & Crow, 2002). While supervision frequently incorporates reflection on practice and related problem solving, common deficits are in the observation of practice, modelling of skills by the supervisor, and skills practice within sessions (Kavanagh et al., 2003).

10.7.2.4 Research Skills

Most addiction specialists will not publish research throughout their career, but day-to-day clinical practice will require a sophisticated and current understanding of research methodology and the abililty to evaluate and appropriately critique research reports.

10.8   Transition from Basic Competence to Expert

Basic competence is expected to be attained by the end of clinical psychology training programs, based on required units and clinical placement experience. Core units of generic clinical programs are unlikely to contain sufficient learning and experience to prepare addiction specialists, although elective coursework and placements could offer a sound foundation.

It may be possible to progress from a basic level of clinical competencies to a specialist or expert level by a combination of extensive supervised practice within an addiction setting, self-directed reading, participation in workshops, and conference or colloquium attendance. Feasibility of this route would be heightened if the practitioner had undertaken elective addiction units in their clinical program. However, a systematic and comprehensive coverage of expert competencies is best assured by the development of specialist tertiary programs and assessment procedures to ensure that competencies have been acquired.

A multidisciplinary postgraduate program on addiction or a postgraduate program for addiction counselors offers some benefits above self-directed learning, although its benefits would fall short of those from specialist psychology programs. Depending on their content, some multidisciplinary programs can offer training toward selected specialist competencies. However, it is difficult for multidisciplinary addiction programs to develop specialist skills to levels that would qualify a practitioner as an expert clinical psychologist in addiction, unless it had coursework and placement streams for specific professions to such an extent that it became indistinguishable from programs specifically for clinical psychologists.

We propose that clinical psychologists who wish to specialize in addiction should have already completed an accredited clinical psychology program, rather than going directly into a specialist program from an undergraduate degree. We take this position because the high occurrence of other comorbidities and their close association with substance misuse require that assessment and management of addictions take account of the full range of clients' problems, rather than exclusively focusing on substance use. Development of addiction as a subspecialty of clinical psychology provides a practitioner with greater breadth and flexibility of skills and with greater occupational choices and utility to services than would be offered by addiction psychology as a totally separate type of psychology practice.

We argue that a post-clinical program in addiction should be of at least a year's duration, in order to cover the expert competencies mentioned above in sufficient breadth and depth. It should include substantial structured clinical experience in the management of substance misuse under close supervision of clinical psychologists with an addiction specialty. A substantial part of specialist placements should be in a specialist addiction facility, in order to obtain an understanding of multidisciplinary addiction teams.

While basic competency in addiction practice requires a general appreciation of research and technological developments, there is a much greater requirement on specialists to maintain currency of their expert knowledge and skills. A specialist license or other recognition would require satisfaction of ongoing professional development, which ideally should include assessments to demonstrate the acquisition of knowledge and skills rather than just attendance.

10.9   Summary

Much of the knowledge and skills that are required for clinical psychologists to practice in substance misuse can be mapped from elements of sound clinical practice (e.g., development of rapport and engagement, conduct of a functional analysis, application, and interpretation of psychometric assessments, report writing, contingency management, ability to work in a multidisciplinary team). Other competencies can be mapped from those in other problem domains such as anxiety (e.g., exposure and response prevention), depression (e.g., cognitive therapy), or social skills. The primary task in these generic competencies is to appreciate their relevance to substance misuse (e.g., the social skill of substance refusal), and learn how to modify them for people with substance misuse.

A second set of competencies is also familiar, since although they originated in substance misuse, they now have wider application. Examples are motivational interviewing and relapse prevention based on prediction of high-risk situations. If these competencies are not already in the standard preparation of clinical psychologists, they should be.

Other aspects, such as an understanding of the nature and effects of substances, mechanisms underlying their effects, risk factors for substance misuse, processes of recovery or relapse, and relevant pharmacotherapies, are more specific to substance misuse domain. Because of the high frequency of substance misuse and its importance for outcomes from other disorders, clinical psychologists should be able to deal with low-severity and commonly occurring substance misuse, if they are to be effective as generalist practitioners.

Specialists of course require a more sophisticated understanding. Since the field is still evolving rapidly, the knowledge of both needs to remain current.

11 Cigarette Smoking

Michael J. Zvolensky · Kirsten Johnson · Andrew R. Yartz ·
Ellen Leen-Feldner

Abstract: There are currently about 1 billion cigarette smokers worldwide. Despite legal regulation against the sale of cigarettes to persons under the age of 18 years, smoking among adolescents is nonetheless highly prevalent. Despite significant public health measures focused on reducing adolescent smoking, rates have not significantly declined. These prevalence findings are alarming, as smoking is a leading preventable risk factor for medical illnesses such as heart disease, a variety of pulmonary diseases (e.g., chronic obstructive pulmonary disease) as well as many types of cancer. Thus, there is a pressing need to understand better manage cigarette smoking and related forms of tobacco use. With this background, the purpose of the present chapter is to provide an overview of the prevalence, detection, current theoretical models, and treatment options for cigarette smoking and nicotine dependence.

11.1 Overview

The need for public health awareness and evidence-based clinical care for cigarette smoking, the most common form of tobacco use, remains a major health-care priority in the USA and beyond. Indeed, smoking remains a leading cause of morbidity and mortality in industrialized countries despite systematic efforts to prevent and control the use of tobacco (Centers for Disease Control [CDC], 2007). There are currently about 1 billion cigarette smokers worldwide (Wald & Hackshaw, 1996), out of which approximately 45.3 million live in the USA (CDC). Approximately, 27.6% of men and 22.1% of women in the USA are current smokers (CDC, 1999), and just under 82% of these people are daily smokers. Smoking is prevalent especially among those with 9–11 years of education and those living below the poverty level. About 5% of the US population have smoked cigars last month (CDC), and rates of smokeless tobacco use are only slightly lower (CDC, 1998). Despite legal regulation against the sale of cigarettes to persons under the age of 18 years, smoking among adolescents is nonetheless highly prevalent, with approximately 22% of 12th graders, 14% of 10th graders, and 7% of 8th graders in the USA reporting smoking in the last month (Johnston, O'Malley, Bachman, & Schulenberg, 2007). Moreover, despite significant public health measures focused on reducing adolescent smoking (e.g., Pechmann & Reibling, 2006), rates have not significantly declined. Thus, aside from the existing population of adult smokers, a new generation of youths within the USA is being exposed to the health risks of smoking.

Smoking is a leading preventable risk factor for medical illnesses, such as heart disease, a variety of pulmonary diseases (e.g., chronic obstructive pulmonary disease), and many types of cancer (CDC, 1994, 2002). As one illustrative example, smoking is responsible for almost 31% of all cancer-related deaths (American Cancer Society [ACS], 2006). In addition, it is increasingly becoming recognized that smoking contributes to certain forms of

mental illness. Daily smoking, for example, is concurrently and prospectively related to an increased risk of developing panic attacks and panic disorder after controlling a variety of theoretically relevant factors (e.g., polysubstance use, temperament, demographic variables; Breslau & Klein, 1999; Goodwin, Zvolensky, & Keyes, 2008; Isensee, Wittchen, Stein, Höfler, & Lieb, 2003; Johnson et al., 2000; McLeish, Zvolensky, & Bucossi, 2007; Zvolensky, Kotov, Antipova, & Schmidt, 2003). These data highlight clinically relevant associations between cigarette smoking and development of *both* certain types of physical health conditions and psychiatric conditions. Based upon these and other findings, it is perhaps not surprising that there is a tremendous economic burden associated with smoking and tobacco use. Some relatively recent estimates, for example, suggest smoking-related medical expenditures exceed US$50 billion per year and another US$47 billion per year for disability related to smoking (CDC, 1993).

Given the health risks associated with smoking, it is important to facilitate smoking cessation. Moreover, tobacco users are well aware of the benefits of quitting (CDC, 1990), yet often have trouble maintaining abstinence from smoking. Indeed, quitting smoking not only decreases risk of developing physical and psychological problems, but also increases the survival time among persons who have already developed smoking-related problems (Samet, 1992). Unfortunately, despite reduction in smoking prevalence over the past 25 years, relapse to smoking remains strikingly common. For example, though nearly 70% of smokers in the USA desire to quit (CDC, 2002), approximately 90–95% of smokers who try to quit smoking on their own (Cohen et al., 1989) and 60–80% who attend formal treatment programs relapse to smoking within 1 year (CDC, 2002). Even among smokers who abstain from smoking for 12 months, approximately 40% eventually return to prequit levels of smoking (U.S. Department of Health and Human Services [USDHHS], 1990). Research suggests that the vast majority of smokers returns to smoking within the first 10–14 days after a quit attempt (Westman, Behm, Simel, & Rose, 1997). Due to the difficulty with quitting smoking, many scholars have come to view nicotine dependence as a "chronic disease" (Fiore & Baker, 1995). Such a perspective helps to communicate that nicotine dependence is characterized by high rates of relapse. From a clinical perspective, as we will discuss, a chronic disease perspective could also help inform how individuals and practitioners intervene to work with smoking cessation attempts and define success in relation to it.

11.2 Recognition of Symptoms and the Assessment

Given the severity of the physical and mental health consequences related to cigarette smoking, there has been a focused public health effort to assist those in need of smoking cessation. A critical piece of effectively disseminating smoking cessation practices to patients relies heavily on medical health providers, as these individuals are most frequently the first line of contact with smokers (e.g., physicians, dentists; Albert, Ward, Ahluwalia, & Sadowsky, 2002; McCarty, Hennrikus, Lando, & Vessey, 2001; Wadland, Keefe, Thompson, & Noel, 2000). Unfortunately, clinicians working in medical fields generally fail to properly assess the tobacco use and target it in the context of health services care. Indeed, there is a large corpus of scientific work that documents various facets of this problem (Thorndike, Rigotti, Stafford, & Singer, 1998). For example, Thorndike et al. (1998) found that only about 20% of smokers attending medical clinic visits received counseling in smoking cessation. Other

research suggests that only a minority of smokers who have visited a medical office for care in the past year were offered smoking cessation services (Goldstein et al., 1997). Here, it is noteworthy that smokers with ongoing (current) tobacco-related disease tend to receive the most focused professional care (Thorndike et al.). Thus, it is not until individuals are experiencing ongoing (current) smoking-related medical problems that they are able to receive psychoeducational and/or pharmacological assistance in efforts to quit (Thorndike et al.). Overall, such global neglect of the smoking population is problematic and concerning for numerous reasons, including the fact that individuals often cite physician advice as a key motivating factor for quitting (Thorndike et al.). Within this context, it is interesting to note that barriers for providing smoking cessation that are commonly cited by physicians include lack of perceived competence (Williams, Levesque, Zeldman, Wright, & Deci, 2003), limited time (Jaen, Stange, & Nutting, 1994), and the perception of a lack of motivation and interest in quitting among patients (Young & Ward, 2001). Thus, extant empirical work suggests that some of the most pressing reasons for not intervening among the smoking population pertain to perceptions of professional competence and knowledge about tobacco use and dependence.

Although efforts have been made to understand smoking assessment and cessation counseling practices of various health professionals (Secker-Walker, Solomon, & Hill, 1989; Silagy & Ketteridge, 1998), it is noteworthy that relatively little attention has been applied to mental health professionals. Given increased recognition of the association between smoking and psychological symptoms and disorders (Breslau, Novak, & Kessler, 2004; Covey, Bomback, & Yan, 2006; Hitsman, Borrelli, McChargue, Spring, & Niaura, 2003; Zvolensky et al., 2008), it is clinically important and timely to evaluate the current state of smoking cessation knowledge and training among mental health professionals (Phillips & Brandon, 2004). For example, one study examined knowledge and perceived competence of smoking assessment and cessation among mental health professionals who specialize in the treatment of anxiety disorders (Zvolensky et al., 2005). Results indicated that therapists assess smoking behavior in only about 30% of clients, and often perceive themselves as "definitely unprepared" to deliver smoking cessation treatment. Moreover, only a minority of such professionals (18%) reported having received formal training in empirically based smoking cessation practices during the past 3 years (Zvolensky et al.). When compared to primary care physicians, these specialists illustrated deficits on "basic" cessation counseling practices (e.g., assessing for smoking behavior). Fortunately, mental health professionals who had received formal training in smoking cessation during the past 3 years reported significantly greater levels of perceived preparedness in helping patients quit and delivered a greater degree of evidence-based smoking cessation treatment (Zvolensky et al.). These findings, in conjunction with those focused on nonpsychiatrically oriented medical practitioners (e.g., Secker-Walker et al., 1989), highlight the need to increase formal awareness of, and training in the assessment and treatment for smoking and tobacco use among health-care professionals.

In a systematic effort to implement a uniform tobacco treatment in the primary care setting, a clinician reference guide was established to help guide health-care providers (*Treating Tobacco Use and Dependence*; Fiore et al., 2000). A key aspect of these guidelines is the process of accurately identifying and assessing tobacco use. Consequently, the "5As" were established as a guide to assess and appropriately intervene with smoking behaviors. These include (1) *ask* patient about current and past tobacco use, (2) *advise* and strongly urge patient to consider

quitting smoking, (3) *assess* patient's willingness to quit smoking, (4) *assist* patient with smoking cessation efforts, and (4) *arrange* for follow-up contact with patient following quit date (Fiore et al.). The US Public Health Service (USPHS) continues to recommend these guidelines, promoting the relative efficacy of the 5As procedure (Katz, Brown, Muehlenbruch, Fiore, & Baker, 2004), and recent research suggests that implementation of the 5As in the primary care setting is significantly associated with greater patient satisfaction with regard to overall health care (Conroy et al., 2005).

11.3 Maintenance Factors for Smoking and Nicotine Dependence

Given the clinical importance of smoking to health-related issues, a primary goal of smoking research has been to identify factors that contribute to the maintenance of smoking behavior. There has been a myriad of factors studied in this domain of study and a variety of conceptual models for guiding such work (e.g., sensory gratification, nicotine addiction, and dependence models). Here, we highlight two of the more promising and historically influential models of smoking maintenance: nicotine dependence and affect regulation.

Nicotine Dependence. A major factor contributing to the maintenance of smoking behavior is *nicotine dependence.* Research in this area was historically stimulated by the recognition that nicotine may be responsible for the repeated use of cigarettes. Although marketing campaigns and widespread use of cigarettes and other tobacco products for many years stymied efforts to recognize the importance of nicotine in continued tobacco use, this perspective began to change in the 1980s (American Psychiatric Association, 1980). According to the National Institute on Drug Abuse (NIDA),

▶ [C]igarettes and other forms of tobacco, such as cigars, pipe tobacco, and chewing tobacco, are addictive and nicotine is the drug in tobacco that causes addiction. Nicotine provides an almost immediate "kick" because it causes a discharge of epinephrine from the adrenal cortex. This stimulates the central nervous system and endocrine glands, which causes a sudden release of glucose. Stimulation is then followed by depression and fatigue, leading the user to seek more nicotine. (NIDA, 2006)

A variety of sources of empirical data, in fact, suggests that nicotine elicits euphoric effects when administered in basic laboratory studies (Henningfield, 1984). Studying smoking in the "real world," however, is difficult to document in regard to the effects of nicotine on biological and affective responsivity (Collins, 1990; Gilbert, 1995; Jaffe, 1980). The cornerstone of nicotine dependence is the same as many addictions. That is, the euphoria created by nicotine initially leads people to smoke. Due to the biological adaptation that occurs to repeated drug exposure, an individual requires more frequent doses to achieve the same effect. Thus, they need to smoke more to feel as "good." Such decreased responsivity to a given dose is a process termed *tolerance.* The regular smoker eventually becomes addicted to nicotine and experiences physical withdrawal symptoms in the absence of smoking, which occurs relatively soon after finishing a cigarette. Thus, over time, the regular smoker "needs" nicotine just to fend off withdrawal and feel "normal."

Given the highly addictive nature of nicotine, individuals who abstain from smoking often experience aversive and severe physical withdrawal symptoms (i.e., symptoms emerging from drug reduction in the body; Hughes, Higgins, & Hatsukami, 1990). Withdrawal sensations can

emerge in the form of physiological (e.g., drowsiness, increased appetite, headaches) or psychological changes (e.g., tension, irritability, difficulty concentrating; U.S. National Library of Medicine & NIH, 2007). These sensations typically begin within 6–12 h following smoking cessation, and can last up to 3–4 weeks after quitting (Hughes, 1992). These aversive internal states precipitated by nicotine withdrawal contribute to frequent use of cigarettes (or another tobacco product) to alleviate the aversive internal state. From this perspective, elimination or reduction of aversive nicotine withdrawal symptoms is a central feature of a smoking maintenance model focused on nicotine dependence as the primary explanation for continued cigarette use. In fact, numerous studies document smokers' reports of "feeling addicted" to cigarettes because they help to reduce aversive sensations (see Robinson & Pritchard, 1992). Although this model shares some commonality to negative reinforcement models of drug learning, the central role of nicotine in such models implies a biologically driven origin to recurrent patterns of use. At present, the biological mechanisms underlying the reinforcing effects of nicotine and its sequelae (e.g., withdrawal symptoms) have yet to be unambiguously isolated. There indeed appears to be many factors that affect the reinforcing value of nicotine, including environmental factors, individual differences, and minimal immediate cost of smoking behavior.

Despite the prominence of this dependence perspective of smoking maintenance, some scholars have noted problems with this type of account (e.g., Collins, 1990; Robinson & Pritchard, 1992). Indeed, inspection of the empirical literature on nicotine dependence indicates that there are a number of formidable explanatory gaps in a nicotine dependence model with regard to the maintenance of cigarette use. For example, empirical work suggests that nicotine withdrawal symptoms vary as a function of environmental cues and individual differences to a greater extent than plasma levels of nicotine concentration (Warburton, 1989, 1990). Additionally, relapse to smoking can and often does occur *after* periods of prolonged abstinence when physiological nicotine addiction has passed (Collins, 1990). Moreover, some smokers do not meet the criteria for nicotine dependence (Shiffman, 1989) suggesting that repeated exposure to nicotine does not invariably lead to dependence and regular use (Shiffman, Fischer, Zettler-Segal, & Benowitz, 1990). These findings, and others, challenge the nicotine dependence model as the *sole* explanatory factor in the maintenance of cigarette use. Thus, from a clinical perspective, it is perhaps best to construe continued smoking behavior (maintenance or relapse) as sometimes rather than always involving dependence on nicotine. Even among nicotine-dependent smokers, the nicotine dependence perspective is empirically insufficient in accounting for the large variability in smoking patterns, rates, and related processes.

Affect Regulatory Models. Another perspective that has been forwarded to explain the maintenance of smoking behavior reflects *affect regulation* perspectives (Eysenck, 1973; Frith, 1971; Tomkins, 1968). These smoking maintenance models have fueled a great deal of scientific work and helped stimulate and integrate nonbiologically and pharmacologically oriented perspectives on cigarette use into the larger literature. There have been numerous specific models that could be loosely categorized within an affect regulation perspective focused on smoking. One of the earliest was that of Tomkins (1966, 1968). Tomkins' model is historically important because it focuses on emotional processes and how such states may "motivate" a behavioral (smoking) response. Tomkins suggested that smoking could be reinforced by reducing negative affect and/or enhancing positive affect. Thus, motivation to smoke was principally emotion-defined. In addition, the model was influential with regard to recognizing individual variability in the motivational basis of smoking both across and within individuals.

A similar influential affect regulation model is one forwarded by Leventhal and Cleary (1980). This perspective focused on the reinforcement of nicotine use due to affective states that have been associated (conditioned) to them (Leventhal & Cleary). Specifically, Leventhal and Cleary postulate that smoking behavior is governed by the regulation of affective states that may be created either by the drug itself (e.g., drops in blood plasma levels of nicotine) or situational stimuli (e.g., life stressors). This perspective was usefully built and expanded upon the work of Tomkins and others by explicitly integrating both interoceptive and exteroceptive stimuli in smoking behavior. Overall, such affect regulation perspectives are distinct from the more traditional addiction-oriented models, which were principally focused on biologically driven mechanisms (e.g., nicotine dependence and physical withdrawal symptoms).

A promising and most contemporary affect regulation account of smoking centers, specifically, on drug motivational processes in explaining the maintenance and relapse of smoking (Baker, Morse, & Sherman, 1986; Baker, Piper, McCarthy, Majeskie, & Fiore, 2004). This perspective suggests that regular tobacco use can produce aversive withdrawal symptoms, and smoking to alleviate such sensations may play a central role in the maintenance of smoking. Specifically, as levels of nicotine fall in the body, the addicted individual begins to detect internal (interoceptive) withdrawal cues such as negative affect in an automatized fashion (Baker et al., 2004). Over time, such individuals learn to escape and avoid these aversive internal states through self-administration of the drug (Baker et al.). Consistent with this type of model, there is a robust relation between severity of aversive (emotionally valenced) withdrawal symptoms and smoking relapse (Piasecki, Jorenby, Smith, Fiore, & Baker, 2003; West, 2005). Thus, smoking may therefore serve as a powerful affect regulation tactic for minimizing short-term distressing withdrawal sensations.

Empirical work has largely supported the relevance of affect regulation in regard to smoking. One line of research in this domain has indicated that there is meaningful individual variation in smoking motives and expectancies about the consequences of smoking (Brandon & Baker, 1991; McKennell, 1970; Shiffman, 1993). For example, individuals who tend to fear the negative consequences of internal states (e.g., bodily sensations), compared to those who express less of such fear, are more apt to smoke for negative affect reduction reasons (motives) (Brown, Kahler, Zvolensky, Lejuez, & Ramsey, 2001; Comeau, Stewart, & Loba, 2001; Gonzalez, Zvolensky, Vujanovic, Marshall, & Leyro, 2008; Novak, Burgess, Clark, Zvolensky, & Brown, 2003; Stewart, Karp, Pihl, & Peterson, 1997). For example, Conklin and Perkins (2005) prospectively examined the impact of negative mood inductions on smoking behavior. They found that a negative mood induction resulted in a quickened latency to smoke while simultaneously increasing the number of self-administered cigarette puffs, suggesting that negative affect may "motivate" smoking behavior. Other work suggests that motives related to craving and withdrawal account for variance in treatment outcome during smoking cessation (Piper et al., 2008). Overall, the study of affect regulation processes in regard to smoking behavior appears to be a promising and clinically relevant line of inquiry.

11.4 Mechanisms of Change Underlying Smoking Intervention

With an increasing number of adults seeking assistance for smoking cessation, a critical practical need is to identify clinically relevant factors that can be changed in order to effectively intervene with smoking behavior. That is, identification of malleable "risk factors" for poor cessation outcome. Led by the work of Kraemer et al., groundbreaking conceptual strides have

created a clearer understanding of various risk processes (Kazdin, Kraemer, Kessler, Kupfer, & Offord, 1997; Kraemer et al., 1997; Kraemer, Stice, Kazdin, Offord, & Kupfer, 2001; Kraemer, Lowe, & Kupfer, 2005). To be clear, a *risk factor* is a variable that is related to, and temporally precedes, an unwanted outcome (Kraemer et al.). *Causal risk factors* reflect variables that, when modified in some way (e.g., through an intervention), produce systematic change (increase or decrease) in the dependent variable of interest among persons who did not previously manifest such problems (Kraemer et al.). *Proxy risk factors* are variables that are related to an outcome of interest, but this association is due to the proxy risk factor's relationship with another causal risk factor (Kraemer et al., 2001). Thus, change in a proxy risk factor would not yield corresponding systematic change in an outcome variable; accordingly, a proxy risk factor may "mark" risk, but not explain, or account for, such risk.

Due to the theoretical and clinical importance of the ability to change a risk factor, both risk and proxy factors often are further categorized on the basis of whether or not they are *malleable* (i.e., can be changed or altered). When a risk factor cannot be changed, it can be classified as a *fixed marker*, whereas when it can be changed, it is considered a *variable risk factor* (Kraemer et al., 2005). These terms clarify whether a variable that is related to an outcome over time can be changed via intervention. If so, it is considered a "risk factor" and if not it is better characterized as a "risk marker." A central goal of developing efficacious smoking cessation programs involves efforts to isolate whether an identified variable is a risk marker or a causal risk factor (Kraemer et al.). Both markers and causal risk factors may be important for identifying vulnerable individuals, but only causal risk factors will be the ultimate direct target of an efficacious intervention. Although there is a number of promising risk candidates for smoking cessation from a biopsychosocial perspective (e.g., social support, proximity to smokers, self-efficacy, coping), here, we provide a brief review of two particularly prominent and promising variables underlying therapeutic change: nicotine withdrawal and negative affect.

Nicotine Withdrawal. Given the well-established physiological and psychological disturbances that occur within hours of nicotine deprivation (Hughes et al., 1990), nicotine withdrawal severity (i.e., symptoms elicited by a reduction in the intake of nicotine among regular smokers) may be the strongest predictor of early lapse and subsequent relapse. Since 1988 Surgeon General's report affirmed the role of nicotine dependence in the initiation and maintenance of cigarette smoking (USDHHS, 1988), nicotine withdrawal research has been an emerging focus of scientific investigation (Hughes, 1992; Hughes, Gust, Skoog, Keenan, & Fenwick, 1991; West, Hajek, & Belcher, 1989). For example, Patten and Martin (1996) reviewed 15 prospective studies that attempted to determine whether the severity of nicotine withdrawal was predictive of relapse following smoking cessation. They found that the results of these studies were equivocal, as only six of the 15 studies indicated a relationship between withdrawal and smoking relapse (Patten & Martin, 1996). This work led to the tentative conclusion that *severity* of nicotine withdrawal symptoms alone does not appear to be the key determinant of relapse, stimulating further research on this important idea.

Subsequent work on nicotine withdrawal and relapse has focused on the affective components of withdrawal as a mechanism leading to poor smoking cessation outcome (Baker et al., 2004; Kenford et al., 2002; Morissette, Tull, Gulliver, Kamholz, & Zimering, 2007). Specifically, *negatively valenced* withdrawal symptoms (as opposed to physical symptoms more generally) may be a critical "missing link" in understanding relationships between nicotine withdrawal and smoking outcomes. For example, Piper et al. (2008) recently examined the impact of withdrawal on the ability to remain abstinent from smoking in a randomized double-blind,

placebo-controlled treatment study. Results indicated that a reduction in withdrawal symptoms, via pharmacotherapy, significantly predicts future abstinence rates (Piper et al.). Other studies, focused primarily on the psychological features of withdrawal (e.g., negative affect), have found similar results. Specifically, such research has demonstrated that systematic decreases in negative affect are associated with lower rates of relapse (Ferguson, Shiffman, & Gwaltney, 2006), while greater levels of negative affect are predictive of failed quit attempts (Brown et al., 2001; Japuntich, Jorenby, Piper, Fiore, & Baker, 2007). These studies highlight the importance of implementing intervention strategies aimed at addressing the emotional features of withdrawal in an effort to effectively change smoking behavior.

Negative Affect. A number of emerging lines of evidence also is consistent with the related perspective that negative affect is an important factor in smoking cessation relapse. First, studies indicate that people who smoke consistently self-report that smoking helps them to cope with negative emotional states, most commonly anxiety, depression, and anger (Gilbert & Spielberger, 1987). Moreover, negative affect processes are a particularly common antecedent to smoking (Gilbert, Meliska, Williams, & Jensen, 1992; Hughes & Hatsukami, 1986; Shiffman, 1982). In one study, 75% of subjects in a smoking cessation trial reported that negative affect precipitated their temptation to smoke, with anxiety being the negative emotion most frequently reported (Shiffman, 1985). Second, prospective studies have found that negative affect after quitting predicts poorer cessation outcomes (Covey, Glassman, & Stetner, 1990; Ginsberg, Hall, Reus, & Muñoz, 1995; West et al., 1989). Third, relapse to smoking often occurs in situations involving negative mood states such as anxiety and depression (Bliss, Garvey, Heinold, & Hitchcock, 1989; Brandon, Tiffany, Obremski, & Baker, 1990; Shiffman, 1982). Fourth, lapses occurring in negative affect situations are more likely than lapses occurring in other situations to lead to complete relapses (O'Connell & Martin, 1987). Fifth, smokers who attribute their smoking to negative affect reduction may have particularly difficult times quitting (Pomerleau, Adkins, & Pertschuk, 1978). For example, O'Connell and Shiffman (1988) found that smoking to reduce negative affect significantly predicted relapse at 1-year follow-up. Sixth, as described earlier, affect-related withdrawal symptoms are more predictive of relapse to smoking than measures of physical dependence and physical withdrawal symptom severity (Piasecki, Kenford, Smith, Fiore, & Baker, 1997).

Aside from negative affect during cessation, smokers with emotion-based psychopathology appear to have a particularly difficult time quitting and tend to experience greater degrees of emotional distress during a cessation attempt (Zvolensky et al., 2008). There is now a variety of evidence consistent with this perspective, with the vast majority of it conducted in relation to depression. This work initially focused on the role of a history of depression in cessation outcome (Anda et al., 1990; Ginsberg et al., 1995; Kinnunen et al., 1996); however, more recent investigations have found evidence that smokers with current depressive symptoms are significantly more likely to have problems quitting smoking compared to smokers without such symptoms (Patten, Martin, Calfas, Lenton, & Wolter, 2001). Research addressing the impact of anxiety disorders on smoking cessation is currently very limited. Some recent work has begun to focus on traumatic experiences and smoking cessation such as that of Lasser et al. (2000), who found that in a large representative sample the lifetime quit rate (defined as the proportion of lifetime smokers who were not current smokers) was significantly lower for participants with posttraumatic stress disorder (PTSD) than for participants without mental illness (28.4% versus 42.5%). Hapke et al. (2005) also reported that, compared to those who had not been exposed to trauma, quit rates were significantly lower among those with PTSD. Most recently, Zvolensky et al. found in a controlled prospective test that smokers with PTSD demonstrated

an increased risk of initial lapse compared to smokers with other anxiety disorders and smokers without any current axis I psychopathology during the first week of a quit attempt. No differences were evident, however, between persons with PTSD compared to persons with other anxiety disorders in regard to early relapse, although both of these groups relapsed significantly earlier than persons with no psychiatric disorder history (Zvolensky et al.). These findings suggest that smokers with anxiety disorders such as PTSD may be more apt to experience early problems in quitting (lapse), possibly due to a hypersensitivity to aversive interoceptive cues (Zvolensky & Bernstein, 2005).

11.5 Evidence-Based Treatment Approaches

In combination with research addressing the mechanisms contributing to smoking maintenance, scientific attention has been focused on the efficacy of cessation strategies. At a broad-based level, these treatment strategies can be divided along two key dimensions: (1) brief-intensive strategies and (2) type of intervention model (e.g., pharmacological, psychosocial, combined). In clinical practice, there often is a degree of overlap and cross-fertilization of these two dimensions. For example, an individual patient may first receive a brief psychosocial intervention (e.g., advice on quitting by the treating physician) when visiting their primary care physician, but then graduate to a more intensive combined intervention as needed based upon their relative degree of success in quitting. Here, we review some of the key elements considered effective in smoking cessation practices across these domains.

Brief Clinical Strategies for Quitting. Brief strategies for helping individuals quit smoking are typically applied in medical settings (e.g., dental office, primary care practices), wherein patients are receiving short-term care visits in the order of minutes. This type of care is brief in the sense that it involves a rapid assessment of smoking behavior and history, and offers a minimal therapeutic recommendation that is to be carried out (and reassessed) by the patient. Such care is important to public health efforts to effectively deal with smoking and tobacco use more generally because medical care is often highly time-limited (e.g., 10–15 min in duration; Stange et al., 1998), and many persons will not seek more intensive clinical care if they are able to successfully quit on their own or choose to continue smoking (Jaen, Crabtree, Zyzanski, Goodwin, & Stange, 1998).

For patients who are *currently wanting* to quit, medical practitioners can facilitate such efforts by applying the five As reviewed earlier. Briefly, medical practitioners can help patients quit by routinely asking about smoking behavior, explicitly advising such persons to quit in a personalized way, evaluating willingness to make a (current) quit attempt, assisting in efforts to aid such a quit attempt, and arranging follow-up care to reevaluate progress in quitting. Although these strategies are principally psychosocial in nature, assisting and encouraging patients in a quit attempt can, and often does, involve the administration or recommendation of pharmacological aids such as nicotine replacement therapy (NRT).

For patients *unwilling to quit*, clinicians should assess smoking behavior and attempt to increase the individual's willingness to make a quit attempt in the near future. There is a large scientific literature on the motivational bases to quitting smoking (and other behavior change efforts more generally; e.g., Colby et al., 1998). Such motivational efforts to promote change in smoking and other health-oriented arenas are best received when a clinician is empathetic, genuine, and facilitates personal engagement and empowerment (Colby et al.). For example,

a clinician may help the patient identify personal reasons for quitting (e.g., to live longer, to complete more physical activities), isolating risk for not quitting (e.g., exposing children to dangers of second-hand smoke), and highlighting the rewards in quitting (e.g., feel better physically and psychologically). For many smokers, the expected short-term benefits of smoking (e.g., "smoking calms my nerves") tend to override the more distal, negative consequences (e.g., potentially life-threatening illnesses). The challenge is to move smokers from general acceptance of potential negative consequences ("smoking is dangerous to health") to personally relevant acceptance of reasons for quitting ("smoking is dangerous to my *own* health") (Fishbein & Cappella, 1977). A concurrent focus on the health benefits of quitting may be especially effective in motivating and sustaining efforts to quit smoking (Brown & Emmons, 1991). In all cases, a key aspect to such motivational work with patients is to continually reinforce the self-evaluative motivational process, as not all persons will show dramatic change in willingness to quit after a single recommendation. That is, motivational activities need to be conducted recurrently over time in order to make the ideas crystallize and prompt clinically meaningful behavior change. This motivational issue of particular relevance to smoking wherein the average smokers will need to make multiple efforts to quit in order to ultimately be successful in maintaining their abstinence (CDC, 1999).

For persons who have already quit in the recent past, brief interventions also are needed and useful for maintaining abstinence. Here, relapse prevention tactics are often useful given the high rates of overall relapse in smoking cessation efforts. These relapse prevention efforts are particularly important for the first year following a quit attempt, as this time period particularly is highly risky for relapse. In this domain, minimal practice interventions for relapse prevention can include such tactics as monitoring smoking urges, encouragement and support for remaining abstinent, making nonsmoking lifestyle changes (e.g., physical exercise routines), and isolating and preparing for potential high-risk scenarios for relapse (e.g., attending a social gathering where smokers will be present). More intensive relapse prevention might include such tactics as cultivating cognitive and behavioral coping strategies for dealing with negative mood vulnerabilities, and actively developing nonsmoking social networks.

Intensive Clinical Interventions. There are many instances where brief interventions are insufficient for promoting effective clinical change in regard to smoking cessation. Here, more intensive treatment strategies are often needed to help the individual quit. As a general rule, the more intensive the treatment, the better the odds of ultimate success in quitting (CDC, 1999), but it is also important to match individuals with quitting strategies that are relevant to their needs. As they incorporate a variety of treatment components, intensive clinical interventions are often appropriate for most tobacco users, regardless of the subpopulation in which they fall (e.g., heavily dependent smokers), so long as the individual is willing and able to actively participate in the program (Cromwell, Bartosch, Fiore, Hasselblad, & Baker, 1997).

Once it has been determined that the individual will make a quit attempt via a more intensive treatment strategy, additional assessment is often recommended to provide useful information for the counseling process. Incorporation of personalized information such as current life stressors, comorbid psychiatric or medical conditions, personal reasons for wanting to quit, and available social support allows the clinician to tailor the intervention to meet the specific needs of the patient. In an intensive treatment program, multiple types of clinicians (e.g., primary care, psychologist, cessation specialist) can be effective in providing effective treatment, and clinicians who specialize in the treatment of tobacco dependence are a particularly valuable resource (Fiore et al., 2000). Although tobacco treatment specialists represent a major

resource in efforts to combat the public health burden of tobacco dependence, it is nonetheless noteworthy that research indicates that they are not always utilized by patients (Lichtenstein & Hollis, 1992). Guidelines based upon clinical research recommend that together, the patient and clinician(s) devote a *minimum* four sessions, lasting at least 10 min each, to cessation efforts (Fiore et al.). Intensive treatment programs may be conducted in an individualized or group format, and typically include elements of practical counseling, intra-treatment supportive interventions, and extra-treatment supportive interventions (Fiore et al.).

The goal of practical counseling is to provide the patient with problem-solving and skills training (Fiore et al., 2000). First, the clinician and patient attempt to identify dangerous or "high risk" smoking situations. These situations are specific to each patient, and can reflect events (being around other smokers), internal states (negative affect), or activities (drinking alcohol) that may theoretically increase the risk of smoking urges or relapse following cessation. Second, the clinician and patient develop and practice coping skills aimed at addressing the identified high-risk situations. Coping skills typically involve cognitive and behavioral strategies that will allow the patient to successfully remain abstinent from tobacco. These strategies can include, but are not limited to, learning to anticipate and avoid temptation (e.g., not attending social gathering where smokers are present), implementing lifestyle changes to reduce stress (e.g., engaging in physical exercise on a regular basis), and applying cognitive strategies aimed at ameliorating negative mood states (e.g., decreasing the tendency to catastrophize about stressful life events). Third, practical counseling often provides basic psychoeducational information regarding smoking and cessation practices (e.g., the importance of setting a specific quit date, enlisting others to offer social support during a quit attempt). Patients also are formally educated about the addictive nature of nicotine and corresponding withdrawal symptoms, as well as the role that they may play in prompting a relapse following cessation attempts.

For intra-treatment supportive interventions, the role of the clinician is to provide encouragement, empathy, and concern regarding the patient's quit attempt (Fiore et al., 2000). Encouragement is communicated to the patient as the clinician reviews the efficacy of tobacco treatments now available while simultaneously conveying their belief in the patient's ability to succeed in cessation. Moreover, it is important that the clinician takes care to inquire how the patient is feeling about their current quit attempt (e.g., fears, ambivalence), and responds supportively, expressing willingness to assist with any challenges. The final element of intra-treatment interventions is to engage the patient in communication about the quitting process. According to smoking cessation guidelines (Fiore et al.), the clinician should be specific in querying about the patient's (1) *reasons* for quitting smoking, (2) *concerns* about quitting smoking, (3) *successes* already achieved, and (4) *difficulties* encountered while quitting.

Although intra-treatment strategies primarily focus on the role of the clinician, extra-treatment strategies promote soliciting support from external resources (i.e., friends, family) (Fiore et al., 2000). Elements of extra-treatment interventions include patient training in support solicitation skills, as well as directly prompting patients to seek outside support. This issue of enlisting support from others can be a clinical challenge, as for numerous reasons some individuals may not see the value in, or desire to, have others involved in their quit experience (e.g., embarrassment if they fail, social anxiety about asking others for help). In training the patient to successfully solicit social support, the clinician models effective support skills (as describe above) and assists the patient in practicing making requests for support from loved ones. This activity also may involve educating the patient about various community resources

that are available to assist in their quit attempt (i.e., hotlines, support groups). Such community-based resources can be instrumental in creating a larger network of support for those struggling with quit experiences. Moreover, these community resources may be particularly relevant when other types of support cannot be accessed. Finally, an important responsibility of the clinician in this domain is to help facilitate outside support networks. For example, the clinician may choose to invite supportive persons (e.g., significant other, co-worker, and spouse) to cessation sessions or assign patients to be support "coaches" for one another with interventions conducted in a group format.

In addition to the psychosocial strategies described above, first-line pharmacotherapy has consistently demonstrated beneficial effects for smoking cessation, including the ability to nearly double successful quit rates (Fiore et al., 2000; Hughes, Shiffman, Callas, & Zhang, 2003). Pharmacotherapy for smoking cessation should always be seriously considered as a component of top-level therapeutic care. Often times, it is useful to work directly with a prescribing physician to determine the best medication for a given individual. Currently, there are numerous medications which facilitate smoking cessation efforts, although the mechanisms underlying these effects may differ across specific drugs. Due to the wide variety of pharmacotherapy options, here, we do not review all these medications and their relative efficacy in detail (see Hughes et al., 2003). However, the most popular types of pharmacological agents are those that rely on a safer (i.e., nonsmoking) nicotine delivery system that can be stepped down gradually as needed by the individual. These NRTs include nicotine gum, nicotine inhalers, nicotine nasal sprays, and nicotine patches. All of these agents are focused principally on maintaining blood nicotine levels to decrease adverse withdrawal symptoms upon smoking abstinence (Hughes et al.). It is possible these NRT strategies also may promote an enhanced expectation of success in quitting (placebo effect), although relatively little scientific work has been focused on addressing this matter. Overall, the exact dosing of these NRT-related drugs varies across individuals, as does the relative degree of efficacy (Fiore et al.). Clinically, therapists may work with clients to isolate the best "match" of pharmacotherapy for their individual clients. For example, some smokers may prefer nicotine gum, whereas others may prefer the patch for a variety of personal reasons.

Another drug that has proven efficacious in facilitating smoking cessation is Bupropion (Zyban). This drug blocks neural reuptake of dopamine and nor-epinephrine; it can be prescribed only by pharmacological agents. Although Bupropion is not appropriate for all patients (e.g., individuals with seizure disorders), it may help decrease the aversive experience of quitting (e.g., decreasing negative affect prior to, or during, a quit attempt). Bupropion also can be used in conjunction with NRT strategies, possibly enhancing clinical benefit for certain individuals by targeting different mechanisms of action. It should be noted that there is a variety of other pharmacological drugs that may be helpful to smokers trying to quit not discussed as extensively in this chapter, such as Clondidine and Nortiptyline. As the effectiveness of these drugs for smoking cessation is yet to be empirically determined, an extensive discussion of these medications is beyond the scope of the present chapter.

11.6   Basic Competencies of the Practicing Clinician

We now turn to a discussion of some core clinical competencies by highlighting both "basic" and "expert" treatment strategies, as well as ways to transition from a basic stage of competency

to a more advanced level. This discussion is broadly relevant to clinical practitioners working in medical, dental, and psychological sectors of the health-care industry.

Given the aforementioned description of the widespread prevalence and overwhelming negative impact of smoking and other forms of tobacco use, there is a strong need to distill "basic" and "expert" levels of competency for practitioners. These competencies, at the most fundamental level, are simply training goals that can guide a more efficacious and globally higher-level standard of tobacco-related care. This section of the chapter is not intended to be equally and fully applicable to all practitioners, as there are likely distinct needs and goals of specific types of providers. For example, a primary care physician who interacts with a large number of patients for relatively short periods of time (e.g., less than 10 min) will have different needs and goals than a practicing psychiatrist or clinical psychologist who may see far fewer individuals and for longer periods of time (e.g., 50 min). Similarly, a practicing clinician specializing in care of adolescents (whether medical, dental, or psychiatrically focused) may have different goals than a clinician working primarily with adults, or the tobacco treatment specialist who has detailed training compared to other practitioners and years of experience working with smoking cessation. Thus, it is not surprising that different training competencies and goals have been employed across distinct clinical settings. In the present section, we attempt to distill the most important clinical competencies in knowledge, skill, and proficiency that can be employed across different types of practitioners in order to provide a broad-based resource to a variety of health-care providers. It should be noted, however, that there are numerous tobacco-related agencies and training programs (e.g., America Medical Association, Association for the Treatment of Tobacco Use and Dependence) that offer additional guidelines for the persons whom they principally serve and aim to educate.

The most basic level of competency of clinical relevance focuses on simply being *aware of the scientifically developed knowledge on the prevalence and impact of tobacco and its disorders*. Here, clinicians should initially strive to attain an overall awareness of tobacco use and behavior as it relates to their clientele. Specifically, it is important for clinicians of any background to acknowledge from a conceptual basis that smoking behavior is integrally connected to general medical and psychiatric conditions. By obtaining such knowledge of tobacco use and its disorders, the clinician is better equipped to offer accurate information about tobacco use to patients. This information can include psychoeducational "facts" (e.g., how tobacco may impact lung disease), but also may involve strategies designated (through scientific evaluation) as helpful to quitting. To gain access to this information, practicing clinicians can consider both informal and formal methods of tobacco education. More specific goal-oriented targets can include, but are not limited to, being able to efficiently and capably do the following:

- Describe the prevalence of tobacco use and its disorders
- Describe regional tobacco use patterns
- Describe the negative physical and psychological consequences of tobacco use and dependence
- Describe the importance and role of tobacco treatment, particularly those methods based on evidenced-based care and clinical guidelines
- Maintain a general awareness of emerging research related to the treatment of tobacco use and its disorders
- Describe the biological, social, and psychological influences on tobacco use
- Understand the criteria used for defining tobacco use and dependence

- Understand the need to adapt and tailor information for tobacco cessation to particular patient populations (e.g., smokers with psychiatric disorders, gender-specific information, youth versus adults)
- Communicate an interest and willingness to consult with other resources when tobacco knowledge may be limited
- Understand the most common processes or factors maintaining smoking behavior (i.e., reasons for smoking)

A second basic competency skill domain of clinical relevance and importance pertains to *developing basic assessment and counseling skills for dealing effectively with tobacco use and its disorders*. This domain of competence naturally builds from the foregoing description of general knowledge and awareness. In order to effectively understand and ultimately intervene with tobacco use and its disorders, a clinician needs to utilize knowledge about tobacco and learn to apply such knowledge to more sophisticated assessment and treatment strategies. This area of work necessarily begins with developing a level of "clinical comfort" with tobacco use topics and being capable of engaging a patient in a discussion focused on this topic. For this reason, the basic competency element in this domain requires counseling skills that strengthen interpersonal connection (e.g., rapport, listening to patient concerns). From the counseling perspective, a variety of core skills are necessary. These include, but are not limited to, the following:

- Have the capacity to be an active listener and demonstrate an empathetic stance regarding clinical care involving tobacco-related issues.
- Be able to communicate the strengths and challenges to evidence-based care treatment approaches for tobacco use and its disorders in a nonthreatening manner.
- Be able to understand basic models of behavior change that pertain to tobacco use and meaningfully communicate levels of "motivational stage and readiness" to patients.

From an assessment perspective, basic competencies are needed in order to understand how to adequately address smoking behavior and history. Without this level of proficiency, it will be challenging to document readiness to quit or success in doing so. In the assessment process, there are both historical and individually based variables to consider. The overarching goal is to learn to comprehensively document and obtain accurate information that can be used in a clinically meaningful manner. The assessment process can be usefully divided into two globally phases: an intake (or initial assessment) and ongoing assessment. For the intake assessment, key variables to assess include: the extent and nature of tobacco use from a lifetime and current perspective, documenting current interest and motivation in quitting, employing evidenced-based technologies for documenting tobacco use and dependence (e.g., Fagerstrom Test for Nicotine Dependence; Heatherton, Kozlowski, Frecker, & Fagerstrom, 1991, carbon monoxide tests), identifying (with the patient) barriers to quitting currently, identifying strengths in the patients or the environment (e.g., social support) for quitting, documenting nature of past quit history and relative degree of success in such attempts, and personal as well as cultural variables that may affect smoking-related decision-making processes. Also, the intake assessment process should integrate information about the patient's medical and psychological history (e.g., concurrent substance use) in order to understand how such factors may influence their ongoing tobacco use or attempts to quit.

Ongoing assessments require an understanding of the individual patient and the specific variables that need to be regularly tracked in order to accurately and objectively document

(and understand) motivation to quit and smoking behavior. Here, there will be differences across individual patients, but in most instances actual smoking behavior, ongoing life stressors, and current motivation to quit are important targets. This information can be used to track and understand ongoing efforts to quit. For example, clinicians should take note of each patient's specific thoughts related to smoking (e.g., belief that smoking functions as an effective method of stress management), primary reason(s) for wanting to quit smoking (e.g., health, social stigma), and situations in which smoking is most likely to occur (e.g., when drinking alcohol, driving). This information, in turn, can be applied to help educate the patient about their specific smoking patterns and ultimately help them formulate a plan for making a quit attempt that is individualized to their specific needs and life circumstances.

11.7 Expert Competencies of the Clinician

The expert level of competency subsumes all of the foregoing basic level of competencies and builds on them. A key distinction between the basic and expert levels of competency focuses on the relative degree of experience, training, and skill in treatment planning activities. Here, it is assumed that the practitioner will be actively and systematically involved in the clinical care of the patient in terms of their smoking behavior and attempts to quit. For this reason, there is a focused need on knowledge development and training in specific methods of cessation interventions and how to work with patients to maximize the clinical benefits of such strategies/tactics. Due to the level of skill required to work clinically with smoking cessation, there is a natural need for more emphasis on formal training programs in smoking cessation. Such programs can include elements of motivational approaches for eliciting behavior change among smokers, as well as provide coverage in empirically supported smoking cessation strategies. The first domain of relevance in treatment planning includes *knowledge and training in psychoeducation and pharmacological approaches to smoking cessation*. The competent clinician needs to be capable of delivering the following elements of smoking cessation care:

- Be aware of the utility in providing one-to-one smoking cessation counseling and be able to explain such benefits to patients
- Know the meaning and five As of tobacco treatment (ask, advise, assess, assist, and arrange follow-up)
- Identify and utilize evidence-based treatment approaches for smoking cessation
- Provide clear and accurate information concerning psychosocial methods and clinical strategies for smoking cessation
- Provide clear and accurate information concerning pharmacotherapy available for smoking cessation
- Maintain a working knowledge of relapse prevention methods and other methods to provide ongoing support for smokers attempting to, or have recently made a, quit attempt. (*Note*: Since the majority of smokers who initially quit resume smoking within several months [Hunt & Bespalec, 1974], maintenance is a critical issue for smoking cessation programs. The most commonly used behavioral maintenance strategies are based on the relapse prevention model [Marlatt & Gordon, 1985].)
- Be aware and capable of clearly explaining the benefits of quitting across all ranges of age and the need to tailor treatment as a function of such developmental stage (see also

subsequent section focused on the *identification of subgroups at highest risk for problems in quitting smoking*).

- Be able to present a rationale as to why evidenced-based approaches to smoking cessation outperform other approaches (e.g., cold turkey) in a nonthreatening and engaging manner
- Be able to identify and provide patients with local (accessible) resources for smoking cessation (e.g., quit hotlines)
- Maintain an active level of connection with local smoking cessation resources to facilitate patient management and integrated approaches to care
- Recognize that persons of diverse ethnic backgrounds may have different expectations and clinical needs in the context of smoking cessation than those from the majority culture
- When applicable, cultivate and maintain an active local community resource for persons from ethnic minority backgrounds seeking help with smoking cessation

Beyond the global smoking cessation knowledge and skill at the expert level, there is a focused clinical need to *identify the subgroups at highest risk for problems in quitting smoking and cultivate the clinical knowledge and skill needed to work effectively with them in regard to smoking cessation*. The exact amount of time involved in each domain may be different depending on the type of practitioner (e.g., primary care physician versus psychiatrist or clinical psychologist). For adults, this clinical knowledge can be aimed at various subgroups.

One such subgroup is female smokers who are, or will soon become, pregnant. Research indicates that 12–20% of women smoke during pregnancy, putting mothers and infants at risk for complications such as premature birth, low birth weight, or miscarriage (Orleans, Barker, Kaufman, & Marx, 2000). In fact, over 1,000 infants die in the USA each year because their mothers smoked while they were pregnant (Orleans et al., 2000). Other studies have found that maternal smoking during pregnancy is linked to sudden infant death syndrome (DiFranza & Lew, 1995) and may cause harmful changes in fetal brain and nervous system development (Lambers & Clark, 1996). Interestingly, some scholars have described the pregnancy time period as a "teachable moment" to help women stop smoking (Orleans et al.). Indeed, women are highly motivated to stop smoking during this time, when they are concerned not only about their own health but that of their infants. Strikingly, about 25% of women smokers quit smoking either as they prepare to become pregnant or as soon as they learn that they are pregnant (Ershoff, Mullen, & Quinn, 1989). To manage the unique needs of this population of smokers at the expert level of competency, there is a variety of key domains to develop clinical knowledge and skill. These include, but are not limited to, the following:

- Understand the risk associated with smoking during pregnancy and be able to explain such risk to patients
- Understand the risk of relapse to smoking for postpartum women who have stopped smoking while pregnant
- Demonstrate a working knowledge of the use of NRT and other pharmacological agents for smoking cessation for pregnant women
- Understand and address provider, systems, and policy barriers to routine intervention in prenatal care
- Understand common clinical issues among pregnant females in regard to quitting and relapse, including weight gain, stress, and being around family members that smoke

Another subgroup of high clinical priority is smokers who have existing psychiatric disorders, or are at high risk for developing psychopathology. Tobacco use and dependence rates are disproportionately high among those with psychiatric or mental disorders. Those with psychiatric disorders are nearly twice as likely to be current smokers as those without psychiatric problems (41% versus 22.5%), and smoking prevalence rates increase as the number of lifetime psychiatric disorders increase (Lasser et al., 2000). Individuals with psychiatric conditions represent 22% of adults in the USA, but they consume 44% of all cigarettes sold (Lasser et al.). These disproportionately high smoking rates place those with psychiatric disorders at increased risk for tobacco-related illnesses, and contribute substantially to the high rates of morbidity and mortality observed in psychiatric disorders (Goldman, 2000). There also is evidence that smokers with psychiatric disorders, or risk factors for such clinical conditions, are at increased risk for lapse and relapse during quit attempts (Hitsman et al., 2003; Kalman, Morissette, & George, 2005; Zvolensky et al., 2008). These individuals tend to perceive the prospect of quitting as personally threatening and challenging (Zvolensky et al., 2007), and may have more pronounced motives to smoke for the management of negative emotional states (Gonzalez et al., 2008). To deal effectively with this subpopulation of smokers, expert-level competencies may include, but are not limited to, the following:

- Broadly understand the nature of psychopathology and distinctions between mental disorders
- Demonstrate knowledge of, and clinically familiarity with, evidenced-based psychiatric screening approaches for mental disorders
- Maintain current knowledge about local mental health providers that can be used as local resources for managing the mental health needs of smoking patients
- Recognize that specialized treatment approaches (e.g., more intensive and protracted protocols) may be needed for smokers with psychiatric disorders or vulnerabilities
- Recognize developmental links between smoking and psychiatric conditions

Somewhat related to this discussion of psychiatric disorders, it should be explicitly noted that there is an especially robust co-occurrence of smoking with other addictions. For example, approximately 85% of alcoholics smoke on a daily basis compared to approximately 25% of individuals in nonalcoholic populations (Bobo, 1989). Relative to those who are not alcohol-dependent, individuals with a history of alcohol dependence are nearly five times more likely to smoke regularly (Kozlowski & Ferrence, 1990), smoke at a higher rate, and have greater difficulty quitting smoking (Burling & Ziff, 1988; Istvan & Matarazzo, 1984). This same pattern of findings is evident in those who seek treatment for alcohol problems. Across studies, approximately 70–90% of those seeking treatment for alcohol problems are smokers (Joseph, Nichol, & Anderson, 1993). High rates of smoking are also apparent among individuals who use illicit drugs. For example, Rounsaville, Kosten, and Kleber (1985) found that 97% of opiate addicts in inpatient treatment were daily smokers. Sees and Clark (1991) found in a large, heterogeneous sample of substance abuse patients, that 77% of the cocaine addicts and 85% of the heroin addicts regularly smoked cigarettes. Smoking prevalence is also high for persons with heavy substance use histories in the general population. Chronic marijuana users are nearly four times as likely as those who do not use marijuana to be nicotine-dependent (Henningfield, Clayton, & Pollin, 1990). Likewise, the prevalence of cocaine dependence is almost ten times higher in persons with nicotine dependence relative to normal control participants (Breslau, Kilbey, & Andreski, 1990).

Despite interest in quitting among substance abuse patients, support for smoking cessation interventions within chemical dependency treatment programs is at best weak. Fewer than 50% of program personnel encourage patients to quit smoking, and 40% believe that smoking cessation should *not* be provided within the context of chemical dependency treatment (Bobo & Gilchrist, 1983; Kozlowski, Skinner, Kent, & Pope, 1989). Less than 15% of alcohol treatment programs encourage and/or provide smoking cessation treatment (Sees & Clark, 1993). Concern about smoking cessation during chemical dependency treatment often relates to issues regarding whether cessation efforts will jeopardize abstinence from alcohol or drugs, and/or doubts that alcohol- and drug-addicted patients can mount a serious effort to quit smoking. Yet, there is little, if any, evidence that smoking cessation impairs alcohol or drug treatment outcomes (Bobo, McIlvain, Lando, Walker, & Leed-Kelly, 1998). In fact, smoking cessation during alcohol and/or drug treatment may actually improve outcome. For example, slightly higher rates of abstinence from alcohol use have been reported among those who successfully quit smoking relative to those who did not (Joseph, Nichol, Willenbring, Korn, & Lysaght, 1990). There may be additive benefits when treatment involves targeting multiple behavior problems, particularly if they are functionally related to a common risk process (e.g., deficits in substance refusal skills). Furthermore, applying coping skills to certain substances (e.g., alcohol) and not others such as nicotine may send a "psychologically conflicting" message to patients about their substance use. This inconsistent message may be most problematic for those addictive disorders that typically rely on inhalation-based methods of administration, such as marijuana dependence. Given these issues, expert level of competency for smoking and other comorbid addictions can usefully ensure that following issues are addressed:

- Maintain an awareness of the co-occurrence of substance use and disorders among patients
- Integrate smoking cessation counseling efforts among those with other types of substance use and disorders
- Addiction treatment personnel, specifically, can advise patients to quit, provide motivational interventions for those who are not ready to quit, and offer assistance to those who are ready to quit

Another subgroup of relevance to expert level of competency pertains to youth (persons below age 18 years of age). There are few theoretical reasons to expect that behavioral principles do not apply equally well to adolescents, although research in treating adolescents is in its infancy. Findings from the Monitoring the Future Study (MTF) indicate 47% of adolescents have tried smoking by the 12th grade and 21% are current smokers (Johnston et al., 2007). Youth smoking rates are even higher in some areas of the country (Youth Risk Behavior Surveillance; CDC, 2005). Although rates of smoking among youth have been decreasing since the mid-1990s, the decline is slowing substantially. Indeed, nonsignificant declines were observed in lifetime, 30-day, and daily smoking rates for 10th and 12th graders from 2006 to 2007 in the MTF; small declines were observed for 8th graders on these outcomes. The rates of smoking among youth are alarming, as empirical work suggests that once an adolescent starts smoking, he or she will continue to smoke for greater than 15 years, on average, among both males and females (Pierce & Gilpin, 1996), thereby potentially incurring long-term physical and mental health risks of tobacco use (Jansen, Glynn, & Howard, 1996). Adolescent smoking differs from adult tobacco use in at least two clinically important ways. First, MTF data suggests that youth tend to disapprove of tobacco use (e.g., 80% of 8th graders "prefer to date someone who does not smoke;"

76% believe "smoking is a dirty habit"; Johnston et al.), suggesting adolescent smokers may be marginalized. Indeed, socializing agents may play a particularly important role in adolescent smoking behavior; for instance, empirical work highlights a complex interplay between parental and peer tobacco use in adolescent smoking uptake and acceleration (Chassin, Presson, Rose, Sherman, & Todd, 1998). Second, a key developmental feature of adolescence is temporal proximity to smoking initiation; adolescence is a "high-risk" developmental period in the sense that initiation of smoking is more likely to occur during adolescence than at any other stage of life (USDHHS, 1994). Whereas adult daily smokers report smoking regularly for several years, the majority of adolescent smokers are at an earlier stage of smoking (e.g., experimentation; Johnston et al.). As adolescents progress from experimental to daily smoking, smoking behavior generalizes from a few discrete settings to multiple contexts. Important developmental changes co-occur with this process, including changes in tobacco use expectancies, self-efficacy, automaticity of cognitive processing relating to tobacco use, and diversity of coping repertoire (Brandon, Herzog, Irvin, & Gwaltney, 2004). Taken together, the unique characteristics of adolescence require a sophisticated understanding of the processes that influence smoking initiation and acceleration during this life stage. Such knowledge is critical for forwarding theory, research, and prevention/intervention efforts among youth during this high-risk period. Expert-level competencies in this domain may include, but are not limited to, the following:

- Understand the risk associated with environmental smoke exposure to children in a household.
- Understand the prevalence of smoking among children and adolescents.
- Understand the role of parent and peer modeling in smoking among youth.
- Demonstrate the capability to identify developmental issues with age-appropriate interventions for tobacco treatment.
- Understand that factors related to "resistance" surrounding smoking cessation may be different for youth versus adults.
- Cultivate knowledge in, and having local resources available for, pediatric-oriented care for youth as part of a multidisciplinary treatment approach for tobacco and its disorders

A final area of expertise pertains to *recognizing and enlisting intensive treatment approaches for smokers with particularly high clinical needs*. That is, certain practitioners who routinely deal with high-risk patients may be able to enlist service-based resources to offer an intensive approach to smoking cessation. There is emerging evidence that such programs show promise. DeBusk et al. (1994), for example, evaluated a case management system for patients hospitalized with an acute myocardial infarction that included the following components: (1) in-hospital counseling by a physician lasting approximately 2 min; (2) an in-hospital comprehensive assessment and counseling session conducted by a nurse trained in behavioral problem-solving skills; (3) provision of a self-help manual focusing on relapse prevention and a relaxation audiotape; (4) telephone calls by the nurse 48 h and 1 week after hospital discharge and monthly for 6 months. Patients who relapsed after discharge also were offered one additional visit with the nurse for further counseling as well as nicotine gum or transdermal nicotine. This treatment was compared to a usual care condition that included physician counseling on smoking cessation and nutritionist counseling on dietary change during hospitalization, and physician-managed, lipid-lowering drug therapy after hospital discharge. Patients in the usual care group also had access to group-based smoking cessation program and group exercise rehabilitation.

The intensive case-management system produced a 1-year smoking cessation rate of 70% compared to a rate of 53% for usual care (DeBusk et al.). These promising findings highlight the utility of developing specialized more intensive systems to intervene with smokers, especially those with severe medical problems and enrolled in other medical (ongoing) care, over extended periods of time. Based upon these findings, it is recommended that expert level of clinical standards include the following:

- Maintain an awareness of the severity of the clinical population in regard to unique opportunities to enlist highly intensive approaches to smoking cessation
- Maintain a flexible and integrated approach to smoking cessation care in intensive clinical settings (e.g., inpatient care) which draws upon the collective strengths and resources available to facilitate smoking cessation among specific populations (e.g., hospitalized smokers with heart disease, cancer)

11.8   Transition from Basic to Expert Competences

In providing smoking cessation clinical services, there is a "natural progression" from a basic to a more advanced level of competency. This transition occurs with the corresponding developmental change in knowledge, experience, skill, and proficiency in specific areas of tobacco-related information. Such development can be facilitated by involvement in more formal training and education in tobacco disorders and treatment interventions (e.g., coursework, attending research or clinical meetings focused on tobacco care). The specific elements of competency may be further advanced by the particular clinical need of practitioners. For example, a practicing pediatrician may need more information and skill development that is expressly focused on parents, youth, and the dynamics of the family unit as a whole. This is different from a practicing internist in a hospital setting, who may benefit from knowledge and training in intensive-oriented smoking cessation interventions that can be applied in a multidisciplinary fashion (e.g., involving persons from distinct medical training backgrounds working together on smoking cessation care). Alternatively, a practicing clinical psychologist may benefit most from cultivating skills and knowledge that are relevant to the specific psychiatric population they specialize in treating (e.g., the role of smoking behavior among individuals with depressive or anxiety disorders). Yet, outside of any degree of "natural progression" in competency in a certain domain, there are areas (described in the subsequent sections) that individuals, systems, and communities can focus on to enhance their respective degrees of knowledge and clinical acumen in regard to tobacco use and its disorders.

Enhancing the Individual Level of Professional Development. A central tenet in the transition of increasing one's level of competency involves making a personal commitment to professional development focused on tobacco use and its disorders. Such professional development can be achieved in a variety of ways, including reading tobacco-specific and other relevant journals (e.g., *Tobacco Control, Nicotine and Tobacco Research*), attending workshops and conferences focused on tobacco use and cessation, attaining certification as a tobacco counselor, and meeting regularly with other tobacco treatment-oriented professionals in one's local community to coordinate community-based resources. As described in the previous section, the exact proportion and type of professional development activity can vary depending on the type of professional service position and focus of clinical work. That is, there is no one set formula for success. In all instances, however, there is a pressing need to know how to better access and

evaluate evidenced-based resources for current information regarding tobacco use and its disorders. Thus, developing or maintaining an educational background in basic aspects of scientific methodology is an important component. For many practitioners such as physicians, psychologists, and nurses, this background is likely to have been included in their formal degree training. Yet, for some individuals, who have not received such formal training, seeking training in tobacco treatment certification and supplementary education in scientific theory and methodology will likely be advantageous for maintaining a precise working knowledge of developing tobacco-oriented research.

Enhancing Support Systems for Tobacco Use and Cessation in the Context of Medical Care. Aside from the individual level of commitment to professional development, it is a reality that most medical care occurs within a context that intersects with other health-care professionals. Transitioning from basic to expert levels of competency can therefore often take the form of enlisting in an integrated manner the systems involved in such clinical work. The need for such systems-oriented care is particularly evident given that the educational efforts solely focused on the individual have not always been met with large degrees of success (e.g., Thorndike et al., 1998). Additionally, many individuals seek medical care in medical systems governed by managed care businesses or other third-party payers. As a result, changes to a system of medical care (e.g., the medial practices governed by a specific managed care business) can have a major impact in terms of the type and quality of care administered by practitioners working with that system. Unfortunately, there is evidence that in the USA, system-level care for tobacco use and its disorders is largely underdeveloped. For example, despite the high cost of smoking on our health-care system, smoking cessation treatment is not uniformly paid for by managed care companies and third-party payers (Aakko, Piasecki, Remington, & Fiore, 1999). Similarly, a lack of financial coverage for tobacco-related treatment is evident for individuals on Medicaid (Barker, Orleans, & Schauffler, 1998). Such a lack of economic support has prompted numerous calls for such companies to offer coverage for tobacco use and smoking cessation (e.g., Healthy People 2010 report; USDHHS, 2000). At a minimum, such financial support could likely increase the quality of tobacco-related care delivered to patients by: (1) increasing awareness of the evidence concerning the institutionalized tobacco-oriented care systems (e.g., prompts for practitioners to ask about tobacco use with patients); (2) developing and implementing systems for tracking smoking counseling behavior of practitioners in a specific medical system; (3) offering feedback to practitioners regarding tobacco-related care; (4) working toward developing a team-oriented (multidisciplinary) approach to medical care that expressly focuses on tobacco; and (5) continuing to encourage tobacco-free standards in the workplace, as well as offer empirically validated intervention services to employees who smoke.

Enhancing Public Health Advocacy. Beyond the individual and system level of care, communities can support an increased level of care for tobacco use and its disorders by increasing the focus on public health policy advocacy. This area of work is important in instilling a consistent and community-wide message on the dangers of tobacco use and an awareness of where specialized care can be accessed. Thus, it is important for individuals to be aware of successful community-based legislations (e.g., smoke-free restaurants and bars), and continue to provide support for such activities in the local community. With the increasing globalization of medical and scientific work, it is likely that such community-focused efforts can draw from national as well as international models. In this domain, utilizing the media to offer a consistent public health message may be particularly important. For example, to the extent that youth are taught about the dangers of tobacco in school, and the local community does not permit the modeling

of smoking in high-profile public areas (e.g., restaurants and bars), it may be possible to eventually decrease the percentage of overall youth from becoming enticed to try using tobacco in the first place.

11.9 Summary

Understanding and treating tobacco use is an extremely important public health priority. Although efficacious behavioral and pharmacological interventions have been identified, many clinicians may not apply these promising interventions routinely with smokers and other tobacco users. There is little doubt that there remains a strong need for increased awareness across healthcare providers regarding the appropriate assessment, tracking, and intervention with their patients who use tobacco. Moreover, additional knowledge and research aimed at the development and application of evidenced-based treatment options are needed. It is likely that such work will have the most clinical impact when it is conducted with reference to an explicit scientifically informed theoretical model that draws from extant empirical work. Promising inroads in contemporary research on the maintenance of smoking appear to be on placing an increasing explanatory role for negative emotional processes and emotion regulatory functions of smoking. Clinically, as more practitioners obtain basic and expert levels of competency in smoking cessation, the global public health burden of tobacco use and its disorders can likely be improved.

12 Sexual Deviation

Yolanda M. Fernandez · Ruth E. Mann

Abstract: Working with sexually deviant clients is a challenging and potentially anxiety provoking endeavour for any clinician. However, it is possible that clinicians working in various settings will eventually be faced with a client who discloses issues with sexual deviance. The types of problems that sexually deviant clients present span a broad range of issues and necessarily require clinicians with strong and varied therapeutic skills. Some clinicians may find this to be a clinical challenge while others may feel the required breadth of skills is an impediment to effective therapeutic intervention. This chapter will review the suggested basic competencies considered important to working with sexually deviant clients. Basic competencies include understanding normative sexual behaviours, using Socratic questioning, using behavioural techniques, generalizing changes in thinking to outside the treatment environment, using group process, and skills for co-facilitation. The chapter moves on to describe competencies that are considered more sophisticated, or "expert" to this line of work. Expert competencies include general therapeutic skill level, interpersonal skills, understanding and accepting clients, using positive language, instilling hope in clients, working collaboratively with clients and personal resilience. Finally, suggestions are made as to how clinicians might move from basic to expert competency.

12.1 Overview

The concept of sexual deviance is a controversial one and is greatly affected by moral judgment rather than statistical evidence (Laws & O'Donohue, 2008). Surveys of general populations reveal high levels of "deviance" – rendering the term literally incorrect. For example, voyeurism is considered to be a paraphilia, yet almost half of adolescent males admit to engaging in opportunistic voyeurism (McConaghy, 2005). Bearing this difficulty in mind, a reasonable working definition of sexual deviance has been proposed to be "paraphilias and related sexual misbehaviors (e.g., rape)" (Laws & O'Donohue, p. 1). In this chapter, we address the clinical skills necessary to work with a client presenting with a paraphilia or who has committed a sexual crime.

Clients struggling with sexual deviance can be a difficult and challenging population for many reasons and, frankly, this is not an area that every clinician would choose. However, while the distinctive issues relevant to this population may pose obstacles in terms of recruiting and training clinicians, those who have chosen to work in this area report that they find the work varied and interesting (e.g., Leicht, 2008). It is imperative that clinicians have a strong and varied arsenal of therapeutic skills, acceptance of others, personal resilience, and flexibility to work effectively with this group. Despite the common misconception that the area of sexual deviance is a "speciality," those working within this area note that the relevant issues are not narrow in focus. In fact, issues relevant to sexual deviance, as you will see in this chapter, cross almost all domains of functioning as a human being. In addition to sexual issues, there are problems with relationships and intimacy, self-regulation,

self-esteem, self-awareness, interpersonal relationships, substance abuse issues, and other more general mental health issues such as depression and trauma. In fact, clinicians working with sexual deviance need to be prepared to handle anything. The broadness of the requirements can be seen as a benefit to clinicians who are interested in expanding their skills, but can also be detrimental if clinicians believe that the population simply poses too many obstacles to effective intervention.

The effectiveness of a treatment ultimately lies in the hands of the clinicians delivering the treatment. The general clinical literature on therapist characteristics has clearly identified both clinician characteristics and techniques that predict beneficial changes in treatment, and those that are related to negative treatment outcome (Marshall et al., 2002). As will be evident from this chapter, while focusing on sexual issues is necessary, it is not sufficient for the treatment of clients suffering from sexual deviance. Although sexually deviant clients may at first glance seem to be unique, in reality, a broad range of skills, many of which are applicable to working with other populations, are critical to this type of work. The therapeutic skills that we take for granted as being necessary to engage, say, depressed clients, are equally necessary for sexually deviant clients. In this chapter, therefore, we will emphasize that excellent therapeutic warmth, empathy, and optimism are vital when working with this population.

12.2   Recognition and Assessment

Clinicians working in a legal, forensic, or clinical setting can expect to have clients essentially identified for them by structures that are already in place. For example, clinicians working within a correctional or prison system will be referred to clients based on their type of offence (e.g., molestation of children). In some systems, clients are in effect sentenced to treatment by the courts, and may, therefore, be involuntary – which is, perhaps, one important way in which the sexually deviant client will differ from the mental health client.

For clinicians not working in a forensic setting, however, sexual deviance issues may be uncovered during therapy for other problems and, as a result, unprepared clinicians may face a significantly greater challenge recognizing and identifying sexual deviance among clients. Part of the difficulty lies in the heterogeneity of the population that struggles with sexual deviance. Problems with sexual behavior occur across socioeconomic groups, educational levels, ethnic backgrounds, and genders. Further, punitive societal views associated with sexual deviance often make clients very unwilling to seek help. Given the stigma associated with sexual deviance and the associated reluctance to self-refer, the majority of research into sexual deviance to date has focused on males who have either been charged with, or convicted of, a sexual offence. As a result, that research will be the focus of this chapter.

Sexual deviance is predominantly presented by male clients. Although there is research to suggest that a small proportion of females may also suffer from some paraphilias (Davin, Hislop, & Dunbar, 1999), females appear less likely to engage in the paraphilias that are illegal (e.g., pedophilia) and, therefore, less likely to come to the attention of authorities or seek treatment because of problems. Around 2% of convictions for sexual assaults involve women (Logan, 2008), although it is generally accepted that criminal convictions underestimate the actual rate of offending by women. Cortoni and Hanson (2005) concluded from a systematic

review of victimization studies that the actual proportion of sexual offenders who were women was 4.8%. Consequently, Logan described sexual abuse by women as "uncommon but not negligible" (p. 493). Generally, clinicians who specialize in sexual deviance can expect to work mainly with male clients and should beware of transferring male models of deviance onto female clients when they do present.

The heterogeneity of the sexually deviant population may create some difficulties in the application of treatment. There have been some attempts to address the issue of client variability by creating subsets of groups classified by sexual behavior, DSM-IV diagnosis, or various classification systems (e.g., Gebhard, Gagnon, Pomeroy, & Christenson, 1965; Groth, 1979; Knight & Prentky, 1990; Seghorn & Cohen, 1980). The most popular method of classifying sexual deviance is likely the current versions of the DSM (i.e., DSM-IV and DSM-IV-TR, American Psychiatric Association, 1994, 2000). However, problems with the DSM in the classification of sexual deviance have been documented by various authors (Levenson, 2004; Marshall, 2006). An identified primary issue is that "sexual deviance" as a term does not exist within the DSM. The section most relevant to issues of sexual deviance appears to be the section on paraphilias. Unfortunately, however, studies of the specific inter-diagnostician reliabilities have not resulted in satisfactory results (Levenson; Marshall, Kennedy, Yates, and Serran, 2002). Further research on diagnostic considerations has been primarily limited to pedophilia and sexual sadism with the other paraphilias receiving almost no attention. Given the above state of affairs, Marshall, Anderson, and Fernandez (1999) have suggested that attempts at classification offer little value and may, in fact, offer a disadvantage. Marshall et al. comment that groups of "mixed" clients provide opportunities for insight, varying perspectives, as well as sharing of common experience. They further suggest that clinicians working with sexual deviance should persuade their sources of funding that DSM diagnoses are not helpful in designing appropriate interventions or making prognoses (Marshall).

Given the difficulties noted with classification systems, clinicians working with sexual deviance may choose to conceptualize cases in terms of problematic versus nonproblematic behaviors and normative versus nonnormative behaviors. For example, a couple attends counseling because they have some disagreement regarding certain sexual behaviors. Perhaps the male partner is interested in engaging in oral sexual activity while the female partner is uncomfortable with this activity. In this case, the sexual behavior in question is problematic, in that it is causing discord between the couple; however, oral sex as a sexual behavior is normative according to research on sexual behaviors practiced by couples (Langstrom & Hanson, 2006) and would not be considered sexual deviance. That said, the clinician would still determine that the couple could benefit from an intervention and might focus the treatment on improving communication between the couple. In another circumstance, a client might mention that he has a fetish for high-heeled shoes but reports that his wife happily purchases high-heeled shoes and models them as part of their sexual activity. In this case, while the sexual interest may be nonnormative in terms of identified sexual behaviors and would probably be considered a paraphilia (fetish), the behavior does not present as problematic and may not warrant further exploration or intervention. Were the clinician to find out that in fact the wife felt displaced by her husband's interest in her shoes during sexual activity, then once again the sexual behavior, in this case also a sexual deviance, could be conceptualized as problematic, and would be a reasonable target for intervention. Certainly some sexually deviant behaviors more consistently result in obvious problems for the clients and the targets of their behavior,

such as sexual activity with children or forced sexual activity. As a result, the focus for clinicians attempting to identify clients with sexual deviance may be to conceptualize cases in terms of the level of distress the behavior is causing the client, or the level of distress that would be caused to others should the behavior be acted out, rather than the specifics of the behavior itself.

12.3   Causal and Maintenance Factors

Sexual deviance is probably caused by a complex interplay of adverse childhood experiences, abnormal neurobiological development (e.g., an overreactive amygdala), and social and emotional difficulties. Adolescence, with its associated sharp increase in sexual and aggressive hormones, is a time when children who are poorly prepared to develop affectionate bonds with others can retreat into a fantasy world where they are more powerful (Marshall & Marshall, 2000). If this fantasy life expands to involve masturbation, then a coping strategy is formed where sex is used to escape from day-to-day anxieties, rejections, and pressures.

Men who have sexually deviant interests typically present with associated beliefs that minimize the harm of expressing their interests (for instance, believing that children are unharmed by sex, or that some women enjoy being raped). These beliefs are often referred to in the sexual offending literature as "cognitive distortions." It is not yet fully understood whether such beliefs precede the onset of sexual deviance, or act as a maintenance factor. Either way, they are usually perceived to be an important target of any intervention. However, not all sexually deviant clients have such beliefs. Some are highly aware that others view their sexual interests as shameful and they have fully internalized this shame.

Other likely maintenance factors include sexual gratification, as the orgasm is a powerful reinforcer, which can quickly shape and maintain sexual interests. Many sexually deviant clients also report enjoying the thrill and danger of expressing an unlawful interest – in the same way that a nonsexual criminal gets a "high" from the knowledge that he is breaking the law. For example, for some serial rapists, part of the attraction of offending may be the sense of achievement and power that is experienced from watching television news bulletins about their offending and knowing that their crimes are perplexing the police. This sense of power over the authorities, as well as over the victim during the offence, can also act as a reinforcer and maintenance factor.

12.4   Mechanisms of Change

In the sexual deviance literature, theories of change have received less attention than theories of causality. In the 1980s, the relapse prevention model was introduced into the sexual deviance field, and remained the dominant model of change for about 20 years. However, in 2005, a large-scale randomized controlled trial of this treatment approach with a convicted sexual offender population concluded that the classical model of relapse prevention did not show a treatment effect in terms of reduced reconvictions (Marques et al., 2005). Two newer models, which have been proposed as a replacement for the Relapse Prevention model, are the self-regulation model (e.g., Ward & Hudson, 2000) and the Good Lives Model (e.g., Ward & Stewart,

2003). Both of these models have been received with enthusiasm, and incorporated into many manualized treatment programs, but so far are largely untested empirically.

The model of change that has the strongest empirical support for forensic populations generally is the Risk-Need-Responsivity (RNR) model (Andrews & Bonta, 1998). This model proposes that an effective treatment must: (a) provide an increase in intensity for those at greatest risk of criminal behavior; (b) target those factors which are empirically established as raising risk of criminal behavior ("criminogenic needs"); and (c) use therapeutic techniques to which the client group are known to respond. Applying the RNR model to sexual deviance provides clarity about the approach that should be taken. First, those at higher risk of criminal behavior must be identified and prioritized for treatment. Second, the targets of treatment must be based on empirical research into the causes of sexual deviance. Third, cognitive-behavioral methods and techniques should be coupled with a warm and motivational therapist style, in order to secure client engagement and change.

12.4.1 Client Motivation

Sexually deviant clients cannot be presumed to be motivated to change. As noted earlier, many of them are mandated into treatment rather than self-identifying. In one study, about 50% of sexual offenders reported that they were uninterested in receiving treatment (Langevin, 2006). There are similarities here with mandated substance misusing clients in particular. In line with motivational interviewing theory (Miller & Rollnick, 1991), motivation to change should not be assumed to be present at the start of treatment, nor is it assumed to be stable. Rather, motivation is expected to fluctuate according to each client's perceptions of gains and strains in treatment.

Motivation for the client to change is increased through:

- Positive therapeutic style (warm and empathic) with an emphasis on positive reinforcement including setting up opportunities for success which can then be reinforced
- Self-esteem enhancing exercises
- An emphasis on inspiring and positive life goals that are seen as incompatible with engaging in the problematic behaviors (see Ward, 2002, for an outline of these goals)
- Group cohesion
- Reinforcement of attitudes and behaviors that are contrary to the problematic behaviors

For example, self-esteem exercises are designed to enhance motivation to change and encourage the belief that life without engaging in the sexually deviant behavior can be satisfying. There is a body of literature suggesting that self-esteem enhancement does indeed increase motivation to both effectively participate in treatment and persist with relapse prevention plans after treatment is complete (Annis & Chan, 1983; Cox, Klinger & Blount, 1991; Marshall et al., 1999).

In addition, it is believed that effective therapeutic processes maintain motivation. For example, Marshall et al. (2003) have shown that a warm and empathic clinician, who is rewarding and somewhat directive, generates significantly greater participation in treatment, and greater behavior and attitude change resulting from treatment. Alternatively, a less empathic unrewarding clinician who engages in somewhat hostile confrontation of the offenders has been shown to reduce participation and generate little or no beneficial changes. Although

historically confrontation has been considered an acceptable approach when dealing with socially stigmatized issues (e.g., addictions, sexual offending), confrontation is no longer considered an appropriate competency for clinicians (Marshall et al., 1999). As noted above, it reduces the impact of treatment. In contrast, a motivational style requires challenging the clients but in a firm and supportive style and such an approach has been shown to be effective with substance abusers (Miller & Rollnick, 1991) and with various other types of behaviors in need of change (McMurran, 2002).

12.5   Evidence-Based Treatment Approaches

Early approaches to sexual deviance were often psychoanalytic in nature. The focus was on helping the client identify and resolve early life conflicts or traumas that were assumed to have triggered the deviant behavior. Sexual deviance was conceptualized as a fixation at various stages of psychosexual development; however, evaluations of this approach to treatment have reported inadequate results (Crawford, 1981). The development of behavioral approaches to treating sexual deviance marked the beginning of empirically based treatment for sexual deviance. Behaviorists considered inappropriate sexual urges to have been "learned" through early associations between sexual arousal and deviant stimuli and maintained through masturbation and fantasy (McGuire, Carlisle, & Young, 1965). Consequently, early behavioral treatment focused on addressing deviant preferences, primarily through aversive therapy. In treatment, deviant stimuli were associated with distressing agents such as nausea-inducing drugs, electric shocks, foul odors, or unpleasant covert images. Fortunately, however, most treatment programs have become considerably more comprehensive and now incorporate cognitive-behavioral and social learning approaches in addition to behavioral strategies.

12.5.1 Evidence-Based Assessment and Treatment Targets

There is a reasonably advanced empirical literature into risk factors for sexual recidivism (e.g., Hanson & Morton-Bourgon, 2004), which provides useful guidance on the essential targets for treating those with sexual deviance (Mann, Hanson, & Thornton, 2008). The established risk factors are often viewed as clustering into four domains (Craissati & Beech, 2003; Hanson, 2000): sexual arousal factors; attitudes tolerant of sexual deviance; interpersonal deficits; and self-regulation deficits.

12.5.1.1 Sexual Arousal Factors

The defining issue that sets sexual deviance apart from most other mental health conditions is, of course, the sexual arousal aspect of it.

Sexual arousal to various stimuli can be assessed in a few ways including self-report and polygraph; however, the most common method for assessing sexual arousal to various stimuli is the penile plethysmograph (PPG) (Marshall & Fernandez, 2003). The PPG can be used for both the assessment of sexual arousal and for treatment of deviant arousal (e.g., pairing deviant images with a noxious substance). There is some suggestion that males who suffer from one

paraphilia are found to suffer from multiple paraphilias when assessed (Abel et al., 1987). Child molesters have been shown to prefer the idea of sexual relations with children to the idea of sexual intercourse with adults, and such a deviant preference has been clearly linked to recidivism risk (Hanson & Bussière, 1998; Hanson & Morton-Bourgon, 2004). This preference is likely to be especially true for offenders with young, male victims (Seto & Lalumière, 2001). There is less evidence for the notion that rapists of adult women show a preference for coercive sexual activity, although this is probably the case with the most dangerous, repetitive, rape offenders. A substantial number of sexual offenders report ongoing deviant sexual thoughts or fantasies, and associated urges (Abel et al., 1987). Furthermore, many males who have committed sexual offences have been found to be sexually preoccupied, placing abnormally high emphasis on the need to have sexual relations frequently (Beech, 1997; Firestone, Bradford, Greenburg, Larose, & Curry, 1998; Hanson & Harris, 2000; Hanson & Morton-Bourgon, 2004). Suitable targets for treatment within this domain, therefore, include the reduction of deviant sexual arousal and fantasy, the increase in pleasure and arousal to ideas of consenting sex with other adults, and the reduction of the level of importance placed on frequent sexual activity.

12.5.2 Attitudes Tolerant of Sexual Deviance

Dysfunctional thinking styles that have been identified as relevant to sexual deviance include sexual entitlement (Hanson, Gizzarelli, & Scott, 1994); negative views of women and their sexuality (Malamuth & Brown, 1994; Marshall & Hambley, 1996); and general aggressive thinking. Studies have found that supportive beliefs regarding sex with children are held more strongly by child molesters than nonmolesters (e.g., Bumby, 1995) and are held more strongly by high-risk molesters than low-risk offenders (Mann, Webster, Wakeling, & Marshall, 2007). However, the relevance of sexual aggression supportive beliefs for rapists is less well established (e.g., Blumenthal, Gudjonsson, & Burns, 1999). Consequently, treatment should address the way in which clients view sex, the importance of sexual activity in their lives, process the errors they may make in interpreting women's and children's behavior, their beliefs about the lack of harm caused by their behavior and the way in which they see their rights in terms of sexual activity.

12.5.3 Interpersonal Deficits

Clients who engage in sexually deviant behavior have been shown to exhibit a wide range of interpersonal deficits (Marshall et al., 1999). For example, identified sexual offenders tend to have negative expectancies of both themselves and others; may suffer from low self-esteem (Thornton, Beech, & Marshall, 2004), external locus of control, personal distress, under-assertiveness (Fisher, Beech, & Browne, 1993), emotional loneliness (Garlick, Marshall, & Thornton, 1996), and paranoid hostility toward others (Firestone et al., 1998; Hanson & Bussière, 1998; Mann, 2005). Perhaps not surprisingly, given these symptoms, clients avoid intimate relationships with other adults (Fisher et al., 1993; Hanson & Morton-Bourgon, 2004). They may be socially isolated, or may seek the company of antisocial peers (Hanson & Morton-Bourgon, 2005) or children (Underhill, Wakeling, Mann, & Webster, 2008; Wilson, 1999). Appropriate targets for treatment within this domain include intimacy and attachment problems, oversexualization of relationships,

skills to relate to others in emotionally supportive and intimate ways, difficulties with self-disclosure, and conflict resolution. Treatment may also need to explore and change paranoid and vengeful schemas about other people.

12.5.4 Self-Regulation Deficits

Poor self-regulation is a key issue for many psychological issues. Self-regulation problems can be divided into three aspects, following Thornton (2002): lifestyle impulsiveness (such as that associated with psychopathy), poor problem-solving, and lack of emotional regulation. Treatment should aim to reduce impulsivity, teach the skills necessary to think through problems and evaluate solutions logically ("detached coping"; Roger, 1995) as opposed to avoiding problems or reacting emotionally to them, and teach strategies for managing problematic emotions such as anger.

12.5.5 Individual Versus Group Treatment

The Safer Society Survey (2000) reported that the majority of the sexual offender treatment programs are delivered in a group format. Although there is no research to date on the issue, it seems safe to assume that those seeking therapy for sexual deviance issues that have not been identified by the legal system are likely receiving individual interventions. There is, unfortunately, little research on the issue of group versus individual therapy in sexual deviance. Those who favor individual therapy describe numerous advantages to this approach such as increased confidentiality; greater opportunities to explore individual issues relating to a client's specific behaviors that might be embarrassing; and flexibility of session and overall treatment length that can be tailored to client anxiety and intellectual functioning (Abracen & Looman, 2004; Maletzky, 1993, 1998; Williams, 1995). However, advantages to group therapy have also been described by various authors. Jennings and Sawyer (2003) pointed out that according to theories of group process, a group offers unique opportunities to its members that simply are not available in a one-on-one setting. They note that the basis of group therapy is that it gains its therapeutic potency from the interactions and relationships that emerge during the group process (Rutan & Stone, 1993; Yalom, 1995). This is particularly relevant to sexually deviant clients, for whom social and intimate relationships are a key issue. Serran, Fernandez, Marshall, and Mann's (2003) discussion of process issues in sexual offender therapy suggested that effective clinicians use group settings to their advantage to provide opportunities to practice skills, promote reinforcement of individual gains, promote mutual encouragement and support, and create a positive therapeutic atmosphere. While proponents of individual therapy have commented that group treatment is more difficult to tailor to individual needs (Maletzky, 1999), Serran et al. (2003) proposed that more effective therapists may incorporate enough flexibility into their treatment program to appropriately address individual issues within the group setting.

For the purposes of this chapter, the majority of the competencies identified for working in the area of sexual deviance will be important for either individual or group formats. However, some competencies specific to group treatment will also be discussed given the preponderance of this approach for the treatment of some deviant sexual behaviors.

12.6 Basic Competencies of the Clinician

As noted above, the majority of interventions designed to address sexual deviance are cognitive-behaviorally based and presented in a group format. As a result, many of the basic competencies necessary for a clinician working with sexual deviance are also essential for cognitive-behavioral clinicians working with a multitude of other behavioral problems. These basic competencies are described below.

12.6.1 Understanding Normative Behaviors and Theoretical Models of Sexual Deviance

The most basic competency required to work in the area of sexual deviance is a reasonable understanding of human sexuality and the key theoretical models of sexual deviance. An understanding of human sexuality, including normative versus non-normative sexual behaviors, and unusual versus problematic sexual behavior, is critical to working with this client population. For example, a common mistake among novice clinicians working in this area is assuming that sexual activity itself is the problem. Such a belief may lead the clinician to erroneously encourage the client to pursue unrealistic management strategies that are doomed to fail, such as complete abstinence from sex. Kohlenberg and Tsai (1994) describe the importance of context in defining a behavior as problematic or not (i.e., that you cannot judge behavior as normal/abnormal in the absence of context). What is acceptable behavior in one context (e.g., physical aggression in sporting events) may not be acceptable in another context (e.g., aggression during sexual behavior). An understanding of human sexuality, and the role it plays in the lives of humans, as well as a thorough understanding of the theoretical models of sexual deviance, enables clinicians to differentiate between problematic and nonproblematic sexual behavior and encourage appropriate and realistic strategies for clients, which would include a fulfilling, consensual sex life (Ward, 2002). In sexual deviance, some of the behaviors that bring clients to treatment may easily be identified as problematic while other behaviors may not be as easy to define. For example, looking at adult pornography might be considered as appropriate progress for a client who suffers from pedophilia, but perilous for a male who has a history of objectifying women who have contributed to aggressive sexual behavior. In such cases context is an important consideration.

12.6.2 Socratic Questioning Used to Develop Alternative Attitudes, Thinking, and Behavior in Clients

Socratic or open-ended questioning is a basic skill necessary to most insight-oriented therapies, including working with clients with sexual deviance. Research has demonstrated that participatory learning is more effective than allowing clients to be passive in treatment (Spiegler & Guevremont, 1998). Socratic questioning involves the ability to employ questions during therapy that encourage learning and insight through the clients' own reasoning. Although clinicians may guide clients in treatment, clients benefit more when they work to improve their insight and understanding into their problematic behaviors. Consequently, clinicians need to

help clients identify for themselves those factors that have contributed to their problem behavior. As noted earlier in this chapter, a significant factor related to sexual deviance is holding attitudes supportive of the problematic behavior. Socratic questioning helps clients challenge their ways of thinking and encourages them to consider and develop alternative ways of thinking or behaving. Clinicians are trained to ask "who, what, where, when, why, and how questions" that provoke thoughtful responses from clients. They are encouraged to stay away from "closed" questions that engender yes or no responses. As an example, a novice clinician might be inclined to ask a client "Did you feel angry when the woman at the bar refused to dance with you?" which clearly calls for a yes or no answer. A more thought provoking question that would require the client to generate some self-insight might be "How did you feel when the woman at the bar would not dance with you?"

When Socratic questions are used in response to clearly problematic attitudes or cognitive distortions (rather than simply for gathering information), this is often referred to as "challenging" the client. This choice of word can unfortunately mislead some into assuming that a confrontational style should be adopted; this is not the case. We have already noted that an important point to remember for novice clinicians is to avoid a confrontational approach to challenging in favor of a supportive but challenging approach to clients. Although a confrontational approach is sometimes rationalized as "being honest" (Egan, 1970), the fact is that those clients who are struggling to come to grips with issues related to inappropriate sexual behavior are taking responsibility for their difficulties. An aggressive approach is likely to be experienced by the client as demeaning and may result in antagonistic interactions between clinician and client. As a result clients may become cynical about their capacity to change. Our experience training clinicians, however, has suggested that encouraging clinicians to avoid a confrontational approach has sometimes been misinterpreted as an endorsement of an approach that is too soft, and essentially collusive with clients. Clinicians who are overly compassionate do not challenge, do not set firm boundaries, and are at a risk of doing a disservice to their clients.

Socratic questions, therefore, can be challenging (i.e., thought provoking) in their content, but the style in which they are asked should remain gentle although persistent.

The following is an example. Darren believes that women cannot be trusted. He has verbalized the following beliefs:

► Once you trust them (women) that's when they'll bite!
   If only women could be trusted I wouldn't get into this trouble.
   I would never hurt anyone who didn't hurt me.
   They know the rules of the game and they know when they deserve to be punished.
   Women who play with your mind deserve what's coming to them.

Clinicians are trained to use Socratic questioning to encourage Darren to challenge his beliefs. Examples might include:

- Why do you believe all women cannot be trusted? Why do a lot of other people and men trust women but not you?
- What would have to happen for you to believe that women could be trusted? Is this realistic?
- Do you personally know any men who do trust women? Why would they do this? Do you think this has given them any benefits?

- Can you think of a situation in which you knew of a woman who actually helped a man? Why would men from around the world choose to have long-term trusting relationships with women if they were just going to be punished?
- What positive effects would being more trusting of women have on your life?

These questions have the potential to encourage the client to explore occasions where his belief does not apply, and hence could allow him to select a more flexible alternative belief. The questions above could be asked in a variety of tones of voice. The same question, depending on how it is asked, could be perceived as attacking or as motivational. Thus, although Socratic questioning is an important technique when working with sexually deviant clients, it will not work unless it is paired with an empathic style within an established therapeutic relationship.

12.6.3 The Effective Use of Behavioral Techniques Such as Positive Reinforcement, Extinction, and Modeling

The appropriate utilization of behavioral techniques, such as the use of reinforcement, extinction and modeling, can lead to significant and lasting change. In fact many everyday social interactions involve behavioral principles. It should be considered a prerequisite that clinicians have a firm understanding of the nature of reinforcement, punishment, extinction, and modeling in order to implement them strategically and effectively.

A basic behavioral strategy for clinicians is the use of social reinforcers (e.g., nodding, smiling, providing time to talk, listening) and clear statements of approval, support, and agreement in response to functional and adaptive statements and behaviors from the client. Of importance for novice clinicians is that reinforcement must be provided immediately following the behavior change and the link between the behavior change and the reinforcement must be made explicit (i.e., clear statements qualifying why approval or praise is being given). The following is an example of providing specific verbal reinforcement when the client has improved their insight in response to a Socratic question:

► Clinician: What happened when you kept things inside?
► Client: I worried that my relationship would end because I wasn't communicating with my wife and I thought I would end up alone. I felt even more unwanted and unloved. I realize now that when I was with my niece I felt accepted and loved by her. I felt I could tell her things and she wouldn't judge me so I spent more and more time with her because I felt good around her.
► Clinician: That's excellent insight. You have made some important links between your thoughts and feelings about yourself and your relationship and how that affected your behavior in terms of spending time with your niece.

Although it may feel cumbersome or awkward to novice clinicians to interrupt the flow of a discussion to provide specific, and often lengthier, reinforcement, the long-term advantages are well worth it. When reinforcement of gains is nonspecific (e.g., limited to nodding by the clinician), clients may become confused and waste time moving in nonproductive directions in an attempt to "figure out" what part of what they have said reflected improved insight. Additionally, novice clinicians should consistently monitor their nonverbal reinforcement such as head nodding in order to ensure they are not mistakenly reinforcing cognitive distortions or problematic attitudes. Nodding is often used in therapy as a signal that the clinician is engaged

in active listening. However, it is possible that clients will interpret nodding as evidence that the clinician agrees with them. Clearly, attentive listening combined with self-awareness by the therapist is critical to ensure that reinforcement is provided only in response to statements and behaviors that are reflective of therapeutic gains.

How then does the clinician respond when the client's contributions are suggestive of continued problematic thinking and behaving? The human and animal learning literature on the processes of extinction (Bouton, 1994; Falls, 1998) suggest that an unreinforced behavior should disappear. Not only do behaviors extinguish when the responses they previously elicited are explicitly not reinforced, they should also extinguish when they are ignored. However, novice clinicians are sometimes less skilled at simultaneously reinforcing adaptive behaviors while ignoring or "nonreinforcing" problematic behaviors, which tends to be more of an "expert competence." As a result, a basic competency for clinicians working with sexual deviance is to learn to show disapproval of nonadaptive thoughts and behaviors, while remaining supportive. Disapproval may include clear statements of disapproval and supportive disagreement as well as nonverbal expression, such as frowning, and showing decreased interest in the client. As with reinforcement, disapproval should be made immediately following the expression of the nonadaptive thought or behavior and the link between the problematic thought or behavior and the disapproval must be made explicit. The following is an example:

► Clinician: You said your wife told you she had cheated on her prior husband. How do you feel when you think about that?
► Client: I feel completely betrayed and my trust in women is destroyed. I think "she's a slut like every other woman"
► Clinician: (knits brow and tilts head to one side). Wow, that seems like a big leap from one piece of information. Why do think that hearing your wife made a poor decision in a previous relationship makes you feel so angry?
► Client: Well, I thought that this relationship was going to give me everything I wanted, that when I became a husband and father I wouldn't be a failure.
► Clinician: It sounds like you expected that your wife would fix the problems in your life. What do you think are realistic expectations of a relationship?

In the above case, the clinician's response to the client's overgeneralization about women clearly indicates disagreement with the statement using nonverbal signals and then explicitly defines why the client's comment is problematic. Of importance, however, is that the disapproval is also followed with a Socratic question aimed at helping the client improve his insight into the link between his feelings of being a failure, his dependence on his wife to alleviate his insecurities, and his resulting anger when she was unable to do so.

Another critical behaviorally based basic competency for clinicians is the use of modeling for appropriate and pro-social behaviors. Modeling by the clinician should include alternative, pro-social, and more effective expressed thinking and behaviors. It should, of course, take place in all interactions between the clinician and client, and explicitly through statements to do with personal attitudes. Clinicians should be taught to "practice what they preach" within the therapy session. This includes modeling supportive and respectful but open interactions with others as well as modeling how to handle conflicts or mistakes. Novice clinicians may believe they are required to be perfect models, when in fact appropriately handling a difficult situation may have a greater impact on clients than consistently handling things perfectly. As an example from my own clinical work, a client presented at a session as angry and disinterested.

When I asked if something was wrong he responded that in our previous session I had dismissed him and trivialized his contribution when he had attempted to participate in a group discussion. When I reflected on the previous session my impression was that I probably had not reinforced his contribution adequately but did not feel that I had been dismissive or trivialized his contribution. That said, it was clear to me that I had not been as clinically effective as I could have been and I surmised that arguing would make the situation worse. As a result, I apologized to the client and assured him that my desire was to have everyone in the treatment group feel that their contributions were valuable. I acknowledged that there are days when I am better at accomplishing this than others and asked all group members to provide me with feedback after sessions to make sure I was improving this skill. The client appeared taken aback by my response as he likely thought that I would disagree with him. My apology not only modeled an appropriate response to a mistake, but inviting all clients to provide me with input supported that I "practiced what I preached" in terms of seeking others' feedback on my behaviors.

Relevant to novice clinicians is that we draw a careful distinction between *modeling* and *self-disclosure*. Modeling includes the expression by the therapist of, for example, pro-social and functional attitudes and behavior. Modeling should take place in all interactions between clinicians and clients. Self-disclosure is used only to assist clients in understanding that the processes that govern their behavior are essentially normative. The perceptions of all people are to some extent self-serving (Nisbett & Ross, 1980) and it is useful to illustrate this by self-disclosure on the part of the therapist of mundane biased inferences. Personalizing examples of cognitive distortions can illustrate for clients that engaging in cognitive distortions is a common process, but that the key is to recognize when it is contributing to problematic behavior. I have used the example of struggling not to eat chocolate cake that is in the refrigerator while I am on a diet. Relevant cognitive distortions might include: "If I eat it all now it won't be there to tempt me tomorrow" or "I'll eat it today and then start 'fresh' with my diet tomorrow." As mentioned, personalizing the example both normalizes the process of cognitive distortions and portrays the clinician as human. Novice clinicians, however, should carefully avoid disclosing any personal unresolved issues and, particularly, any sexual experiences, from their own history.

12.6.4 Generalization of Alternative Thinking and Behavior Outside of the Treatment Environment

There is no guarantee that client changes resulting from effective Socratic questioning and appropriate behavioral techniques within therapy will generalize to the client's behavior outside the therapy room. In fact, the evidence suggests that in the absence of direct attempts to produce generalization, it is unlikely that changes in the treatment context will appear in the client's daily life (Spiegler & Guevremont, 1998). Thus, creating and implementing strategies designed to help clients practice and use alternative thinking and behavior are critical basic competencies, if generalization is to occur. Role-play rehearsals of appropriate behaviors can provide the opportunity to refine responding before it is practiced in the real world. These practice opportunities are individualized for each client and involve practical assignments related to areas of deficit for that person. For example, a role play in which the client practices having a conversation with someone he or she finds attractive may help the client

feel better prepared to attempt this task in the real world. The clinician must promote the practice of new skills in the client's everyday life, which may require the clinician to seek the cooperation of others, such as friends or the client's intimate partner. The following is an example:

► Client: I felt jealous when my wife went back to work and started going out with friends but was afraid to talk to her about it. I thought if I talked about it, it would make things worse, that she would realize her new life with her job and friends was better than her life with me. I've never been good at talking about things that are bothering me.

► Clinician: Okay – that's an important thing for you to understand, but what makes things easier is practice so I'm going to give you an assignment. I want you to ask your wife how she feels about going back to work. Listen to her response; ask her questions, and then write it all down, including how you felt about what she said. Bring the assignment back to treatment and we'll talk about how the reality of bringing up this issue compared to what you thought would happen.

Of note is that once the client has practiced the assignment outside of the therapy context, he reports back on its implementation and receives feedback and reinforcement. This type of follow-up in terms of the client providing a detailed summary and analysis of their between-therapy assignment is critical. Occasionally new clinicians are so focused on what happens during a therapy session that they fail to follow-up on previously assigned tasks. This, however, leaves the client with the mistaken impression that the tasks are less important than in-session work and thus considerably decreases the chance of generalization of therapy gains. In our experience training clinicians, we have found that novice clinicians sometimes feel more comfortable with purely cognitive therapeutic strategies (e.g., cognitive reframing) and are considerably less comfortable with more behavioral strategies such as role plays. The best response we can provide is that the skill of incorporating, practicing, assigning, and analyzing role plays only improves with practice.

12.6.5 Understanding and Using Group Process

While Socratic questioning and supportive challenging are important skills for a clinician, one of the advantages of working with clients in a group setting is that the group members can do much of the difficult questioning and challenging. Serran et al.'s (2003) discussion of process issues in sexual offender therapy suggested that effective therapists use group settings to their advantage to practice skills, promote reinforcement of individual gains, promote mutual encouragement and support, and create a positive therapeutic atmosphere. Beech and Hamilton-Giachritsis (2005) note that in highly cohesive groups, appropriate challenges by members are more likely to be accepted because participants feel supported rather than attacked. However, creating an environment in which the group is cohesive, supportive, and takes responsibility for each member's progress, is a competency in and of itself. Using the group process effectively requires an understanding of group dynamics and familiarity with the individual group members and how they interact. Clinicians are trained to watch and listen to all group members, observe how they respond to each other, and how they behave when someone else is speaking. A common mistake among novice clinicians working in group settings is to engage in "one-on-one therapy with an audience." That is, to fail to pay attention to

what is going on with other group members when they are focused on issues relevant to one member. One strategy that reminds clinicians to pay attention to the whole group is for the clinician to encourage the other group members to ask the majority of questions and to do most of the challenging, perhaps by consistently asking group members to respond to something that has been said. For example:

► Client: Most women who go to bars are looking to get laid.
► Clinician: What do other group members think about this conclusion?
► Other client: Well, I sometimes go to bars with buddies after work to relax and I would think women do that too. I know my sister sometimes goes to bars with her friends and I don't think she's a slut or looking to get laid.
► Clinician: (watching reaction of other group members to the challenge) That sounds like a more balanced view. What do you think about what [the other client] suggested?

This technique allows the clinician to take on more of an observer role and to assess the process of the group rather than being singularly focused on helping one client make gains.

12.6.6 Cofacilitation of Treatment

Working with a co-therapist can provide distinct advantages but requires a unique skill. Of the few studies on this topic, it appears that more positive gains are associated with co-therapist teams who present as consistent (i.e., provide similar messages to clients), as opposed to inconsistent (Piper, Doan, Edwards, & Jones, 1979). Interestingly, dissimilarity between the clinicians (i.e., gender, age, race, or personality) is also associated with somewhat better outcome. Working closely and effectively with another clinician modeling a relationship that is egalitarian, respectful, supportive, and pro-social and promotes appropriate and acceptable thinking and behaviors can be a powerful tool. For example, a male clinician voicing respectful attitudes and demonstrating this through his interaction and behavior with a female clinician sends a strong visual template for clients on which to base their interactions with members of the opposite gender. Learning to work in tandem with another clinician is a skill that requires flexibility, acceptance, and an ability to identify and promote another person's strengths, but can be a very worthwhile endeavor.

12.7 Expert Competencies

For clinicians working with sexual deviance, expert competencies are reflective of a more sophisticated approach to treatment. Expert competencies require deeper self-insight, and ability to read others' verbal and behavioral cues, including the nuances and subtleties of what clients are saying. Expert clinicians are able to surmise motivations even when the client is not able to articulate their feelings. Finally, expert clinicians recognize a client's underlying schemas, and can apply cognitive therapy techniques to explore and review schema-driven interpretations of situations. Expert therapy involves more proficient use of the cognitive-behavioral techniques described earlier in this chapter but also involves the skills necessary for the effective supervision and management of other clinicians.

12.7.1 Expert Therapeutic Skills

Numerous positive therapeutic features have been identified in the research literature as critical for psychological treatments to be effective. All schools of therapy have identified empathy, warmth, and genuineness as being a therapist's characteristics necessary to generate benefits from treatment. However, in order to be effective with sexually deviant clients, clinicians need to exhibit more than these personal characteristics. As noted earlier in this chapter, this is a challenging population to work with. Clients often feel apprehensive about entering treatment, and may present as unmotivated or hostile. The expert clinician is reflective and strives to be consistently encouraging and energetic, equally with all sexually deviant clients, especially within a group setting.

12.7.1.1 Interpersonal Skills

It is difficult to imagine that expert clinicians could be individuals who are themselves deficient in interpersonal skills. Numerous authors have concluded that the success of therapy is very much dependent on the clinician's interpersonal skills (Beck, Rush, Shaw & Emery, 1979; Egan, 1998; Frank, 1971; Kleinke, 1994; Kohut, 1990; Lambert, 1989; Luborsky, 1984; Rogers, 1975). Certainly empathy, genuineness, warmth, respect, supportiveness, confidence, emotional responsivity, self-disclosure, open-ended questioning, directiveness, flexibility, encouraging active participation, and rewarding behavior have been identified in the literature as having a positive impact on therapy (for a summary of research on these interpersonal skills see Marshall et al., 2002). Additionally, numerous studies have confirmed a relationship between the interpersonal skills of the clinician and maximizing the therapeutic alliance (see Ackerman & Hisenroth, 2003 for a review).

In research on programs targeting sexual deviance, Beech and Fordham (1997) reported that among community-based programs in the UK, the greatest treatment changes were found in groups that were well organized, well led, cohesive, encouraged the open expression of feelings, produced a sense of group responsibility, and instilled a sense of hope in members. A later study found that leader support, described as the help and friendship shown by group leaders, was related to group cohesion and expressiveness as well as other positive group processes (Beech & Hamilton-Giachritsis, 2005). Drapeau (2005) indicated that clients being treated for sexual deviance said they assessed the quality of the treatment based on their perception of the clinician's competence. Positively valued clinicians were viewed as displaying leadership, confidence, strength, competence, and persuasiveness when necessary.

Interpersonal skill as an expert competency includes an openness to consider your own ways of thinking and feeling, behaving and coping, as well as an ability to receive feedback about your strengths and need areas, and then change your behavior based on this feedback. Finally, an expert clinician will have strong self-awareness of their limits as a clinician and appropriate ways of coping with thoughts and feelings generated by working in this field.

12.7.1.2 Understanding and Accepting the Client

Clinicians are drawn from a population exposed to lurid negative stereotypes of the sexually deviant man, and these stereotypes can affect interactions with clients despite conscious efforts

otherwise. Where the client has victimized another person, clinicians, who tend to be empathic people, can find themselves naturally empathizing with the victim and this can lead to an uncomfortable sense of hostility towards the client. Clinicians need to be prepared to reflect constantly on their feelings about their clients; and to drive out any antitherapeutic influence that may arise. Both rejection of the client and low interest displayed by the clinician have been related to negative treatment outcome (Lambert, 1983). This does not, of course, mean that the clinician should collude with sexual deviance or close their minds to its effects on others. Balancing the tension produced by an aversion to sexually deviant behavior coexisting with the need to develop a productive and genuinely optimistic relationship with the client is one of the most demanding aspects of working with this client group. This demand does not, in our experience, lessen over time and should never be considered to have been achieved.

Expert clinicians must therefore be willing and able to understand their clients' perspective and use this understanding when interacting with them. Clients' perceptions of the therapist's involvement, emotional engagement, and positive feelings have been found to determine their view of the value of treatment and their willingness to engage in the therapeutic process (Saunders, 1999). Seligman (1990) examined studies of treatment derived from various psychotherapeutic orientations and showed that positive outcomes were significantly related to an emphasis on client support, display of interest in the client, acceptance of the client's beliefs and values, and an ability to engage clients. When working with sexual deviance, an expert competency is the ability to understand the client, take their perspective, and still accept them as someone with positive features and strengths. For example, a male client who has engaged in sexually aggressive behavior may have difficulty trusting women because of prior negative experiences and this may have contributed to a fear of intimacy. However, these fears may be expressed as hostility or negative attitudes toward women, which can be off-putting to the clinician, particularly if the clinician is female. Having the ability to understand the client's reactions ensures that the clinician will respond appropriately and help the client work through these issues. Similarly, men who have engaged in illegal sexually deviant behavior typically minimize aspects of their behavior or provide justifications for their behavioral choices. While this may be frustrating for the clinician, his or her ability to understand that these clients are trying to protect their self-image and maintain their self-worth can aid the clinician in assisting the client in accepting responsibility while simultaneously protecting their self-esteem. I can remember being involved in a meeting with a number of clinicians who work with sexual deviance when one clinician stated that she "just could not understand necrophilia" (sexual interest in corpses). I thought about the issue for a few minutes and then responded that I could understand that a client might have an interest in a sexual partner who would not resist his or her particular interests. I could also recognize that some individuals derive sexual arousal from the idea that they are engaging in a behavior that others would consider "naughty" or distasteful and therefore necrophilia did not seem that different from other sexual deviations to me. The ability to place yourself in the shoes of another person and attempt to see a behavior from their perspective, no matter what the behavior might be, strikes me as a more sophisticated competency.

12.7.1.3 Using Positive Language

Historically programs targeting sexual deviance have operationalized treatment goals in predominantly negative terms. The focus of the intervention is often described using terminology like *eradicating* problematic issues, *eliminating* negative attitudes, *reducing* cognitive distortions,

extinguishing deviant sexual interests, and having clients *avoid* people, places, and things that are considered to increase risk for engaging in the problematic behavior. Ward et al. (Ward, 2002; Ward & Marshall, 2004; Ward & Stewart, 2003) have suggested that research on the "good lives" (Deci & Ryan, 2000; Emmons, 1996) should be adapted for work with sexual deviance. As noted above, clients who engage in sexually deviant behaviors may be seeking satisfaction of normative needs but do so in ways that cause problems in their lives. The task of the clinician is to teach attitudes, perceptions, thoughts, feelings, and skills necessary to meet needs in a prosocial and effective manner, without negative consequences, with the underlying theory being that a fulfilled and happy person is unlikely to engage in behaviors that are hurtful to themselves and others. To this end, expert clinicians are able to expand the focus of therapy to helping clients develop a satisfying and fulfilling life rather than on simply eliminating problematic behaviors. Consistent with this is Mann's (2000) contention that approach goals are to be the preferred target's treatment. Mann outlined her concerns with traditional Relapse Prevention strategies which concentrate on avoidance-based goals (i.e., things and situations to avoid) but that often fail to appeal to clients or inspire a dedication to improving their lives in other ways. She pointed to an extensive body of literature (Emmons, 1996; Gollwitzer & Bargh, 1996) demonstrating that avoidance goals are rarely maintained, whereas approach goals are more likely to endure. In addition, people who have predominantly avoidance goals are less psychologically healthy, less happy, and less successful than those who have approach goals. In terms of treatment, Cox et al. (1991) demonstrated that alcohol abusers who worked toward avoidance goals were more likely to relapse than those whose targets were appealing approach goals. Comparing sexual offenders who were assigned to relapse prevention programs that either focused on avoidance or approach goals, Mann, Webster, Schofield, and Marshall (2004) found that those with approach goals were more engaged in treatment, completed more homework assignments, were more willing to disclose problems, and were judged to be more genuinely motivated to live an offense-free life.

Similarly, the expert clinician is careful with their terminology. In some programs, for example, cognitive distortions are described as "stinking thinking," which suggests that engaging in distortions is both aberrant and restricted to offenders when, in fact, most people distort or excuse their behavior after a transgression (Maruna & Mann, 2006). The word "grooming," which refers to nonviolent behaviors used to gain cooperation (e.g., buying gifts, paying compliments), has similar negative connotations. Using the word grooming as a descriptor for what are essentially courting behaviors fails to acknowledge that many of these activities would be considered appropriate in a different context. As a result some clients may be at a loss to know how to pursue appropriate interactions. An expert competency is the ability to adopt positive language to aid clients in identifying their existing strengths and adapting these strengths to meet their needs more appropriately. One particularly valuable way to do this is to refrain from labeling clients solely in terms of their offending (e.g., sexual deviant, sex offender, child molesters). Distinguishing people from their behaviors has a long tradition in behavioral research and treatment (Kazdin, 1978), and avoids all the problems inherent in labeling (Fink & Tasman, 1992). It is also important not to allow clients to label themselves in terms of their offending, as the client is then likely to experience disintegrative shame where he sees himself as unchangeable (Tangney & Dearing, 2002). Negative labels for the components of treatment (e.g., "relapse *prevention*," "changing deviant sexual interests") may inexorably draw the clinician to focus on negative goals rather than on more healthy goals, and may cause the clinician to ignore areas of strength in the clients. Renaming Relapse Prevention strategies as "self-management" or "respectful living," or renaming

the components of treatment that target deviant sexual arousal as "healthy sexual functioning," may be more attractive to resistant clients. Using positive language makes it easier to convince clients that they have areas of strength that can be built upon.

12.7.1.4 Instilling Hope for Change

It is striking that some clinicians who work with sexual deviance, and are competent at cognitive-behavioral techniques, continue to hold the belief that sexual deviance cannot be altered. The failure of clinicians to instil hope in clients is likely to lead clients to believe that they do not have the ability to change and has been related to a lack of motivation by clients to make the necessary changes in their lives (Snyder, 2000). Frank (1989) has suggested that hope is the primary factor in producing treatment gains. Clients low in hope have been shown to readily give up in the face of obstacles (Snyder). Snyder suggests that clinicians who do not encourage clients' efforts to practice new skills fail to increase the client's "agentic thinking" or self-efficacy, which is one of the three elements identified as crucial to effective functioning in hope theory. In support of this, one of the aspects of group process linked to treatment changes in sexual deviants was instilling hope in group members (Beech & Fordham, 1997). The way in which clients' past actions are construed by the clinician can negatively impact clients' sense of hope and their belief that they can change. For example, treatment programs targeting sexual deviance typically have clients to identify the needs their sexually deviant behavior was meeting (e.g., sexual gratification, avoidance of intimacy, desire for power and control, acceptance). All too often these objectives are presented as unacceptable when, in fact, they are normative needs and it is the way in which the client elects to meet these needs that is problematic. An expert competency involves interpreting these motivations as reflecting normative needs, which should serve to instil hope in the client that he or she can meet needs more effectively and without negative consequences. Finally, the language we use influences the clients' perceptions of treatment.

12.7.1.5 Working Collaboratively with the Client

In the role of a clinician, it is sometimes easy to perceive that you are in control of the therapy and forget that the person truly in charge of therapy is the client. Even the most manualized or structured therapeutic intervention will be more effective, if the clinician approaches the intervention as a collaborative process with the client and as such working collaboratively is an expert competency. Working collaboratively with clients is a basic competence in the cognitive-behavioral tradition, but has often been excluded from clinical literature about the treatment of sexual deviance. In fact, early text books on working with sexual deviance expressly warned against collaborative working, suggesting that sexually deviant clients will not be able to set healthy goals themselves but will manipulate the therapist into collusion should collaboration be attempted. This assumption has now been challenged, and the need to work collaboratively with clients who struggle with sexual deviance has been described (Shingler & Mann, 2006). The authors note that not allowing clients to select some aspects of their treatment objectives that are personally meaningful may increase resistance and lower motivation to pursue other, possibly crucial, goals. This was supported in Drapeau's (2005) study in which child molester subjects reacted negatively, if they felt they were denied participation in early decision making in treatment or if they

felt pressure or coerced. When clients were excluded from decision making, they became oppositional and resistant because they felt this was their only viable course of action.

A key feature of collaborative working is transparency. Because many sexually deviant clients are present within the criminal justice system, they may have developed an often-justified suspicion of the motives of those employed by that system. Therapists can of course simply hope that their genuine intentions will become clear to the client as therapeutic rapport develops, but in our experience, such suspicions are much better addressed through upfront conversation about the concerns that the client might have.

12.7.1.6 Personal Resilience

Novice therapists are likely to experience some personal reactions when working with sexual deviance. Typically, experiences are reported such as increased vigilance about personal safety, concern about family members, and intrusive thoughts about details that their clients have revealed (Leicht, 2008). Novice therapists should request, and receive, support as necessary to cope with, and learn to manage, such symptoms. Expert clinicians will have developed a range of personal resilience strategies to manage any effects from prolonged exposure to accounts of sexual deviance. Detached coping, where the clinician is able to separate from the client's problems and view them as intellectual challenges rather than personal threats, is the hallmark of the expert clinician. In contrast, emotional coping (including a dependence on others to manage emotional reactions) and avoidance coping are often stages that the novice clinician works through en route to achieving expert status. This is not to say that the expert clinician is immune from experiencing vicarious traumatization – and to repeat comments earlier in this chapter about reflection and self-awareness, the expert clinician will monitor his or her own reactions to the client's disclosures and identify in the early stages when their therapeutic work is affecting them. Expert clinicians are not afraid to ask for assistance in coping, and they have the skills to articulate their experiences and discuss solutions appropriately with others. They will be willing and able to recognize when they may need a break from the work, and to seek feedback within both their personal and professional relationships about how they are seen to be coping by those closest to them.

12.8   Transition from Basic to Expert Competence

In this section, we will consider methods by which novice therapists can develop their competence in working with sexual deviance.

12.8.1 Professional Networks

Clinicians may belong to large or small organizations or may be self-employed. For those in the latter category in particular, the value of belonging to a professional network is hard to beat. Professional organizations, such as the Association for the Treatment of Sexual Abusers (ATSA; in North America), or the National Organisation for the Treatment of Abusers (NOTA; in the UK) to name but two examples, offer training events, e-mail discussion groups, and local support groups for professionals with a client base of this nature.

12.8.2 Supervision

We strongly advise that therapists embarking on work with a sexually deviant client should arrange for professional supervision from someone more experienced in this area. In fact, we would advocate that all professionals, however well qualified or highly experienced, will continue to benefit from the opportunity to reflect on their work from a more detached colleague. Supervision for the novice therapist assists the therapist to locate their clients' problems within a theoretical framework. Supervision for the experienced clinician can assist the clinician to recognize and manage developing stereotypes, along the lines of "All sexually deviant clients are like x."

12.8.3 Keeping Up To Date with the Literature

It is sometimes surprising how little attention clinicians pay to the research literature in their field. This can be the only explanation forwhy so many clinicians continue to pursue outdated treatment models, or address matters with their clients that were advocated 20 years ago, but have since been proved to have no causal link to sexual deviance. The sexual deviance field is advancing rapidly, and we acknowledge that it is time-consuming to remain up to date with the full range of forensic and sexual deviance journals, but membership in a professional organization and/or attendance at professional conferences can ensure that the clinician is aware of at least the major advances in theory and empirical development. And just to push matters even further, we also advocate at least some attention to the broader psychotherapeutic and psychological literatures. We note that most of the major breakthroughs in understanding sexual deviance have occurred when a theory developed in another area of psychology has been adapted, applied, and evaluated among the sexually deviant population. Given the multitude of issues relevant to this population and the overlap of these issues with other mental health populations, it seems prudent to review effective theories and interventions from other areas of psychology rather than consistently attempting to "reinvent the wheel."

12.8.4 Conducting Research

Bill Marshall, a leading therapist and researcher in the sexual deviance field, once remarked to us that clinicians make the best researchers because they know what questions to ask. We would add to this statement that researchers often make surprisingly good clinicians, because they approach clinical work in a scientific, hypothesis-driven, way. Clinicians who also engage in research are more likely to be able to read emerging literature critically and have excellent skills at interpreting the meaning of empirical research for clinical practice.

12.8.5 Being Observed

The fastest way to improve clinical skills is to subject oneself to the observation of others. This can occur in vivo – e.g., by asking a respected co-therapist to act as a "critical friend" for feedback, or by securing permission for a supervisor to sit in on a treatment session. Another, less intrusive, observational method is for the clinician to videotape treatment sessions and then

ask a supervisor to participate in an observation and feedback session. Another variant of observation is for the supervisor to observe a session through a one-way mirror, but the advantage of videotaping is that an excerpt of the session can be reviewed together, as many times as necessary, by the therapist and supervisor, to enable reflection on how the therapist's behavior may appear from other perspectives, including the client's. In our experience, sexually deviant clients rarely object to the taping of sessions, as long as they are given clear explanations of the purpose and the security procedures that will be applied to the tapes.

12.8.6 Observing Others

Both of us have had the fortunate experience of being able to observe expert-level clinicians work with sexually deviant clients as part of our own training, and therefore we speak from the heart in recommending that novice clinicians seek such an opportunity. Learning from modeling is a proven way of developing new skills and enables the novice clinician to figure out strategies in unexpected clinical situations by asking himself or herself, "What would X do here?"

12.9 Summary

The assessment and treatment of sexual deviance is a demanding field. Clinicians working in this area require a plethora of clinical skills to meet the needs of this challenging population. We believe that the basic competencies necessary for clinicians include a good foundation in therapeutic process as well as cognitive and behavioral techniques (e.g., modeling, behavioral rehearsal, contingency management, reinforcement, shaping, and extinction) in order to facilitate the acquisition of skills in clients and provide therapists with strategies for influencing and managing client behaviors. In addition, efforts to ensure generalization of treatment gains to the client's natural environment need to be given careful consideration. Expert competencies require a higher level of personal insight, perspective taking, understanding of group processes, and personal resilience. Expert competencies are primarily gained through experience and a willingness to seek supervision, feedback, and guidance from other experienced clinicians. Although the treatment of sexual deviance may not be for every clinician, those who have dedicated themselves to this area report they consistently feel challenged and that they continue to develop as a clinician throughout their careers.

13 Marital Dysfunction

William Fals-Stewart · Wendy K.K. Lam

Abstract: The institution of marriage is in a state of great evolution, changing in response to rapidly shifting social values and norms. Indeed, even the definition of marriage is the subject of much heated social and political debate; it is one of the 'hot button' topics in both the scientific and lay press. In the context of such social transition, it is not at all surprising that there has been a rapid increase in relationship distress and dysfunction, evidenced by substantial increases in marital separations and divorce during the last century. Marital dysfunction manifests itself in a number of different ways and is very often marked by deficits in commitment to the relationship, low levels of mutual caring behaviors between the partners, problems with communication, and corrosive conflict resolutions skills. In turn, many dyads seek professional help to address the myriad of relationship problems in efforts to save their marriages in the context of multiple psychosocial pressures. In this chapter, a general description of marital dysfunction is provided. Additionally, a very commonly applied framework for understanding marital dysfunction, referred to as the 'Seven Cs', is described. Methods of relationship evaluation and assessment, including collection of communication samples, clinical interviewing, and use of self-report measures, are reviewed. An overview of empirically supported relationship intervention approaches is also provided, including a discussion of potential mechanisms of therapeutic action. Lastly, fundamental core and expert competencies for clinicians who provide relationship therapies are described, along with a brief description of the transition from basic competencies to expert.

13.1 Overview

As well chronicled in both the scientific and lay press, the institution of marriage in the USA and throughout the world is in a state of swift evolution, dynamically changing in concert with, and in response to, very rapidly shifting social values and norms. The cultural shifts that have had the greatest impact on marriage are the more liberal attitudes about sexual relationships and physical intimacy, as well as the ever growing economic and political power of women in our society, not to mention the substantial reforms in divorce law (Gurman, 2008).

The evolving state of marriage can best be understood when viewed through the lens of recent history. May (1980) provides a cogent analysis of the change in marriage from the late nineteenth century through much of the twentieth century. As the nineteenth century was drawing to a close, marriage was accepted by the adult population as a vehicle that facilitated procreation and helped ensure economic stability for the (growing) family. The primary expectation of husbands was to provide the basic necessities of life for wives and children via hard work and suppression of vice; chastity and duty were the primary expectations of wives. By today's standards, those circumscribed expectations seem very low indeed. Today, in our society, partners in a relationship typically expect marriage to be the

primary source of intimacy, support, and companionship. Thus, expectations of marriage have moved from duties and sacrifices toward personal satisfaction (sexual, social, leisure, and so on).

As only fewer marriages could meet the evolving expectations, relationship dissatisfaction grew and divorces become increasingly common. As time passed, during the twentieth century, divorce overtook death as the primary terminator of marriage (Pinsof, 2002). By the end of the twentieth century, the divorce rate rose upto a staggering 2,000% during the previous 100 years. An often-quoted statistic is that roughly 50% of first marriages will end in divorce and that this rate was growing. In fact, it appears that the divorce rate has declined, with first marriage dissolutions hovering around 43–46% across the past decade (Schoen & Standish, 2001; Schoen & Canunda-Romas, 2006). Nevertheless, divorced people typically try again: the rate of first remarriage is approximately 75%, yet the rate of divorce for second marriages is about 60%. Currently, it has been estimated that nuclear families containing the original mother, father, and children constitute only about a quarter of the American households; another 25% of the households are step families; and the remaining households do not contain two parents; rather, they are made up of single-parent families, singles in groups, and same-sex adults. Increases in cohabitation also obscure actual trends in family stability (Centers for Disease Control and Prevention [CDC], 2007; Raley & Bumpass, 2003). Broken marriages result in increased risks that their children will divorce and that the children, along with their parents, may suffer significant psychological adjustment problems during, and sometimes long after, the event (Amato & DeBoer, 2001).

Unfortunately, increases in marital conflict and divorce levy an enormous toll on children, families, and society more broadly. Relationship problems are among the most difficult problems adults face and, in the course of marital conflict and dissolution, partners suffer with depression, anxiety, drinking problems, physical problems and medical disabilities, and so on. Children who live in homes where parents' marriages are distressed also demonstrate increased psychosocial adjustment problems, marked by significant elevation in internalizing symptoms (e.g., depression, anxiety) and externalizing symptoms (e.g., conduct problems, acting out).

In recognition of the corrosive effects of marital distress on the emotional and physical well-being of adults and children, there has been a societal movement of sorts to preserve marriages. As an example, for more than a decade, the Smart Marriages Conference has been held annually and brings together over 2,500 marriage educators, therapists, sociological and clinical researchers, and married partners who are dedicated to enhancing the prevalence, the stability, and the quality of marital relationships. The overarching philosophy of the conference is that healthful marriage serves as an important protective factor against the problem described above; the evidence for this is rather compelling. Let us consider a few of the salient findings: (a) in general, women and especially men and children enjoy relatively better mental and physical health benefits being in versus out of the state of marriage (CDC, 2007; Myers, 1999); (b) men and especially women and children benefit socioeconomically from being in versus out of marriage (CDC; Ross, Mirowsky, & Goldsteen, 1990); and (c) research indicates that, with the exception of marriages that include high conflict or high abuse, the divorce process itself generally has negative short-term and long-term health and economic consequences for both adults and children, compared to families that stay together (Amato, 2000). Therefore, it is increasingly clear that there are many positive benefits in staying married and attempting to improve the function and quality of the adult intimate relationships.

These findings set the stage for the development of primary, secondary, and tertiary interventions designed to promote marital health.

Accordingly, from a societal perspective, given the mental, physical, and socioeconomic well-being implications for its members, marital therapy constitutes an important area for clinical psychology to pursue. As such, beginning nearly 40 years ago, clinicians and researchers alike have developed and tested theories and interventions to help those seeking help for problems in their marriages (Azrin, Naster, & Jones, 1973; Weiss, Hops, & Patterson, 1973).

The purpose of this chapter on marital dysfunction is to provide a fairly comprehensive overview of the major existing psychological approaches that have been developed over the past 4 decades to conceptualize and treat distressed relationships. Conventionally, authors interchangeably use the terms marital therapy, marriage therapy, and couple therapy. Couples may seek therapeutic assistance on their own or be referred for evaluation and treatment options by a variety of health care providers, community contacts, friends, and relatives.

13.2 Recognition of Symptoms and Their Assessment

13.2.1 Description of the Disorder

The *Diagnostic and Statistical Manual of Mental Disorders* (*DSM-IV*; American Psychiatric Association [APA], 1994, p. 681) includes v61.1, Partner Relational Problem, "when the focus of clinical attention is a pattern of interaction between spouses or partners characterized by negative communication (e.g., criticisms), distorted communication (e.g., unrealistic expectations), or noncommunication (e.g., withdrawal) that are associated with clinically significant impairment in individual or family functioning or the development of symptoms in one or both partners." Typically, individuals displaying symptoms as indicated above have an adjustment disorder, which, according to *DSM-IV,* is the development of emotional or behavioral symptoms in response to an identifiable psychosocial stressor(s) occurring within 3 months of the onset of the stressor(s) (APA, p. 623). For couples, the unnamed stressor may be marital conflict. The *DSM-IV* further codifies adjustment disorders according to specific types of symptom expression (e.g., adjustment disorder with depressed mood, anxiety, disturbed emotions or conduct). Additionally, certain couples may experience other *DSM-IV*-identified problems related to abuse, such as physical or sexual abuse of adults. Within marriage, the former is exemplified by spouse beating, the latter by sexual coercion or rape (APA, p. 682). Moreover, there is no doubt that marital distress can be either the cause or the result of any number of major psychological disorders experienced by partners or other family members. These problems include, but are not limited to, depression, anxiety, substance abuse, personality disorders, and chronic medical problems.

Ideally, one day there will be a single standardized "diagnostic system" for marital dyads. Such a system also would indicate the most appropriate method of treatment for a given couple. At present, such a standardized diagnostic system is far from reality, even though the field of marital therapy is increasingly embracing integrationist and couple-oriented perspectives. Nevertheless, given the practical challenge of being clinically competent in the practice of all types of approaches, most therapists end up learning well one, or possibly two, basic approaches.

In practice, what is assessed and how it is assessed tend to be heavily influenced by the interviewer's theoretical orientation and the couple's presenting problems. For example, marital

therapists who are more traditional, psychodynamically oriented, or emotion-focused may rely exclusively on the interview method for history-taking assessment information. In comparison, behaviorists, as well as certain strategic family therapists, may de-emphasize history-taking and instead focus on here-and-now interactions. Moreover, the so-called brief treatment family therapists may employ only a short problem-focused assessment interview and then proceed with strategic interventions within the first hour of contact.

13.2.2 Procedures for Gathering Information

Couple therapy, particularly those from a social learning, cognitive-behavioral approach, has a widely recognized tradition of beginning the relationship evaluation process by employing three interrelated methods of gathering information in order to understand the problems and strengths of a given relationship and plan various interventions to accomplish the therapeutic goals. First, there are a series of semi-structured and unstructured clinical interviews, typically conducted over the course of two to four sessions, which often include separate interviews with each partner, as well as meeting the partners together in a conjoint format. In general, the objectives of these assessment interviews are to: (a) screen clients for the appropriateness of couple therapy; (b) determine the nature and course of events related to partners' presenting complaints; (c) determine the expectations and goals of the partners for couple therapy; (d) establish an effective therapeutic relationship; and (e) orient the couple to the therapist's orientation and approach to treatment.

Each partner has one or more reasons for initiating couple therapy. Very often, in the first meeting, the therapist will help the partners to develop a problem list, which indicates each person's perception of the problems in the relationship. Problems can be categorized into matters of *content* and *process*. Problematic content areas often include specific stresses that adversely affect the marriage, such as unemployment, disrupting external events, finances, sex, in-laws, and children-rearing problems, annoying personality traits, and managing mental or physical illnesses. Process concerns have to do with couple adaptive processes or *how* the couple interacts. Typical complaints include ineffective ways of communicating with one another and concerns regarding how they attempt to solve problems and manage relationship disputes.

Additionally, it is also important during the evaluation stage to ascertain the partners' respective goals and expectations for couple therapy. For example, are they both committed to the relationship or is one partner planning separation or divorce? Are the problems identified negotiable for both partners? Are their goals and expectations realistic given the partners' levels of competence and motivation? Before making a treatment plan, all these interpersonal competence and motivational issues must be considered. Finally, the initial interviews allow for the therapist to establish a therapeutic relationship with the couple. The therapist must possess sufficient credibility, gain trust, and offer hope that the partners' pain, suffering, dissatisfaction, and distress can be addressed effectively. If this step is not accomplished, the couple may not engage in the therapeutic process.

One way to aid in the accomplishment of this preliminary bonding is to explain in advance the purpose and value of the various evaluation and intervention procedures. What is expected from the clients? What are the roles and responsibilities of the therapist? How will information be gathered and what is the prognosis for resolving their problems?

Second, a common assessment procedure used to gather diagnostic information about the couple is the administration of various self-report questionnaires and inventories to learn more about specific strengths and problem areas for each couple. Indeed, several standardized questionnaires have been designed to assess one or more of the following variables: global relationship satisfaction; communication skills and deficits; areas of change requested by the partners; types of conflict; intensity levels of conflict and styles of conflict resolution; partners' cognitions, expectations, and beliefs about the relationship that may be causing problems; sexual function and dissatisfaction; participation in pleasurable events and rewarding social activities; and steps toward divorce (for a discussion, see Fals-Stewart, Birchler, & Ellis, 1999). Practitioners typically ask the couple to complete a selected set of instruments either before or at the very beginning of the evaluation process. In most cases feedback and interpretation of the results are given to the couple regarding their responses.

The third assessment procedure that is routinely conducted is observation and analysis of a sample of in vivo marital conflict resolutions. That is, couples are helped to identify an existing issue about which they have disagreement; they are asked to spend 10–15 min in the session talking together in a demonstration of just how they go about attempting to resolve the problem. The therapist may or may not leave the room to less obtrusively observe and/or videotape the communication sample for later review and analysis. The conflict resolution communication sample provides unique and important information regarding the level of problem-solving skill the couple possesses to resolve relationship conflicts and the extent to which improvement in these adaptive processes will become treatment goals. In addition to the development of complex and sophisticated couple interaction coding systems (Backenstrass et al., 2007), several investigators have developed and employed a simple therapist coding system to quantify a given couple's communication and problem-solving skills (Basco, Birchler, Kalal, Talbott, & Slater, 1991; Heyman, Weiss, Eddy, 1995).

In summary, the multi-method assessment procedures employed by many couple therapists provide a solid basis for describing a couple's presenting problems and relationship strengths. The procedures provide both converging and diverging types of information that are used in a systematic manner to conceptualize relationship (dys)function and to formulate a treatment plan.

13.2.3 Additional Assessments Required

Broadly speaking, beyond the basic relationship assessments described above, there is often a need for additional evaluation to determine the nature and severity of other concomitant problems that often accompany relationship distress. For example, even though the couple is presenting for marital dysfunction, one or both partners may be suffering sufficiently from individual problems such that additional assessments regarding these problems may be indicated. These individual problems include, but are not limited to, drinking and other drug abuse, significant affective or anxiety disorders, dementia, psychosis, disabling medical problems, and posttraumatic stress disorders. When present, these clients may need specialized psychodiagnostic testing or mental status examinations performed by the couple therapist or via referral to another clinician. Second, certain problems identified in the form of couple problems may require additional assessments beyond the typical and standard evaluation procedures. Common examples here include the presentation of intimate partner violence issues, in

which safety and behavior control assessments need to be made; the assessment of children, when parenting conflicts or child behavior problem issues are primary; and evaluation of sexual dysfunction, when complex sexual problems are encountered. For a given couple, problem-specific inventories and additional interview-based diagnostic sessions may be required to complete a comprehensive diagnosis of marital dysfunction.

13.3 Maintenance Factors

13.3.1 Conceptual Models for Understanding Couple Relationships

Recently, a number of researchers and theoreticians who examine marriage and relationship functioning have offered certain conceptual schemes and heuristic models for understanding the factors that influence and determine the functional status of a couple relationship (Bradbury, Fincham, & Beach, 2000; Epstein & Baucom, 2002; Halford, 2001; Karney & Bradbury, 1995). Taken together, these models suggest that the quality of a couple relationship, at any point in time, is a function of the interaction and adaptation of two individuals. They bring into the relationship their own developmental and personal characteristics, they are significantly influenced by the cultural contexts from which they came and in which they live currently, and they must cope with life events and environmental factors that demand acceptance or changes of them.

Birchler, Doumas, and Fals-Stewart (1999) have offered a behavioral-systems framework for evaluating couple dysfunction called "The Seven Cs" (7Cs). During the course of diagnostic interviewing and treatment planning, clinicians may well seek to learn about a given couple's relative strengths and areas for improvement according to these areas of function: Character features, Cultural and ethnic factors, Contract, Commitment, Caring, Communication, and Conflict resolution (Cole, 1989; Levenson, Carstensen, & Gottman, 1993; Nichols, 1988; Wynne, 1984).

Briefly, we will define the 7Cs and note some concepts underlying these domains of personal and interpersonal function as they relate to being in a couple relationship. These concepts link to the assessment procedures described above and the intervention procedures, which will be described in following sections. First and foremost, we are concerned with the (inter) personal abilities and emotional qualities of the two individuals attempting to create the relationship. In our framework, *Character features* refer to the aggregate of features and traits that form the individual nature of a person. On one end of the continuum of the potential for interpersonal intimacy is an individual who, by virtue of often complicated bio-psychosocial misfortune, has certain handicaps, personality traits, emotional vulnerabilities, and perhaps such limited or pathological personal resources such that she or he is not a good candidate for marriage. On the other end of this continuum is the individual who is capable of loving well, in the broadest sense. She or he is responsible, resourceful, adaptive to varying and stressful circumstances, able to consistently give and get positive responses, and can achieve a healthy and functional balance of independence and interdependence in the relationship. In this domain, theoretical factors relating to individual development, the course of mental illnesses, mate selection, and attachment theory are important considerations for clients with marital dysfunction.

Cultural and ethnic factors refer to the cultural, ethnic, racial, religious, family of origin, socioeconomic, and other societal variables that collectively form the past and present context

in which individuals and couples exist. Certainly, given these important and broad developmental and contextual parameters, many adjustments by the couple are required and the potential exists for many types of conflicts to occur, both between the partners and between the couple and extended family or the community. In this domain, considerations of cultural diversity, the impact of family of origin issues (i.e., family systems theory), and role preferences and role strain are relevant.

As applied in this framework, the notion of *Contract* comes from mate selection theory, family systems theory, and social exchange theory. The contract between the partners may refer to explicit agreements between the two for the doing or not doing something specified and expected. However, in marital relationships, this is more often a complicated set of implicit expectations which partners have concerning how they will define the relationship and interact with another. In or out of awareness, contract problems suggest that partners' expectations do not match their experiences and due to which significant dissatisfaction and conflict may result.

Commitment is thought of as the state of having pledged, devoted, or obligated oneself to another; to be involved, remain loyal, and maintain the relationship over time. It has been said that virtually all approaches to the treatment of marital dysfunction can be successful if the partners are committed to one another. In contrast, when partners are not committed the prognosis for improvement is poor. This is a complicated interpersonal variable and can cause much distress within a couple. We attempt to simplify it conceptually by being concerned with two or three aspects. First, are partners committed to stability (e.g., no threats or behavioral steps toward separation or divorce; no intention of leaving their partner)? Second, are both partners committed to quality, that is, are they willing to invest in a process to improve the relationship through involvement and collaborative work? In the absence of these levels of commitment, prognosis is once again poor regarding the remediation of marital dysfunction.

Caring, obviously an important element of an intimate relationship, is grounded in social learning theory in our approach. We refer to the ability to express and exchange relational behaviors that are designed to promote emotional and physical intimacy, including mutual affirmation, support and understanding, demonstrations of affection, and sexual activities. Also, partners need to establish an effective balance between other-care and self-care regarding the experience of pleasant events and sources of reinforcement and validation.

Communication is conceptualized and known to be a core effective intervention element of BCT. We define communication as the open and honest sharing of information between two people, when the messages intended and sent by the speaker are exactly the same as the messages heard or received by the listener. The analysis of observed couple communication and communication training are usually critical to the remediation of marital dysfunction. A number of assessment procedures exist and training manuals have been developed to assist distressed couples to improve in the area of the number one complaint of couples seeking therapy.

Finally, the last of the 7Cs, *conflict resolution* refers to the personal skills and interpersonal patterns of interaction that facilitate effective decision making, individual and joint problem solving, the management of anger, and the resolution of marital conflict. Once again, assessments and interventions related to the skill of problem solving and conflict resolution are core elements of an empirically validated cognitive-behavioral approach to the remediation of marital dysfunction. The notion is that people are often deficient in the skills of problem solving, anger management, and conflict resolution and that, given the proper

motivation to improve the relationship, couples often can make significant improvements in this important domain of couple function.

13.3.2 Summary of the 7Cs

Most of the ingredients important to a long-term intimate relationship can be accounted for by an analysis of the 7Cs. For many couples, these domains of function constitute strengths to build upon or goals to strive for: (1) socially compatible personal values and a healthy personality (i.e., character); (2) strong family traditions and compatible or stimulating cultural and ethnic backgrounds; (3) a marital contract that offers ongoing adaptations and a viable match between partners' expectations and experiences; (4) loyalty to the marriage with a long-term perspective and the ability and desire to work out the inevitable problems (i.e., commitment): (5) love, affection, emotional support, and an optimal balance of individual and mutually rewarding activities (i.e., caring): (6) open and effective communication; and (7) problem-solving and anger management conflict resolution skills.

13.4   Evidence-Based Treatment Approaches

There is a number of accepted approaches to the conceptualization and treatment of marital distress. Suffice it to say that there are many practitioners of these approaches and they have been active over many years and have varying degrees of empirical support. The seven approaches described below are discussed generally in chronological order according to their development, although some programs were developed during similar time periods. All are recognized clinical programs designed to treat distressed intimate relationships.

Problem-Focused Couple Therapy. As perhaps the oldest and most widely applied approach to couple distress, problem-focused couple therapy (PFCT) has been known by several names over the years. The literature still offers descriptions of these family systems theory-based programs under the following labels: brief strategic couples therapy (Shoham & Rohrbaugh, 2002), structural strategic marital therapy (Keim & Lappin, 2002), and short-term structural family therapy with couples (Nichols & Minuchin, 1999). The basic tenet of PFCT is that dyads, like families, operate according to family systems rules and interactive processes. A distressed couple, therefore, is caught up in a negative cycle of interpersonal interactions, and the partners' efforts to solve the problems ironically tend to maintain them. The approach is nonpathologizing, seeking to avoid use of individual diagnostic labels. Rather, PFCT is sensitive to the normal family processes associated with the family life cycle and how distressed families (and couples) fail to adapt successfully to a number of inevitable family transitions (Carter & McGoldrick, 1988). The goal of PFCT is to focus on the primary problem offered either by the couple or imputed by the therapist and facilitate a solution in the most efficient way possible. With the exception of abuse, problem behavior is often viewed as being motivated by underlying desires to help or protect loved ones. As an example, nagging can be conceptualized as one's attempt to help another do the right thing. To the extent that nagging makes the problem (e.g., partner withdrawal and refusal to discuss an issue) worse, the couple gets caught in a self-fulfilling vicious cycle that results in circular causality. That is, the more one nags, the more the other resists compliance, and so on.

Interventions in PFCT relate to identifying both the interactional sequence that is causing the couple distress, as well as a preferred interactional sequence. Sessions with the therapist and homework assignments are thus devoted to disrupting the faulty sequence and reinforcing the preferred one. PFCT therapists are quite directive and often use strategic instructions to get couples to alter their problematic interactions. For example, in a case where a couple is incessantly arguing several times a day, the therapist may suggest that the arguments suggest a passionate connection to one another and a struggle to improve the relationship. The partners may be instructed to save their exuberant energy, prepare their arguments, and plan to argue for a full hour between 5 and 6 p.m. every day. Such a directive has the potential to put the couple in a therapeutic paradox, sometimes called a therapeutic bind, such that no matter what they do with respect to this assignment, the dysfunctional system can be altered. In this example, if the couple complies with the directive, participants end up arguing much less frequently and thus less destructively than before. If the couple fails to comply and does not argue between 5 and 6 p.m. daily, the therapist can work with them to determine how they avoided arguing then and apply that strategy to other periods in the day.

PFCT is a "here-and-now" approach; there is very little attempt to understand the origins or causes of the presenting problems. Moreover, insight is not viewed as required to resolve the existing interactional problems. Typically, there is no emphasis on structured communication or problem-solving skills training. The therapy is brief and typically fewer than ten sessions. Some interventions may be straightforward, even psychoeducational in nature; others may be quite strategic and use what might be viewed as gimmicky or tricky suggestions designed to trigger a change in the family systems process that is dysfunctional. PFCT was very popular during the 1960–1980s, but its use has waned in the past 2 decades, perhaps in large part due to the emergence of both derivative and alternative therapies that have broader appeal and more empirical support.

Insight-Oriented Couple Therapy. In his development and description of insight-oriented couple therapy (IOCT), Dicks (1967) adapted the Sullivanian psychoanalytic object relations theory for understanding couple dynamics. Dicks' contribution was to describe how two personalities in a marriage unite not just at the level of conscious choice, compatibility, and sexual attraction, but also at the level of the unconscious, where the personalities match but the couple is unaware. Partners are attracted to one another to complete or work through prior intrapsychic conflicts via the relationship. In an unhealthy marriage, the match fails to unlock and resolve constructively inherent intra-individual repression and consequently deepened unconscious and conscious conflicts ensue.

IOCT is a developmental approach that creates a therapeutic environment in which the couple's pattern of defenses can be displayed, recognized, and analyzed until the underlying anxieties can be identified, explored, and experienced at the conscious level. Basic interventions include: (a) *setting the frame*, which means establishing the environment, ground rules, and parameters of therapy (e.g., number and length of sessions, therapist structure of activities in the sessions, setting of fees, and other expectations); (b) *creating psychological space for understanding* by containing the couple's anxieties at the outset and fostering exploration and disclosure over time; (c) *listening to the unconscious*, observing conscious and exploring unconscious communications between the partners and between partners and the therapist; (d) *following the affect* because moments of emotion provide access to the unconscious; (e) *observing transference and countertransference*, that is, partners' feelings about the therapist and the therapist's feelings about the partners also can provide clues to the unconscious

conflicts; and (f) *interpretation of the defense*, which constitutes pointing out the recurring patterns of interaction that serve a defensive purpose and may be subject to insight, understanding, and revision for the health of the relationship. The goals of treatment are relatively vague compared to other approaches because of the variable and unknown nature of the disruptive unconscious processes at the outset of therapy. Accordingly, IOCT may be open-ended and long-term in nature (Scharff & Bagnini, 2002).

Despite the long tradition of psychoanalytic and psychodynamic theory and practice in the field of individual psychotherapy, it was not until approximately 1989 that an organized IOCT was actually favorably compared to behavioral marital therapy (BMT) in an empirical study of therapeutic outcomes (Snyder & Wills, 1989). When introduced, the IOCT approach described by Snyder and Wills was much less psychoanalytically oriented than previous approaches. More recently, Snyder and Schneider (2002) have described a pluralistic, developmental approach to marital therapy called Affective Reconstruction. This approach incorporates insight-oriented interventions designed to address the notion that couples' difficulties often derive from previous relationship injuries that cause sensitivities and interpersonal vulnerabilities within and between the current partners. Effective therapy helps partners to depersonalize the negative aspects of their interactions and be better able to empathize with the origins of one another's sensitivities and their disruptive influences. An emphasis is placed on identifying, understanding, and possibly modifying partners' maladaptive interpersonal schemas and relationship dispositions. Certain behaviors and thinking styles that may have served the individuals well in previous relationships (i.e., in families of origin or prior adult intimate relationships) may not be working well in the present relationship. The pluralism attributed to this approach suggests that some couples may benefit from structural, behavioral, and cognitive interventions (described elsewhere in this section) offered either before or during the insight-oriented interpretive work.

Behavioral Couple Therapy. Originally called BMT and now called behavioral couple therapy (BCT), the behavioral approach originated in the late 1960s and continues to be one of the most widely used forms of partner-involved therapies for distressed couples. BCT is founded on social learning theory, which posits that people will be attracted to partners and situations that are socially rewarding and they will be unhappy with partners and situations that are not rewarding or are punishing. Accordingly, early studies investigated the operant conditions, social reinforcement situations, and partner behavioral exchanges that differentiated happy from unhappy couples (e.g., Birchler, Weiss, & Vincent, 1975; Gottman, Markman, & Notarius, 1977). By 1980, two classic treatment manuals describing BCT were available, incorporating extensive empirical support for the approach (Jacobson & Margolin, 1979; Stuart, 1980).

Basically, two interventions were proven to be related to the status of, and improvement in, relationship satisfaction: (1) communication and problem-solving skills training, and (2) behavioral exchange. Communication problems are the most commonly cited complaint of couples seeking therapy. Effective communication is the major tool that couples possess (or do not possess, as the case may be) to address virtually all the problems that arise in their relationships. During the past several decades, evolving from the observation of thousands of conflict resolution communication samples, speaker–listener interventions have been developed systematically to help unhappy couples communicate more effectively. Acquisition, development, and practice of these skills alone were found to reduce the divorce rate by half for newly married couples during 5-year periods (Markman, Renick, Floyd, Stanley, & Clements, 1993). Together with basic communication effectiveness, problem-solving skills were also found to

discriminate between distressed and nondistressed couples. Along with the processes of effective communication and problem solving, behavioral exchange was found to be the second factor that differentiates happy from unhappy couples. Nondistressed couples emit and exchange more positive behaviors; distressed couples engage in more negative behavioral exchanges. Accordingly, in the application of BCT, couples are taught to take inventory of the various behaviors expressed in their relationships and how to negotiate and compromise toward more rewarding (i.e., desired) behaviors and how to eliminate (or at least reduce) undesired behaviors.

Hallmark characteristics of BCT include teaching partners to (a) focus on the present and not the past, (b) make positive and specific requests versus generalized negative complaints, (c) initiate and reward self and partner change, and (d) seek compromises for the good of the relationship. BCT typically consists of 12–16 conjoint sessions, accompanied by standardized assessment measures administered before and after therapy. A three- to four-session evaluation period is followed by 2–3 months of weekly psychoeducational sessions. Therapists are structured and directive, plan certain activities for the upcoming sessions, employ instruction, modeling, coaching, and typically make extensive use of weekly homework assignments and bibliotherapy to augment the consultation activities in the sessions. To a greater or lesser extent, all BCT interventions are designed to enhance couple communication and problem solving and improve the quantity and quality of behavioral exchanges. Often booster or follow-up sessions are offered to couples to help them to maintain treatment gains over time.

Cognitive-Behavioral Couple Therapy. Soon after BCT reached considerable stature by 1980, several behaviorists hypothesized that the effectiveness of BCT could be enhanced by taking into account not only partners' behaviors and responses to them, but also their manner of thinking about relationship events. When certain interventions designed to assess and modify partners' cognitions were added to the BCT technology, the combined approach came to be known as cognitive-behavioral couple therapy (CBCT). As partners react to specific events in their relationships (positive or negative), studies determined that each partner has a unique set of *selective attention* factors (e.g., Beck, Rush, Shaw, & Emery, 1979), *attributions* (beliefs about the causes for, and/or meanings of, events; Epstein, 1985; Holtzworth-Munroe & Jacobson, 1985), and *expectancies* (partners' explanations for present and future behaviors based on their past experiences; e.g., Fincham & Bradbury, 1989). Moreover, partners were found to have broad relationship beliefs (for better or for worse) that involve one's *assumptions*, which are beliefs about the characteristics of individuals and intimate relationships and *standards*, which are an individual's core beliefs about how things should be (e.g., Baucom, Epstein, Sayers, & Sher, 1989). Taken together, these cognitive styles can be powerful determinants of one's experience and behaviors expressed in an intimate relationship. Based on a fairly large and growing body of empirical research, distressed partners have been found to possess significantly more faulty cognitions, about themselves, their partners and their relationships than their nondistressed counterparts (Baucom & Epstein, 1990).

CBCT incorporates an assessment of partners' cognitions that may be detrimental to a given relationship, while also taking account of behavior change options as in the case of BCT. After helping partners to recognize their self- and relationship-defeating cognitions, various interventions are employed, such as cognitive restructuring, monitoring and testing assumptions, and helping men and women explore and be open to, and curious about, the cognitive structure of one's partner. Mutual understanding of the complexity of one another's thinking patterns, cooperative efforts to eliminate or reduce the effects of unfavorable cognitions, and

mutual efforts to enhance a pro-relationship set of expectations and experiences constitute the core CBCT interventions. Well-developed CBCT treatment manuals are available, which provide rich descriptions of the theoretical foundations for CBCT as well as components of the intervention that apply to distressed couples (Baucom & Epstein, 1990; Epstein & Baucom, 2002).

Solution-Focused Couple Therapy. Also in the early 1980s, a number of family system therapists began to diverge from the traditional PFCT formulation (see earlier) and focus specifically on a strength-based, solution-focused brief therapy approach to couple distress (e.g., de Shazer, 1982; Lipchik, 1988). The basic conceptualization of relationship problems in solution-focused couple therapy (SFCT) is that distressed couples are: (a) locked into a negative mindset, (b) are stuck in problem talk, (c) have inherent strengths but are not seeing or utilizing them, and (d) are not noticing the exceptions to when the problem occurs. In SFCT, problem talk is completely discouraged; the goal is to help the couple identify and co-construct active solutions to the problem. Solutions are found in the exceptions to the problematic behavior (i.e., what is happening when the problem behavior is not occurring). Similar to its parent approach, PFCT, there is no attempt to pathologize partners or dyadic processes, no interest in the development or origins of the problem, and usually little emphasis on structured communication or problem-solving skills training.

Language is a primary tool in this therapy: changing problem talk to solution talk. There are several standard techniques associated with SFCT. The *miracle question* asks partners what it would be like if a miracle happened overnight and the problem was gone; what would each partner notice, how would they behave differently, and so on. Based on the answers, experimental behavioral assignments are made. *Scaling questions* ask, for example, on a scale of 1–10 how committed are you to this marriage; how happy are you with this behavior, how happy are you in this relationship. Whatever the partners' answers, the therapist asks what it would take to get to the next level. *Exception seeking* consists of asking the couple when the problem does *not* occur. The answers are examined for determinant situational factors and attempts are made to apply these to the problematic behaviors and situations.

In SFCT, as in PFCT, the therapist is not an expert, but rather acts as a collaborator who helps the couple to co-construct solutions to their problems. The therapy is brief, sometimes lasting only one to two sessions, and rarely more than ten. Termination occurs when the clients are satisfied that their goals have been achieved. A treatment manual was developed for this approach that attempts to enhance the basic SFCT approach with certain integrative features, such as a focus on the role of emotions in the therapeutic relationship (see Lipchik, 2002).

Emotion-Focused Therapy. For many years, the role of affect in marital distress was downplayed or seen as secondary to the primary effects of behaviors (BCT), cognitions (IOCT and CBCT) or principles of family systems (PFCT and SFCT). However, more recent integrative approaches to the treatment of couple distress now include intervention components designed to account for the role that *emotion* plays in the development and resolution of dyadic difficulties (see Epstein & Baucom's enhanced CBCT, 2002; Jacobson & Christensen's integrative behavioral couple therapy, 1998; Snyder & Schneider's affective reconstruction couple therapy, 2002). However, some of the most definitive work to offer primacy for emotions began to be published in the late 1980s under the programmatic title emotion-focused therapy (EFT; Greenberg & Johnson, 1988). The authors suggest that EFT is integrative in that the approach incorporates experiential/gestalt principles and family systems theory influences. However, it should be noted that EFT is not a behavioral approach.

Over the years, attachment theory has taken a more central place in the conceptualization and practice of EFT (Bowlby, 1988). In every relationship, attachment behavior is aimed at maintaining closeness and contact with other people while simultaneously striving for individuality. Just as in their families of origin, adults can form secure or insecure attachments with their partners. Due to problems in attachment, individuals hide their primary emotions (i.e., sorrow, sadness, inadequacy, shame) and exhibit secondary or "reactive" emotions (i.e., frustration, anger, or fear). Based on the expression of secondary (sometimes called *hard*) emotions, negative interaction patterns begin to shape the relationship. According to EFT, these emotions organize and drive the couple's interactions, not their cognitions or behaviors. Distressed couples have failed to successfully express their emotions and partners feel invalidated and misunderstood. EFT is designed to help each partner to access this emotional pain and successfully express their primary (often called *soft*) emotions, while the listening partner is taught to be open, empathetic, and supportive of the other. The goals of EFT, with the therapist playing a fairly directive and strongly collaborative role, are to expand constricted emotional responses, identify and restructure negative interactions, and establish new solutions while fostering positive cycles of comfort and caring. The majority of the couple's emotional work takes place in the sessions and there is almost no use of homework. Therapy typically lasts from 18 to 20 sessions, unless there has been a major attachment injury experienced by either partner, in which case therapy may take much longer. Treatment manuals have been published for EFT (Johnson, 1996, 2002).

Integrative Behavioral Couple Therapy. Integrative behavioral couple therapy (IBCT; Jacobson & Christensen, 1998) grew out of the BCT tradition, but was designed specifically for those couples who seemed to benefit the least from BCT, namely, those who were most distressed, most rigid, had divergent relationship goals, or were emotionally distant. In short, IBCT was designed for couples who no longer had a "collaborative set," an ability to work together as a team to create personal and relationship change.

IBCT is based on the theory that relationship distress develops through a process in which normal interpersonal differences become viewed as deficiencies. All partners ask each other for occasional behavioral change, but when ongoing attempts are fruitless, differences are eventually vilified. For example, a spouse is no longer "easygoing" but has become "lazy and uncaring." Over time, repeated unsuccessful efforts to change each other lead partners to become increasingly entrenched in their own behavior patterns, or "polarized," creating a "mutual trap" in which both partners feel stuck in the pattern, helpless to change it, and blaming each other. IBCT relieves relationship distress and helps couples to create a collaborative set by improving understanding of the polarization process and increasing emotional understanding, acceptance, and tolerance of differences.

After an extensive relationship assessment, IBCT therapists identify the theme behind a couple's polarization process. This theme is typically one of fundamental differences in personality, values, or needs (e.g., desired closeness/distance or amount of responsibility/organization) that have usually been present since the beginning of the relationship. The therapist provides feedback to the couple presenting a formulation consisting of their individual theme, polarization process, and mutual trap; from this evolves a treatment plan.

Although traditional BCT techniques may be used, the primary emphasis in IBCT is on nondidactic acceptance-based interventions. These include: (a) *empathic joining*, which breaks the mutual trap by increasing emotional closeness through the disclosure of softer, more vulnerable emotions; (b) *unified detachment*, which focuses on seeing relationship problems as

an "it," a pattern that the couple engages in, rather than a "you," something one partner deliberately does to the other; and (c) *tolerance-building*, which prescribes exercises that help partners cope with individual differences that they may never like, but are not "deal breakers." In building tolerance, partners are not taught to tolerate abusive or significantly inappropriate behaviors; rather to become less frustrated with partners' personal styles or behaviors that may be unlikely to change. Although IBCT is a relatively unstructured therapy with significantly less emphasis on changing specific behaviors than in BCT, the emphasis on acceptance often leads to change. Paradoxically, when partners no longer feel pressured by the other to change, they are more likely to engage in the initially desired behaviors. Recent clinical trials of IBCT support its effectiveness in treating relationship distress (Christensen et al., 2004; Christensen, Atkins, Yi, Baucom, & George, 2006).

13.4.1 Marital Therapy Outcomes

To date, the only couple therapy modality for relationship distress with extensive empirical support is BCT (Chambless & Hollon, 1998; Powers, Vedel, & Emmelkamp, 2008). This is partly because BCT is the oldest and by far the most studied of the couple therapy modalities. Newer treatments that have increasing empirical support include emotion-focused therapy (Byrne, Carr, & Clark, 2004), IOCT (Snyder, Wills, & Grady-Fletcher, 1991), integrative BCT (Christensen et al., 2004), and CBCT (Epstein & Baucom, 2002). On average, couple therapy has effect sizes ranging from 0.50 to 1.30 for the treatment of relationship distress (Snyder, Castellani, & Whisman, 2006), indicating a moderate to large effect of treatment compared to no-treatment control conditions. As described above, couple-based treatments for co-occurring relationship distress and individual difficulties have also been examined and found to be effective in several areas, including substance abuse (Fals-Stewart, O'Farrell, Birchler, Cordova, & Kelley, 2005) and depression (Beach & Gupta, 2003).

However, not all couples respond to treatment. Research demonstrates that only 50–60% of couples experience significant gains as a result of couple therapy, and not all of those are able to maintain their gains long term (Jacobson, Schmaling, & Holtzworth-Munroe, 1987; Snyder et al., 1991). As a result, there is an increasing emphasis on studying the mechanisms of change in couple therapy and the predictors of response to treatment (e.g., Doss, 2004; Snyder et al., 2006). The future of couple therapy research seems to lie in determining what works best for which people with what problems and why, as much as in developing new theoretical approaches and treatment modalities (Christensen, Baucom, Vu, & Stanton, 2005).

13.5 Mechanisms of Change

At this point in the empirical literature on couple therapy, however, far greater emphasis has been placed on the evaluation of whether or not it works, rather than *how* it works. Yet, various schools of couple therapy have theoretical mechanisms of therapeutic effect that are believed to underlie the outcomes observed. For the cognitive-behaviorally oriented couple therapy approaches, it is believed that the learning of new healthful behaviors and modification of unrealistic expectations leads to more positive partner exchanges and less relationship conflict.

These schools of couple therapy are primarily skill-based teaching approaches in which a therapist teaches more effective relationship behaviors. These include training in communication skills, problem solving, negotiation, and contracting. These skill-based elements are often augmented with various cognitive interventions, such as identification of unrealistic expectations of the relationship and/or the partner and replacement with more realistic beliefs (e.g., Baucom & Lester, 1986).

IOCTs theorize a different set of change mechanisms. These intervention approaches promote increased insight into the conflicts, any cycles that might maintain them, and the emotional process that maintain the relationship distress. Therapists using this framework try to facilitate insight for each of the partners into his or her own personality and behavior as well as the dynamics of the partner's relationship.

However, are the theorized mechanisms of change *actually* those that lead to improvements? As with individual psychotherapy, there is much controversy as to what actually brings about change in couple therapy (Simon, 2006; Sprenkle & Blow, 2004). Is it the "specific ingredients" of the interventions or the "common factors" that can be found in virtually all successful therapies? "Specific ingredients" refer to clearly identified circumscribed techniques that are elements of a given couple-based intervention package. These might include techniques such as communication skills training, cognitive reframing, empathic listening and responding, and so on. In many situations, these techniques are operationalized in detailed therapy manuals to which clinicians adhere to achieve a particular outcome. In many important respects, the notion that implementation of specific ingredients is conceptually akin to a pharmacotherapy model of psychotherapy in which a well-described psychotherapeutic technique is administered to produce a desired psychological or behavioral outcome, is much like administering a pill to produce a desired changed in physical state.

Conversely, different couple therapy approaches have a great deal in common with each other; these "common factors" refer to aspects of therapy that are not specific to any particular approach but are nonetheless curative. These common elements include client factors, such as motivation and expectation for change, and therapist factors such as the ability to form alliances with clients, attending to clients' needs, and creating a corrective emotional experience for clients. Indeed, it may be that the common factors themselves may account for most of the change observed in couple therapy versus specific techniques employed within a given couple intervention.

Is there any support for the notion that it is common factors and not specific ingredients that lead to change? Although not directly on point, there is some evidence that support this idea. More specifically, comparisons of outcomes of different couples therapy, compared in "horserace" randomized clinical trials, have revealed that different approaches to couple therapy produce better outcomes than control conditions, but there are few differences between active couple interventions (e.g., Dunn & Schwebel, 1995).

In individual therapy, there has been movement toward understanding change mechanisms that may transcend particular therapies (Beutler, 2003); comparative research in couple therapy has lagged behind. As cogently argued by Sexton T. and colleagues (2008), there is a great need in couple therapy research to evaluate empirically the mechanisms of action that lead to measurable positive change across intervention approaches. It is simply not clear at present how many specific ingredients and how many common factors account for observed outcomes (separately, additively, or interactively).

13.6 Basic Competencies of the Clinician

13.6.1 Overview

Although there would most certainly be a rather spirited debate about exactly what a provider who works with couples should know and understand, there are nonetheless fundamental areas of knowledge and skill or "competencies" that nearly everyone would accept as necessary, if not sufficient, for a professional therapist to achieve an acceptable level of service quality and care. Indeed, to guide training and continuing education among its constituents and other stakeholders, the American Association for Marriage and Family Therapy (AAMFT, 2004) described competencies in six core areas that they deemed all marital and family therapists must possess to practice independently:

- Decision making over admission to treatment
- Clinical assessment and diagnosis
- Treatment planning and case management
- Therapeutic interventions
- Understanding of legal issues, ethics, and standards
- Current knowledge of research and program evaluation

Certainly, each of these is very broad in scope. Within each of these primary domains, AAMFT also describes the types of skills and knowledge that marital and family therapists must develop, which are referred to as "subsidiary domains" in this scheme: (a) conceptual, (b) perceptual, (c) executive, (d) evaluative, and (e) professional. Refining the primary competencies with the subsidiary domains, AAMFT describes 128 interrelated competencies. Although it is beyond the scope of this chapter to describe all of these competencies, a broad overview of the primary core competencies provides a framework for providers who treat couples to guide self-evaluation of basic skills and the need for further training and education.

13.6.2 Brief Descriptions of Core Competencies

Decision-Making Regarding Admission to Treatment. In many important respects, the therapeutic relationship starts with the decision-making process regarding whether or not a client (whether that be an individual, couple, or larger element of the family system) should enter into some form of treatment. Such a determination for a couple therapist requires an evaluation of the appropriateness of couple therapy or other types of interventions for the presenting problem or problems, combined with an understanding of the providers' professional scope of practice and competence. In part, this involves gathering and reviewing intake information and attending to individual, familial, community, cultural, and contextual factors. Of course, the picture that evolves from this information may reveal the need for referral to specialized services or other providers. Admission to treatment also requires determining who should participate in the treatment and in what configuration (e.g., individual, couple, family, others). On a practical level, admission to treatment also involves describing to clients practice-setting rules, policies, and procedures (e.g., fees, payment, responsibility of parties, obtaining consent for parties to participate, confidentiality).

Clinical Assessment and Diagnosis. Couple therapists should have a strong knowledge base on the most prevalent behavioral health disorders (e.g., depression, anxiety, substance use, intimate partner violence), including epidemiology, etiology, phenomenology, effective treatments, course, and prognosis. Relatedly, this includes having a working knowledge of couple and family evaluation methods that are appropriate to the presenting problem and practice setting. There are a variety of assessment approaches that are often used in the course of couple therapy. As described earlier, use of structured assessments allows providers to efficiently collect information on the nature and extent of problems that a given couple may have and potentially tailor the treatment plan accordingly. Couple therapists should have some familiarity with administration and interpretation of certain standard measures of couple adjustment which include the Dyadic Adjustment Scale, Areas of Change Questionnaire, and the Marital Satisfaction Inventory – Revised. Providers should also have a sense of the advantages and disadvantages of various assessment approaches. Perhaps most importantly, a couple therapist should diagnose and assess strengths and problems from a systemic perspective. This includes describing strengths and problems from the perspective of each member of the dyad. Finally, part of the assessment and diagnostic process involves determining provider–client level of agreement on the partner's strengths, problem areas, and direction for treatment.

Treatment Planning and Case Management. Developing a treatment plan (both initial and subsequent updates) requires knowing approaches and techniques that are most effective for the problems identified during the course of assessment. Treatment planning includes such tasks as (a) developing a set of clear treatment goals, (b) structuring the intervention to meet clients' needs and facilitate systemic change, (c) potentially working in collaboration with others who have significant influence on the dyadic system (other family members, other significant persons, other providers, and so on), (d) modifying goals as treatment progresses and as necessary, and (e) developing termination and aftercare plans. Case management also includes evaluating managing risks, crises, and emergencies. This can also include assisting clients with managing complex systems of care, particularly when referral to other services may be involved. On a more practical level, couple therapists must be able to write treatment plans and other case documentation in accordance with setting rules, professional standards, and state and federal regulations.

Therapeutic Interventions. During the last 2 decades, there has been movement in the professional field toward the use of evidence-based practice (see Chambless & Hollon, 1998). There is a need for practitioners to know couple therapy models for which there is substantial evidence for effectiveness, such as BCT, insight-oriented marital therapy, functional family therapy, multidimensional family therapy, and parent–child interaction therapy (for a review, see Sexton & Alexander, 2002). Relatedly, providers should appreciate the value of outcomes data from well-designed randomized clinical trials while also understanding the limitations of applying the results of such studies to actual clinical practice (Levant, 2004). Additionally, therapists need to understand important therapy process variables and how to adapt interventions based on feedback during the course of therapy (Pinsof, 2004). In this regard, it is also important that providers match treatment modalities with clients' needs, goals, and values. Couple therapists should have skills to understand and reframe partners' problems from a relationship and systemic perspective. As treatment plans evolve, it also requires modification of interventions to address changes in therapy course and goals. Ongoing evaluation of progress is necessary to ensure that interventions which are not working are changed. In the context

of couple therapy, it is incumbent on the provider to form healthful therapeutic alliances with partners and set appropriate boundaries, manage issues of triangulation, and develop collaborative working relationships.

Understanding of Legal Issues, Ethics, and Standards. In the course of their training, providers are routinely taught to perform all professional activities in a manner that is consistent with a standing code of ethics (e.g., American Psychological Association, 2002) as well as any applicable state, federal, and provincial laws. However, it is also important to recognize that formal ethical and legal codes are often developed with individual clients in mind and not larger systems, such as couples or families. It is important to recognize that couple therapists operate within the legal system, but, in many cases, know little about it and are frightened by it. As such, it is critical for couple therapists to understand legal and ethical issues unique to the treatment of couples, including the definition of the client, the relationship the provider has with each person in the dyad, complexities of confidentiality and its limits, managing multiple relationships, and so on. Couples therapists need to recognize when legal consultation may be necessary and monitor professional issues as they relate to ethics, laws, regulations, and professional standards. They also need to have a strong working knowledge of how to develop safety plans for those clients and couples who present with issues related to self-harm, suicide, abuse, or violence. As such, couples therapists must know how to report information, as well as what information, to appropriate authorities as required by law (including legal aspects of obtaining releases of information, protecting the record as necessary, and responding to subpoenas and court orders). From a more day-to-day practice perspective, couples therapist must maintain clinical records with timely and accurate notes and bill clients and third-party payers in accordance with professional ethics and relevant laws and policies.

Current Knowledge of Research and Program Evaluation. There is a large and growing empirical literature on couple therapy, not only for general relationship distress, but also its application to other problems (e.g., depression, substance abuse). A provider must learn evidence-based models of couple therapy and apply that information to systemic interventions with the couples with whom they work. To do that, providers need to have some familiarity with research and program evaluation methodologies (both quantitative and qualitative) relevant to couple therapy and broader mental health services. This allows providers to critique the emerging empirical literature and assess the quality of the investigations. Additionally, couple therapists very often have the opportunity to contribute to the development of new knowledge via participation in research that involves couples and families. Research contexts are a unique and complex setting for the provision of service, since the goals of investigation may be to determine if a treatment is effective and how it works. In that situation, a couple therapist may be providing a service that may ultimately have no benefit (or even be harmful) to those clients who are involved, which usually cannot be determined until after the investigation is complete and the data are analyzed.

13.7 Expert Competencies of the Clinician

The core competencies described above represent knowledge and skill areas that all providers who treat couples and other family systems have some mastery; yet, these core competencies represent a minimal standard. In many important respects, a couple therapist who has the requisite background, training, education, and experience in the core competencies communicates

to potential consumers of services with increased confidence that participation in therapy will not result in any harm. In other words, having mastered these core competencies is a rather low threshold to surpass for providers who treat couples and families.

However, providers can and often do rise above a basic level of competence toward a greater level of recognized expertise. Indeed, there are more specialized knowledge, skills, and background that designate a level of competency that appreciably exceeds the core competencies. These areas include the following:

- Consultation and inter-professional collaboration
- Supervision
- Integration of individual and cultural diversity into practice

Of course, these expert competencies are not completely distinct from the core competencies, but represent a knowledge and skill base that should be viewed more as augmentations and enhancements. In many respects, these expert competencies reflect professional activities and aspects of professional identity more closely aligned with couple and family therapy "experts."

Consultation and Inter-Professional Collaboration. As is often the case, the provision of couple therapy occurs in many different settings, such as medical schools, outpatient mental health settings, or in the home (McDaniel, Belar, Schroeder, Hargrove, & Freeman, 2002). Thus, couple therapists who work in different settings must be able to establish effective collaborative relationships among the various stakeholders and, in turn, develop a multidisciplinary solution to presenting problems that are in the best interest of the couple. It requires an understanding of the dynamic relationship between the couple therapist and the context where therapy is provided, with an effort to capitalize on the strengths of the setting to increase the likelihood of healthful outcomes.

As an example, couples and family therapy providers very often find themselves giving services in various healthcare settings in which therapists provide relationship-centered care within the context of a collaborative family healthcare approach (e.g., McDaniel & Campbell, 1996). Many therapists serve couples in the context of a family illness of some kind (e.g., illness in children, illness of a partner's parents); in these settings, the therapist must have advanced skills in family assessment, methods of family support, and disease management from a familial perspective (Kazak, Rourke, & Crump, 2003). This skill set includes making efforts to engage the couple and other family members as full partners in their health care, attend to collaborative values within the family and the health care team, and negotiate issues of communication, problem solving, and conflict resolution between the family and the health care professionals.

Supervision. The need for competency in supervision has emerged as a significant practice area for couple therapists, who very often find themselves involved in supervising other couple therapists and family treatment providers. In a time of shrinking health care dollars, it is often viewed as more cost-effective to have an expert therapist provide supervision to several less experienced (and presumably lower paid) providers. Thus, couple therapists are often promoted to supervisory positions and, as such, must develop and hone the skills necessary to provide quality oversight of other providers.

As has been recommended by several authors (e.g., Fraenkel & Pinsof, 2001; Lee & Everett, 2004), it is most productive and appropriate to provide supervision based on either (a) *theoretical eclecticism*, in which supervisees are exposed to multiple theories and can, in turn, select from different approaches when confronted with different presenting problems, or (b) *assimilative integration* in which supervisees are introduced to multiple theoretical perspectives but are

allowed to maintain a secure base in one. Most couples and family therapists who oversee other providers should use, and be comfortable with, fairly tried-and-true supervisor techniques: case presentations, tapes (audio or video), live supervision, and co-therapy (Sprenkle & Wilkie, 1996). Of course, supervisory formats depend on the preferences of the participants (i.e., supervisees, couples, family members), the learning goals of the supervisee, and the professional setting where the supervision occurs (Storm, Todd, Sprenkle, & Morgan, 2001).

In the context of evidence-based practice and the conduct of couple and family therapy in research settings, such interventions are usually guided by therapy manuals, which pose important challenges to the supervisory process (e.g., Liddle, Becker, & Diamond, 1997). The manuals prescribe specific therapy approaches and provider behaviors, as well as proscribe behaviors that are not recommended or prohibited. Manuals allow for very clear supervisory targets, allowing for evaluation of adherence to the manuals and competence of delivery. However, providers can also experience manuals as a factor limiting creativity and not flexible enough to address the needs of diverse populations, problems, and treatment contexts. Supervisors in this context are required to ensure that those providing manualized interventions follow the manuals to ensure treatment fidelity.

Integration of Individual and Cultural Diversity into Practice. Integration of multicultural conceptualization and treatment of emotional and behavioral problems have become a cornerstone of professional practice, including couple and family therapy. As an example, there has been more explication in the literature on psychotherapy with gay, lesbian, and bisexual couples (Division 44, 2000). All of the basic and advanced competencies must be understood with attention to factors, such as age, gender, gender identity, race, ethnicity, culture, religion, spirituality, sexual orientation, disability, language, and socioeconomic status. Providers must also be self-aware and have knowledge of the impact of ageism, racism, sexism, and homophobia in all aspects of practice (Daniel, Roysircar, Abeles, & Boyd, 2004). The integration of individual and cultural diversity into practice underscores the importance of providers becoming familiar with one's own culture and the cultures of the couples and families with whom they work (e.g., Lee & Everett, 2004).

In addition to the above, many expert couple therapists also develop expertise in the application of couple and other systemic approaches to individual, diagnosable adult psychiatric/psychological disorders. Research on couple treatment has shown that individual problems and relationship problems influence each other dynamically. Many experts have applied couple therapy to many psychiatric disorders, including alcoholism and drug abuse (e.g., Fals-Stewart, O'Farrell, & Birchler, 2003), depression (e.g., Beach & O'Leary, 1992), personality disorders (e.g., Fruzetti & Fantozzi, 2008), and sexual dysfunction (McCarthy & Metz, 2007).

13.8 Transition from Basic Competencies to Expert

The transition from basic to expert competency involves three interrelated professional processes: (a) ongoing and increased didactic education, (b) training and supervision from experts, and, in some instances, (c) designation by a recognized professional body as an "expert." Of course, these tasks are inherently developmental in that it takes time over the course of a career to accrue the necessary background, education, training, and experience to be deemed an "expert" in couple therapy.

As a framework for understanding the transition from basic to expert competency, it is informative to examine established criteria for certification or designation as an expert that are

used by professional organizations. Once such professional organization is The American Board of Couple and Family Psychology (ABCFP), which is a member board of the American Board of Professional Psychology (ABPP). The ABCFP is responsible for establishing criteria related to the definition, education, training, and competencies leading to certification as a specialist in Couple and Family Psychology. Such board certification assures the profession and the public at large that the designee has the competencies required to provide quality service in couple and family therapy.

To attain certification from the ABCFP, according to their Web site (http://www.abpp.org/brochures/FM.pdf) applicants must meet the following general eligibility requirements:

- A doctoral degree from a program in professional psychology that is accredited by the American Psychological Association or the Canadian Psychological Association
- Licensure or certification to practice independently as a psychologist in the State, Province, or Territory in which the psychologist practices

In addition, ABCFP notes three specialty-specific eligibility requirements:

- Completion of a recognized internship and
- A recognized postdoctoral residency program in Couple and Family psychology or
- At least one postdoctoral year of supervised practice in Couple and Family Psychology and two graduate Couple and Family Practicum courses or equivalent and 40 h of continuing education in Couple and Family Psychology or closely related activities

Beyond these general eligibility requirements, applicants are also required to pass an individualized, peer-reviewed examination. The examination encompasses the following competencies:

- Assessment and intervention
- Science base and application
- Ethics and legal foundation
- Professional identification
- Consultation and supervision

As is evident, these competencies fall in the core and expert areas. The exam involves, in part, the application of knowledge and skills to complex problems – individual, dyadic and family problems – conceptualized from a systemic perspective. Thus, it requires the advanced understanding of all competencies, both basic and advanced.

13.9   Summary

Judging by the volume of attention in the scientific and lay press, marriage has been and remains an extremely important social institution. It is one which definitely has challenges and inherent difficulties as well as rewards. Societal changes occur in the popularity and stability of marriage over time. Nevertheless, over 90% of the adults in the USA ultimately give it a try and, when successful, the union provides the basis for better psychological, physical, and financial health for partners, parents, and children alike. The field of marital therapy also has persisted as a method and profession to help distressed relationships improve partners' relationship satisfaction and functioning and/or to avoid relationship breakup. Although some marriages are inherently unhealthy for participants and should be dissolved, many suffer from self- and

relationship-defeating patterns of interaction that can be modified to provide the relationship quality that partners sought at the outset. The first part of this chapter provided a comprehensive overview of the clinical competencies which are necessary to recognize and assess relationship functioning and conceptualize couples' strengths and weaknesses in areas that may inform treatment, and seven evidence-based approaches to marital therapy that have been thoroughly developed over the past 4 decades. Compared to treatment outcomes for many other psychological problems, those for marital therapy generally are quite good. These approaches offer different insights into the potential mechanisms of action that may effect healthful outcomes for the couple.

The American Association for Marriage and Family Therapy (2004) has identified six core areas in which couple therapists should possess minimum competencies to practice: treatment decision making; assessment and diagnosis; treatment planning and case management; knowledge of evidence-based therapeutic interventions; and legal and ethical issues. As the couple therapist progresses in his or her professional development, shifts toward expert competency broaden toward mastery of supervision of other therapists; collaboration across relevant providers; and integration of cultural and contextual diversity issues of the couple. Credentialing, as through professional certification by the American Board of Couple and Family Psychology, offers an important mechanism by which professionals and clients alike may recognize a therapist's advanced level of expertise. However, at any stage of a practice career, the therapist must recognize that there is always room for improvement, not only in determining what components of various approaches work for which couples with which particular problems, but in developing innovative, integrative, accessible, and efficient services that are effective.

14 Organic Disorders

Karlee D. Fellner · John R. Reddon

Abstract: Organic mental disorders, in contrast to functional (i.e., psychological) disorders, have historically been defined as mental disorders that can be attributed to biological pathology. Disorders that were classified as organic mental disorders in previous editions of the DSM have been divided into three separate sections in the DSM-IV: (1) Delirium, Dementia, and Amnestic and Other Cognitive Disorders; (2) Mental Disorders Due to a General Medical Condition; and (3) Substance-Related Disorders. Organic mental disorders may be classified as either acute or chronic based on duration, abruptness on onset, and defining symptoms. Proper assessment and diagnosis of organic disorders is essential, as leaving them untreated may lead to further deterioration or premature death. The majority of organic disorders are maintained by the underlying biological cause, and therefore require medical treatment to ameliorate the condition. However, a biopsychosocial approach to treatment is required to address all symptoms, particularly as organic disorders often have affective and relational consequences as well. Psychotherapy and cognitive rehabilitation strategies have been shown to be effective with a variety of acute and chronic organic disorders. Although therapeutic interventions with chronic degenerative conditions, such as Alzheimer's dementia, cannot produce permanent change, they can optimize the person's functioning and increase quality of life. In other cases, such as moderately severe amnesia, memory functions that have been compromised may be recovered through neuro-rehabilitation. Each individual (i.e., case) is unique and depends not only on the physical factors involved but also on personal, relational, and contextual features. Thus, clinicians that practice with this heterogeneous population need considerable knowledge and clinical experience which should include competence in geropsychology and neuropsychology as well as rehabilitative and psychotherapeutic procedures.

14.1 Overview

Organic mental disorders have traditionally been defined as mental disorders that result from underlying physical processes, distinct from "functional" disorders, which are considered to be psychological in origin (Lipowski, 1984; Spitzer et al., 1992). This dichotomy originated with acceptance of Cartesian dualism in the seventeenth century (Spitzer et al.). From this emerged two separate classes of psychiatry: one emphasizing the anatomy and physiology of the brain, and the other the unconscious mind and other mental phenomena (Spitzer et al.). The DSM-I included a section titled "organic brain disorders" [sic], which consisted of acute (reversible) and chronic (irreversible) classifications (American Psychiatric Association [APA-psychiatry], 1952). The DSM-II renamed the disorders "organic brain syndromes" [sic], which were subdivided into psychotic and nonpsychotic, and further narrowed down as acute (reversible) or chronic (irreversible; APA-psychiatry, 1968). Both sources defined the essential feature of these disorders as "basic organic brain syndrome" [sic] – a unitary clinical picture characterized by global cognitive impairment (Lipowski, 1980, 1984; Seltzer & Sherwin, 1978). These approaches

were very restricted, and led to invalid prognoses and inadequate treatments, especially with regard to the chronic/irreversible versus acute/reversible distinction (Lipowski; Seltzer & Sherwin). The DSM-III expanded the definition of an organic disorder from "basic organic brain syndrome" [sic] to "psychological or behavioral abnormality associated with transient or permanent dysfunction of the brain" (APA-psychiatry, 1980, p. 101). With this revision, the distinctions between psychotic/nonpsychotic and reversible/irreversible were abolished. It was recognized that symptoms consisted of more than cognitive impairment, and that they may even manifest in a similar manner to nonorganic syndromes (Lipowski). Since that time, there has been debate over the appropriateness of the term "organic disorders," and with the release of the DSM-IV in 1994, it was abolished altogether. It has been argued that the use of this term implies that "functional disorders" do not have an organic basis; in other words, that symptomatically nonorganic problems should not be investigated for organic etiology (Hays, 1985; Kopelman & Fleminger, 2002; McEvoy, 1981; Spitzer et al.). Because organic disorders may manifest as functional syndromes, this prevents proper diagnosis and deprives the client of necessary treatment (Hays; McEvoy; Spitzer et al.; Taylor, 2007). Classifying a patient as having either an organic or functional issue may bias professionals' conceptualization of the syndrome, leading to erroneous diagnosis and treatment (Drossman, 2006; Spitzer et al.). The term "organic disorders" is also problematic in that it implies that biological processes do not contribute to nonorganic disorders, though we now know that this is not true (Kopelman & Fleminger; Spitzer et al.). What were once called "organic disorders" are now divided into Delirium, Dementia, and Amnestic and Other Cognitive Disorders; Mental Disorders Due to a General Medical Condition; and Substance-Related Disorders in the DSM-IV (APA-psychiatry, 2000). Despite this, the term "organic disorder" will be used throughout this chapter for ease of reference to these categories.

Organic mental disorders may be classified as either acute or chronic based on duration, abruptness of onset, and defining symptoms. Acute reactions have an abrupt onset, and the majority of them can be reversed when the organic pathology is treated. The most important diagnostic feature in acute conditions is impairment of consciousness, namely deficits in memory, thinking, and attention. Chronic disorders, on the other hand, are marked by general cognitive impairment that may initially manifest as changes in behavior. They have a more gradual onset than acute reactions, and they are typically the result of widespread affections of the brain, although some may be localized. It is sometimes difficult to distinguish between acute and chronic disorders, and there is the possibility for an acute condition to develop into a chronic condition over time (Lishman, 1998; also see the forthcoming revision of this text by David, Fleminger, Kopelman, Lovestone, & Mellers, 2009).

The primary change in acute organic reactions is impairment of consciousness, which may range from slight clouding of awareness to severe coma. This may include difficulty in judging time, focusing attention, or thinking clearly. Disruptions in sleep are also present in most cases. These impairments often fluctuate, typically worsening at night, a characteristic that distinguishes an acute reaction from a chronic one. As impairment of consciousness increases, motor behavior tends to deteriorate, and emotionality progresses to a flat affect. In a minority of cases, the opposite occurs – hyperactivity, boisterousness, and repetitive, purposeless behavior accompanied by affective disturbances such as depression, paranoia, fear, and anxiety. Logic and reasoning also become impaired, and subjective reality supersedes external reality in the person's consciousness. Delusions may become a part of this reality, the most common being persecutory ideation. Disordered perception is common in acute

reactions, often resulting in depersonalization and difficulty in accurately perceiving auditory and visual stimuli. The most common perceptual disturbances are visual hallucinations. Registration, retention, and recall of information may also be impaired. Upon recovery from the condition, there is often an amnesic gap with vivid memory of sensory impressions, particularly hallucinations. In its early stages, an acute organic reaction may present with features seen in phobia, depression, hypochondriasis, conversion disorders, and schizophrenia (Lishman, 1998).

The majority of chronic organic disorders emerge gradually without an obvious precipitating incident, although some cases follow acute episodes such as anoxia or trauma. The earliest signs of chronic organic disorder are typically seen in deterioration of memory or more general intellectual impairment, particularly in terms of abnormal behaviors, loss of initiative, and episodes of confusion. If these changes are not obvious right away, one may notice changes in personality such as inappropriate social behaviors or exaggeration of preexisting personality traits. As the condition progresses, reduced concentration, decreased ability to pursue decisive action, and mental fatigue become evident. Thinking is slowed, and logic and abstract reasoning are impaired. Judgment is impaired, and the person typically does not have insight into his or her condition. Disorientation to time typically occurs early on, while disorientation to place and person occurs later in the illness. Memory deficits are usually global, involving impairment of registration, retention, and recall. Memory for names and past events may become disorganized as well, and confabulation often occurs. As with acute organic reactions, persecutory delusions and paranoia may become part of the person's reality. Poverty of speech is typically manifested in perseveration, reduced vocabulary, and poor sentence construction. In the later stages of the illness, the person may become mute or express only selected words. Hygiene and continence tend to deteriorate. Early in the course of the illness, agitation, anxiety, depression, anger, confusion, and suspicion are often seen. As the condition worsens emotions become shallow and flat, at times characterized by periodic outbursts of laughing, anger, or crying (Lishman, 1998).

Disorders that were previously classified as organic mental disorders have been divided into three separate sections in the DSM-IV: (1) Delirium, Dementia, and Amnestic and Other Cognitive Disorders; (2) Mental Disorders Due to a General Medical Condition; and (3) Substance-Related Disorders. The first group of disorders is characterized by a significant change in cognitive functioning that is due to a general medical condition, a substance, or a combination of these. The second section describes mental disorders that are the physiological result of a general medical condition. Finally, substance-related disorders are caused by taking medication, ingesting drugs or alcohol, or exposure to toxins. This section of the DSM includes two categories: Substance-Induced Disorders and Substance Use Disorders. This chapter does not cover Substance Use Disorders because they do not fall under the category of organic mental disorders (APA-psychiatry, 2000).

14.2   Recognition of Symptoms and Their Assessment

One of the most challenging aspects of working with clients with psychological or physical disorders is correctly diagnosing the condition. Many organic disorders are manifested in behavioral, mental, and emotional symptoms that are commonly associated with psychological disorders (Taylor, 2007). Although most clients who present for assessment and/or treatment

have psychosocial issues, clinicians must be careful to assess for, and rule out, organicity (Taylor), as failure to recognize an organic disorder may lead to severe deterioration or even death (Dilsaver, 1992). The current section provides an overview of organic disorders and their symptoms as defined by the DSM-IV-TR (APA-psychiatry, 2000), and then focuses on the assessment and diagnosis of these conditions.

Delirium. Delirium is the most clinically severe acute organic disorder (Goodwin & Guze, 1996). A diagnosis of delirium requires a disturbance in consciousness and a change in cognition that is not accounted for by dementia. Deliria are usually of rapid onset and are directly caused by medication, substance intoxication or withdrawal, toxin exposure, a general medical condition, or a combination of these. The client experiencing delirium will find it difficult to focus or shift attention, and may perseverate on ideas. Common cognitive deficits include impaired memory, disorientation to time or place, perceptual disturbances, and speech or language impairments. The disturbance of consciousness, rapid onset, and fluctuation in symptom severity throughout the day distinguish delirium from dementia (APA-psychiatry, 2000; Broshek & Marcopulos, 1999).

Dementia. Most cases of dementia are the result of brain disease or loss of brain tissue (Goodwin & Guze, 1996). Dementia is diagnosed based on the presence of multiple cognitive deficits, including memory impairment and at least one of agnosia (inability to identify or recognize objects), aphasia (degeneration of language), apraxia (difficulty executing motor activities), or disturbed executive functioning (decline in abstract reasoning and difficulty with planning and completing complex behavior) (APA-psychiatry, 2000). Clients with dementia may initially present with somatic complaints or depressive symptoms (Goodwin & Guze). These symptoms are of gradual onset and are the result of a general medical condition or the continuing effects of substance use, or both. Memory impairment is first observed in the client's difficulty learning new material. He or she then forgets recent memories, eventually forgetting earlier ones. These symptoms significantly impair the person's social or occupational functioning (APA-psychiatry; Perez Riley, 1999). The DSM-IV further differentiates between ten subtypes of dementia based on etiology, such as Alzheimer's dementia, vascular dementia, and dementia due to head trauma (APA-psychiatry), with 60–80% of the cases being Alzheimer's (Pelton, 2003). Each type of dementia has unique features with implications regarding prognosis and treatment (O'Donnell, Molloy, & Rabheru, 2001; Perez Riley, 1999).

Amnestic Disorders. Amnestic disorders are characterized by memory impairment that is caused by substance use or a general medical condition. As with dementia, this deficit severely inhibits the client's social or occupational functioning, and shows a marked decline from his or her previous level of functioning. Learning and recall of new information is always impaired, whereas ability to recall previously learned information depends on the extent of the brain damage. In the early stages of development, symptoms associated with delirium, such as disorientation and confusion, may be evident, but these typically diminish over time. Amnestic disorders are distinguished from deliria through the ability to shift and focus attention, and from dementias through the absence of additional cognitive deficits (APA-psychiatry, 2000).

Mental Disorders Due to a General Medical Condition. Mental disorders due to a general medical condition are the direct physiological result of such a condition, as determined through laboratory tests, history, or physical examination. Although it may be difficult to link a disorder directly to a medical condition, evaluation of a number of factors can help this: a temporal association between psychiatric symptoms and onset, remission, or exacerbation of a medical

condition, presence of features not typical of the primary disorder, and remission of medical and psychiatric symptoms with treatment of the medical condition. The DSM-IV distinguishes between ten disorders that may be due to a general medical condition, including personality change, psychosis, sexual dysfunction, catatonia, and, delirium, dementia, and amnestic disorders (APA-psychiatry, 2000).

Substance-Induced Disorders. Substance-induced disorders are the result of toxin exposure, ingestion of a drug of abuse, or side effects of medication. The DSM-IV identifies 12 categories of substances that may cause a substance-induced disorder, such as alcohol, amphetamines, caffeine, cannabis, nicotine, opioids, sedatives, and polysubstances. Substance intoxication and withdrawal are common to each substance but nicotine does not cause intoxication. Symptoms are substance-specific, and in order to be diagnosed, there must be clinically significant impairments in functioning. These syndromes are temporary, and symptoms remit at some point after discontinuation of substance use. Substance-specific descriptions are provided in the DSM. Other substance-induced disorders are categorized in the DSM-IV according to the nature of their symptoms, for example, sexual dysfunction, mood disorder, dementia, and psychotic disorder (APA-psychiatry, 2000).

Accurate assessment and diagnosis are vital with clients with organic disorders, as some of these conditions may lead to further decline or death if left untreated (Broshek & Marcopulos, 1999; Dilsaver, 1992; Lishman, 1998). Unfortunately, this is often complicated, as symptoms of organic conditions often closely resemble those of psychological disorders. Some of the more common symptoms include paranoid delusions associated with schizophrenia, depression, mania, anxiety, obsessions and compulsions, and violent behavior (Goodwin & Guze, 1996; Lishman; Taylor, 2007). Further complicating this, there may be losses and stressors in the person's life that the clinician may mistake for playing an etiological role in a psychosocial dysfunction. Psychological and organic disorders may also coexist. Therefore, when a client with a psychiatric history presents with new symptoms, they must be assessed independently as they may not be of psychological origin (Taylor). These disorders may also interact and affect symptom presentation (Sullivan, 1990).

Beyond overt presenting symptoms, there are several subtle characteristics that differentiate organic from psychological disorders (Dilsaver, 1992; Goodwin & Guze, 1996; Lishman, 1998; Taylor, 2007). A disorder is more likely to be organic than psychosocial, if onset of the first episode is after the age of 40, there is no family or individual history of psychiatric illness, the client has a systemic disease, the client is taking centrally acting drugs, the client exhibits disorientation or recent memory impairment, the client is experiencing epileptic fits, the client is not able to discriminate sensory input, there is a temporal association between the episode and withdrawal of a drug, the client is using a substance of abuse, the client has an autonomic dysfunction, the client is experiencing nonauditory hallucinations, the client's reasoning abilities have diminished, or if the client was functioning well prior to symptom onset (Dilsaver; Goodwin & Guze; Lishman; Taylor). Taylor has also indicated seven situations in which organicity should be assumed until proven otherwise: the client has suffered a head injury, has noticed a change in his or her headache pattern, is experiencing visual disturbances such as double vision, has speech deficits such as dysarthria or aphasia, has difficulty with balance and changes in gait, has sustained deviations in vital signs such as heart rate, or is experiencing changes in consciousness such as drowsiness and lapses. Differential diagnosis among the organic disorders themselves may also be complicated and ambiguous, but is essential for treatment planning (Zarit & Zarit, 2007). The reader is encouraged to consult the DSM-IV-TR

(APA-psychiatry, 2000) and Lishman for specific details on differentiating among organic disorders and between organic and psychological disorders.

Given the challenges presented in accurate diagnosis of organic disorders, very thorough clinical assessment procedures need to be carried out. Throughout assessment, the clinician must attend to the client's appearance, general behavior, mood, and thought content (Howieson & Lezak, 2008; Lishman, 1998; Taylor, 2007). History taking from both the client and others in the client's life is essential, and is often the key to determining whether a disorder is organic or psychological in origin (Campbell, 2000; Dilsaver, 1992; Goodwin & Guze, 1996; Howieson & Lezak; Lichtenberg & Duffy, 2000; Lishman; Taylor). In addition to narrowing down the diagnosis, obtaining a detailed history also guides further assessment procedures, gives a context in which to interpret test results, provides an opportunity to assess the client's perceptions and nonverbal behaviors, and helps determine the appropriate treatment direction (Dilsaver; Goodwin & Guze; Lishman; O'Donnell et al., 2001; Strauss, Sherman, & Spreen, 2006; Taylor). It is important to look at the client's past medical history, particularly for diseases associated with psychosis, as well as family medical and psychiatric history, as many organic disorders have a genetic basis (Campbell; Dilsaver; Goodwin & Guze; Lishman; Strauss et al., 2006). Recent and past use of alcohol, drugs, and medications needs to be discussed, particularly in terms of any temporal relation between use and the onset of the disorder (Campbell; Dilsaver; Lishman; Strauss et al., 2006). For detailed instructions regarding interviewing and history taking refer to Strauss et al.

A complete neuropsychiatric evaluation is time-consuming and expensive. Therefore, when time or resources are limited, brief screening tests may be used. These tests may facilitate differential diagnosis, allowing more prompt and effective treatment (Serper & Allen, 2002). Some simple tests that, if positive, indicate organicity are likely to include the Write-a-Sentence Test (assesses global brain dysfunction), the Draw-a-Clock Test (assesses visual-spatial ability and ability to write sequential numbers and tell time), and the Copy-a-Three-Dimensional-Figure Test (assesses spatial appreciation; Taylor, 2007; Zarit & Zarit, 2007). Brief cognitive screening tools that may be used include the Standardized Mini Mental Status Examination (SMMSE; Molloy, 1999) and the Modified Mini Mental Status Examination (3MS; Teng & Chui, 1987), the Neurobehavioral Cognitive Status Examination (COGNISTAT; Kiernan, Mueller, Langston, & Van Dyke, 1987), the Cognitive Capacity Screening Examination (CCSE; Jacobs, Bernhard, Delgado, & Strain, 1977), the High Sensitivity Cognitive Screen (HSCS; Fogel, 1991) which may detect mild impairments, and the Repeatable Battery for the Assessment of Neuropsychological Status (RBANS; Randolph, 1998), which is suitable for more severely impaired clients (Serper & Allen; Strauss et al., 2006; Zarit & Zarit). Despite the utility of these instruments, the clinician must pursue further evaluation, if there is ambiguity regarding diagnosis.

When diagnosis remains unclear after the interview and screening, the client should be referred for physical and neurological examinations (Dilsaver, 1992; Lishman, 1998; Taylor, 2007). Examinations often identify etiology and guide treatment (Boutros, Thatcher, & Galderisi, 2008; Howieson & Lezak, 2008; Lishman). A medical examination may confirm organicity; however, clinicians are cautioned not to disregard evidence of organicity if the patient has been medically cleared, as signs of organic etiology may be missed, especially early on (Taylor). Physical signs that are important to watch for are listed in Lishman. Ancillary investigations are often required as well, including procedures such as electroencephalography (EEG), radiography, computerized axial tomography, and magnetic resonance imaging (Boutros et al., 2008; Lishman). If the diagnosis is still unclear, the client should undergo a

neuropsychological assessment (NPA; Campbell, 2000). NPA is the best way to assess cognitive impairments resulting from damage to brain tissue (Manning, 2001). It involves a report of impaired and preserved cognitive functions, and may distinguish between organic and psychological symptoms. Furthermore, it may detect subtle neurological deficits in the early stages of the illness, when other tests, such as medical exams, fail to find any evidence of dysfunction (Manning). A complete assessment should examine orientation, attention and concentration, memory, intelligence, general knowledge, conscious awareness, affect, language functions, verbal fluency, and visuospatial and constructional abilities (Campbell; Howieson & Lezak; Lishman; Manning; Taylor).

Neuropsychological testing is unique in that it involves comparing the client's current functioning with the estimated level of premorbid functioning, as well as comparing his or her current functioning in different areas (Howieson & Lezak, 2008; Zarit & Zarit, 2007). Some of the cognitive tests that are commonly used include the Dementia Rating Scale-2 (DRS-2; Jurica, Leitten, & Mattis, 2001), the Delirium Rating Scale (DRS; Trzepacz, Baker, & Greenhouse, 1988), the Wechsler Adult Intelligence Scale-III and the Wechsler Memory Scale-III (Psychological Corporation, 2002), the Bender–Gestalt Test (Bender, 1938), the Kaplan Baycrest Neurocognitive Assessment (KBNA; Leach, Kaplan, Rewilak, Richards, & Proulx, 2000), the National Adult Reading Test-2 (NART-2; Nelson & Willison, 1991), the Boston Naming Test (Kaplan, Goodglass, & Weintraub, 1983), and the Kendrick Cognitive Test for the Elderly (Kendrick, 1985). The Neuropsychological Assessment Battery (NAB; Stern & White, 2003) consists of modules assessing major functional domains important to NPA, and is appropriate for use with adults up to the age of 97 (Strauss et al., 2006). If a client is severely impaired, other screening tests such as the Severe Impairment Battery (SIB; Panisset, Roudier, Saxton, & Boller, 1994) may be used to prevent a floor effect. There are several assessment instruments that focus specifically on different elements of cognition, executive function, personality and affect, conceptual functions, attention, memory, language, perception, and sensory and motor function (Howieson & Lezak; Lichtenberg, 1999a; Strauss et al.; Sultzer, 2000; Zarit & Zarit). For further information on these, the reader is encouraged to consult Strauss et al. and Lishman (1998).

It is important to keep in mind that people may perform poorly on these cognitive tests for a number of reasons aside from impairment, including education, cultural differences, language or hearing difficulties, or age (Campbell, 2000; Molloy, Darzins, & Strang, 1999; Perez Riley, 1999). Therefore, tests should be carefully selected based on characteristics of the particular client. For example, there are several brief assessment batteries that have been designed for use with an elderly population so as to avoid lengthy NPA batteries (Lichtenberg & Duffy, 2000). Similar or related abilities should be assessed with multiple measures to increase validity of test interpretation (Howieson & Lezak, 2008; Zarit & Zarit, 2007). Due to the difficulty of differential diagnosis, the extensive nature of NPA, and the immediate importance of identifying the disorder, assessment and diagnosis of organic disorders should ideally be carried out by a multidisciplinary team of experienced professionals (Broshek & Marcopulos, 1999).

14.2.1 Maintenance Factors in Organic Disorders

The factors that contribute to maintenance of an organic disorder depend largely on its primary etiopathology (APA-psychiatry, 2000). Chronic conditions are usually progressive, and

are maintained by the damage that has been done, as well as the further damage that typically occurs as a result. However, gradual improvement or a halt in degeneration may be obtained through treating the primary pathology or presenting symptoms (Lishman, 1998). Acute conditions are maintained by electrical, biochemical, or mechanical disturbances in brain function, and are typically resolved when the underlying pathology is treated (Lishman).

Delirium results from a dysfunction in neurotransmission, neuronal metabolism, or input from subcortical structures (Blass, Nolan, Black, & Kurita, 1991). There are a number of potential causes, such as primary central nervous system disorders, systemic disturbances, and drug or toxin exposure. Generally, delirium is maintained by its underlying cause. For example, delirium due to medication, such as anticholinergic drugs, benzodiazepines, or opiates, typically continues so long as the drug remains in the system (Trzepacz & Meagher, 2008). However, there are specific factors that may prolong an episode of delirium (Lishman, 1998; Trzepacz & Meagher). Medications, particularly pain medications and anticholinergic drugs, tend to aggravate the condition (Trzepacz & Meagher). Delirium lasts longer when there have been structural and degenerative changes in the brain, making older individuals, especially those with dementia, particularly susceptible (APA-psychiatry, 2000; Trzepacz & Meagher). Stressful environments and situations may also prolong or exacerbate symptoms (Tune, 2000; Zarit & Zarit, 2007). As well, multiple etiologies often occur serially or concurrently, which generally increases the length of the episode. Recovery is faster when the underlying etiological factor is corrected or self-limited (Trzepacz & Meagher).

In most cases, dementia is a chronic degenerative condition maintained by the progressive loss of neurons in the brain (Lishman, 1998; Trzepacz & Meagher, 2008). However, depending on the etiology, dementia may also be static or may even remit (APA-psychiatry, 2000; Lishman, 1998). The most common form, Alzheimer's dementia, is a progressive neurodegenerative condition caused by the accumulation of specific proteins in the brain (APA-psychiatry; Trzepacz & Meagher). In addition to the primary effects, this also sets off other neurological events that contribute to additional damage, eventually leading to death (Zarit & Zarit, 2007). In vascular dementia, the damage resulting from hemorrhages or ischemia is permanent, but further degeneration may be prevented by treatment of the vascular disease and hypertension (APA-psychiatry; Reichman, 2000; Trzepacz & Meagher). The majority of dementias due to general medical conditions, such as HIV, Huntington's, and Parkinson's disease, are progressive. However, some may be static or show improvement, such as dementia due to head injury if there is only one incident of injury (APA-psychiatry; Lishman; Trzepacz & Meagher). Dementia may be exacerbated by factors such as high levels of psychological stress, ingestion of certain medications, or the existence of comorbid health or psychological issues, such as depression (Trzepacz & Meagher; Zarit & Zarit). In cases where the dementia is a result of a treatable problem, such as nutritional deficiency, hypothyroidism, or toxin exposure, the dementia typically worsens so long as the etiological source is present; alleviation of the original cause may stop progression of the dementia, and possibly partially reverse it (Zarit & Zarit).

Amnesia may result from a variety of factors, such as head injury, medical conditions, substance use or abuse, electroconvulsive therapy, and strokes (APA-psychiatry, 2000; Trzepacz & Meagher, 2008). The duration of amnesia depends on the underlying primary pathology (APA-psychiatry). The neural mechanisms underlying memory are unclear, and theories up to this point are incomplete and speculative (Eslinger, Zappala, Chakara, & Barrett, 2007; Lishman, 1998), although it has been established that in cases of brain injury, longer amnestic episodes are associated with more hemispheric lesions (Trzepacz & Kennedy, 2005). As well, damage to

middle-temporal lobe structures appears to cause persisting impairments in declarative memory (APA-psychiatry; D'Esposito, 2000). On average, amnestic disorders due to brain injury last longer than those due to other causes, perhaps due to the extent of the damage (Trzepacz & Kennedy). With concussions, anterograde amnesia may last a few seconds to several hours, although it rarely exceeds a day. Retrograde amnesia typically "shrinks" over time (Collins, Iverson, Gaetz, & Lovell, 2007). Amnesia following mild traumatic brain injury typically lasts less than 30 min (Iverson, Lange, Gaetz, & Zasler, 2007). With more severe brain trauma, amnesia may last a few minutes to months after the injury. In these cases, memory usually improves gradually over time (Eslinger et al., 2007). Older clients experience longer episodes of amnesia than younger ones, implicating the role of age in the maintenance of these disorders (Trzepacz & Kennedy). As with the other organic disorders, if the primary cause is addressed, amnesia may be ameliorated.

Specific maintenance factors associated with disorders due to a general medical condition depend on the individual case, as there are a variety of medical conditions that may be involved, as well as several different symptom presentations. In general, these disorders are maintained by the persistence of the underlying medical condition. If the medical issue is addressed, the disorder may subside, although some conditions lead to permanent neurological damages that maintain the disorder (APA-psychiatry, 2000).

Substance-induced disorders are maintained by the immediate or residual effects of the substance on the central nervous system, and thus typically disappear at some point after exposure to the substance is discontinued (APA-psychiatry, 2000; Lishman, 1998). However, some substances cause permanent changes to the function and/or structure of the nervous system (Doctor, 2008). Effects of the substance on the person are highly dependent on the individual, the type of substance, particularly in regard to mechanisms of action and half-life, and the length of exposure to it (APA-psychiatry; Doctor). For example, if one is exposed to certain nerve agents, symptoms are maintained for prolonged periods because acetylcholinesterase has been completely inactivated, and it takes a significant amount of time to regenerate the enzyme. With a condition caused by carbon monoxide poisoning, symptoms are maintained by high levels of carboxyhemoglobin, which is eventually reduced by supplemental oxygen (Doctor). With drugs of abuse, during the time of use, they influence the brain by interacting with specific neurotransmitter receptors or affecting the quantity of neurotransmitter present at the synapse (Nestler & Self, 2008). Therefore, so long as these chemicals remain in the brain symptoms will be observed. When drugs and alcohol are used repeatedly over time, protein synthesis and patterns of gene expression may be altered for extended periods, producing long-term symptoms (Nestler & Self). The three chronic substance-induced disorders are Substance-Induced Persisting Dementia, Substance-Induced Persisting Amnestic Disorder, and Hallucinogen-Persisting Perception Disorder (APA-psychiatry). Aside from those disorders, symptoms should resolve within 4 weeks after the cessation of withdrawal or intoxication symptoms (APA-psychiatry).

14.2.2 Evidence-Based Treatment Approaches

Historically, organic disorders have been treated as biological diseases distinct from functional disorders, which have been considered psychological in origin (Spitzer et al., 1992). However, through modern research and practice, it has become clear that there are complex interactions

between psychological and biological phenomena in both organic and functional illnesses (Spitzer et al.). In organic disorders, psychological and neurological factors typically interact to contribute to symptom presentation, and thus a biopsychosocial approach to the client is required for effective treatment (Drossman, 2006; Forrest, 2008). A detailed neuropsychological assessment provides key information about potential treatments and approaches (Howieson & Lezak, 2008). Treatments range from molecular pharmacotherapy to psychotherapeutic interventions (Horst & Burke, 2008). Because organic disorders have traditionally been viewed as medical issues, research on psychotherapeutic intervention is relatively limited, but has been shown to be very effective in many cases (Forrest).

Psychotherapy with Older Adults. Although organic conditions may be diagnosed at any age, the elderly are particularly susceptible to the development of these disorders (Lipowski, 1980, 1984; Seltzer & Sherwin, 1978; Taylor, 2007). Thus, it is important for the clinician to be aware of the unique aspects of psychotherapy with this population. According to Zarit and Zarit (2007), "geriatric-focused psychotherapy" [sic] involves paying particular attention to assessment, the treatment setting, preparing the client for therapy, goals of therapy, the therapeutic relationship, the role of family, and any medications and medical conditions. It is particularly important to discuss the client's past experiences in therapy, and his or her expectations of the current therapy, as older clients may have misconceptions about the process of therapy (Gallagher-Thompson & Thompson, 1996; Lewinsohn & Tilson, 1987; Zarit & Zarit). In establishing goals, the therapist should focus on supporting the client's autonomy as much as possible, and identifying the treatable aspects of his or her condition. Although the prognosis may be bleak, as with Alzheimer's dementia, there is much that the therapist can do to enhance strengths and increase the client's quality of life (Zarit & Zarit). Effective approaches are typically brief, structured, positively focused, and goal-oriented (Lewinsohn & Tilson; Teri & Logsdon, 1992). When counseling the elderly, it is more likely that family members will become involved in the process, and in the case of degenerative disorders they may also enter therapy to deal with the stress of caring for their loved one (Zarit & Zarit). The therapist may have to slow the pace of therapy, accommodate sensory deficits by presenting information in several modalities, and use written reminders to facilitate memory of details within and between sessions (Gallagher-Thompson & Thompson; Zarit & Zarit). Theoretical orientations typically used with the elderly include behavioral, cognitive-behavioral, psychodynamic, and family systems, in addition to some supportive counseling, psychoeducation, and relaxation (Gallagher-Thompson & Thompson, 1995; Teri & McCurry, 2000; Zarit & Zarit). Although pharmacotherapy may be important in addressing symptoms of organic disorder, potential damaging effects are unpredictable and dangerous, and thus clinicians should carefully monitor their clients' progress (Grossberg & Manepalli, 1995; Zubenko & Sunderland, 2000). Older clients are sensitive to the toxic effects of psychotropic medications in particular, and these medications tend to interact with neurological drugs that may be used to target biological issues (Dubovsky & Buzan, 2000; Grossberg & Manepalli). Where possible, then, supportive and behavioral interventions should be used instead of neuroleptics (Grossberg & Manepalli).

Cognitive Impairment. Cognitive deficits are common in many organic mental disorders (APA-psychiatry, 2000). The areas to be targeted in treatment are determined through a thorough neuropsychological assessment, and the etiology and prognosis will determine the individual treatment program and goals (Franzen & Lovell, 2008; Gordon & Hibbard, 2005; Pierson & Griffith, 2006). In many cases of cognitive impairment, an individualized cognitive rehabilitation program will be implemented. This typically involves a multidisciplinary team

and various techniques intended to increase functioning in specific daily activities (Belleville, 2008; Cicerone, 2007; Gordon & Hibbard; Pierson & Griffith; Ylvisaker, Hanks, & Johnson-Greene, 2002; Zarit & Zarit, 2007). Common interventions include cognitive remediation, stimulation, and training. Cognitive remediation is typically carried out by a psychologist and focuses on strategies to assist clients to complete daily tasks that are difficult due to the impairment (Cicerone; Gordon & Hibbard). Cognitive stimulation may be done in groups, and involves activities intended to increase general social and cognitive functioning (Belleville; Wenisch et al., 2006; Zarit & Zarit). Cognitive training is implemented individually or in small groups and involves specific, targeted exercises to increase cognitive functioning in activities of daily living (Belleville; Cicerone; Gordon & Hibbard; Zarit & Zarit). Interventions have been developed to address impairments in executive functioning, language, attention, visual perception, and memory (Bangirana, Idro, John, & Boivin, 2006; Cicerone; Franzen & Lovell; Gordon & Hibbard; Pierson & Griffith). Computer-assisted programs may be used to augment these techniques, and handheld computers may be used as compensatory aids to daily living (Bangirana et al., 2006; Franzen & Lovell; Gentry, 2008; Tesar, Bandion, & Baumhackl, 2005). When impairment is caused directly by brain injury, such as a stroke or physical trauma, the efficacy of cognitive interventions is not affected by the severity of the damage, although more damage slows the rate of learning (Gordon & Hibbard). The greater the intensity and duration of therapy, the greater the increase in cognitive functioning (Bode, Heinemann, Semik, & Mallinson, 2004; Gordon & Hibbard; Saxena, Ng, Yong, Fong, & Ko, 2006). To maintain benefits gained as a result of these cognitive interventions, clients should attend brief booster sessions as needed, and consult their therapists if they experience any significant changes in their daily lives (Gordon & Hibbard). Long-term psychotherapy should also be provided alongside cognitive interventions to provide education, promote awareness, and help with adjustment issues (Cicerone; Gordon & Hibbard; Ponsford, 2005). In addition, psychotherapy may be provided to address behavior problems associated with cognitive impairment (Benedict et al., 2000; Franzen & Lovell). Adequate nutrition and physical exercise have also been shown to be important in the enhancement of cognitive functioning, and thus should be addressed as part of the client's treatment regimen (Bangirana et al.; Pierson & Griffith). For more information on evidence-based cognitive rehabilitation strategies, see Cicerone.

Delirium. Delirium is a dangerous condition, as it is associated with high mortality rates. Research has been done on the prevention of delirium, particularly in the elderly who have higher prevalence rates of the disorder (Inouye et al., 1999; Trzepacz & Meagher, 2008). Inouye et al. implemented a prevention program targeting six risk factors for delirium in hospitalized elders: hearing impairment, sleep deprivation, visual impairment, cognitive impairment, dehydration, and immobility. The program decreased the incidence of delirium, as well as the duration of the episodes that did occur (Inouye et al.). Preoperative patient preparation and education have also been shown to be helpful in reducing rates of delirium (Trzepacz & Meagher). Postoperative passive music therapy may reduce the incidence of delirium in elderly patients (Trzepacz & Meagher). Primary prevention is the most effective strategy in reducing the frequency and complications associated with delirium (Inouye, 2006; Inouye et al.).

Timely identification and treatment of delirium are vital. The immediate priority is for medical professionals to determine the underlying cause of the delirium and treat it (Rabins, 1991; Trzepacz & Kennedy, 2005; Trzepacz & Meagher, 2008; Zarit & Zarit, 2007). In addition, environmental manipulation, treatment of behavioral symptoms, and psychosocial support for the client and family should be implemented (Inouye, 2006; Trzepacz & Kennedy;

Trzepacz & Meagher; Tune, 2000). If the physician is able to identify and alleviate the underlying etiology, delirium will subside, although recovery may be slow (APA-psychiatry, 2006; Inouye; Rabins; Zarit & Zarit). However, if the underlying source cannot be determined, the patient should be kept in a calm, dim lit room on close observation for 12–24 h, and may be given an antipsychotic to assist with relaxation (APA-psychiatry; Inouye; Zarit & Zarit). During the episode, the patient should be kept on close observation by medical staff, particularly in regard to fluids, vital signs, and oxygen level (APA-psychiatry; Inouye). Patients, their families, and other staff members should also be educated about the current delirium and its expected course (APA-psychiatry; Rabins; Trzepacz & Meagher). Manipulating the environment to be calming and reassuring may prevent worsening of the condition. This may be achieved through changing lights to cue day and night, using orienting items such as calendars, correcting auditory and visual impairments, regulating stimulation, and having familiar objects and people present (APA-psychiatry; Inouye; Rabins; Trzepacz & Kennedy; Trzepacz & Meagher; Tune; Zarit & Zarit). Patients should be reassured that their condition will pass, and should be reoriented frequently (APA-psychiatry; Rabins; Trzepacz & Meagher; Tune). Psychological interventions that can decrease cognitive disturbance include explaining of recent events, clarifying misperceptions, repeating information, and validating real events (Broshek & Marcopulos, 1999; Tune). To deal with affective reactions, the clinician may reduce feelings of isolation, acknowledge affect, encourage realistic hope, emphasize familiarity, and help the patient gain a sense of control (Broshek & Marcopulos). In some cases, electroconvulsive therapy may also be used to treat a delirium (APA-psychiatry; Coffey & Kellner, 2000; Dubovsky & Buzan, 2000). Physical restraints and pharmacotherapy should be avoided, as they may exacerbate the delirium, and may have particularly adverse effects in the elderly (Inouye; Rabins; Zarit & Zarit). However, if the person is a danger to themselves or others, antipsychotics may be used to ease the symptoms, except in the case of delirium due to alcohol withdrawal, where benzodiazepines would be prescribed (Dubovsky & Buzan; Rabins; Trzepacz & Meagher). It is important to note that management of a delirious patient is specific to the etiology, and thus treatments must be tailored to the individual case (APA-psychiatry). Once delirium has subsided, support should be provided to help the client adjust to what has happened and educate him or her on how to minimize risk of a future episode (APA-psychiatry; Inouye; Trzepacz & Meagher). Depression or posttraumatic stress disorder following the delirium may also need to be addressed (Trzepacz & Meagher).

Dementia. With development of medications that may slow the degenerative process of dementia, there is increasing emphasis on early diagnosis and intervention (Ritchie & Portet, 2006; Zarit & Zarit, 2007). Identification of Mild Cognitive Impairment (MCI), early-stage cognitive decline that may develop into dementia, also allows practitioners to work with the client and family members on coping skills and future planning that facilitates prevention of predictable problems that typically accompany dementia (O'Donnell et al., 2001; Vance & Burrage, 2006; Wenisch et al., 2006; Zarit & Zarit). When possible, clinicians should work with both clients and caregivers, individually and together in sessions, to educate them about the illness and address issues such as coping with memory loss, relationship changes, and feelings of grief (Miller & Reynolds, 2006; Zarit, Femia, Watson, Rice-Oeschger, & Kakos, 2004; Zarit & Zarit). A strong relationship with the caregiver(s) is vital, as with the progression of the dementia, it will be increasingly important to maintain therapy with them. If the client does not have social support, the therapist must obtain appropriate support that is in the best interests of the client (Zarit & Zarit). The primary goal of therapy with the client with MCI is to enhance

communication skills and decrease dysfunctional behavior, improving social interactions and self-image (O'Donnell et al.). Cognitive-behavior therapy has been shown to be efficacious in increasing quality of life and decreasing comorbid mood disorders such as depression and anxiety in clients in the early stages of dementia (Laidlaw, Thompson, Dick-Siskin, & Gallagher-Thompson, 2003; Scholey & Woods, 2003; Thompson, Wagner, Zeiss, & Gallagher, 1990). Programs such as cognitive stimulation, remediation, and training may be used to optimize cognitive functioning and delay decline (Belleville, 2008; Savorani et al., 2004; Wenisch et al.; Zarit & Zarit). Promotion of healthy habits, such as proper nutrition and abstinence from substance use, may reduce cognitive degeneration (Vance & Burrage). Memory strategies can also be used to preserve daily functioning (Troyer, Murphy, Anderson, Moscovitch, & Craik, 2007). Group therapy for clients that have been diagnosed with early-stage dementia has been shown to be beneficial for coping and decreasing feelings of isolation (Zarit et al., 2004; Zarit & Zarit). Reminiscence on intact memories encourages self-esteem, and an overall focus on the here and now promotes development of coping strategies (Zarit & Zarit). Group therapies with both clients and caregivers have also been shown to increase quality of life and decrease family conflict (Logsdon, McCurry, & Teri, 2006; Zarit et al.). Research into pharmacological primary prevention based on known risk factors and biomarkers, particularly for Alzheimer's dementia, is on the rise, and will hopefully decrease the prevalence of this disease in the years to come (Cummings, Doody, & Clark, 2007).

Traditionally, psychotherapy with clients who have dementia has been regarded as ineffective, particularly as it cannot arrest the course of the illness (Lichtenberg & Duffy, 2000; Zarit & Leitsch, 2001). However, advances in psychotherapy research with these clients have revealed benefits of several forms of therapy, including memory training, aromatherapy, validation therapy, pet therapy, milieu therapy, cognitive-behavior therapy, visual imagery and art therapy, reminiscence therapy, touch and massage therapy, cognitive rehabilitation, reality orientation, speed feedback therapy, music therapy, and environmental manipulation (Abraham, Neundorfer, & Currie, 1992; Desai & Grossberg, 2005; Forrest, 2008; Laidlaw et al., 2003; Lichtenberg & Duffy; O'Donnell et al., 2001; Ootani, Nara, Kaneko, & Okamura, 2005; Savorani et al., 2004; Teri & McCurry, 2000; Wilkins & Carr, 2000; Zarit & Zarit, 2007). As with MCI, cognitive rehabilitation programs may be used to enhance cognitive function (Belleville, 2008; Zarit & Zarit). With later-stage dementia, cognitive techniques become less relevant, but affective orientations may still be beneficial. Although verbal exchanges may be lacking in logical content, they can be emotionally meaningful to the client (Forrest; Lichtenberg & Duffy; Werezak & Morgan, 2003). Interactions with the individual should be supportive and involve aspects like humor and empathy (Werezak & Morgan). Identifying activities that are pleasant to the client is important in maintaining quality of life, and in severe clients may be assessed using the Pleasant Events Schedule-AD (PES-AD; Teri & Logsdon, 1991). In most cases, behaviorist techniques, particularly classical conditioning, reduce behavioral problems, and support coping skills and activities of daily living (Lichtenberg, 1999b; Lichtenberg & Duffy; Logsdon, Teri, & McCurry, 2006; O'Donnell et al.; Teri, 1996; Teri, Huda, Gibbons, Young, van Leynseele, 2005; Zarit & Zarit). The focus of treatment is contributing to temporary gains in mood, daily functioning, and behavior (Zarit & Leitsch). The physical and psychosocial environment has been shown to be very important for functioning and quality of life in people with severe dementia. Physical layout of living space should include memory aids and promote orientation and wayfinding; private space should be cognitively stimulating and personalized (Forrest; O'Donnell et al.; Werezak & Morgan, 2003). Setting up a positive environment like this reduces the need

for physical and chemical restraints (O'Donnell et al.; Werezak & Morgan). See Thomas (1996) for a description of The Eden Alternative, a conceptual framework for creating institutional settings that are comfortable and home-like (Tavormia, 1999). Group therapy is also effective with dementia patients, and is conducive to expressive therapies like music and art (Abraham et al., 1992; Lichtenberg & Duffy). Pharmacologically, cholinesterase inhibitors are the preferred form of treatment of cognitive impairment, although not all dementias are associated with degeneration of cholinergic markers (Apostolova & Cummings, 2008; Desai & Grossberg; Dubovsky & Buzan, 2000; Holtzheimer, Snowden, & Roy-Byrne, 2008; Lerner & Riley, 2008; Olazaran et al., 2004; Ritchie & Portet, 2006; Rongve & Aarsland, 2006; Wilkins & Carr; Zarit & Zarit). Psychotropic medications for reducing agitation and behavioral difficulties have had mixed results in terms of efficacy, and nearly always contribute to further cognitive and motor decline, and should be avoided where possible (Apostolova & Cummings; Dubovsky & Buzan; Holtzheimer et al., 2008; Zarit & Zarit). If medication is necessary, atypical antipsychotics may be considered to treat these symptoms, as they tend to have fewer side effects (Apostolova & Cummings; Holtzheimer et al.; Zarit & Zarit). Regardless of the approach to treatment, it is important that the practitioner recognizes that at best, outcomes may consist of only modest gains or delay of further decline (Zarit & Leitsch).

Family therapy and caregiver education are very important when working with clients with dementia, as caregivers play a large role in treatment, and this disorder often upsets the balance of relationships (Apostolova & Cummings, 2008; Forrest, 2008; Lichtenberg & Duffy, 2000; Miller & Reynolds, 2006; Teri & McCurry, 2000; Zarit & Leitsch, 2001). Caregivers generally experience physical, social, financial, and emotional losses; 90% report being emotionally affected, and 66% report depression (Desai & Grossberg, 2005). Therapy helps caregivers more effectively interact with the dementia client by increasing their well-being and promoting skill development in behavior management and coping. There also are interventions focused directly on helping the caregiver to support the dementia client, leading to more positive outcomes in patients, including delayed institutionalization (Apostolova & Cummings; Coon, Thompson, Steffen, Sorocco, & Gallagher-Thompson, 2003; Laidlaw et al., 2003; Logsdon et al., 2006; Teri, 1996; McCurry, Gibbons, Logsdon, Vitiello, & Teri, 2003; Mittelman, Roth, Haley, & Zarit, 2004; Teri et al., 2003; Teri, Logsdon, Uomoto, & McCurry, 1997; Teri & McCurry; Teri, McCurry, Logsdon, & Gibbons, 2005; Whitlatch, Zarit, Goodwin, & von Eye, 1995; Zarit & Leitsch).

Amnestic Disorders. In cases of amnesia that are due to reversible underlying etiologies, such as poisoning, malnutrition, and infections, amnesia typically subsides if the cause is properly treated by a physician (Taylor, 2007). In longer-term or permanent cases of amnesia due to head trauma and/or structural damage to the brain, symptoms may be reduced through rehabilitative techniques (APA-psychiatry, 2000; Franzen & Lovell, 2008). Internal strategies improve memory ability, whereas external strategies compensate for memory deficits through the use of aids (Dobkin, 2000; Franzen & Lovell; Troyer et al., 2007). Typically when one form of memory is impaired, another remains intact, and thus internal mnemonic strategies may be used to maximize utility of remaining skills (Cicerone, 2007; Franzen & Lovell). Visual imagery is commonly employed to assist in registration and retention of verbal information (Cicerone; Dobkin; Franzen & Lovell). Some techniques that may be used include peg mnemonics, the method of loci, and face–name association (Franzen & Lovell; Glasgow, Zeiss, Barrera, & Lewinsohn, 1977; Lewinsohn, Danaher, & Kikel, 1977). The efficacy of these strategies, however, is largely dependent on the nature of the brain damage as well as individual characteristics. Verbal mnemonic strategies may also be used with some clients, and involve exercises such as rhyming strategies,

spaced retrieval, and semantic elaboration (Cicerone; Franzen & Lovell; Troyer et al.). For clients who have difficulty registering written information, the PQRST approach may be used: Preview information, Question the information, Read actively, State the information over again, and Test retention by answering the questions that were written (Franzen & Lovell; Glasgow et al., 1977). Internal techniques are most effective in the long term, if there is contextual interference and intermittent, rather than constant, feedback throughout therapy (Dobkin). Cognitive rehabilitation involves both internal and external memory strategies designed to address attentional impairments, followed by impairments in encoding and recall of information (Dobkin). External memory aids may be used to compliment internal exercises, or may be used in place of them with clients with severe amnesia. Strategies should be practical and aimed at daily activities, as the goal of such techniques is to support daily functioning (Cicerone; Troyer et al.). Memory storage may be achieved through keeping a memory book that lists one's schedule of daily activities. Electronic storage devices such as personal digital assistants (PDAs) may also be used (Cicerone; Dobkin; Franzen & Lovell). External cues, such as timers and calendars, are very useful for informing the client when behaviors must be performed at a particular time (Cicerone; Dobkin; Franzen & Lovell; Troyer et al.). External strategies are most effective when the client is educated about them, followed up by initiation and maintenance of the new behaviors and recognized for the positive changes in his or her daily life (Troyer et al.). Studies have examined the efficacy of pharmacotherapy for memory impairment, and depending on the nature of the damage, some cholinergic and catecholaminergic medications have demonstrated reduction of attentional and memory deficits (Dobkin; McAllister, 2005). For any given memory intervention to be effective, there must be a thorough assessment to pinpoint the memory systems that need to be targeted, and interventions must be tailored to these and other individual characteristics (Glasgow et al.; Lewinsohn et al., 1977).

Mental Disorders Due to a General Medical Condition. Generally, treatment of mental disorders that result from an underlying medical condition is addressed by medical professionals. Once the cause has been alleviated, the disorder typically subsides. However, some disorders due to a general medical condition may have long-term or permanent effects, for example cognitive or memory dysfunction, the symptoms of which are usually addressed by mental health professionals (APA-psychiatry, 2000; Franzen & Lovell, 2008). Treatments of other disorders due to general medical conditions, for example sexual dysfunction, personality change, anxiety disorder, and mood disorder, are beyond the scope of this chapter. For more information on psychotherapy with clients with organic disorders, see Forrest (2008).

Substance-Induced Disorders. Treatment of substance-induced disorders is largely dependent on the particular case due to individual and environmental factors, the nature of the disorder, and the substance associated with the disorder (APA-psychiatry, 2006), although intoxication and withdrawal typically subside after removal of the substance from the system (Doctor, 2008). Depending on severity, clients experiencing symptoms of intoxication or withdrawal may require hospitalization to ensure appropriate treatment of medical symptoms (APA-psychiatry). Intoxicated clients should remain in a controlled environment with periodic reorientation, reassurance, reality testing, and decreased exposure to stimuli (APA-psychiatry). In the majority of cases, intoxication is self-limiting and will resolve naturally (APA-psychiatry). However, some substances are dangerous or may have been consumed in high doses, and may require removal from the body through methods such as gastric lavage and the administration of charcoal (Doctor). If necessary, drug effects may also be reversed by giving the client antagonists, or the client may be sedated if he or she is extremely agitated (APA-psychiatry). Specialized

medical treatments are often required in cases of toxin exposure (Doctor). Withdrawal symptoms may be treated pharmacologically with an agonist associated with the particular substance, as well as other medications that ease symptoms, such as benzodiazepines for alcohol withdrawal (APA-psychiatry). Withdrawal from particular substances, such as opioids, may require complex drug treatments and long-term agonist or antagonist treatments if there is a history of abuse (APA-psychiatry). Clients experiencing withdrawal should also be given reassurance and general support. As well, the patient and his or her family should be educated about substance use (APA-psychiatry).

Substance-related issues may sometimes lead to health complications, general impairment, and an array of secondary mental disorders (APA-psychiatry, 2000; Maxwell, 2005). For example, unless a client is treated with thiamine to reverse the effects of chronic alcohol use, he or she may develop Korsakoff's syndrome, a persisting amnestic disorder (APA-psychiatry, 2006). In addition, general medical conditions can develop as a result of substance use, and may in turn lead to the development of a mental disorder due to medical complications (APA- psychiatry; Maxwell). Behavioral disturbances may also result from substance use (APA-psychiatry; Maxwell). Therapeutically, substance-induced delirium, dementia, and amnestic disorders are generally addressed in the same manner as when these disorders result from different etiologies (APA-psychiatry). The treatment of other substance-induced disorders, such as sleep, psychotic, anxiety, and mood disorders, is beyond the scope of this chapter.

14.2.3 Mechanisms of Change Underlying the Intervention

Due to the biological nature of organic mental disorders, medical treatment is often the primary intervention. Specifically in acute cases of delirium, amnesia, substance-induced disorders, and disorders due to a general medical condition, symptom alleviation typically occurs through medical treatment of the underlying cause (APA-psychiatry, 2000, 2006; Doctor, 2008; Inouye, 2006; Rabins, 1991; Taylor, 2007; Zarit & Zarit, 2007). However, even in these cases, cognitive, behavioral, and affective interventions may be applied to address specific issues or decrease symptom presentation (Forrest, 2008). Chronic conditions, on the other hand, typically require psychological interventions for functional recovery or symptom amelioration.

Cognitive Impairment. Cognitive rehabilitation programs are tailored to the individual client, and may include interventions that involve environmental modification, compensatory mechanisms, or recovery of cognitive ability itself (Gordon & Hibbard, 2005). Environmental modifications improve daily functioning by tailoring the client's environment to his or her specific needs (Gordon & Hibbard). Compensatory approaches involve learning new skills or behaviors, and may involve the use of aids such as handheld computers (Franzen & Lovell, 2008; Gentry, 2008; Gordon & Hibbard). For example, skills training focuses on increasing cognitive functioning in daily life; thus, training is specific to tasks that the client will be performing, and rehabilitation occurs through acquisition of domain-specific knowledge (Cicerone, 2007). Direct interventions are intended to recover cognitive functions that have been lost (Gordon & Hibbard). Recovery depends on there being a range of neurological processes that can be used to complete a given task under a variety of conditions (Cicerone). When a client is motivated and actively participates in his or her cognitive rehabilitation program, reorganization of neurologic and cognitive processes may take place, as intra-systemic processes may take over the role of the damaged tissue and/or intact higher cortical centers may

influence lower levels of function (Cicerone; Franzen & Lovell). Specific cognitive areas may be targeted, known as process-specific remediation. Here, it is assumed that improvements in the specific function will generalize to similar cognitive areas (Cicerone). Comprehensive programs that involve psychotherapy, cognitive remediation, functional skills training, and individual and group treatments are the most effective (Cicerone; Gordon & Hibbard). Groups are particularly helpful in enhancing social skills and interpersonal functioning, and psychoeducation is crucial in helping clients to adapt to cognitive impairment (Belleville, 2008; Gordon & Hibbard; Zarit & Zarit, 2007). Comprehensive programs are effective because they improve overall functional application of intact cognitive abilities (Cicerone).

Delirium. The environmental modifications recommended in the treatment of delirium decrease symptom expression by reducing factors known to aggravate the condition (Trzepacz & Meagher, 2008; Tune, 2000). Reassurance and therapeutic conversations with the client work in a similar manner, as they reduce agitation and cognitive and emotional disturbance (Broshek & Marcopulos, 1999; Tune). Because clients experiencing an episode of delirium are cognitively impaired and confused, failure to provide orientation, reassurance, and a calm, structured environment may lead to further confusion or fear that may interfere with medical treatment and pose a risk to the patient and staff (Trzepacz & Kennedy, 2005).

Dementia. For the most part, therapeutic work with dementia patients is not intended to produce permanent change, but rather temporary gains in daily functioning, affect, and behavior (Zarit & Leitsch, 2001). Cognitive rehabilitation techniques for persons with dementia are used to optimize residual functioning (Lichtenberg & Duffy, 2000). Verbal communication remains important with severely impaired individuals because it is emotionally meaningful to them due to the nonverbal and subvocal aspects of these exchanges, and memory of affective experiences remains when cognitive recall does not (Forrest, 2008; Lichtenberg & Duffy; Werezak & Morgan, 2003). Dementia patients continue to experience emotions, and these emotions in turn affect their behavior (Werezak & Morgan). Treatments, such as pet therapy, music therapy, and touch therapy, have a calming effect on dementia patients, reducing agitation and therefore dysfunctional behaviors (O'Donnell et al., 2001). Even with the most severely impaired individuals, comfort and sensual pleasure can increase quality of life and should be provided as part of care (O'Donnell et al.). Adapting the physical environment for clients with dementia is important in reducing disorientation, confusion, and agitation (O'Donnell et al.; Werezak & Morgan). This is achieved through reducing over-stimulation and setting up an environment that promotes orientation, a sense of control, and social interactions (O'Donnell et al.; Werezak & Morgan). Behavioral interventions with dementia patients typically follow an ABC model – Antecedent, Behavior, Consequence (Zarit & Zarit, 2007). Once the triggers of the behavior have been identified, these can be avoided in order to prevent the behavior from occurring (Ford & Urban, 1998; Logsdon et al., 2006; Zarit & Zarit). Problem behaviors may also be maintained through the positive consequences that follow them. Therefore, identifying and removing this reinforcement should decrease the behavior (Ford & Urban; Zarit & Zarit).

Amnestic Disorders. Internal memory strategies aimed at the recovery of lost function work through the same neurological reorganization mechanisms as remediation of other cognitive deficits (Cicerone, 2007). Through a rehabilitation program, remaining memory functions can replace those that have been lost (Cicerone; Franzen & Lovell, 2008). For example, visual imagery strategies may be used with patients that have impairments in verbal memory (Frazen & Lovell). With clients with severe amnesia, internal strategies are typically ineffective

(Cicerone). Therefore, in these cases, and to compliment internal strategies in milder cases, external and compensatory strategies are common. These work through providing an immediate external reminder or cue – they do not require the client to use his or her memory to remember when or how to complete particular tasks (Cicerone; Dobkin, 2000; Franzen & Lovell; Troyer et al., 2007).

Mental Disorders Due to a General Medical Condition and Substance-Induced Disorders. Organic disorders falling under these two categories are addressed by treating the underlying etiology. Once the condition that is causing the neurological issue is eliminated, symptoms typically disappear (APA-psychiatry, 2000, 2006; Doctor, 2008). The mechanisms underlying treatments that may be used for remaining long-term effects, such as cognitive or memory impairment, are discussed elsewhere in the current section.

14.3   Basic Competencies of the Clinician

At a minimum, psychologists should be familiar with the signs and symptoms of organic disorder so that they can appropriately refer clients to certified clinical neuropsychologists. Psychologists wishing to work with patients with a range of organic disorders require knowledge in both neuropsychology and geropsychology due to the high incidence of these disorders in the elderly (Haley & Mangum, 1999; Lipowski, 1980, 1984; Seltzer & Sherwin, 1978; Taylor, 2007). If a clinician chooses to work with particular subtypes, depending on their nature, he or she may choose to focus on one field and supplement particular areas with knowledge from the other. For example, clinical neuropsychologists may choose to focus on geriatric neuropsychology, integrating competencies from geropsychology into their established knowledge of neuropsychology (Hannay et al., 1998). However, if a clinician wishes to work in pediatric neuropsychology, specialized knowledge of geropsychology is not necessary.

Competency in both neuropsychology and geropsychology will be covered in the following sections. It is assumed that practitioners already possess competency in general clinical practice in psychology.

Neuropsychology. Clinical neuropsychology is recognized as a practice specialty, and thus even basic competence requires specialized knowledge and training (Hess & Hart, 1990). Because clinical neuropsychology stems from the integration of clinical psychology and neuroscience, competent practice in this domain requires knowledge and skills in both areas (Hess & Hart). For a psychologist to work ethically with patients with organic disorders, he or she must have knowledge of brain function and organization, psychopathology and systemic pathology, clinical interviewing and history taking, a variety of assessment instruments and techniques of administration, specific interventions pertaining to this population, pharmacology, consultation, patient education, ethics, and effective strategies for working with families and institutions such as hospitals and schools (American Psychological Association [APA-psychology], 2008b; Bush, 2007; Hess & Hart). Psychologists who wish to practice with this population should have formal training in these areas. For example, the clinical interview alone requires a history of varied experience in neuropsychological assessment and in-depth knowledge of neuropsychology (Strauss et al., 2006).

Geropsychology. Although licensed psychologists possess skills that can be applied to their work with older adults, ethical standards dictate that psychologists working with this population should have some prior training and, ideally, supervised experience (APA-psychology,

2004; Haley & Mangum, 1999; Qualls, 1998; Zarit & Zarit, 2007). Basic knowledge may be obtained through self-study, graduate training, or continuing education (Qualls). At a minimum, such training should include information on psychopathology and the psychological, biological, and social changes that accompany aging, such as cognitive and sensory deficits, developmental issues, and physical illness (APA-psychology; Lewinsohn, Teri, & Hautzinger, 1984; Qualls; Zarit & Zarit). Clinicians should be familiar with the tests and procedures used to assess for, and diagnose, organic disorders in older adults, and should be aware of how to optimize conditions for testing with this population in order to obtain valid results (APA-psychology; Haley & Mangum; Lewinsohn et al., 1984; Zarit & Zarit). Psychologists should know how to tailor therapy to client characteristics through techniques such as pacing and accommodating sensory deficits (Lewinsohn et al.; Zarit & Zarit). They should also be familiar with specific interventions that have been shown to be appropriate with older adults with organic mental disorders (APA-psychology; Lewinsohn et al.). The clinician should have a basic understanding of pharmacology as it applies to organic disorders, and the potential effects of different medications on symptom presentation (APA-psychology). When working with this population, it is particularly important for clinicians to monitor their potential age-related biases (APA-psychology; Zarit & Zarit). Negative stereotypes may lead to over-pathologizing and unreasonably low expectations for therapeutic success, decreasing the quality of treatment and prevention (APA-psychology). On the other hand, some practitioners may tend toward a positive bias, minimizing negative attributions and thus preventing effective treatment (APA-psychology; Zarit & Zarit). Multicultural competency is crucial in working with this population as well, as factors such as sexual orientation, ethnicity, gender, and socio-economic status may influence symptom presentation and how assessment and treatment should be addressed (APA-psychology). A key factor in basic competence is being able to distinguish between clients who can be treated by the generalist versus those that should be referred to an expert in geropsychology (APA-psychology; Qualls).

14.4   Expert Competencies of the Clinician

Neuropsychology. Clinical neuropsychology is a practice specialty that is regulated by the American Board of Clinical Neuropsychology (ABCN) under the American Board of Professional Psychology (ABPP; ABPP, n.d.). A diploma from the ABCN is the primary credential recognizing a practitioner's competence in clinical neuropsychology (ABCN, 2007; ABPP, n.d.). Clinical neuropsychologists have expertise in using assessments and interventions with clients based on their knowledge of human behavior as it relates to normal and abnormal functioning of the central nervous system (American Academy of Clinical Neuropsychology [AACN], 2007; Hannay et al., 1998). Specialists in neuropsychology have in-depth knowledge in the core domains of this field of practice, including consumer protection, assessment, supervision, intervention, research, professional development, and consultation (Hannay et al.; Hess & Hart, 1990). Clinical neuropsychologists possess specialized knowledge of neuroimaging, neuropsychology of behavior, neuroanatomy, neurochemistry and psychopharmacology, neuropathology, effects of systemic conditions on the central nervous system, and the etiology, symptom expression, prognosis, and treatment of neurological and related disorders (AACN; APA-psychology, 2008b; Hannay et al.; Hess & Hart). Their clinical knowledge includes neuropsychological research design and analysis, neuropsychological assessment and intervention,

practical implications of neuropsychological disorders, and professional and ethical issues in neuropsychology (APA-psychology; Bush, 2007; Hannay et al.; Hess & Hart). Ethical issues of particular importance include autonomy, informed consent, issues in third party assessments, confidentiality, and test security (AACN; Bush). Clinical neuropsychologists have practical skills in a variety of areas. Within the domain of assessment, practitioners are proficient at gathering information and history taking, selecting assessment instruments, administering and scoring assessment tools, obtaining and integrating multiple sources of information, interpreting assessment results, providing diagnoses (differentiating between organic and psychogenic disorders, as well as between different etiologies of neurogenic disorders), writing up reports, planning treatments, and giving feedback to clients and/or their families (AACN; APA-psychology; Hannay et al.; Hess & Hart). In formulating a diagnosis, they are also aware of any factors that could potentially exacerbate or ameliorate the patient's presenting issue (AACN). In terms of treatment, neuropsychologists are able to specify intervention targets and needs, implement an intervention plan, and assess treatment outcome (APA-psychology; Hannay et al.). Some primary neuropsychological interventions include cognitive remediation, psychoeducation, psychotherapy, cognitive retraining, and environmental manipulation (APA-psychology). In both assessment and intervention with neuropsychological issues, practitioners must remain aware of cultural, disability, linguistic, and other socioeconomic and demographic variables, individualizing their work with the client accordingly (AACN; APA-psychology; Bush; Hannay et al.). Particularly with assessment, these factors may affect the meaning of test results or the tests may not be valid for the population, in which case supplementary information must be obtained (AACN). Competency is also required in the areas of consultation, research, teaching, and supervision (Hannay et al.). Once competence has been established clinical neuropsychologists should frequently engage in continuing education activities in order to maintain it (AACN; Bush; Hannay et al.). A key source that will assist in maintaining currency in this area in the immediate future is the revision of Lishman's (1998) classic text, scheduled to be published in 2009 (David et al., 2009).

Geropsychology. Clinical geropsychology is recognized as a practiced proficiency by the American Psychological Association, and signifies a higher level of competence than basic (APA-psychology, 2008a; Qualls, 1998). Although practitioners who are proficient in geropsychology are not considered experts, they have a high level of competence in working with this population, and constitute the majority of psychologists providing services to older adults (Qualls). According to the American Psychological Association, practitioners with this proficiency provide consultation, assessment, and intervention services to older adults in regard to a number of issues, such as capacity for decision making, behavioral problems, problems in daily living, and psychopathology. To be recognized as having this proficiency, one must have specialized knowledge in research and theory on aging, biological aspects of aging, social and psychological aspects of aging, and cognitive psychology, particularly in regard to normal and abnormal changes in cognition (APA-psychology, 2004, 2008a). Geropsychologists have a thorough understanding of assessment instruments that are psychometrically suitable for older adults, and are familiar with the theories and research behind them (APA-psychology; Haley & Mangum, 1999). They are comfortable with, and skilled at, gathering information from informants for assessment and treatment purposes (APA-psychology). These clinicians know how to accommodate sensory impairments, and any other potentially interfering factors, in order to obtain valid assessment results (APA-psychology; Zarit & Zarit). They have thorough knowledge of evidence-based treatment approaches with this population, as well as interventions

that may be used with caregivers and families (APA-psychology). Some distinctive interventions with this population include psychoeducation for caregivers, reminiscence therapy, expressive therapies, and grief therapy (APA-psychology). Geropsychologists know how to work within an interdisciplinary team, and are familiar with the role of each discipline, particularly within residential and inpatient settings (APA-psychology). They are familiar with psychotropic drugs and other types of medication, and their potential to interact with each other and with organic disorders (APA-psychology). Practitioners with this proficiency typically have some knowledge about behavioral medicine, such as how factors like nutrition and exercise can affect mental health in older adults (APA-psychology; Lichtenberg & Rosenthal, 1994). Geropsychologists should have worked through any biases or attitudes they previously held toward the elderly, and therefore have a realistic perception of the abilities and vulnerabilities of older adults (APA-psychology). They are knowledgeable in cross-cultural factors pertinent to the therapeutic process, and familiarize themselves with cohort experiences and how they may affect treatment (APA-psychology). Psychologists at this level of competence are aware of the common ethical issues pertaining to working with older adults, such as informed consent, confidentiality, and conflict of interest between the client and his or her legal guardian in making treatment decisions (APA-psychology; Whitehouse, 2000; Zarit & Zarit). They are also able to deal with such issues effectively (APA-psychology). Knowledge about ethics and legal issues related to death is important as well (APA-psychology). Finally, geropsychologists must remain current in their knowledge of new developments in the field through continuing education (Haley & Mangum).

With difficult cases, practitioners with proficiency in clinical geropsychology may need to consult a specialist with expertise in the area (Qualls, 1998). Because clinical geropsychology is not formally recognized as a specialty, expertise is determined through an informal process (Qualls). Expert status is reserved for those professionals who "devote their careers to advanced practice, research, and training in geropsychology" (Qualls, p. 24). These practitioners advance the field through setting standards for practice, providing consultation, training clinicians at the proficiency and specialty levels, and contributing to the development of new knowledge in the field (1998). Typically a clinician must be considered an expert to work as a mental health consultant in an institutional setting (Zarit & Zarit, 2007). Not only are specialized knowledge and skills required, but the therapist must also know how to function within a greater system that includes working with a variety of disciplines (Zarit & Zarit). For more information on working as a consultant in a geriatric inpatient or residential setting, see Zarit and Zarit.

14.5 Transition from Basic Competence to Expert

Neuropsychology. Because expert competency in clinical neuropsychology is formally acknowledged when a practitioner has obtained specialist certification from the ABPP, the process of developing expert competence in the field is aligned with fulfilling the requirements of this diploma. General requirements and recommendations for obtaining certification are described below. Please note that specific eligibility criteria may differ based on certain individual factors, such as when the person received his or her doctorate (ABCN, 2007; ABPP, n.d.).

Specialization is built upon existing clinical competency in a health service delivery predoctoral program (APA-psychology, 2008b; Hannay et al., 1998; "Reports of the INS," 1987). Therefore, training is obtained either through specialty programs at the predoctoral and

internship levels or through postdoctoral training in a specialized clinical neuropsychology program (AACN, 2007; ABPP, n.d.; APA-psychology; Hannay et al.; "Reports of the INS"). Continuing education is not adequate for establishing competence in clinical neuropsychology (AACN; Hannay et al.). To be eligible for certification, practitioners must possess a doctorate in psychology and have obtained the equivalent of 3 years of experience in clinical neuropsychology and 2 years of supervision in the area, either through a graduate internship or through a postdoctoral residency equivalent to 2 years of full-time education and training (AACN; ABCN, 2007; Hannay et al.; "Reports of the INS"). For graduate students wishing to specialize, internships should be completed through a CPA or APA accredited program (ABPP, n.d.; Hannay et al.), and may be initiated following 2 years in a Ph.D. program in clinical neuropsychology or clinical, counseling, or school psychology ("Reports of the INS"). Practicing clinicians wanting to specialize must have a Ph.D. in one of these areas, or have achieved equivalency through postdoctoral respecialization ("Reports of the INS"). The internship or residency should involve direct neuropsychological services for at least 50% of the time, with interns spending at least 20% of their time in general training in clinical psychology, and postdoctoral practitioners devoting at least 25% of the time to clinical research ("Reports of the INS"). Internships and residencies should be associated with a hospital setting that has neurological/neurosurgical services, as a psychiatric setting alone will not offer the same degree of experience in neurology ("Reports of the INS"). Practicum training must include training in neurological diagnosis, consultation to neurological/neurosurgical services, consultation to psychiatric or medical services, consultation to clients and referral sources, neuropsychological interventions, and neuropsychological assessment, interpretation, and report writing ("Reports of the INS"). Experiential training should occur in each of these areas, with sufficient exposure to work with neurological patients as well as patients with psychiatric conditions and medical patients with neurobehavioral disorders ("Reports of the INS"). Upon completion of the residency or internship, the practitioner is expected to have participated in scholarly activity and is expected to demonstrate advanced knowledge of brain–behavior relationships and advanced skill in assessment, treatment, and consultation with professionals and neuropsychological patients (Hannay et al.; "Reports of the INS"). He or she must also be eligible for licensure for independent practice, as a license is required to apply for certification through the ABPP (ABCN; ABPP, n.d.; Hannay et al.). ABCN then determines if the candidate is eligible for certification, and if the application is accepted, the practitioner completes a written exam, work samples, and an oral exam (ABCN; ABPP, n.d.). For more detailed information regarding eligibility and the application process, see ABCN. Information regarding education and practicum training in clinical neuropsychology may be obtained through the American Psychological Association Division 40 Web site (www.div40.org/training/index.html). For further information on competence in clinical neuropsychology, see Hannay et al.

Geropsychology. There are three primary strategies for obtaining proficiency in geropsychology: continuing education/respecialization programs, readings, and supervised practice (APA-psychology, 2004, 2008a; Qualls, 1998). There are several workshops and conferences that provide continuing education in geropsychology (Qualls). Psychologists in Long-Term Care (PLTC) also provide training to promote development of consultation, therapy, and assessment skills in working with older adults (APA-psychology). On top of pursuing education, psychologists wanting to gain proficiency in geropsychology should consult the published

literature within the discipline. Practice handbooks, conference summaries, and books are available for practitioners seeking knowledge on research and practice in the field (Qualls). For a list of some valuable resources in this area, *see Psychological Services in Long-Term Care Resource Guide* (Duffy, 2006). Qualls has also identified some useful journals, including the *Journal of Clinical Geropsychology*, *Journal of Mental Health and Aging*, *Clinical Gerontologist*, *Aging and Mental Health*, *The Gerontologist*, *International Journal of Aging and Human Development*, and *Psychology and Aging*. In addition to continuing education and self-study, the practitioner seeking proficiency in geropsychology must obtain supervised clinical experience (Qualls). He or she must have at least 100 h of supervised client contact at the pre- or postdoctoral level of training, including experience in interviewing, assessment, and treatment in a variety of settings (Qualls). Through this experience, the practitioner should become familiar with treatment institutions used by the elderly, and with working with other disciplines frequently involved in the treatment of older adults (Lichtenberg, 1999b; Qualls). For students wishing to pursue a career in this field, training in clinical geropsychology is provided in some graduate programs (APA-psychology; Lewinsohn et al., 1984). Further information on continuing education and training opportunities may be obtained through Division 20 (Adult Development and Aging; apadiv20.phhp.ufl.edu) and Division 12, Section II (Clinical Geropsychology; www.geropsych.org) of the American Psychological Association (APA-psychology; Qualls). For additional details on competency in geropsychology, see Santos and VandenBos (1982).

14.6 Summary

A variety of diverse mental illnesses are subsumed under the category of "organic disorder." Although the DSM-IV abandoned this terminology so that all mental disorders would be acknowledged as involving brain function, it remains that the primary feature of this class of disorders is their medical origin. Proper assessment and diagnosis is essential, as leaving organic disorders untreated may lead to further deterioration or death. Most organic disorders are maintained by the underlying biological cause, and thus treatment of that cause is an important factor in ameliorating the condition. However, a biopsychosocial approach to treatment is required to address all symptoms, particularly as organic disorders often have affective and relational consequences as well. Psychotherapy and cognitive rehabilitation strategies have been shown to be effective with a variety of acute and chronic organic disorders. Although therapeutic interventions with chronic degenerative conditions, such as Alzheimer's dementia, cannot produce permanent change, they can optimize the person's functioning and increase quality of life. In other cases, such as moderate amnesia, memory functions that have been lost may be recovered through neurological reorganization. Each individual case is unique depending on the factors involved in the damage and other personal, relational, and environmental traits. Thus, clinicians that practice with this heterogeneous population must be very knowledgeable and experienced. Unless they choose to specialize in a particular area of neuropsychology, practitioners should have competence in both geropsychology and neuropsychology. Maintenance of competence in this area is vital, as research in this field continues to grow. We are bound to see continuing developments in this area as our knowledge of organic and other psychiatric illness increases.

15 Partner Abuse

K. Daniel O'Leary · Heidi Lary Kar

Abstract: Partner violence was almost unknown in the 1960s, but the field of intimate partner violence (IPV) has become widely known and there are now a number of specialty journals that cover this topic. The early stages of the field involved major surveys about the prevalence of IPV and many studies on correlates and predictors of IPV. It is now known that IPV occurs in about 10% of the general populations of men and women and that there is a clear need to assess for IPV in clinical populations. Fortunately, there are measures of IPV, Fear of Partner, and Injury, and these assessment instruments can be used by any clinician. Treatment of IPV for men mandated by courts to intervention programs has a small but significant effect over and above monitoring by the courts, but there is a strong need for treatment of differing levels of aggression. It is quite possible that treatments could be successful for men and women who engage in infrequent physical aggressive to their partners and who do not make them fearful or injure them.

Clinicians need to know the ethics of reporting of partner abuse, how to develop safety plans with a client, availability of local shelters, how and when to treat substance abuse, and when to treat marital problems. There is no one size fits all treatment, and some low level IPV can be treated conjointly whereas severe IPV may require both group and/or individual treatment for the perpetrator. Careful assessment and case conceptualization regarding risk factors for the IPV are needed to determine the best treatment options.

15.1 Overview

Partner aggression was largely ignored by mental health professionals in the 1960s. In fact, our search of Psych Literature indicated that there were only five articles about partner abuse in the 1960s, but there were 74 articles in the 1970s (Poggi, Vander Ven, & O'Leary, 2009). Further, articles about wife abuse in the 1960s basically involved explicit or veiled blame of the wife because of frigidity and aggressiveness. For example, Snell, Rosenwald and Robey (1964) characterized the family structure of men whose wives reported an assault as one in which the husband's passivity, indecisiveness, and sexual inadequacy and the wife's aggressiveness, masculinity, frigidity, and masochism allowed the couple to have a working equilibrium.

Fortunately, in 1979, there were two important books published regarding partner aggression. First, Murray Straus, Richard Gelles, and Susan Steinmetz published their book, *Behind Closed Doors: Violence in the American Family*. This book presented the first representative sample survey in the USA of physical aggression directed toward intimate partners (IPs). Unexpectedly, the study showed that approximately 12% of men *and* women in the past year had engaged in physical aggression against their partners. This book served to bring the attention of physical aggression and violence in the family to the fore because it used a representative sample. After the Straus et al. book, one could no longer say that physical aggression and violence at home were only seen in family memebers who are poor

and who have relatively low levels of education. Straus et al. showed that while there was a slight association between lower socioeconomic levels and physical aggression against a partner, such aggression occurs at all socioeconomic levels. In addition, as has been shown by other national surveys, physical aggression against partners occurs in about 10% of the general population and it occurs in considerable higher percentages in younger populations.

The second book to have a major impact on the field was Lenore Walker's now classic work, *The Battered Woman* (1979), in which she showed how women become entangled in a "cycle of violence." Initially, there is closeness, but that is followed by arguments and sometimes physical aggression. Following "fights," the male often apologizes albeit while not taking full responsibility for his actions. Walker believed that without any major intervention, abuse and misuse of power and control tactics will not stop. While there certainly are instances in which violence desists, in many instances there is persistence of violence as Walker argued. In some of our early work with couples from the community, we showed that of the men and women who engage in physical aggression at premarriage, about half of them were not physically aggressive at 18 months into the marriage (O'Leary et al., 1989), and thus there appeared to be considerable desistance or cessation of aggression. However, when physical aggression was assessed at all of the various points across the first 30 months of marriage, we found very considerable stability. More specifically, stability of physical aggression was examined in newly married couples who were assessed 1 month prior to engagement and again at 6, 18, and 30 months postmarriage (Lorber & O'Leary, 2004). Over 76% of men who were physically aggressive during the engagement period were physically aggressive at one or more of the next three assessments across the initial 30 months of marriage. Nearly 62% were severely aggressive at one or more assessments. Thus, Walker's interview and retrospective data led to conclusions in the late 1970s that were upheld much later with longitudinal data that did not exist in the late 1970s and early 1980s.

Fortunately, there was a grassroots movement that helped gain recognition of partner aggression and abuse. Basically, feminists and grassroots organizers helped awaken the public to the issue of domestic violence (Schecter, 1982) when mental health professionals ignored it. Given that some early mental health professionals characterized abused women as masochistic (Hilberman, 1980) and some others blamed wives for their husband's violence, a divide occurred between mental health workers and personnel who staffed shelters and services for battered women.

Since the 1990s, there has been a veritable explosion of research and scholarly activity on the issues of physical aggression in intimate relationships. There are now at least five journals that cover partner aggression, namely the *Journal of Family Violence*, *Journal of Interpersonal Violence*, *Violence and Victims*, and *Violence Against Women*. In addition, *Partner Abuse*, appeared in 2009. Moreover, mainstream journals in psychology, psychiatry, and medicine publish articles on partner abuse. Specifically, the American Psychological Association journals, the *Journal of Consulting and Clinical Psychology* and *Family Psychology*, often publish articles on family violence. In addition, the most cited journal of all in the health and mental health field, *The New England Journal of Medicine*, has addressed partner abuse and the need for physicians to address the issue of domestic violence as a health issue (Eisenstat & Bancroft, 1999).

Partner abuse has been a highly politicized field, but it has grown less so as there is an increasingly large knowledge base and as facilities for abused women have become very

common. Further, now many states even have treatment programs for abused men as well as for abused women. The increasing knowledge base has been seen most clearly in research on correlates and risk factors for partner aggression/abuse. The progress towards prevention and treatment of partner abuse has received less research attention, but knowledge about interventions for batterers has been significant even if sometimes depressing because of the very small effects of such interventions. The growth of research on etiology and treatment is such that individuals need to develop competencies in the assessment and treatment of partner abuse, and this chapter is designed to alert clinicians about the necessary skills that one should acquire to assist men and women in relationships characterized by physical aggression and abuse.

15.1.1 Recognition of Symptoms and Their Assessment

The distinction between partner aggression and partner abuse is not simple, but like many other problems or disorders, there is a need to distinguish between the rather commonly occurring physical aggression in intimate relationships and the more serious kinds of aggression called abuse. Jacobson and Gottman (1998) made a distinction between the common couple aggression and battering on the basis of the presence of fear of the partner and the presence of injury. According to them, fear of partner and/or injury had to be present for the problem to be called battering or what some call abuse. Nonetheless, like most other psychological problems, assessment on a continuum is necessary for the field to progress reasonably, and this chapter is designed to assist the clinician in knowing what to assess in evaluating partner aggression/abuse in an individual or a couple.

Physically Abusive Behavior. Occurrence and extent of physically aggressive behavior can be detected through interview and self-report methods. A wide variety of measures had been developed to assess physically aggressive behaviors against an IP. A review of such measures along with related relationship measures appears in an excellent resource book by Rathus and Feindler (2004), entitled: *Assessment of Partner Violence: A Handbook for Researchers and Practitioners*, and The Centers for Disease Control also published a compendium of measures used to assess intimate partner violence (IPV) of both a psychological and physical nature (Thompson, Basile, Hertz, & Sitterle, 2006). Various measures of physical aggression against a partner will not be reviewed here, but the most widely used measure of such will be discussed.

The most widely used measure to assess physical aggression in intimate relationships is the Conflict Tactics Scale (CTS) developed by Straus (1979). The measure was designed to be used both as a self-report of physical aggression toward an IP as well as a report of the extent to which the respondent was the recipient of acts of physical aggression by an IP. Because of the very widespread use of this measure, it is reviewed herein. This measure has three "warm up items" used to prompt the respondent to indicate the extent to which he or she discussed issues calmly, gotten information to back up his or her side of things, and brought in, or tried to bring in, someone to help settle things. After these three warm up items, there are six items used to assess psychological aggression such as insulted or sworn at partner, threatened to throw something at partner. Finally, there are eight items to assess physically aggressive behavior toward an IP such as slapped his or her partner and pushed, grabbed, or shoved his or her partner.

This measure has been used in hundreds of studies on dating and marital violence, and it was designed to be used in community and population surveys of physical aggression in families in the USA. The measure became well-known because it was the first of its kind to be used in a population-based survey (Straus, Gelles, & Steinmetz, 1980), and variations of it have been used in hundreds of studies of IP aggression. For example, it was used in a survey of partner aggression in the US Army by Pan, Neidig, and O'Leary (1994) in which over 11,000 men were sampled at 37 army bases in the USA. It was used by Schafer, Caetano and Clark (1998) in a population-based survey of 1,635 individuals of IPV in the USA, and it has been used in a Center for Disease Control population-based survey of 8,000 individuals (Tjaden & Thoennes, 2000).

There is a revision of the CTS and the revision includes more items and a sexual-abuse scale (Straus, Hamby, Boney-McCoy, & Sugarman, 1996). The physical aggression measure of this scale has quite reasonable partner agreement (O'Leary & Williams, 2006), especially when partner agreement about physical aggression is compared to how partners negotiate positively on the Negotiation Scale of the CTS as well as on positive behaviors of the Dyadic Adjustment Scale (Spanier, 1976). Internal consistency measures of the aggression scale for both perpetration and victimization were in the 0.70 range, and Kappa agreement on aggressive acts between husbands and wives in a representative sample of parents of young children was 0.47 for men and 0.45 for women. Overall agreement representing both occurrence and nonoccurrence agreement was 0.79 for men and 0.76 for women. Pearson agreement was 0.47 and 0.44 for men and women, respectively.

Psychologically Abusive Behavior. Though psychological aggression has not received as much of attention as physically aggressive behaviors, psychologically aggressive behaviors can also be measured reliably. Various assessment measures of psychological aggression were reviewed by O'Leary (2001). Rathus and Feindler (2004) have also reviewed different measures of psychological aggression. There is no single measure of psychological aggression that has received the research attention of the physical aggression scale of the CTS, and the particular scale of interest should be related to the theoretical constructs and clinical interests at hand. For example, if one is interested in the extent to which battered women in a shelter have been psychologically abused, one needs to have a measure which will assess factors like financial control (takes car keys, closes bank and savings accounts, restricts and/or monitors phone access, makes daily demeaning comments to partner). On the other hand, if one wishes to assess psychological aggression in a sample of high school dating partners, the type of psychological aggression will be different than that used against women in a shelter. More specifically, one would want to know if the partner tries to restrict access to friends, tries to influence/control the clothing one wears, and demeans the partner by calling the partner names.

One of the most commonly used measures of psychological aggression is the Tolman Maltreatment Against Women scale (Tolman, 2001). This scale was developed to assess psychological aggression against women, though the scale has been modified to measure psychological aggression against men also (O'Leary, Slep, & O'Leary, 2007). The scale includes items like "tried to convince me that I am crazy, threatened to have an affair, threatened to leave the relationship, threatened to take the children away, restricted the use of my car, kept me from getting the care I needed, and ordered me around". This scale has acceptable psychometric properties of internal consistency (O'Leary et al., 2007; Tolman, 1989; Tolman).

The CTS (Straus, 1979), as well as the Revised Conflict Tactics Scale (Straus et al., 1996), also has a Psychological Aggression Scale that has excellent internal consistency (O'Leary & Williams, 2006; Straus et al.). The original scale includes eight items like insulted or sworn at you, sulked or refused to talk, stomped out of the house, did something to spite your partner, threatened to hit or throw something at partner, threw, hit, or kicked something. This scale has been shown to be predictive of physical aggression in young married couples where no physical aggression yet occurred (Murphy & O'Leary, 1989). The revised CTS psychological aggression scale of the CTS has not been the subject of as much research as the original CTS, but one would expect that the revised scale will do as well or even better than the original scale.

Injury. The Revised Conflict Tactics Scales has a measure of injury, and we have found it to be useful. The vast majority of physically victimized men and the majority of physically victimized women in a representative sample do not report any injury (Lary & O'Leary, 2008). More specifically, in a representative sample of parents of young children of those participants self-reporting any physical victimization, there were no significant gender differences in those reporting any injury (27.9% for women and 27.4% for men). Among female participants who reported experiencing any injury in the last 12 months, 91.9% reported experiencing moderate injury only and 27% reported experiencing severe injury. Among male participants reported any injury in the last 12 months, 95% reported moderate injury and 12.2% reported severe injury.

While the majority of physically victimized women in a representative sample did not report injury, it was the case that injured women were much more likely to be depressed than noninjured women. That is injured women and men were more likely to have elevated depression scores than noninjured women. Thus, the impact of injury has adverse effects for both men and women.

A clinician should always ask client about the presence of injury because it is the clinician's obligation to protect clients and know about the extent, severity, and consequences of physical aggression (O'Leary, 2008). It is the clinician's responsibility to use information about the extent and consequences of physical aggression to be able to develop a safety plan to prevent injury or harm to a client.

Fear of Partner. Fear of partner is also a factor that should be assessed by all clinicians since fear of partner is clinically and empirically significant. Fear of partner's future abuse is one of the best predictors of future aggression by the partner (Heckert & Gonfolf, 2005). In fact, in one study, fear of partner was a better predictor of future aggression than a set of 25 risk factors drawn from the literature (Weisz, Tolman, & Saunders, 2000). In addition, it is important to know about the extent of fear of partner because the kinds of intervention chosen should be based at least in part on knowledge of the fear a client has of his or her partner. Fear of partner can be assessed reliably; a 25-item self-report questionnaire has high internal consistency on measures of physical/sexual abuse (alpha = 0.72) and emotional abuse (alpha = 0.90) (Cohen & O'Leary, 2007). Fear of partner can be through self-report and/or interview with straightforward questions like "How much do you fear your partner will hurt or engage in the type of behaviors he or she has engaged in previously? As we have shown, women and men fear the specific behaviors that their partners used in the past (Kar & O'Leary, 2009). Further, women reported more fear of the specific behaviors that their partners engaged in than men, and physically victimized women reported more overall fear of their partners than physically victimized men.

15.1.2 DSM Diagnosis and Its Potential Impact

Partner abuse was first addressed in the DSM IV, and it appears that it will continue to be recognized in DSM IV. O'Leary and Jacobson (1994) wrote the chapter, Partner Abuse, for the DSM IV supplement, and the specific diagnosis, Physical Abuse of Adult, is a V code (V 61.1 with a specifier 995.81 to designate if the focus is on the victim). The overall area in which physical abuse is covered is under the overall rubric, Problems Related to Abuse or Neglect. However, the specific criteria for the various diagnoses subsumed under the rubric Problems Related to Abuse or Neglect were not contained in the DSM IV itself, but rather in a series of chapters in *DSM-IV*® *Sourcebook*, Volume 3. It is unclear how many individuals have received treatment from mental health professionals, and, in turn were reimbursed by insurance companies for matters or abuse – either as a perpetrator or as a victim. However, it is important to have a diagnosis under which an individual may obtain legitimate reimbursement from an insurance company for matters of abuse, since victims and perpetrators are sorely underserved.

One reason why the process of making official diagnoses and individuals receiving insurance reimbursement may be slow is that many individuals who work in programs for abused wives and physically abusive husbands are not licensed mental health professionals. In fact, many men who conduct groups for "batterers," are formerly abusive men. In addition, battered women often receive services from individuals who have been abused, but who are not clinical psychologists or social workers. Further, there was some opposition by service agencies to having an official diagnosis because of the concern that any diagnosis might lead men to be able to be less responsible for their aggressive behavior. However, if agencies can get insurance reimbursement for services provided to clients, they may gradually move to hiring licensed mental health workers to help maintain the agencies that serve men and women in situations characterized by physical aggression and abuse. That is, there could be financial advantages to the use of DSM diagnoses and licensed mental health professionals.

Of course, another specific advantage of an official diagnosis is that researchers could select individuals for various research projects who have the specific diagnosis, partner abuse. Classification is an initial important step in any research endeavor, and the use of specific diagnoses will allow for potential replicability across clinics and laboratories. Fortunately, there is reasonably good data on the diagnosis of partner abuse, and it appears that DSM V will likely have an official diagnosis code that covers IP aggression or partner abuse (Heyman & Slep, 2006). Further, there has been pressure by some professionals in the Division of Family Psychology and the Association for the Advancement of Cognitive and Behavior Therapy to include the diagnosis of partner abuse in a section of the DSM IV with both the diagnostic label as well as the criteria for diagnosis.

15.2 Maintenance Factors of the Disorder or Problem

Prediction of partner aggression has been the subject of over 2 decades of research, but the bulk of that research is correlational not longitudinal. However, there are some longitudinal studies of young married or engaged couples that do involve prediction of first instances of physical aggression or prediction of repeated aggression. Because the research on correlates and risk factors for partner aggression is so voluminous, it is worthwhile to provide some overall conceptual rubrics for placing these risk factors in context.

There are various theoretical conceptualizations for multivariate analyses of partner aggression but they can be broadly classified in terms of the following:

I. Cultural/demographic variables
   Income
   Education
   Attitudes and laws supporting aggression against women/partners

II. Family of origin variables
   Observation of violence
   Direct target of violence

III. Individual variables
   Personality
   Mental problems/disorders
   Substance abuse

IV. Relationship variables
   Relationship discord
   Communication problems
   Psychological aggression

O'Leary et al. (2007) used variables from each of the above four categories to test a multivariate model of partner aggression in a sample of 453 randomly selected parents of young children from Long Island, New York. Twenty-five variables have significant associations with partner aggression, but they then assessed how those variables interacted with one another, and tested causal models of partner aggression for both men and women. They found that demographic variables like young age and lower income levels had a small but significant association with partner aggression for both men and women. Similarly, family of origin variables also had small but significant associations with perpetration of partner aggression both for males and females. Individual variables like alcohol use and impulsivity had significant associations with partner abuse, but the relationship variables like marital discord, dominance, and jealous behaviors had the strongest associations with partner aggression.

Dutton (1995) used the nested ecological theory, a set of propositions espoused by Urie Bronfenbrenner to predict educational outcomes, to account for partner violence.

The nested ecological theory has four levels of variables as follows:

I. Macrosystem: cultural values and beliefs
II. Exosystem: formal and informal social structures such as friendship, workplace and support groups
III. Microsystem: characteristics of immediate setting in which the abuse takes place such as the family unit; relationship dynamics; antecedents and consequences of abuse
IV. Ontogenetic level: individual factors of the perpetrator of aggression

Testing models of partner abuse requires that there be specific measures of the constructs in the models, and often the models are too complex to be fully tested. However, Stith et al. used the nested ecological theory of Dutton to help them select variables to be tested in a multi-variable meta-analysis of partner abuse. Therefore, they used measures that could be used by clinicians. They found large effect sizes for prediction of perpetration of partner abuse and

five risk factors (emotional abuse, forced sex, illicit drug use, attitudes condoning marital violence, and marital satisfaction). They found moderate effect sizes for perpetration of partner abuse and six risk factors (traditional sex-role ideology, anger/hostility, history of partner abuse, alcohol use, depression, and career/life stress). The researchers also evaluated predictors of physical violence victimization and found a large effect size between physical violence victimization and the victim using violence toward his or her partner. Moderate effect sizes were found between female physical violence victimization and depression and fear of future abuse.

Capaldi, Shortt, and Kim (2005) follow a dynamic developmental systems approach to account for partner violence. This model uses four developmental phases with risk factors in each. Specifically, in childhood and adolescence, there are unskilled parenting and parental antisocial behavior and depression. In adolescence, there are deviant peer associations, and adolescent conduct problems and depressive symptoms. In young adulthood, there is at risk couple partnering, and in young and later adulthood, there is aggression to partner and unskilled relationship processes. In addition, the stage of development of both the individual and the couple as reflected in the age of each of the partners and the length of the relationship is important.

Riggs and O'Leary (1996) used two overall sets of variables to predict dating aggression, namely background and situational variables. Under these two major sets of variables were a number of subvariables. Background variables included factors like violence in the family of origin and aggressive personality style while the situational variables included factors like relationship satisfaction, intimacy, communication skills, alcohol abuse and aggression of the partner. Riggs and O'Leary found support for the background and situational model of courtship aggression. With 345 college undergraduates (232 women, 113 men), there was support for background-situational model and for both men and women, dating aggression was directly related to the individual's attitudes about dating aggression, history of aggressive behavior, and conflict within the relationship. However, the predicted association between family of origin violence and attitudes toward aggression and general aggressive behavior was found only among women. Among men, the predictors explained more than 60% of the variance in the latent variable of relationship aggression; among women, 32% of the variance was explained. In short, the situational variables explained more of the variance than background variables. Luthra and Gidicyz (2006) also evaluated the Riggs and O'Leary model of courtship violence with a sample of 200 college students and found that the model accurately classified 83% of aggressive women but only 30% of the aggressive men.

Research on IP aggression was extended to premilitary experiences of IPV among US navy recruits by White, Merrill, and Koss (2001), who found support for the Riggs and O'Leary (1989) model of courtship aggression with over 1,000 males and 1,000 females. The situational components explained more variance than did the background components; and for both women and men, the amount of variance accounted for was almost tripled after the addition of the situational factors. Partner aggression contributed to a substantial increase in the amount of variance. Partner's verbal aggression was the single best predictor of aggression, and partner's physical aggression was the second-best predictor. The situational component substantially increased the predictive power of the model.

Dutton (2007) has a model whose core is Borderline Personality Organization (BPO), but like most other models it also has family of origin variables, specifically rejection by mother and rejection by father. The core variable, BPO, is held to lead to anger, and verbal and physical abuse.

BPO does not refer to borderline personality but rather a set of three factors labeled: (1) identity problems (I feel empty inside; I find it hard to describe myself), (2) reality testing problems (I do things which get other people upset and I do not know why such things upset them; I hear things that other people claim are not really there), and (3) primitive defense problems (It is hard for me to trust people because they so often turn against me or betray me; uncontrollable events are the cause of my difficulties). In fact, Dutton presented evidence for this model with 160 males who were physically abusive to their wives and with 46 males who were not abusive to their wives. In both cases, the BPO was associated with abusive behavior though on the smaller sample, it was not associated with physical abuse but rather psychological abuse.

Stuart and Holtzworth-Munroe (2005) tested a model of partner aggression and they found that impulsivity led to marital discord and aggression in a sample of community men. And, in a sample of men arrested for domestic violence, antisocial behavior of the perpetrator led to the trait anger; in turn, the trait anger led to relationship discord and psychological aggression of the perpetrator. In short, there is some evidence that impulsivity leads to aggression against partners, although the association does not always exist and may be measure-dependent. Finally, there is evidence from Stuart et al. as well as others that antisocial personality traits predict partner aggression.

Because relationship discord or marital discord has been seen as such a major risk factor for partner aggression, marital discord was the subject of a separate meta-analysis used to predict partner aggression. Stith, Smith, Green, and Ward (2008) conducted a meta-analysis investigating the relationship between marital satisfaction/discord and IPV in heterosexual relationships with 32 articles. There was an overall small-to-moderate effect size (−0.27) that supported a significant and negative relationship that existed between marital satisfaction/discord and IP aggression. However, they also showed that standardized measures of marital discord like the Dyadic Adjustment Scale (Spanier, 1976) and the Index of Marital Satisfaction (Hudson, 1982) had larger effect size (−0.31) than nonstandardized measures (−0.21).

Multivariate models that have been evaluated are clearly different but not necessarily conflicting. And, there certainly is a need for more such evaluations and evaluations that will contrast the predictive power of various risk factors. It is abundantly clear that there is no single cause of IP aggression, and that our ability to have data from different laboratories on the predictive value of various risk factors will be very useful. Hopefully, in the next decade, there will be empirical evaluations of different though not necessarily conflicting models of partner aggression.

15.3 Evidence-Based Treatment Approaches

There has been a number of reviews of treatment approaches to partner aggression, and the overall conclusion that can be reached from those reviews is that there is a very small treatment effect that is obtained when one compares court-ordered programs for batterers with court monitoring (Babcock, Green, & Robie, 2004). In fact, based on the experimental studies, the effect size (d) due to treatment was only 0.09 and 0.12, based on victim report and police records, respectively. As the authors reported, the effects size obtained means that treatment was responsible for an approximately one tenth of a standard deviation improvement in recidivism. Based on partner's reports, batterers who received treatment had a 40% chance of being successfully nonviolent, and if batterers did not receive treatment, the men had a 35% chance of maintaining nonviolence. Thus, there was a 5% increase in success rate attributable

to treatment. To a clinician, this meant that a woman was 5% less likely to be reassaulted by a man who was arrested, sanctioned, and went to a batterers' program than by a man who was simply arrested and sanctioned.

The effect size obtained could be seen as so small as to suggest that psychological treatments are not worth the cost and effort needed to make them happen. In fact, whether one thinks treatment programs for batterers should be supported depends upon the importance one places on a 5% reduction in partner aggression. As Babcock et al. noted, while a 5% decrease may appear insignificant, this small treatment effect would equate to "approximately 42,000 women per year no longer being battered" (p. 1044). In addition to providing an analysis of the overall effects of intervention programs for batterers, Babcock et al. also evaluated the relative effects of the Duluth model and a cognitive-behavioral model of interventions for partner aggression. No differences were found for these treatments that used police records or partner reports of partner aggression. Thus, the two major interventions used to treat partner aggression were not significantly different from one another.

One interpretation of these data is that no treatment is very successful but another interpretation is that the legal intervention and the monitoring of the court by probation officer visits to the home of the woman who was victimized is quite successful. The success can be judged by the fact that approximately 60% of the men do not continue to engage in any physical aggression against their partners after a court intervention and monitoring. That is the court intervention itself seems to be quite powerful, and that if any psychological treatment is successful, the treatment must beat the court intervention and monitoring. Thus, one approach to the problem of reducing partner aggression would be to analyze the components of the interventions that appear to be successful in facilitating a reduction in partner aggression. However, since court interventions are generally not compared to no interventions, while it is assumed that they are effective, it is unclear whether legal interventions themselves are effective and that they would surpass the reductions in physical aggression that might have occurred with no intervention. No intervention may be seen as unethical because of the risk of repeated partner aggression, and thus an alternative approach would be to focus on interventions for partner aggression at low levels of aggression and where there is little or no fear of the partner, and where the aggression is reciprocal (O'Leary & Vega, 2005).

15.4 Mechanisms of Change in Interventions for Partner Aggression

In order to have clear evidence of mechanisms of change in an intervention program, having evidence of moderators and mediators of treatment would be extremely helpful. However, there are very few such studies. The partner abuse field is relatively new and there are basically no treatment studies that would allow one to have treatment outcome results which would satisfy the APA criteria for a validated treatment. More specifically, there are very few studies that have used a no treatment control (O'Leary & Vega, 2005). In addition, unfortunately, there has been little conceptual variability in the theoretical approaches that have guided treatment, and such lack of variability in intervention approaches contributes in part to the absence of cross-fertilization of approaches to evaluate intervention foci that would contribute to therapeutic outcome.

15.4.1 Prevention of Drop Outs

While research on mechanisms of change has been sparse, there are data that bear directly on treatment outcome such as the data on prevention of drop out from treatment. Given the drop out from treatment can be as high as 50% or greater, any methods of reducing drop out presumably would be of value in reducing partner aggression, especially if there is some evidence that interventions are successful.

In an outcome study comparing dyadic- and spouse-specific approaches to reducing partner aggression, Brown and O'Leary (2000) showed that there was an association between session one observer ratings of the working alliance and reductions in both physical and psychological abuse in a self-referred sample of couples in therapy for male-perpetrated violence. This study was the first to look at alliance as an outcome predictor in interventions for partner abuse, but additional data from a court-mandated sample would help buttress the importance of alliance in the more commonly used court-mandated programs.

As Taft, Murphy, King, Musser, and DeDeyn (2003) noted, process factors in psychotherapy typically account for a larger proportion of variance in outcome than the specific treatment approaches. Moreover, varied treatments may produce similar effects due to factors common to almost all forms of therapy. As of 2003, unfortunately, no study had examined treatment process variables among a predominantly court-mandated sample of partner-violent men. Taft et al. showed that therapist working alliance ratings predicted lower levels of physical and psychological abuse at the 6-month follow-up and were the strongest predictors of outcome. They also found that greater group cohesion during treatment, assessed by client report, also predicted lower physical and psychological abuse at follow-up. These results are in accord with other areas of treatment outcome and they may not be surprising to some. However, these results are quite important in that they point to the utility of using the general psychotherapy literature to help build effective treatments for partner abuse. The results also challenge the use of confrontational approaches in interventions for partner abuse.

15.5   Basic Competencies of the Clinician

This section is intended for those mental health professionals who come into contact with cases of partner abuse, but whose primary focus and experience is not necessarily focused on partner-abuse issues.

15.5.1 Ethics of Reporting Partner Aggression

Ongoing debates about whether partner abuse should be reported in the same ways as child abuse continue. Proponents of mandatory reporting laws for partner abuse suggest that such laws would enable early identification of victims, encourage continuity of care, and help secure access to recourses (Freed & Drake, 1999). Those against such policies prioritize the need for victims to feel in control and empowered to make their own decisions. This argument has gained support from the studies that demonstrate that women are often at heightened risk for abuse after they report the abuse and/or try to leave the home (e.g., Waltermaurer, McNutt, & Mattingly, 2006).

Researchers have asked women and physicians whether they would support a mandatory reporting system. For example, Malecha, Lemmey, McFarlane, et al. (2000) determined that 81% of a sample of 161 abused women supported some sort of mandatory reporting system (2000). However, other researchers found that though 73% of women thought a mandatory reporting system would make it easier for women to get help, 52% of them also feared an increase in abuse was likely with such a reporting system (Gielan, O' Campo & Campbell, 2000).

15.5.2 Assessment of Aggression and Abuse

Research suggests that mental health professionals are not necessarily any more diligent in screening for, and addressing, IPV than other health professionals (e.g., Dimidjian, Berns, & Jacobson, 1999). Gondolf (1992) found that out of 92 patients visiting an emergency department, 55% had been to the emergency department previously for an injury associated with family violence. Though in 70% of these cases, the assessing clinician did ask IPV-related questions about the newest injury, the clinician described the IPV as a primary problem in their report to the supervising psychiatrist in only 37% of cases. In another study of marital and family therapists, only 22% of professionals correctly identified abuse as the primary problem of sample case studies depicting severe abuse (Hansen, Harway, & Cervantes, 1991).

There are several imperatives to proper assessment of domestic abuse. First, proper assessment for domestic violence must be done individually, apart from their partner. There are several methods of assessment, namely interview and self-report. It is advised to begin the discussion with general questions about how the couple handles conflict and how conflicts generally end. Normalizing conflict by explaining that all couples experience conflict and handle that in different ways can help the client feel more comfortable in disclosing their particular situation. Once these discussions have taken place, it is very important for the provider to ask concrete, behaviorally specific terms to probe for abuse because some individuals will not endorse more global constructs of abuse (O'Leary, 2008). Additional areas to explore in an interview include tactics of control used in the relationship, level of fear of the partner and safety planning, and witnessing or involvement of children in domestic violence incidents. If severe abuse is disclosed by a client, it is appropriate and necessary to assess for risk of homicide. The Danger Assessment Instrument is such an instrument that has been designed to assess for this risk and should be used in cases where there is concern about more severe types of abuse and/or homicide (Campbell, 1995).

15.5.3 How to Develop a Safety Plan

There are two situations that should alert the mental health professional of the need to develop a safety plan. The first such situation is if it becomes apparent that the aggression or abuse has been escalating over time. The second situation is if the client reports that they fear their partner. Fear of partner has been shown to be an extremely reliable predictor of future aggression (Weisz et al., 2000), so this signal must not be overlooked.

The professional should begin by asking the client (usually a woman who has fear for her safety) what options she would have in the event she needed to get away from her partner whether she is at home or at work. Identifying the social supports the client could call on like

family members, friends, coworkers, or shelter resources is usually the first step. Transportation to a safe place and a brainstorming of the kinds of things she would need to have ready and accessible must be discussed. Important documents like her/his children's birth certificates, passport, marriage license, and bank books should all be put in a special place that only she knows about and can access quickly. Other things she should have packed are clothes, money, medications, phone numbers/addresses of her social supports, and children's belongings. Explaining that keeping a charged cell phone, if the person has one and can afford one, is also important. If the client has a restraining order or order of protection, she should give copies to her workplace security team and/or boss Children suspecting anything so as not to invite any questioning. Research has demonstrated that a woman is at a heightened risk of homicide in situations where she is separating from an abusive partner after having lived with him, after she has left the home she shared with the abusive partner, or after she has asked the abusive partner to leave the home (Campbell et al., 2003).

15.5.4 Knowledge of Local Shelter and Intervention Services

In order to adequately address issues of prevention of, and intervention for, IPV, it is imper-l ative that mental health professionals and local advocacy and support agencies join forces. Though local shelters and intervention agencies ultimately have the same goal for a battered victim as does the mental health professional, differing ideologies and principles at many times perpetuate the separation and lack of dialogue. Oftentimes shelter and advocacy staff operate under a system-change type of focus, whereas mental health professionals focus most of their attention on the client, from an individual perspective (Warshaw & Maroney, 2002). It is the responsibility of all professionals working with domestic violence clients to bridge connections with each other and become knowledgeable about the full range of services available to their clients.

15.5.5 When to Treat Substance Abuse Problems

A wealth of literature describes the clear association between domestic violence and substance abuse for both male and female perpetrators (e.g. Fals-Stewart, 2003; Cunradi et al., 1999). Kaufman, Kantor, and Straus report that just prior to the most recent and severe act of abuse for a national sample, 20% of men and 10% of women were drinking (1990). It has also been demonstrated that in a sample of partnered individuals seeking alcohol or drug treatment, the proportion of these dyads reporting at least one episode of IPV was four to six times higher than is true for the general population (Fals-Stewart, Golden, & Schumacher, 2003). In fact, Fals-Stewart demonstrated that on days in which the men in the treatment program drank alcohol, the odds were eight times higher that there would be a reported instance of male-to-female aggression as compared to days with no alcohol consumption. Though most research to date has focused on perpetrator's use of substances, particularly alcohol, evidence suggests the victim's use of alcohol is also related to their own victimization (Kaufman Kantor & Straus, 1990).

Several research studies have demonstrated that addressing substance abuse problems aids in decreasing or eliminating IPV for both male and female perpetrators (O'Farrell, Fals-Stewart,

Murphy, & Murphy, 2003). Since results demonstrate that IPV does decrease after standard alcoholism treatment, it is logical to surmise that clients with substance abuse problems should be given treatment for those problems, at least as part of the overall IPV intervention plan. Since these positive reductions in IPV only seem to hold in cases of alcohol or substance abstinence and given the high relapse rates following alcohol and substance abuse treatment programs, substance abuse intervention programs cannot serve as the standalone intervention for IPV (Fals-Stewart & Klostermann, 2009).

Unfortunately, combined substance abuse and IPV treatment approaches are relatively rare in research settings and community treatment programs. The few that have been described, however, have had positive results. The most empirically supported approach at this point is Behavior Couples Therapy (BCT), which is an alcohol and substance abuse intervention that utilizes partner involvement through safety skill training and does include a focus on conflict in the relationship. Two very promising individual treatment approaches that address both substance abuse and IPV include Dade County's Integrated Domestic Violence Model (Goldkamp, Weiland, Collins, & White, 1996) and Yale's Substance Abuse Treatment Unit's Substance Abuse-Domestic Violence (SATU-SADV) Program (Easton & Sinha, 2002). Though an intervention plan which addresses both substance abuse and IPV is the preferred type of intervention in many cases, careful assessments should be utilized which enable the assessor to determine the extent to which substance abuse is, in fact, contributing to IPV in that particular relationship.

15.5.6 When to Treat Relationship/Marital Problems

Many studies demonstrate that IPV is highly prevalent among couples presenting for marital therapy (Jose & O'Leary, 2009). Whether or not mental health professionals ought to provide couple therapy for partner aggression has been hotly debated. The literature contains varied testimonials that family and marital therapies for IPV are unethical, potentially dangerous for the victim, and generally inappropriate (e.g. Bograd & Mederos, 1999). Part of the reason for the unwillingness to support marital approaches comes from several assumptions. The first is that since conjoint therapies emphasize shared responsibility for behavior, the victim will be accused of sharing responsibility for their own victimization. The second assumption is that since conjoint therapy's foundation is built on open and honest communication, there is high probability that in being honest, the victim could put herself/himself in a more dangerous situation based on the conflict their honest responses may elicit from the abusive partner (Fals-Stewart & Klostermann, 2009).

There is a host of research, however, that offers a lens into this concern. Distinguishing between common couple aggression and abuse/battering is crucial in determining whether or not conjoint treatment is appropriate and safe (Jacobson & Gottman, 1998). Relationships in which there is either fear of partner or a history of injury and in which the violence is perpetrated out of an attempt to control and/or manipulate are classified as battering relationships. In these cases, marital therapy should not be used to treat the abuse (O'Leary, 2008). If this occurs, one should meet with both partners separately and in doing so help the victim become acquainted with community resources and go through the process of developing a safety plan with the client. The abusive partner should not know what was discussed with the victim, in an effort to protect the victim from further abuse after the session. The majority of couples presenting for marital therapy for aggression treatment will fall into the common couple violence

subtype and as such, be typified by mutual, low-level violence. Unlike the situation of battering in which conjoint treatment is inappropriate, research has demonstrated that in cases of common couple aggression, conjoint therapy focusing on mild to moderate types of aggression can be quite effective (O'Leary, 2008; Stith, Rosen, McCollum & Thomsen, 2004).

15.5.7 Different Treatments Needed for Partner Aggression and Abuse

There is no one-size-fits-all type of treatment for aggression, as the reasons for the aggression and the severity of the aggression can vary widely and are clinically meaningful. As discussed above, minor types of aggression that are not based on efforts to control and dominate, like common couple violence, can be successfully treated through marital therapy. More severe types of abuse on the other hand in which there is a history of injury and/or fear need to be treated with individual or group therapy for the perpetrator alone. In these cases, if the mental health professional is able to meet with the victimized partner, they should offer information about community resources and help the person develop a safety plan for themselves.

The severity of the abuse is also a determinant on the probable length of treatment that will be needed. Less severe aggression will be able to be treated in a shorter length of time than will more severe types of aggression. It is important to keep in mind that some very severe abuse may be too severe to be effectively treated with any of the treatments we currently have available. In these cases, communication and safety planning with the partner of the abuser is crucial.

15.5.8 Transition from Basic Competencies to Expert

In order for one to move from the basic to the expert competency level, it is important that the mental health professionals have a range and depth of experience in the field of partner abuse in order that they have a nuanced understanding of the issues involved, both for victims and perpetrators of partner abuse. Someone who has reached the expert level has had varied experience in seeing both male and female clients, under supervision, and if possible both heterosexual and homosexual cases in which partner abuse was the primary presenting problem. This person will have participated in conducting evaluations of partner-abuse interventions either in a group or as an individual. They will be abreast of the current empirical and theoretical work in the field through regular reading of the pertinent journals and chapters. An expert is someone who would be attending regular workshops or training sessions related to partner abuse and would be involved in some sort of partner-abuse prevention program. This person is also someone who is able to keep an open mind and always be thinking of new ways to treat or intervene with the problem of partner abuse.

15.6   Expert Competencies of the Clinician

15.6.1 Assessment of Individual Precipitating and Maintaining Factors

Since partner abusers are a heterogeneous group (e.g., Johnson, 1995), developing a set of IPV risk factors that are applicable to the diverse population has been, and continues to be,

a complex task. That said, there is a number of cognitive, affective/psychopathological, and relationship-behavioral precipitating and maintaining factors that seem to cut across subgroups of this population (Murphy & Eckhardt, 2005). Though there are a range of demonstrated precipitating factors associated with an increased risk of partner abuse IPV, (Schumacher, Feldbar-Kohn, Selp, & Heyman, 2001), this section will focus on those factors which can be intervened upon and which are proximal, in nature, to the partner abuse.

A common perspective within the cognitive literature is that abusive partners endorse attitudes, beliefs, and points of view that support and accept their abusive actions (Murphy & Eckhardt, 2005). Partner abusive men tend to blame the abuse on hostile intentions of their female partner (e.g., Byrne & Arias, 1997). Erroneous beliefs may also work to influence selective attention in relationship conflict situation, the emotional reaction to a situation, and the response to the situation (Murphy & Eckhardt).

Emotional disturbances and psychopathology also contribute to risk of IPV perpetration. The National Comorbidity Survey found that psychopathology in males, but not females, was predictive of IPV and the IPV was specifically predicted by the presence of the following disorders: premarital major depression, alcohol dependence, generalized anxiety disorder, and nonaffective psychosis. Severe acts of abuse were predicted by dysthymia, adult antisocial behavior, and nonaffective psychosis (Kessler, Molnar, Feurer, & Appelbaum, 2001). Other studies have corroborated the finding that presence of axis I disorder is related to abusive behavior (e.g. Danielson, Moffitt, & Caspi, 1998). Other variables such as anger/hostility, negative affectivity, low self-esteem, attachment insecurities, personality disorders including antisocial personality disorder substance use and abuse problems, and relationship distress have all been shown to be related to increased risk for IPV.

With regard to relationship-behavioral factors, research has demonstrated that relationship discord is a consistent correlate of IPV (Schumacher et al., 2001). Some posit that this link has to do with power and control dynamics. However, the vast complications with defining the construct of "control" have cast some doubt on the relationship (Malik & Lindahl, 1998). Negative communication and problematic interactional style of partners have also been found to be related to IPV (Jacobson et al., 1994). Finally, abusive partners have been found to have larger deficits in communication skills such as *spouse-specific* assertiveness (e.g., Rosenbaum & O'Leary, 1981) and appropriate expression of feelings (e.g. Eckhardt, Jamison, & Watts, 2002).

It seems that there are at least two different subgroups of abusive men that may be clinically relevant. One of these groups includes men who are solely aggressive within their family or intimate relationship. These men show signs of relationship discord but are otherwise reflective of the normal population in terms of psychological testing assessments. The second group has general problems with anger and/or aggression within and outside the family, impulse control deficits, and personality problems including antisocial and borderline tendencies as described above. This more disturbed cluster has more associated clinical problems such as substance abuse and childhood history of violence exposure (e.g., Waltz, Babcock, Jacobson, & Gottman, 2000) and perpetrate violence in a more frequent and severe pattern (Murphy & Eckardt, 2005).

Different grouping categories have been reported which may map onto these two subtypes or in some way refine our conceptualizations of IPV perpetrators. One of the distinctions has been between instrumental aggression, which occurs in the absence of sympathetic arousal and is goal-directed, and hostile aggression, which is believed to occur under conditions of

high emotional arousal (Bushman & Anderson, 2001). A second categorization system is that of reactive aggression, which is an impulsive response, and proactive aggression, which includes planning and calculated use of aggression (Dodge, 1991). Remington and Murphy (2001) found that antisocial personality-disordered abusive men were more likely than other abusive men to report engaging in preparation for the abuse and more likely to report positive emotions after inflicting abuse upon their partner (2001). This may mean that this group of men uses more proactive-instrumental aggression (Murphy & Eckardt, 2005).

The behavioral assessment process for partner abuse outlined by Rathus and Feindler (2004) prioritizes (1) observable behaviors (over inferred characteristics), (2) present and recent events (over historical or developmental factors), (3) environmental and situational determinants of behavior (over intra-psychic determinants), (4) ideographic, individual analysis (over nomothetic or normative analysis), (5) multiple sources of assessment data (over single-source information from the client), and (6) ongoing or continuous assessment (over one-time assessment). This assessment process should serve as the guideline for the mental health professional to use when assessing for partner abuse.

Early in the assessment process, it is important to assess the level of risk and dangerousness that the client poses to their partner. Since research has demonstrated that predictions of future violence are best done with empirically derived methods (Monahan et al., 2001) and we know clinical judgment underperforms in comparison to objective methods of prediction, it is important to use standardized, validated measures to assess. In order to assess risk of reassault on an IP, one can assess for risk of homicide with the Danger Assessment Instrument (Campbell, 1986, 1995); the risk of spousal violence with the Spousal Assault Risk Assessment Guide (SARA; Kropp, Hart, Webster, & Eaves, 1995), and the risk of violence recidivism for men with the Partner Assault Prognositc Scale (PAPS; Murphy, Morrel, Dlliott, & Neavins, 2003).

It is extremely important to be able to contact the partner of the abuser early in the assessment process. Reasons for the early risk assessment are to be able to offer resources and an opportunity to engage in safety planning with the victim, if the abusive partner is deemed to pose significant risk. In some cases, a partner will agree to be in touch with the mental health professional to lend insight into the abusive partner's behaviors which then can be used in the treatment process. Following an initial assessment of current risk to partner and, if necessary, contact of the partner, an in-depth clinical interview needs to be administered to the partner-abuser (Murphy & Eckhardt, 2005). This interview should begin with a process of gathering broad-based questions about relationship problems and conflict and specific, detailed information on one or two most serious incidents. Though some highly motivated clients will be able and willing to discuss the relevant details and will describe their role, others will need to be assessed over a few sessions during which rapport building and motivational interviewing will aid in their progress through the change process (Murphy & Eckhardt). It is important to let the client know that the assessment information will be used in order to help guide the treatment process and will be held confidential, unless they give their written permission otherwise. Other focal areas of the interview should: (1) assess the precipitating conflicts that prompt use of violence, (2) assess the process of conflict escalation, (3) uncover the cognitions involved during the initial and escalating phases of relationship conflict, (4) probe into the short-term consequences of the abusive behavior, (5) identify the dynamics of influence and control in the relationship, and finally, (6) investigate other clinical issues that may be associated including trauma history, personality traits, attachment problems, and psychopathology (for a template of an interview, see Murphy & Eckhardt). Standardized measures to assess for most of the key

correlates of IPV are available and should be incorporated into any clinical assessment of precipitating and maintaining factors (for a review see Murphy & Eckhardt).

15.6.2 Delivery of Treatment in Both Individual and Group Modalities

The vast majority of partner-abuse treatment programs is designed with group delivery in mind (e.g., Pence & Paymar, 1993). The group format has advantages such as less cost and potential for positive peer influence. However, there is a series of disadvantages. Research on delinquent adolescents has demonstrated that deviant tactics are often swapped among participants (Dishion, Spracklen, Andrews, & Patterson, 1996). In addition, a group format necessarily introduces a lack of flexibility for mental health professional leading the group (Murphy & Echardt, 2005). Many perpetrators of abuse have issues in their past such as sexual and/or physical-abuse histories, substance-abuse issues, and other psychopathology issues that are not able to be addressed in a group format. The sensitive nature of some issues make them inappropriate to discuss in a group setting and the heterogeneity of co-occurring issues and precipitating factors make addressing each person's unique issues related to their IPV impossible (Murphy & Echardt).

15.6.3 Reducing Attrition in Treatment: Developing Bonds of Trust

As with any type of therapeutic relationship, treating the partner-abusing client with respect and refraining from judging them is very important to foster trust and develop a strong alliance. Since the therapeutic alliance has shown to have a strong relationship to treatment outcomes (Horvath & Symonds, 1991), this is very important. There is growing evidence that a strong working alliance with partner abusers, in particular, does predict completion of treatment program and treatment outcome (e.g. Brown & O'Leary, 2000). This task is difficult for many mental health professionals, as many construe that providing warmth and empathetic listening means that one is complicit with the types of pain the abuser has in, or is, inflicting on others (Murphy & Echardt, 2005). However, clinical observations have demonstrated that the more a clinician truly understands the patient, the better the case conceptualization, the intervention planning, and ultimately, the more likely it is that the patient will ascribe to the therapy offered. Realizing that many partner abusers have had very difficult and painful histories, themselves, often helps in promoting empathy in the mental health professional. Learning as much about the client as possible can help the client feel understood and can inform case conceptualization and treatment approach, and can help the professional develop empathy for the hardship that the person has had to face in their own lives.

Drop out from treatment programs is an issue of interest for all mental health practitioners. Indeed, there is high attrition from partner-abuse treatment group programs on the level of 50–70%, despite many being court-mandated to participate (Daly & Pelowski, 2000). The situation for partner abusers is complicated because though many are motivated to attend treatment in order to avoid a jail sentence, often their motivation to change is low (Scott & King, 2007). In these cases, a strong working relationship with the mental health professional can help increase motivation for change. Musser et al. report that utilizing a motivational interviewing process in an individual format helps to increase compliance with group therapy and lead to a stronger alliance (2005).

15.6.4 Competency Conclusions

Competency can be thought of as a collection of three key parts: knowledge, skills, and values (Gebbie et al., 2007). In order for one to be competent, they must have threshold-level grasp over the key issues for each of these arenas. In order to have a basic competency in partner abuse, one must have clear understanding and knowledge of the ethical issues involved, the array of resources available to victims and perpetrators, the instances in which co-occurring issues need to be dealt with either prior to IPV treatment or simultaneously, the situations in which treating aggression and/or abuse is or is not indicated, and finally what types of treatments are effective for the different types of aggression and abuse. A professional with basic competency also must have the skills necessary to carry out a complete and informed assessment of the IPV including the motivations for the abuse, the severity of the abuse, whether or not the abuse has escalated, and the extent to which the victim is informed and prepared. The professional must also possess the skills to design a safety plan in collaboration with the victim, provide the appropriate treatment for the partner abuse and any co-occurring problems or else know of a competent referral source to provide to the client. Finally, in order to be competent at any level in the arena of partner violence, one must be able to approach all clients, victims and perpetrators alike, in a nonjudgmental way.

An expert level of competency in partner abuse necessarily includes a higher level of the same knowledge, skills, and values expected for basic competency requirements. An expert in the field of partner abuse must be able to assess for the factors that have coalesced to precipitate abusive behavior and the factors that are working to maintain that type of behavior. They must be knowledgeable and skillful in treatment delivery and aware of the conceptual basis for different types of treatment. The expert in partner abuse will also be someone who has developed advanced skills in therapeutic process and has learned how to find their empathy for a client, regardless of the behaviors that client has or is currently engaging in.

15.7   Summary

While partner violence research was almost unknown in the 1960s, the field of IPV has exploded in the past 3 decades. Research on correlates and risk factors have been a major focus of the majority of research, but interventions have been the subject of increasing attention. Fortunately, in addition, multivariate models of IPV have begun to be evaluated, and there is converging evidence from different research groups that violence in the family of origin, antisocial and/or aggressive behavior as a teen, anger, alcohol abuse, relationship dissatisfaction, psychological aggression, and power/control tactics have all been shown to predict partner violence. Batterer intervention has been the most common approach for dealing with partner violence issues, but the evidence supporting such interventions is weak. Thus, it seems appropriate to keep open minds to alternative conceptualizations for varied interventions such as marital therapy for aggression at lower levels and where there is no fear of partner. Further, given that IP aggression occurs in approximately 35% of young couples in a general population, prevention of partner violence before it exists at all and reduction and/or cessation of partner violence at lower levels seem especially important.

16 Sexual Offenders

Robert A. Prentky · Adeena M. Gabriel · Anna I. Coward

Abstract: A small but growing niche of clinical practice involves services provided to sexual offenders, typically within the criminal justice system. This is an emotionally, and ethically, challenging area of practice that has, for all practical purposes, been unregulated, with the sole exception of the efforts of one professional organization (Association for Treatment of Sexual Abusers). Given the unusual demands placed on the clinicians working with sex offenders, and the high stakes nature of their work (providing effective treatment for clients disposed to committing sexual offenses, and offering evaluative judgments about the risk posed by these clients), it would seem reasonable to expect that this area of practice would be well regulated. As noted, this appears not to be the case. In this chapter we provide a framework for establishing guidelines for professional competence at two levels of practice – basic and expert. Our mission is not to provide an end product, but rather a blueprint to initiate dialogue and, in so doing, a process that will eventuate in a uniformly adopted standard for professional competence in this area.

16.1   Overview

The past several decades have witnessed an unprecedented number of state and federal laws intended to curb sexual violence. Federal legislation has included the Violence Against Women Act of 1994 (VAWA), the expanded VAWA legislation in 2000 (P. L.106–386, 18 U.S.C. 2261), The Wetterling Act, passed in 1994 as part of the Violent Crime Control and Law Enforcement Act (42 U.S.C. 14071), the amended Wetterling Act of 1996, known as "Megan's Law" (P. L. 104–145), the amended Federal Rules of Evidence in 1995 to include prior sex crimes, the Pam Lynchner Sexual Offender Tracking and Identification Act (42 U.S.C. 14072) in 1996, The Wetterling Improvements Act of 1997 (P.L. 105–119), the Victim's of Trafficking and Violence Prevention Act of 2000, and the Adam Walsh Child Protection and Safety Act of 2006 (P. L. No. 109–248, 42 U.S.C. 16901). The Adam Walsh Act established a comprehensive national system for the registration of all sex offenders (Title I, §301). The 2005 Florida law, referred to as "Jessica's Law," was introduced at the federal level during the 109th Congress. The federal bill (H.R. 1505), known as The Jessica Lunsford Act, mandates more stringent tracking of sex offenders. The most impactful legislation at the state level has taken the form of civil commitment laws targeting sex offenders.

This form of legislation first appeared in its current incarnation in 1990 in the State of Washington (WA Laws of 1990, chap. 3). Twenty states now have such laws (cf. Gookin, 2007). In addition, as of 1997, every state has had some variant of a sexual offender public notification law pursuant to the federal Wetterling Act of 1996.

All sex offenders, upon returning to society, are evaluated for risk by a state registry board and most end up in some form of outpatient treatment. All 20 states with civil commitment laws have prison-based treatment programs for those who are committed. In addition, many states provide prison-based treatment for noncivilly committed sex offenders (i.e., those

serving their criminal sentence). As noted above, most sex offenders returned to society are mandated or volunteer to enter treatment. Treatment for sex offenders, whether in prison or in the community, has evolved into a niche of clinical practice that employs a sizeable and growing number of practitioners. The largest professional organization, Association fo r Treatment of Sexual Abusers (ATSA), has 2,049 clinical members (as of 04/2009), and that number does not reflect the numerous therapists who treat sex offenders and do not belong to ATSA. Roughly 50–60% of those attending ATSA conferences each year, for instance, do not belong to the organization. Given the increasing demand for therapists to treat sex offenders, the emotionally – and ethically – challenging nature of the practice, and the unregulated nature of the "industry," it would seem prudent to establish, at minimum, guidelines for professional competence. It does not appear that this has ever been done, at least not in any formal sense. Our mission is not to provide an end product, but rather a blueprint to initiate dialogue and, in so doing, a process that will eventuate in a uniformly adopted standard for professional competency in this area.

16.1.1 Recognition of Symptoms and Their Assessment

Symptom recognition is complicated by the nature of the population being served. Sex offenders do *not* constitute a diagnostically or clinically homogeneous group possessing a discrete set of symptoms. If anything, "sex offender" is a legal term and refers to a person who has committed a sexual offense according to the legal standards of the jurisdiction in which the offense took place. This term is differentiated from "sexually deviant behavior," which does not necessarily imply illegal behavior and typically refers to a paraphilia.

Although some sex offenders can be diagnosed with a paraphilia called *pedophilia*, most sex offenders do not undergo any formal DSM-IV-TR (American Psychiatric Association [APA], 2000) diagnosis specific to being a sex offender. Simply stated, sex offenders are markedly heterogeneous with regard to their backgrounds, emotional problems, personality traits, treatment needs, and the nature of offenses they commit (Knight & Prentky, 1990; Knight, Rosenberg, & Schneider, 1985). As such, there is no discrete set of symptoms associated with being a sex offender. The best thing that we can do is to note what the clinical literature reports as being most frequently observed among child molesters and among rapists.

Although relatively little is known about the etiology of child molestation, there has been considerable speculation about the dimensions that are hypothesized to differentiate among different types of child molesters (Knight et al., 1985). Such dimensions include (a) sexual preference for children, (b) psychosocial and psychosexual immaturity; poor social skills, low social competence, poor self-esteem, and (c) impulsive, antisocial behavior. They define three core subtypes that appear to have clinical utility: (1) a child molester with an exclusive, long-standing sexual and social preference for preadolescents (i.e., a pedophile), (2) a child molester whose sexual offenses represent a "regression" or downward drift from an adult level of psychosocial adaptation in response to chronic stressors and perceived rejection (i.e., an incest offender), and (3) an exploitative, predatory child molester with a track record of impulsive, antisocial behavior and very poor social skills who turned to children because they were easy prey (Knight & Prentky, 1990; Knight et al., 1985; Prentky & Burgess, 2000).

In sum, etiologic factors gleaned from the empirical literature on child molesters include: (a) deviant sexual arousal to children, (b) other paraphilias (i.e., other deviant sexual interests), (c) developmental immaturity, poor social skills, and "stunted" relationships with adults, (d) antisocial behavior, and (e) the presence of highly intrusive sexual abuse, typically lasting for a protracted period and beginning at an early age. These factors do not, however, constitute *symptoms*. Psychiatric symptoms, usually in some combination, point towards the presence of a specific disorder or abnormality. There is no single disorder that captures all child molesters. As noted, the closest that we can come to is pedophilia, which is appropriate for a subset of child molesters.

Since the Diagnostic and Statistical Manual (DSM) was first published in 1952 (APA, 1952), there has always been a category for pedophilia. The current Manual (DSM-IV-TR) requires evidence of (1) recurrent, intense sexual behaviors, urges or fantasies involving sexual activity with a prepubescent child (generally age 13 or younger) for at least 6 months, (2) the individual has acted on these urges or is markedly distressed by them, (3) the individual is at least 16 years old and at least 5 years older than the victim, and (4) late adolescents who are involved in ongoing relationships with 12 or 13 year olds are excluded. Although there are multiple criteria noted above for diagnosing a pedophile, there essentially is only one symptom – recurrent, intense sexual behaviors, urges or fantasies involving sexual activity with a prepubescent child. All child molesters who have acted on their urges over a time period of 6 months or longer can be diagnosed as pedophiles. Hence, the DSM provides a single diagnostic category with a single symptom that can subsume most child molesters. Taxonomic models that differentiate among child molesters (e.g., Knight & Prentky, 1990), however, clearly reflect diversity of deficits, emotional and psychological problems, and motives.

Several investigators have developed and tested useful path models for explaining sexual aggression against women (e.g., Knight & Sims-Knight, 2003; Malamuth, 2003; Malamuth, Sackloskie, Koss, & Tanaka, 1991; Malamuth, Heavey, & Linz, 1993; Malamuth, Linz, Heavey, Barnes, & Acker, 1995). In Malamuth's earliest version of his confluence model (Malamuth et al., 1991), two major paths were identified, each with three factors. The first path consisted of (1) an abusive home environment, (2) delinquent behavior in adolescence, and (3) impersonal sexuality in adolescence and adulthood (e.g., early onset of sex, numerous brief partners, high frequency of sexual activity). The second path consisted of (1) cognitive distortions (irrational attitudes) that supported rape, (2) personality traits that included narcissism, entitlement, and hostility toward women, and (3) low empathy. A subsequent hierarchical-mediational version of the confluence model (Malamuth et al., 1995) added proneness to hostility (general anger) as a precursor of cognitive distortions on the second path. This additional hostility factor, along with low empathy and hostile masculinity (personality traits on the second path) are a theoretical match to Factor 1 of Hare's Psychopathy Checklist (PCL-R) (Harpur, Hakstian, & Hare, 1988), while impersonal sex on path one is a theoretical match to some of the items on Factor 2 of the PCL-R (Malamuth, 2003). Knight and Sims-Knight (2003) revised the Malamuth model, noting that the important dimension of hostile masculinity was not univocal. Knight and Sims-Knight (2003) tested a three path model on adult sex offenders and a sample of community controls (non-offenders). Path one begins with an abusive home environment, leads to callousness and lack of emotion (flat affect), which disinhibits sexual fantasy and sexual urges. Path two begins with sexual abuse, which disinhibits sexual fantasy and sexual urges. Path three begins with early onset antisocial behavior, which leads directly to sexual aggression.

The principal difference between these path models is the single dimension of hostile masculinity in the confluence model or a bifurcation into separate dimensions of antisocial behavior and callousness/unemotionality in the Knight model. This research, and the models issuing from it, has been pivotal in providing sound evidence for a unified, theoretical explanation of sexual aggression against women. Distilling the essence of this research, multiple major etiologic factors (dimensions) have been identified: (a) an abusive home environment, (b) a stable record of antisocial behavior, generally beginning in adolescence, (c) classic PCL-R Factor 1 traits, including narcissism, grandiosity, arrogance, and entitlement, callousness indifference to others, and lack of empathy, and (d) misogynistic attitudes. Unique to Malamuth's confluence model is the additional factor of impersonal sex, including promiscuity, high sexual drive, and numerous brief sexual encounters.

As with child molesters, these etiologic factors are not, in the conventional sense, psychiatric symptoms. Although rape is a specific behavioral (and criminal) outcome, it is not a specific psychiatric disorder. There has never been a category for "rape" in the DSM. As illustrated above, there are different paths that lead to an outcome of rape and each of those paths will comprise of a different set of *symptoms*. Although the extant literature described numerous dimensions associated with rape (cf. Prentky & Knight, 1991), it is reasonable, based on more recent literature, to reduce those dimensions to roughly five: (a) impulsive, antisocial behavior, (b) anger, (c) attitudes associated with hostile or negative masculinity, (d) traits common to Factor 1 on the PCL-R, such as lack of empathy, entitlement, narcissism, grandiosity, and callousness, and (e) impersonal and promiscuous sexual behavior.

16.1.2 Maintenance Factors of the Disorder

The basic mechanism underlying the continuation of sexual offending behavior is, at least theoretically, the offense cycle, described originally by Pithers, Marques, Gibat, and Marlatt in 1983. The basic process is as follows: life stressors lead offenders to experience intense affect that is distressing or disturbing. This negative affect is coupled with a sense of subjective deprivation, prompting the individual to seek relief or diversion from negative affect and noxious life experience. These individuals begin to make a series of superficially trivial decisions that undermine self-restraint, placing themselves in high-risk situations in which there is an increased likelihood of both unstable emotions and contact with potential victims, clearly a maladaptive response to aversive affect. By placing themselves in such situations, offenders lose their sense of self-control over refraining from offending (i.e., they have "lapsed"). This stage can include fantasies about offending, arousal to such fantasies, and distorted thinking that will allow acting on those fantasies. At this juncture, the short-term benefits of offending become more powerful than the long-term consequences, allowing offenders to slide from lapse into relapse: sexual contact with a victim. Post-relapse, offenders evaluate themselves, their victims, and the offense. Negative self-evaluation is common but temporary, giving way to cognitive distortions that rationalize the offense. Thoughts occurring during this stage provide justification for the offense that is essential to maintain offending behavior. In order to break the cycle of offending, it is crucial to intervene before a lapse develops into a relapse; doing so is the only way to prevent the justificatory thought processes that encourage future relapses. The offense cycle and its treatment will be described in more detail later in this chapter in the context of the relapse prevention treatment modality.

Another possible maintenance factor is mental illness. Anywhere from 15% to 24% of inmates in the USA have a severe mental illness (Teplin, Abram, & McClelland, 1996), and half of inmates have at least one mental health condition (James & Glaze, 2006). Inmates with major psychiatric disorders such as bipolar, schizophrenia, and nonschizophrenia psychotic disorders are more likely to have been previously incarcerated than those without psychiatric disorders (Baillargeon et al., 2009), suggesting that mental illness may play a role in recidivism. Although relatively few sex offenders are known to have major mental illness, a much larger proportion of sex offenders are thought to have some affective disorder necessitating antidepressant medication. As noted above, aversive affect is thought to underlie much sexually deviant and sexually criminal behavior. In the case of general dysphoria or clinical depression, sexual gratification may be a learned response that temporarily brings relief from depression. Clearly, this is not the case for all sex offenders, but it may well be a contributing factor in many cases. Substance abuse falls in the same category as a maintenance factor. Alcohol and drugs may serve the same purpose as sexual gratification – temporarily relieving the individual of chronic, noxious thoughts and feelings.

Lastly, the most obvious maintenance factor for some, by no means all, sex offenders is sexually deviant thoughts, fantasies, and urges. As a maintenance factor, sexual deviance is noted primarily among those child molesters who have an exclusive sexual preference for children and underage adolescents. Although sexual deviance may also be noted among child molesters with nonexclusive preferences (i.e., they have relationships with adults), there is a greater likelihood that other maintenance factors play a critical role as well. Sexual deviance may be observed among rapists as well (e.g., sadism), but it is rare.

16.1.3 Evidence-Based Treatment Approaches

Effectiveness of treatment can be measured by one question: does treatment reduce sexual reoffending, and if so, by how much? The management and treatment of sex offenders is often uninformed by research and is more often driven by personal feelings, moral convictions and political agendas. However, several meta-analyses have shown the treatment of sex offenders to be effective.

A 1995 study conducted by Hall brought together 12 studies of treated sexual offenders for a total of 1,313 men. Hall found a small but significant decrease in rates of reoffending as a result of treatment: sexual recidivism for non-treated offenders was 27%, while recidivism for treated offenders was 19%, an overall decrease of 8%. For studies that employed cognitive behavioral methods or anti-androgen medication, the decrease in recidivism was even larger. Hanson et al.'s Collaborative Outcome Data Project on the Effectiveness of Psychological Treatment for Sex Offenders (2002) examined 43 studies for a total of 9,454 offenders, approximately 54% of whom had received treatment. Across studies, sexual recidivism was about 12% for treated and 17% for untreated offenders. When examining only the most recent studies using the most current methods (e.g., CBT), they found sexual recidivism to be around 10% for treated and 17% for untreated offenders. The largest meta-analysis conducted to date, with 69 studies and 22,181 offenders, demonstrated a 6% reduction in sexual recidivism with treatment (Losel & Schmucker, 2005).

A 2000 study by Nicholaichuk, Gordon, Gu, and Wong compared 296 treated to 283 untreated offenders, finding the conviction rate for sexual reoffending to be 15% for treated

and 33% for untreated offenders. This sizable discrepancy may not be as encouraging as it appears on first glance; Nicholaichuk et al. (2000) acknowledge that this difference is likely due to the high rate of reoffending for the untreated offenders rather than a reduction in recidivism for untreated offenders. Zgoba and Simon (2005) investigated offenders from New Jersey's state prison for sexual offenders, which provides treatment to sexual offenders from the general prison population. Fourteen percent committed a new sexual offense within the 7-year follow-up period, with no statistically significant differences between treated and untreated offenders.

To date, only one randomized clinical trial has been conducted to investigate effects of treatment for sexual offenders: California's Sex Offender Treatment and Evaluation Project (SOTEP) (Marques, Day, Nelson, & West, 1993; Marques, Nelson, Alarcon, & Day, 2000). Volunteers were randomly assigned either to treatment or no-treatment conditions; guided by the possibility that willingness to participate might predict better treatment outcome, a randomly selected group of offenders who did not volunteer were also included as a control group. Participants who completed a course of treatment were found to have a higher rate of recidivism (22%) than did the volunteer control group (20%) or the non-volunteer control group (19%) (Marques, Wiederanders, Day, Nelson, & van Ommeren, 2005).

There is a clear discrepancy between results of the meta-analyses and those of the individual studies, the former indicating that treatment for sexual offenders is effective and the latter demonstrating that it is not. All three meta-analyses yielded similar results. However, due to the large sample sizes, minor differences in the rates of recidivism across the studies could reach statistical significance without achieving practical significance; Zgoba and Simon's (2005) considerably smaller sample, for example, was unable to achieve significance. According to Barbaree (1997), recidivism studies often do not pick up on the effects of treatment. Base rates for recidivism are fairly low to begin with (10–40%); when the sample size is also small, the treatment effect must be very large (e.g., 50%) to achieve significance between treated and untreated offenders. This sets the bar for significance very high and is a criterion that many researchers struggle to achieve.

Considering the difficulty in achieving significance, it may be tempting to rely on the findings of the meta-analyses and conclude that treatment works. Such a conclusion, however, ignores the findings of the most methodologically sound study conducted to date (SOTEP). How to interpret these findings has become a matter of controversy in itself (Marshall & Marshall, 2007, 2008; Seto et al., 2008), since it is risky to override what it widely regarded as the gold standard of research design. Due to the current lack of certainty regarding effectiveness of treatment for sexual offenders, treatment should be regarded as one potentially effective method for managing the risk of recidivism. It should neither be viewed as a panacea for offenders, nor be utilized in isolation. Rather, it should be included as an element of a rehabilitation plan that may include medication, probation, GPS monitoring, and other interventions.

16.1.4 Mechanisms of Change Underlying the Intervention

As we have pointed out in this chapter, the leading treatment utilized with sex offenders is Cognitive Behavioral Therapy (CBT). Through CBT, sex offenders achieve a sense of accountability for their behavior and an understanding of the impact of thinking on behavior.

By learning to identify problem thoughts (cognitive distortions), how to self-monitor these thoughts, and eventually replace these distorted thinking patterns with adaptive thinking, offenders undergo the changes necessary to reduce the risk of recidivism (Lipsey, Landenberger, & Wilson, 2007). Generally, CBT involves changing cognitions and thinking patterns, but specific skills such as anger management may be highlighted to initiate change. In their analysis of the effect of different cognitive behavioral programs on recidivism, Lipsey et al. (2007) found that cognitive behavioral therapy in general and not any CBT program specifically was responsible for change.

CBT with a sex offender population usually incorporates a Relapse Prevention model. Polaschek (2003) points out that Relapse Prevention is now part of nearly all sex offender treatment programs in the USA and is widely used in other countries as well. As discussed elsewhere is this chapter in greater detail, Relapse Prevention attempts to eliminate the possibility of a relapse by identifying triggers. By taking steps to deal with triggers in an adaptive way, the subsequent lapse or relapse can be avoided. Essentially, the process of identifying triggers for relapse and engaging in new behaviors following triggers interrupts the offense cycle. This is the mechanism of change that is sought in employing Relapse Prevention with sex offenders. In order for this to work and change to occur, the requirement at the outset of Relapse Prevention treatment is the desire to change. Offenders must be able to identify their behavior as problematic and be willing to make the changes necessary to stop engaging in the behavior. Without this first step it is understood that Relapse Prevention Treatment cannot take place.

In addition to the aforementioned methods through which change is achieved, Serran, Fernandez, Marshall, and Mann (2003) have pointed out the importance of the therapeutic alliance in effecting change in clients. Serran et al. (2003) highlight the importance of empathy, warmth, flexibility, support, and encouragement in effectively engaging clients in change through therapy. Additionally, the authors discuss the importance of boosting self-esteem when working with sex offenders. These elements should not be overlooked, as they are linked to the effectiveness of therapy through the client's willingness to participate in treatment, remain in treatment, and ultimately undergo change through the treatment process and the therapeutic relationship.

16.1.5 Basic Competencies of the Clinician

The APA (1992) defines competence as consisting of (a) education, training, and experience; (b) knowledge of scientific and professional information on services being rendered, including related fields of knowledge; (c) ongoing efforts to maintain competence; (d) efforts to protect the welfare of clients; and (e) the ability to recognize when effectiveness is compromised. The APA (1992) has outlined additional standards of competence for forensic psychologists, indicating that their activities should be based on suitable and sufficient data and that there should be a clear understanding of the limitations that constrain generalization in that field. It is important for psychologists training in all fields to understand that competence is not an endpoint, but rather an ongoing process of change and renewal that is measured by education, training, supervision, consultation, and other appropriate professional experiences (Nagy, 2005). Experience gained over time is essential for developing high-quality skills, as both experience and time are essential ingredients in developing sophisticated internal models

(Ericsson & Smith, 1991), as well as learning to link information and to distinguish between relevant and irrelevant information in problem solving (Patel & Groen, 1991).

Although more refined gradations in level of competence may be useful, for purposes of this chapter, we focus on a simple distinction between a "basic" level of competence that may be expected of most practitioners in the field and a more advanced level of competence that may be expected of "experts" in the field. Since we are focusing on the question of competencies for clinicians that assess, evaluate, and treat sexual offenders, we are always assuming some forensic context to the provision of services; hence, when we refer to clinicians, we are speaking about "forensic clinicians." In the broadest sense, basic competencies are those that a forensic clinician would require to develop and implement treatment plans, whereas expert competencies are more likely those that would be required to supervise and manage programs and to serve the courts. Each level encompasses three areas of competence: legal knowledge, assessment, and treatment. Basic legal knowledge is required to be able to work with offenders, and includes such topics as civil commitment, community notification, and registration laws, as well as the regulations governing the local sex offender registry board that oversees the clinician's clients. Expert legal knowledge requires a more extensive familiarity with legislation applying to sexual offenders. Basic assessment skills primarily focus on the task of developing an informed plan for provision of treatment services, including the assessment of individualized treatment goals. Assessment typically centers on the gathering of history at intake, both through self-report, psychological testing, and review of archival documents. The task of an expert that has been retained to evaluate an offender for a court proceeding may include a range of forensic assessments, such as competency, risk, civil commitment, malingering, and diminished capacity. Basic therapy skills consist of familiarity with the most commonly used treatments with sex offenders, an awareness of the role of medication in treatment, and an understanding of how and why medications are used to complement certain types of treatment. Expert therapy skills include a wider range of less frequently employed treatment interventions, more advanced knowledge of the use of medication, sophisticated supervisory skills, and an in depth knowledge of the treatment literature. We will now explore each of these areas of competence in detail, following a simple structure for this chapter: Three major areas of competence, each delineated for two levels of competence. We begin with basic competence, discuss each area, followed by expert competence, with a discussion of each area.

16.1.6 Education

Before embarking on an exploration of the legal, assessment and therapeutic knowledge a competent clinician must possess, we should address the question of what, if any, course of formal study provides a foundation for acquiring the skill to work with sex offenders. To begin with, there is *no* course of undergraduate study that trains one to work with sex offenders, other than basic education in core areas of psychology (e.g., abnormal psychology, developmental psychology, personality theory, and social psychology) and criminology (e.g., delinquency, violent crime, psychology of criminal behavior, and victimology). Some undergraduate majors in psychology include a concentration in forensic psychology. When a concentration in forensic psychology is absent, a minor in criminology is a good complement to psychology. Some institutions now offer graduate programs leading to a Master's degree in forensic psychology, with more targeted courses applicable to work with sex offenders, including electives on sex offenders or field placements working with that population. At present, the optimal course of formal

education for basic competence would be a Bachelor's Degree in Psychology or Criminal Justice, followed by a Master's degree in Forensic Psychology. A doctoral degree is required for expert competence. Since, with minor exceptions (e.g., John Jay College of the City University of New York), there are no doctoral-level degrees in Forensic Psychology, the conventional route is a Ph.D. or Psy.D. in clinical psychology, followed by postdoctoral forensic training.

In addition, and perhaps even more importantly, are the numerous opportunities for workshops and training offered by professional organizations, such as ATSA. These workshops provide focused training on sex offender-specific topics (e.g., the latest revisions to the RP model; new assessment techniques; techniques for working with special populations of sex offenders, such as females, juveniles, the developmentally disabled, and those with major mental illness; coping with burnout; new adaptations of covert sensitization or aversion therapy; the latest uses of anti-androgen and antidepressant medication; motivational interviewing; etc.). Since there is no formal educational program that prepares for work with sex offenders, such workshops, in conjunction with hands-on training, intensive supervision, and awareness of the literature, provide the primary education for this work.

16.1.7 Legal Knowledge

Clinicians working with sexual offenders must be aware of the legislation governing both incarceration and release conditions, specifically civil commitment, registration, and community notification. As noted, the country's first Sexually Violent Predator law was Washington's Community Protection Act of 1990. The Community Protection Act, providing for the civil commitment of sexual offenders, sought to protect the public by keeping the "most dangerous" offenders off the streets through indefinite incarceration. The decision to civilly commit is based on an assessment that an offender suffers from a "mental abnormality" that increases the likelihood that he will reoffend if released into the community (*Kansas* v. *Hendricks*, 1997). The US Supreme Court has given the states a great deal of flexibility in determining who is at risk of reoffending, and clinicians must be familiar with the prescribed procedures in their state.

Sex offender registration was introduced in 1994 with the passage of the Jacob Wetterling Act, a component of the Violent Crime Control and Law Enforcement Act (42 U.S.C. 14071), which required states to implement a sex offender registry wherein all offenders released into the community must provide the state with the location of their residence. In 1996, the Wetterling Act was amended by "Megan's Law," which required states to establish a community notification system making state registry information available to the public (P. L. 104–145). Megan's Law requires that every sex offender must be evaluated by the state's sex offender registry board (SORB) upon release from prison. Depending on the individual's level of risk for reoffending, as determined by the SORB, presumptive risk-mitigating procedures will be instituted, including notifying the public of the offender's identity and location. Since 1997, every state in the USA has adopted a public notification law.

In 2006, the Adam Walsh Child Protection and Safety Act (P. L. No. 109–248, 42 U.S.C. 16901) was passed, which organizes offenders into three tiers based on the severity of their offense histories. The Walsh Act mandates that Tier 3 offenders (the most serious) be subject to lifetime registration and update their whereabouts with the state registry board every 3 months. Tier 2 offenders are to remain registered for 25 years and update their whereabouts every

6 months, and Tier 1 offenders must remain registered for 15 years and update their whereabouts annually. Failure to register or to update is considered a felony. Clinicians must possess rudimentary knowledge about such management strategies and the known or anticipated impact of those strategies on their clients.

Basic competency includes general knowledge about how sex offenders are civilly committed, the elements that must be satisfied for commitment, acquaintance with the diagnostic issues related to the determination of *mental abnormality*, a rudimentary understanding of the legal concept of risk, the local laws governing registration and community notification, and the tier system used by the local sex offender registry board for classifying risk.

16.1.8 Assessment

As with any client, assessment of sex offenders should be preceded by a thorough review of all available documents and file records. Document review is followed by a comprehensive interview, the purpose of which is to corroborate or cross-check history, facilitate defensible diagnoses, and inform treatment plans, goals, and objectives. A comprehensive history includes such basic information as demographic, developmental, family, social, educational, work, and medical history, past and present substance use, psychiatric history, including treatment and inpatient hospitalization, psychological testing, and medication history. In addition, information must be gathered on psychosocial, psychosexual, cognitive development, history of trauma and maltreatment, history of conduct disordered, delinquent, and antisocial behavior, and lastly a complete history of all sexually deviant, coercive, and criminal behavior.

A mental status exam is typically included, covering the offender's appearance, attitude, behavior, speech, mood and affect, thought process and content, perception, cognition (including orientation, memory and concentration), insight and judgment. Both indirect means, such as observation, and direct means, including brief psychological tests (e.g., counting backwards by sevens from 100 or spelling the word "world" backwards), should be employed.

Supervision around the interview and treatment sessions is essential, as those who receive no supervision can be expected to make slower progress in developing population-specific clinical skills than trainees who receive feedback from seasoned supervisors (Lambert & Arnold, 1987). Arguably, ongoing supervision should be mandated for *all* clinicians treating sex offenders, regardless of how seasoned the clinicians are. The most "expert" clinicians can be fooled by the most wily, manipulative offenders. Supervision should address, among other things, boundary violations; cognitive distortions; minimization; superficial, flat, or inappropriate affect; feigned empathy; and factual distortions, as well as emotional impact on the clinician.

16.1.9 Treatment

Basic competence is generally the skill level required for providing conventional clinical and treatment services for sex offenders. Of all the basic services provided by clinicians, treatment is overwhelmingly the most common. Consequently, our major focus, when discussing basic competence, is on treatment.

16.1.10 Nonspecific Factors

When working with sexual offenders, clinicians should become familiar not only with treatment protocols to be utilized, but also with the nontreatment-specific factors associated with working with this population.

Emotional Preparedness and Burnout. Maslach (1976) defined burnout as therapists' loss of all concern and emotional feelings for the clients they work with, leading therapists to treat clients "in detached or even de-humanized ways." Therapists may become cynical towards their clients, blaming them for their own psychological distress and labeling them in derogatory terms (Farber & Heifetz, 1982). Burnout can result from a variety of experiences; according to a survey conducted by Farber and Heifetz (1982), 57.4% of therapists attributed their burnout to nonreciprocated attentiveness, giving, and responsibility demanded by the therapeutic relationship, and 73.7% cited "lack of success" as the single most stressful aspect of therapeutic work.

Clinicians working with sexual offenders, either in prisons or in the community, must be emotionally prepared for burnout. Working with sex offenders places greater than usual demands for self-protection from high-stress working conditions and high-voltage clinical issues. Clinicians vary in their sensitivity to stress, and certain job conditions may be more problematic for some than for others. Therefore, those aspiring to work with this population should carefully consider their own histories and motivations before entering the field (e.g., those with histories of personal and/or family victimization). Providing therapy for others as a vehicle for resolving one's own issues is likely to undermine treatment efficacy and possibly take a personal toll. Conducting therapy even under "normal" conditions can lead to burnout, but clinicians must consider the added personal and professional stress of working with this population, including uncooperative, unmotivated, and potentially malingering offenders; presenting behaviors that include violence toward children and women; and presenting childhood histories that may include severe trauma, as well as the added stress of working in a prison setting. Students considering this line of work should consult with those already in the field for first hand feedback about what to expect, keeping in mind that such feedback will be unique to the individual providing it and may not be a "good fit."

Awareness of, and Sensitivity to, Individual Differences. According to the APA's Multicultural Guidelines (2003), psychologists are encouraged to recognize that they may hold attitudes and beliefs that can negatively influence their perceptions of, and interactions with, clients who are different from themselves. Though this was intended as a reference to ethnic and racial prejudices, it can also be considered in the context of biases against sexual offenders due to the nature of their crimes.

Historically, cultural sensitivity training has been utilized to prepare clinicians for working with diverse populations, as it provides knowledge of politically correct terminology, mannerisms, and identifying characteristics of various groups (Back, 1973). However, this approach has not proven successful, as cultural generalizations are not always applicable to individuals (Myers, 2000). For example, referring to a Black client as African-American may not be politically correct (or sensitive), if the client does not identify as such. A human relations approach may be more useful. Instead of attempting to learn obscure facts about innumerable ethnic and cultural groups, psychologists should instead operate on the understanding that there are no rules about groups, that everyone is different, and that no one should be categorized culturally,

racially, or ethnically. Categorization may lead to generalizations that foster bias and judgment error (cf. Monahan, 1981). A human relations approach advocates a style of communication that can bridge cultural gaps. It is intended, moreover, to motivate the clinician to learn about each individual client, rather than the group in which they are believed to be a member (Myers, 2000). Social and cultural norms cannot be disregarded completely, however, as they can be useful in differentiating between normal and deviant behavior and in implementing appropriate interventions. What is out of the ordinary in one culture may be acceptable in another, and the application of one's own norms to an individual of differing background is equivalent to a failure to assess for individual differences. The result can be a false assumption of pathology or a failure to recognize pathology.

Despite an awareness of individual differences and the ways in which one might endeavor to be sensitive to them, it can still be difficult for clinicians to see past the heinous nature of the crimes committed by some sexual offenders and to make neutral and dispassionate assessments of people whose behavior they find reprehensible. We should acknowledge, however, the natural process of self-selection. Clinicians with a low tolerance threshold for sexually aggressive behavior are unlikely to be attracted to working with sex offenders. Having said that, there are many clinicians who, from time to time, are caught off guard and find that their objectivity is taxed by an offender's behavior. In the therapeutic realm, one solution lies in the treatment alliance. A strong alliance can control, contain, and place in perspective one's negative attitudes and adverse emotional reactions to the offender's behavior. A great deal of research has demonstrated a significant positive relationship between therapeutic alliance and outcome (e.g., Horvath & Symonds, 1991; Martin, Garske, & Davis, 2000). Yalom (1980) asserted that it is the therapeutic relationship itself that generates healing and makes a collaborative working relationship with clients essential. This is particularly true of clients who may be viewed as lacking motivation for participating in treatment, such as men who have sexually offended (Serran et al., 2003).

Cultivating an alliance with offenders can go a long way towards improving the quality of the treatment. Offenders need to feel accepted by their therapist, regardless of their previous behavior. Therapists working with sexual offenders will maximize their influence and increase the chances that the offenders will overcome their criminal propensities if they display empathy and warmth in a context where they provide encouragement and some degree of directiveness (Marshall, 2005). Such techniques, in conjunction with being rewarding, speaking the right amount and in an appropriate tone of voice, and asking open-ended questions have been shown to correlate with an increase in offenders' coping skills, while being confrontational correlates with a decrease in coping skills (Marshall et al., 2003a). Being respectful of offenders is also important, as it reflects acceptance and valuing of the offender and leads to more positive outcomes (Rabavilas, Boulougouris, & Perissaki, 1979; Strupp, 1980). Respect is demonstrated through an acceptance of personal strengths and interests, and is especially important when working with offenders, whose behavior is frequently the object of public condemnation. Therapists should make it clear to offenders that they distinguish between the individual and the crime, that disapproval is directed towards the offending behavior rather than the enactor of such behavior. As a rule, feeling bad about oneself leads to shame, which stifles change, whereas feeling bad about one's behavior leads to guilt, which facilitates change (Tangney & Dearing, 2002). When utilized properly, these techniques can have a positive effect, leading to the positive changes observed in sexual offenders as a result of treatment (Marshall et al., 2003b).

Forensic Ethics. Not every clinician working with sex offenders will be doing so in a prison setting; much of the work is conducted in the community. Regardless of where the work is conducted, clinicians must become familiar with their ethical obligations, both as psychologists in general and as practitioners providing services to a forensic population in particular. The APA (2002) has stated that forensic practitioners have an ethical obligation to understand the laws and rules governing their roles. However, equally as important is an understanding of what is ethical and appropriate practice. Practitioners must make every effort to define their role at the outset of their involvement, as different roles suggest responsibility to different parties (Heltzel, 2007): a treating clinician may report directly to a supervisor who works for the prison or is in the employ of a vendor hired by the prison. By contrast, a forensic clinician assigned to evaluate an offender will report directly to the attorney that hired her/him or directly to the court. Failure to define roles may have serious implications and may result in a breach of confidentiality if a clinician reports or discloses to an improper authority. Furthermore, clinicians involved in ambiguous relationships with offenders run the risk of engaging in dual or even multiple relationships as the distinctions between roles blur. In the code of ethics, the APA (2002) explicitly warns against engaging in multiple relationships with clients due to the considerable potential for impairment of the clinician's objectivity, and hence effectiveness, as well as the possible exploitation of the client. Because sex offenders in prison are a "captive" audience, they may solicit seemingly small "special favors" (e.g., Can you call my lawyer for me? Can you mail this for me? Can you make a copy of this for me?). A bright line must be maintained between the appropriate duties and responsibilities of the clinician and the slippery slope that crosses that bright line into inappropriate and unethical acts. The offender may be asking for a letter to be mailed, for instance, to circumvent the normal prison surveillance of outgoing inmate mail, or the offender may be requesting a copy of a document that is not supposed to be copied.

The Committee on Ethical Guidelines for Forensic Psychologists (1991) has published additional standards of practice. Practitioners must: (a) be prepared to present to the court the knowledge, skills, experience, training, and education that qualify them as experts, as well as the boundaries to their competence; (b) possess a "fundamental and reasonable" level of knowledge and understanding of the legal standards that apply to them; (c) be aware of the civil rights due to offenders and act in a manner that in no way diminishes or threatens those rights; (d) recognize that their own values and beliefs may interfere with their ability to practice competently, and under such circumstances must decline to participate or must limit their assistance in a way that is consistent with professional obligations; and (e) when testifying, present all findings and conclusions in a fair manner, without engaging in distortion or misrepresentation, nor avoiding, denying, or subverting the presentation of any evidence that may be contrary to their position. Every effort must be made to remain current with changing legal and ethical standards.

16.1.11 The Treatment Protocol: Relapse Prevention

The core model for treating sexual offenders is cognitive behavioral therapy (CBT) with an emphasis on relapse prevention (RP). Developed by Beck (1997) in the 1960s, CBT is a goal-oriented psychotherapeutic approach that attempts to influence problematic and dysfunctional cognitions, behaviors and emotions. The objective is to identify and monitor thoughts, assumptions, beliefs, and behaviors that are related and often accompanied by debilitating negative

emotions and to ascertain those which are dysfunctional, inaccurate, or simply unhelpful. This is done in an effort to replace such damaging thoughts with more realistic and useful ones. CBT has been used to treat a wide variety of disorders, ranging from disruptive behaviors in childhood to depression, anxiety, phobias, pain management, smoking, substance dependence, and even positive symptoms associated with schizophrenia.

RP was developed by Marlatt in the early 1980s (Marlatt & Gordon, 1985) and was designed to strengthen self-control by providing alcohol-abusing clients with methods for identifying problematic situations and analyzing decisions that lead to relapse. Its goal is to develop strategies to avoid or cope more effectively with "risky" situations. During the 1980s, the potential utility of RP for sex offender treatment was explored by Marques and Pithers and a model developed that was an adaptation of RP (Laws, 1989; Pithers et al., 1983). In the context of alcohol abuse, RP was originally intended to be used during the maintenance phase of treatment, following a phase during which abstinence was first achieved. However, this progression was not applicable to the treatment of sex offenders, for whom the behavior in question has often ceased prior to entering treatment. In practice, RP is used as an organizing principle for sex offender treatment. Since the early 1990s, numerous articles, chapters and books have been written about the application of RP to sex offenders (cf. Laws, Hudson, & Ward, 2000) and almost every sex offender treatment program in North America has reported the use of RP in their treatment in some way (e.g., Freeman-Longo, Bird, Stevenson, & Fiske, 1994). RP has been adopted by treatment programs in many other countries as well, including Canada, England, Australia, and New Zealand (Hudson, Wales, & Ward, 1998).

RP proposes that a variety of factors influence whether or not an offender will commit an offense, and that the interaction of these factors affects the probability of relapse (Pithers, 1990). The basic pattern of relapse has been identified as follows (Pithers et al., 1983): the offender feels that the pleasant events in his life are outweighed by adverse life events, resulting in the experience of acute stress. This stress results in a subjective sense of deprivation (known as lifestyle imbalance) that leads the offender to desire indulgence. As a result, the offender makes a series of superficially trivial decisions that undermine self-restraint and lead to high-risk situations, which could be an emotional state (e.g., feeling sad) or an environmental situation (e.g., going to a park where children play). Finding oneself in the midst of a risky situation threatens the offender's sense of control over abstinence from offending. This results in a lapse, such as fantasizing about offending behavior or viewing pornography. At this point, the short-term benefits of offending become salient, allowing the offender to slide from lapse into relapse and to experience a series of negative attributions and affects due to the failure to refrain from engaging in offending behavior. Some sex offenders relapse in situations that would have been difficult to anticipate, but many set themselves up for relapse by consciously or unconsciously placing themselves in high-risk situations. The probability of relapse further increases when offenders selectively remember the positive aspects of the offense (e.g., sexual gratification) rather than the negative aspects (e.g., getting arrested) (Pithers, 1990).

RP begins by dispelling the myth that treatment will "cure" the offender and continues with an assessment of the offender's high-risk situations and coping skills. Pithers (1990) has outlined the assessment procedures to be used in RP. Prior to meeting with the offender, the therapist must analyze the offender's case records to learn about predisposing factors and to develop hypotheses to test during the interview. During the interview, the clinician investigates affective, cognitive, and behavioral patterns associated with offending, as well as the offender's pattern of sexual arousal; what the offender finds sexually stimulating may indicate something

about the pattern of abuse and choice of victim. To identify the determinants of sexual aggression, the clinician should assess why the offender's response to a stressful situation led to a sexual offense rather than any other type of response. Self-report measures may also be used to assess the offender's history and behavioral patterns. To assess coping skills, the clinician presents the offender with hypothetical situations and asks the offender to indicate which coping skills he would utilize and to rate how much difficulty he would have enacting such a response and avoiding a lapse. Problems are considered to exist when the offender does not provide a response, elaborates on the risky elements of a situation, provides a strategy that is unlikely to be successful, or responds only after a long pause. The offender is then asked to provide a fantasized account of a future relapse, which allows the clinician to determine where adaptive and maladaptive coping responses are being used.

The treatment phase of RP has been conceptualized differently by different researchers. Pithers (1990) organized the treatment into two distinct groups of procedures: those for avoiding lapses and those for preventing lapses from becoming relapses. To avoid lapses, Pithers recommended that the clinician first identify offense precursors: many events preceding relapse can be avoided, and clinicians must teach offenders to recognize such events. Clinicians assist offenders in identifying behaviors and attitudes that were not previously recognized as being tied to offending; self-monitoring techniques can be useful at this stage. Once the relapse process has been delineated, treatment begins to focus on identifying the specific precursors for that offender, which could be emotions, thoughts, behaviors, or some combination of the three. The clinician should provide strategies to minimize lapse and to cope more effectively with momentary falters in self-management, assisting the offenders in viewing lapses not as signs of failure but as opportunities to enhance self-management. When a lapse is reported, the offender and clinician analyze it together with an emphasis on the circumstances that preceded the lapse; this helps to reduce the likelihood of recurrence under similar circumstances in the future.

Once offense precursors have been established, the treatment begins to focus on specific strategies the offender can use to avoid future lapses. When external stimuli lead to lapses, offenders can be taught to enhance their self-control through the use of stimulus control procedures that remove such stimuli from the environment or avoid such circumstances altogether. Since it is unlikely that offenders will be able to avoid every situation that may lead to relapse, escape strategies can aid offenders in removing themselves from a dangerous situation should one arise unexpectedly. The clinician should emphasize that escape strategies must be employed as early as possible when the offender finds himself in a situation he is unequipped to handle, and that the most important aspect of this strategy is the speed with which it is executed. As escape is not always a viable option, learning to cope with urges is a necessary skill. Offenders should be taught to deal with positive outcome expectancies through a reminder that initial gratification is typically followed by delayed negative effect; for example, though an abusive encounter might have been sexually gratifying, it may also have resulted in incarceration. Urges may dictate behavior; giving in to an urge is an active decision, and offenders must take responsibility for it. Treatment should help them see that if they refrain from acting on an urge, urges will eventually weaken and pass with time. If offenders find themselves unable to cope with their urges, programmed coping responses can be used to manage difficult situations: using a standard problem-solving process, offenders can be taught to describe problematic situations in detail, brainstorm potential responses, evaluate the likely outcome of each response, and rate their own ability to execute each response. The most adaptive response is

then selected for practice. Lastly, skills building interventions can be used to remediate deficits in anger management, problem solving, stress tolerance, sexual knowledge, interpersonal empathy, and basic survival skills.

According to Pithers (1990), there are two major techniques used to prevent lapses: cognitive restructuring and contracting. The former is used to restructure the offenders' interpretation of lapses. Instead of viewing lapses as an irreparable failing, clinicians should teach them to view lapses as mistakes that provide an opportunity to learn and the possibility to develop new coping skills, which can increase self-control. As treatment progresses, offenders should come to view lapses as slips in self-management rather than unchanging negative personality characteristics and as a single event rather than a predictor of catastrophe, provided that the event is dealt with in an appropriate and timely fashion. Clinicians should encourage offenders to summarize this material on a reminder card that can be carried with them at all times: when a lapse occurs, the offender should review the card and be reminded that this is a temporary lack of judgment that need not culminate in relapse. A complementary approach to preventing relapse is the use of contracting, in which the therapist and offender agree upon and commit in writing the specific limits to which the offender may permit himself to lapse. The offender is an active participant in determining the "lapse limit," but it is the responsibility of the therapist to ensure that it is a reasonable limit from which the offender will be able to return without danger of relapse. In addition to specifying the limit to which lapses will be tolerated, the contract requires the offender to limit his exposure to stimuli that lead to offending and to view offending behavior as a choice that demands a penalty.

Polascheck (2003) has conceptualized RP with sex offenders somewhat differently, organizing the treatment in terms of the sequence of events that led to offending in the first place; since there are different motives for engaging in offending, there must also be varying methods for preventing relapse. In this model, offending behaviors are identified as being due either to approach or avoidance. According to Polascheck, it is unclear whether offenders with approach motives should even be accepted into RP programs: "RP's core treatment philosophy is that the client is at least minimally motivated to refrain from the target behavior. …As such, RP is ill-matched to individuals who *want* to engage in the prohibited behavior" (p. 365). However, clinicians working within the prison system are often not authorized to decide who will and will not receive treatment, and must be prepared to work with offenders whose offense history is approach-based. Therefore, Polascheck provided guidelines for working with such individuals.

Approach goals are divided into two patterns, each with their own set of procedures: approach-automatic and approach-explicit. The approach-automatic pattern is a rapidly unfolding offense process that lacks planning, and such offenders often report that their behavior was spontaneous or reflexive. When working with such individuals, the goal of treatment is to disabuse them of the notion that their offenses simply "happened" (Hudson & Ward, 2000) and to lead them to acknowledge that their behavior had identifiable antecedents in which they knowingly and willingly engaged. Since offenses tend to occur rapidly once the offender begins to make contact with the victim, the key skill for approach-automatic offenders to learn is self-monitoring, which should be used to enhance self-control before behavior can escalate into offending. Contrary to the approach-automatic pattern, in which offenses occur without prior planning, approach-explicit offenses occur because the offender wants them to occur and arranges them. Such offenders typically feel no remorse following an offense. When working with this group, the major treatment task is to alter core beliefs associated with sexually or generally exploitative worldviews and hostile beliefs (Hudson & Ward, 2000). Cognitive

restructuring techniques may be useful, but attempting to purge such offenders of their deeply entrenched, highly reinforced, offense-justifying distorted attitudes will likely prove daunting.

Avoidance goals are also divided into two categories: avoidant-passive and avoidant-active. Avoidant-passive offenses occur due to chronic under-regulation of moods and behavior coupled with a lack of awareness of one's own agency in the offense. Such offenders seem genuinely oblivious to their own internal states and as such do not believe themselves responsible for their external behavior. These offenders must be taught to challenge this sense of helplessness. A main goal of the treatment is actively to engage in self-monitoring, so that offenders can identify emotional and behavioral antecedents such that situations do not appear to have arisen from nowhere. In contrast, avoidant-active offenses occur when offenders actively take steps to reduce offending, but the steps are poorly chosen and have the opposite effect (e.g., drinking alcohol and masturbating in an attempt to reduce sexual fantasies [Ward & Hudson, 1998]). Traditional RP works well with this group, as offenders are generally aware of their own contributions to the problem. However, treatment efficacy will be based on whether offenders can accept that these exacerbating strategies have a detrimental effect.

No matter what the approach to RP, clinicians should always be realistic and candid with offenders about the likelihood of relapsing. If an offender believes that the treatment program will cure him, he is more likely to see a momentary lapse as an irreversible trend and to give up on therapy. However, if an offender sees a momentary loss of control as an opportunity to benefit from lessons learned from the lapse and to gain greater self-control when similar situations arise in the future, lapses can become an instrumental part of therapy.

We have discussed some of the basic tenets of the RP model as originally formulated by Marques and Pithers. In reality, there is a considerable clinical literature on treatment of sex offenders (e.g., Laws, 1995; Laws et al., 2000; Schwartz & Cellini, 1995, 1997), as well as theoretical developments (Ward & Hudson, 1996, 1998; Ward, Louden, Hudson, & Marshall, 1995; Ward, Hudson, & Keenan, 1998), and recent applications of old treatment modalities (e.g., Hanson, Bourgon, Helmus, & Hodgson, 2009). Many of these developments, although refreshing, remain untested and have minimal practical utility for most therapists. We recommend for clinicians practicing with basic competence a thorough understanding of the theory and the application of RP. With training and supervision, basic competence might also include other behavioral modalities commonly used with sex offenders (e.g., systematic desensitization and aversion) and psychoeducational modules commonly used with sex offenders (e.g., anger management and social skills training).

16.1.12 Medication

As mentioned previously, the CBT platform upon which RP is built has been shown effective in treating a variety of psychological disorders. In some cases, however, psychotherapy, augmented by medication, may yield an improved response. Although nonmedically trained clinicians will not, as a rule, be responsible for prescribing medication, the treating clinician, as the individual primarily involved in the offenders' care, may be the first to determine that medication may be helpful. With regard to basic competency, we would set the knowledge bar fairly low. We recommend that it is incumbent upon the clinician to be familiar with medications commonly used with sex offenders, principally the anti-androgens and the (SSRI) antidepressants, and to know all of the behavioral indicators or signs suggesting the need for these

medications. As the potential "first-line responder," the clinician must be vigilant to the need for medication and to know when to make a referral to a physician.

In sum, under the umbrella of basic competencies, clinicians should be aware of the classes and names of drugs commonly used with sex offenders as well as the emotional and behavioral signs and symptoms that reflect a possible need for those drugs. We will discuss medication in somewhat greater detail under expert competencies.

16.2   Expert Competencies of the Clinician

Expert clinical work with sex offenders requires knowledge of specific techniques and interventions beyond the basic competencies. A general overview of the areas of basic competence for this niche of practice was presented earlier in this chapter, and will now be readdressed with respect to expert competence. According to the APA ethics code, adopted in August of 2002, "When assuming forensic roles, psychologists are to become reasonably familiar with the judicial or administrative rules governing their roles." Clinicians must become familiar with the issues and problems that are specific to not only a forensic population in general, but to sexual offenders in particular. This section will discuss expert competencies for assessing and treating this population.

Legal Knowledge. The interface of the mental health system with the practices and procedures of the Sexually Violent Predator courtroom is fraught with problems that have been addressed extensively elsewhere (e.g., Janus & Prentky, 2003; Prentky, Janus, Barbaree, Schwartz, & Kafka, 2006). Experts practicing in this interstitial world are expected to have an in-depth understanding of the legal requirements of the prevailing statute, case law, if any, related to the statute, and the aforementioned problems commonly encountered with these cases. Although experts do not interpret laws, they must understand the language and the putative intent of the laws to provide opinion testimony that will be useful to the court. In particular, experts must be conversant with the relevant case law and social science literature that address two key topics: (1) mental abnormality (the full array of diagnostic issues related to a statutory finding of mental abnormality), and (2) risk assessment. With regard to risk assessment, the expert must be acquainted with (a) the literature addressing the comparative efficacy of clinical assessments of risk and mechanical (actuarial) assessments of risk, (b) the empirical literature supporting the variable strength of different risk factors in predicting reoffense, (c) the critical methodological concerns that compromise objectivity (and accuracy) in rendering opinions about risk (e.g., base rate estimates and illusory correlations between presumptive risk factors and reoffense), and (d) the admissibility issues related to mechanical risk assessment, including Daubert criteria and scale-specific issues (e.g., error rates), should they arise.

16.2.1 Assessment

Assessing sexual offenders presents unique challenges to the clinician. According to Clipson (2003), "all forensic assessments must address the possibility that the person being interviewed may minimize, deny, exaggerate, or feign a psychiatric disorder to obtain a desired outcome." Beyond the potential for malingering, which will be addressed later on in this section, Clipson points out that sex offenders may be reluctant to honestly discuss their offending behavior due

to the legal implications of doing so, as well as embarrassment (i.e., awareness that their behavior is not only legally but socially unacceptable). Consequently, a well-crafted interview is essential, the sophistication of which can be expected to improve over time with experience, training, and supervision. Although conducting an interview is clearly part of basic competence, a "basic" interview will most often be restricted to history gathering, mental status, and informing a treatment plan. An "expert" interview, by contrast, may delve into a range of much more difficult issues, including (a) criminal responsibility, (b) malingering, (c) assessing psychopathy, (d) assessing symptoms of ADD, PTSD, or affective disorders, (e) formulating and exploring evidence for hypotheses about etiology, (f) gathering evidence related to risk, and so forth.

Lanyon (2001) noted that forensic psychologists require a structure "that delineates the relevant issues and provides some basic knowledge about appropriate assessment procedures." He proposed a six-step structure for assessing sex offenders. The six questions that can serve to guide the clinician in their initial assessment are as follows: (a) What kind of a person is this – what are the person's general psychological characteristics? (b) What kind of an offender is this – what are the person's deviant sexual interests? (c) What is the risk of reoffense – how dangerous is the person? (d) What is the person's amenability to treatment? (e) To what extent is the person engaging in self-serving misrepresentation during the evaluation? (f) In regard to forensic contexts, how well does the person fit specific formal criteria, either legal or other, such as "sexually violent person" or "pedophile?" The following sections will cover steps a through e presented above.

16.2.2 The Interview

Steps (a) and (b) described above are applicable to the initial interview with a sex offender. The first step, according to Lanyon, involves the assessment of personality and the gathering of background information to aid in an understanding of the individual to be treated. A detailed and extensive clinical interview should be used not only to gather pertinent information, but to establish rapport and provide a preliminary assessment of clinically significant behaviors that may aid in potential future diagnosis. In performing a preliminary assessment of a sex offender or an individual characterized as sexually deviant, there are areas that should be explored with greater detail than may be required in most initial assessments. Information pertaining to the psychosexual development and adaptation of the individual is pertinent and will aid in providing a comprehensive understanding of the specific manifestation of symptoms or behaviors in the sexually deviant individual. In addition, gathering a thorough history of childhood maltreatment and sexual history is necessary, and frequently critical. Areas, specific to the presenting problem, will be explored beyond that required of a general interview. This information will not only clarify potential sexually related disorders, but will serve to inform appropriate treatment and identify target behaviors.

16.2.3 Assessment of Sexual Attitudes, Sexual Fantasies, and Sexual Preference

Within step (b) Lanyon points out, in accordance with the diagnosis of a DSM-IV-TR Paraphilia, the importance of assessing the range of sexually deviant behaviors, the strength of interest in

the behaviors, and the comparison with nonsexual interests. There are several assessment tools designed to aid in assessing sexually deviant behavior and acquaintance with these instruments is imperative. Clinicians should be aware that psychometric tests exist for specific ages (e.g., children, adolescents, and adults), types of offenses (e.g., rape, pedophilia), and types of sexually deviant behaviors. Due to the wide variety of assessment tools available, a complete and clear understanding of the individual should be determined through the initial interview and information gathering. A short, incomplete list of commonly used measures specific to assessment of sex offenders is presented below. Clinicians should be aware that assessment tools used with a general clinical population do not necessarily translate to use with sex offenders. Clinicians should therefore be cautious of the relevance and validity of using any measure within this specific forensic context. Although assessment can inform treatment and aid in diagnostic formulation, no measure is infallible and should be considered only part of the information gathering.

Although the following is not intended to be exhaustive, or even comprehensive, we will list a number of commonly used measures that experts should be familiar with. Familiarity includes not only acquaintance with the relevant literature but a working knowledge sufficient to supervise the use, scoring, and interpretation of the procedure.

Cognitive Distortions. Offenders frequently use cognitive distortions (irrational attitudes) to justify, minimize, and occasionally deny their behavior. Consequently, cognitive restructuring is a commonly used treatment modality, and the assessment of cognitive distortions is occasionally included in a clinical assessment battery. Two well-known measures are the *Abel, Becker & Kaplan Cognitions Scales* (specific to sexual behavior with children, this assessment measures distorted ideas and attitudes about sex) and the *Bumby Cognitive Distortion Scales* (includes the Molest Scale and the Rape Scale, used with adolescents and adults). Although the use of any one of these scales may be infrequent, expert competence clearly includes facility with them.

Sexual Fantasies and Behaviors. There are a variety of self-report measures that are well-known and commonly used to assess sexual and paraphilic fantasies and behaviors, including the (a) Clarke Sex History Questionnaire (Langevin, Handy, Paitich, & Russon, 1985), currently published by Multi-Health Systems, (b) the Multiphasic Sex Inventory, published by the authors, Nichols and Molinder, (c) the Sexual Experiences Scale (Koss & Gidycz, 1985), and (d) Attraction to Sexual Aggression Scale (Malamuth, 1989a, 1989b). A resource guide for practitioners provides a much more complete list (Prentky & Edmunds, 1997). As noted above, although the use of any one of these scales may be infrequent, expert competence clearly includes facility with them.

16.2.3.1 Sexual Preference

Penile Plethysmograph (PPG)

The penile plethysmograph is a medical device used to measure male sexual preference by quantifying erectile responses to auditory and visual stimuli depicting normative and deviant sexual themes. There are two methods: circumferential and volumetric. Circumferential, the method commonly used in the USA, measures changes in the circumference of the penis using a transducer, either a mercury strain gauge or an electromechanical gauge. Generally, PPG assessments are done only in clinical settings and only for clinical purposes (e.g., to monitor changes as a function of treatment). There seems to be general agreement, moreover, that the PPG should not be used for forensic purposes (McConaghy, 1989; Murphy & Barbaree, 1994). Travis, Cullin, and

Melella (1988) went as far as to suggest that, "the only purpose that erectile measurements have in a forensic setting would be as one evaluative element contributing to an expert opinion offered to the court regarding potential treatment" (p. 248). Expert competence does not include ownership and routine use of the PPG. Expert competence does include, however, working knowledge of PPG, methodological issues, answers to frequently asked questions that may come up in court (cf., Lalumiere and Harris, 1998), and admissibility case law related to the PPG.

Abel Assessment for Sexual Interest-2 (AASI-2)

Abel developed a method for assessing sexual interest that is noninvasive (involves no measurement of erection), requires no stimuli depicting nudity, and always yields some response (i.e., there are no "flat liners" or "nonresponders" as are occasionally seen with the PPG) (Abel, Lawry, Karlstrom, Osborn, & Gillespie, 1994). The ASSI is a computerized assessment of self-reported sexual interest in images of children, teenagers, and adults. Because this visual reaction time procedure is easily transported and administered, noninvasive, and less expensive than the PPG, it has gained a considerable following and is widely used, especially when assessing sex offenders known to be, or suspected of being, pedophiles. As with the PPG, it is not assumed that an expert will own the ASSI. It is assumed, however, that expert competence includes working knowledge of the test and admissibility case law surrounding the test.

16.2.4 Assessment of Risk

Perhaps the single most challenging and demanding area of sex offender assessment is the assessment of risk. As stated in step (c), assessment of risk is an area common to sex offender evaluation. Expert competence requires practitioners working with sex offenders to be well acquainted with the myriad issues – legal, theoretical, empirical – that arise with risk assessment (cf. Janus & Prentky, 2003; Prentky et al., 2006). Although risk assessments may be called upon for a variety of reasons, including preparedness for community-based treatment, tier classification by the registration board, and other discretionary and management decisions, the most frequent use of risk assessment is in the adjudication of offenders petitioned for civil commitment as "sexual predators." Experts must be conversant with the different methods for assessing risk and the empirical literature that compares those methods (cf. Janus & Prentky, 2003). Experts must be conversant with the commonly used actuarial risk assessment scales, including the Violence Risk Appraisal Guide (VRAG), the Sex Offender Risk Appraisal Guide (SORAG), the Rapid Risk Assessment for Sexual Offense Recidivism (RRASOR), the Static-99, Static-2002, and the Minnesota Sex Offender Screening Tool-Revised (MnSOST-R) (Janus & Prentky, 2003; Seto, 2005), the rationale for using a particular scale, and the literature addressing the validity of that scale. Experts must be familiar with the empirical literature on risk predictors and relative effect sizes of each. Experts must strive to "avoid parochialism by embracing models and methods that are used by more 'mature' disciplines, far more seasoned in the ways of assessing risk" (Prentky, 2003, p. 22). Experts must be aware of the different types of risk predictors (e.g., static, dynamic, protective, etc.) and how each functions in an assessment. Experts must be conversant with, and make use of, the growing literature on acute and stable dynamic risk predictors. Experts must be cognizant of important potential risk mitigators, such as age, as well as risk aggravators, such as unruly institutional behavior. Experts must be aware of the impact of base rate estimates on their assessments. Overall,

experts must, "in the scientific vernacular, strive to reduce uncertainty" by paying acute attention to the sources and nature of uncertainty in risk assessment with sexual offenders (Prentky, 2003, p. 22).

Psychopathy Checklist-Revised (PCL-R)

The current procedure for assessing psychopathy is the well-known semi-structured interview (PCL-R) developed by Hare almost 30 years ago (Hare, 1980). Extensive research over the past decade has examined the factor structure, reliability, and validity of the scale. Use of the PCL-R is a complex undertaking, requiring formal training, or, at the least, informed supervision. We do not assume that those possessing expert competence with sex offenders will include being trained to use the PCL-R, in part, because assessing psychopathy is a relatively unusual demand when working with sex offenders. If the PCL-R is called for, however, the expert must acquire adequate training or turn the psychopathy assessment over to someone that is properly trained.

16.2.4.1 Assessment of Deception

Evaluating misrepresentation in called for in step (e). When discussing deception, clinicians commonly focus on malingering. According to the American Psychiatric Association (2000), malingering is the intentional production or exaggeration of symptoms for secondary gain. We feel it is necessary to point out that while deception within any clinical population includes the possibility of malingering, deception is far more complex and includes a variety of forms of deception and dissimulation. Additionally, manifestation of deception within a general clinical population differs from that of a forensic population, such as sex offenders.

Rogers (1997) has delineated the basic types of dissimulation that may occur and of which clinicians should be aware. When performing psychological assessment, an individual's response style can be indicative of the type of dissimulation in which they are engaging.By understanding the different response styles a respondent may employ, a clinician will be provided with clues as to the respondent's level of motivation to tell the truth or to deceive, as well as the sophistication of their attempt at dissimulation. Rogers has broken down response styles into six types: (a) *Malingering*, the intentional falsification or overreporting of symptoms; (b) *Defensiveness*, the minimization of symptoms; (c) *Irrelevant responding*, disengaging from the assessment in an attempt to produce results that do not provide an accurate picture of the respondent; (d) *Random responding*, failure to attend to the task in order to provide meaningless results; (e) *Honest responding*, which leaves it to the clinician to determine the reason behind inaccuracies in the results; and (f) *Hybrid responding*, any combination of the above response styles.

Dissimulation is common among sex offenders and can occur for various reasons. Sewell and Salekin (1997) explore deception among sex offenders. The authors cite a 1992 study by Kennedy and Grubin that described four patterns of denial based on a study of 102 male sex offenders. Pattern 1, consisting of 18% of the sample, was comprised of offenders who admitted their offense but denied any harm to their victims. They typically offended against young boys and claimed to have helped rather than hurt their victims. Pattern 2, consisting of 20% of the sample, was characterized by externalizing responsibility. They typically offended against young girls and were likely to blame their victim or another person for their behavior. Pattern 3, consisting of 35% of the sample, completely denied their offense. The offenders in this group

typically offended against adult females and were characterized by a lack of insight into the benefits of psychological treatment. Pattern 4, consisting of 27% of the sample, exhibited a dissociative style and attributed their behavior to "a temporary aberration of behavior or altered mental state." This group included heterosexual incest perpetrators.

It is clear that deception among sex offenders is more complex than a mere understanding of the concept of malingering. Not only can deception take place for a variety of reasons, but it can take many forms. Clinicians should be aware of the ways in which offenders deceive and why they do so. Detection of deception is indispensable to producing a valid diagnostic and clinical understanding of the individual. Beyond a solid definitional and theoretical understanding of the manifestations of deception, clinicians should become familiar with the assessments of deception. The most well-known method for assessing malingering and deception is Rogers' Structured interview of Reported Symptoms (SIRS). In addition, the Minnesota Multiphasic Personality Inventory-2 (MMPI-2) is occasionally administered and validity scales for detecting deceptive responding reported. The Multiphasic Sexual Inventory-II (MSI-II), which is occasionally paired with the MMPI-2 when assessing sex offenders, also includes scales that assess deceptive responding.

16.2.5 Treatment

Elsewhere we have discussed efficacy of treatment with sex offenders. Treatment efficacy with sexual offenders is measured by whether or not it reduces the targeted behavior. Lanyon indicated in his steps that amenability for treatment should be considered. We argue that this is in fact a moot point, as often treatment is required of sex offenders whether incarcerated or in the community. At present, there is no definitive way of determining an individual's amenability to treatment, however, the individual's motivation to participate in treatment seems to play a key role in whether or not treatment will be effective for a particular individual. In forensic settings, treatment is largely forced upon offenders, it is understandable that those who voluntarily participate in treatment and seek out therapy are more likely to benefit from treatment.

For the expert clinician, treatment extends beyond relapse prevention. Though that is the primary modality used with sexual offenders, it is often insufficient to meet their needs or to address additional pathology that may be contributing to or perpetuating their offense cycles. Therefore, it is imperative that the expert clinician become familiar with, and proficient in, a variety of treatment approaches that may be useful in working with this population.

16.2.6 Beyond Relapse Prevention

Beyond relapse prevention, many other treatment interventions have been adopted from other areas of clinical practice that have utility for target problems observed among some sex offenders. For example, if depression is a significant factor in an offender's offense cycle, it must be addressed, and the most effective interventions may be medication or medication combined with CBT. If trauma is a significant factor in an offender's offense cycle, trauma therapy or EMDR might be called for as a compliment to RP. In this section, we discuss treatment interventions commonly used in sex offender treatment programs that clinicians must be acquainted with. It is important to note that, with the noteworthy exception of medication and some

modes of behavior therapy (covert sensitization and aversion), there is a dearth of research investigating the efficacy of these treatments for sexual offenders. It is incumbent on sex offender treatment providers to know what interventions have been empirically validated with sex offenders and which have not. Empirical support for procedures and interventions developed for other client populations cannot be taken as empirical support for the application of those procedures to sex offenders. As with our discussion of RP, this section is not intended to instruct novice clinicians in the provision of the treatments detailed therein, but rather to familiarize clinicians with the treatments most commonly used with this population.

Posttraumatic Stress Disorder (PTSD). Four types of therapy are commonly used in treating posttraumatic stress disorder (Resick, Monson, & Rizvi, 2008): (a) Coping- or skills-focused treatment. The most commonly used coping/skills-based treatment is stress inoculation, which imparts coping skills in an effort to provide clients with a sense of mastery over fear. This is achieved through deriving an explanatory framework through which clients can understand the origin and nature of their fear and anxiety, thereby making sense of their trauma and its aftermath. Clients are also taught skills for dealing with physical, behavioral, and cognitive reactions, including relaxation and breathing control, covert modeling, role-playing, and guided self-dialogue. (b) Exposure techniques. Exposure involves reexperiencing the traumatic event in some way; techniques typically include imagining oneself in fear-producing situations, recalling traumas for extended periods of time, and confronting feared situations in vivo. A hierarchy of feared and avoided stimuli is generated, and clients are instructed to confront the feared cues daily for a prespecified amount of time, beginning with the least anxiety-provoking items on the hierarchy and eventually working up to the more distressing items. The therapist guides clients in reliving their trauma in the imagination, asking them to describe it aloud. As therapy progresses, clients are asked to describe the trauma in increasingly more detail, including thoughts, physiological responses, and feared consequences, with the goal of achieving habituation. (c) Cognitive therapy. Daily diaries and monitoring forms are often used to elicit dysfunctional and disturbing thoughts the client has experienced during the week. Therapy focuses on the meanings the traumatic event has for the client, and how those meanings confirm or contradict previously held beliefs about self and others. The therapist guides clients in discovering how they may have distorted the event in an effort to maintain prior beliefs about self and others, or how they may have changed their beliefs too much to cope with their trauma. Clients are taught to identify and dispute unrealistic thoughts about themselves, the world, and their futures through reasoning and evidence-based arguments. (d) Combination treatments. Such treatments typically combine exposure and cognitive elements, but may also include relaxation or coping elements.

Cognitive, exposure, and combined treatments have been found equally effective and more effective than relaxation exercises (Marks, Lovell, Noshirvani, Livanou, & Thrasher, 1998). Furthermore, prolonged exposure and prolonged exposure plus cognitive therapy have been found to work equally well (Foa et al., 2005), suggesting that exposure is the active ingredient in the treatment for PTSD. Whatever approach is selected, the therapist should be aware that clients with PTSD can be ambivalent about therapy and therefore somewhat difficult to work with; therapists should therefore expect some avoidance in the context of treatment (Resick et al., 2008).

Phobias. When treating phobias, the main goal is to decrease fear and phobic avoidance to a level that no longer causes distress or impairment. Both CBT and medication have been found effective in doing so, and both appear to work equally well when treating social phobia (First & Tasman, 2004). Exposure-based treatments have been shown to be useful in treating a

range of specific phobias (e.g., Foa, Blau, Prout, & Latimer, 1977; Muris, Mayer, & Merckelbach, 1998), and they work best when sessions are spaced close together, exposure is prolonged, and avoidance is discouraged; in addition, real life exposure is more effective than imaginal, and exposure is more effective when the therapist is involved than when a client is alone (Antony & Barlow, 1998, 2002).

As social phobia can be a factor in sexual offending, we focus on the treatment of that particular disorder. There are four main types of treatment for social phobia, and there is often overlap among these treatments (First & Tasman, 2004). In exposure-based treatment, clients list anxiety-provoking situations in a ranked hierarchy. The therapist then assists clients in repeatedly approaching feared situations, working from least to most anxiety-provoking, until the situations no longer elicit fear. Repeated exposure demonstrates to clients that feared consequences do not emerge despite having confronted the situation. In cognitive treatment, the therapist helps clients to identify and change their anxious thoughts by considering other ways of interpreting situations and by examining the evidence for their anxious beliefs. Social skills training is used to help clients become more socially competent in their interactions with others. The training includes modeling, behavioral reversal, corrective feedback, and social reinforcement. Lastly, applied relaxation is used to teach clients to relax their muscles during rest, during movement, and eventually in anxiety-provoking social situations (Ost, Lindahl, Sterner, & Jerremalm, 1984).

Inappropriate (Deviant) arousal. Sexual offending may be motivated by sexual arousal to inappropriate stimuli, inappropriate object choices (i.e., children), or inappropriate situations. Therefore, a primary therapeutic goal is to decrease deviant or inappropriate sexual arousal. The two principle behavioral modalities are olfactory aversion and covert sensitization. Covert sensitization has been used to treat sexual disturbance (Barlow, Leitenberg, & Agras, 1969; Callahan & Leitenberg, 1973; Segal & Sims, 1972) as well as a variety of other problems, such as alcoholism (Ashem & Donner, 1968; Cautela, 1970) and obesity (Cautela, 1967). The treatment is based on classical conditioning: deviant arousal is paired with an unpleasant stimulus, causing the deviant arousal to become aversive and therefore avoided. Nausea and vomiting have been used as aversive stimuli, and verbal descriptions of repulsive scenes in conjunction with imagined sexual behavior have been reported successful in controlling deviant sexual behavior in controlled studies and have been identified as the effective therapeutic ingredient in covert sensitization (Barlow et al., 1969). In covert sensitization, clients are asked to imagine a situation that would lead to arousal; however, it is important to note that they are not asked to imagine engaging in intercourse or anything else that might lead to a culmination of the arousal. Immediately after the imagined arousal, the aversive stimulus is introduced. When the aversive stimulus is removed, feelings of relief are emphasized; during this period of relief, offenders are asked to imagine a normative sexual experience (Levin, Barry, Gambaro, Wolfinsohn, & Smith, 1977), with the goal that offenders will develop an association between normative sexual experience and relief. This method has been shown to be effective for sex offenders as part of a behavioral modification program (Marshall, Jones, Ward, Johnston, & Barbaree, 1991).

16.2.7 Old Interventions Newly Applied to Sex Offenders

It is incumbent on all clinicians providing treatment for sex offenders to be aware of new developments, and one interesting new development is the application of the Risk-Need-Responsivity

(R-N-R) model developed by Andrews and Bonta (Andrews & Bonta, 1998; Bonta & Andrews, 2007) for general offenders to sex offenders (Hanson et al., 2009). Hanson et al. reported that programs that adhered to R-N-R evidenced the largest reductions in both sexual and general recidivism. Program effectiveness increased as the total number of R-N-R principles adhered to increased. The R-N-R model proposes that the most intense treatment services be reserved for those at greatest risk (the Risk part), that treatment programs target those "criminogenic needs" with empirical support (the Need part), and that programs use only techniques with demonstrated responsivity (i.e., techniques that sex offenders are known to respond to) (the Responsivity part). It may be empirically defensible to argue that modern RP-based treatment programs adhere to the Responsivity component. We would further argue, however, that, by and large, the Risk and the Needs components are neglected. This is a good example of a newly developing application of an old offender treatment model that all clinicians, irrespective of competence level, should be aware of.

16.2.8 Medication

Drugs have been used in the USA to reduce sexual drive for over 60 years. Female sex hormones (i.e., estrogen) were the most commonly used substances in the late 1940s and early 1950s and major tranquilizers were used in the 1960s. Until recently, the principal alternative to the major tranquilizers has been the anti-androgens. The anti-androgen drug of choice in the USA has been medroxyprogesterone acetate (Provera, Upjohn). Since reduction of sexual drive in sex offenders is not an indicated use for Provera, it is used in the USA only on an experimental basis with sexual offenders (i.e., "off-label").

The first systematic use of Provera for the treatment of sexual offenders was initiated in 1966 at Johns Hopkins University. The early research at Johns Hopkins during the 1960s and 1970s was conducted by Money (1970), and followed in the 1980s by Berlin (e.g., 1989). Research on another anti-androgen, cyproterone acetate, has been conducted by Bradford (e.g., 1998). In general, these anti-androgen drugs reduce overall sexual drive by reducing libido, sexual fantasies, nocturnal emissions, spontaneous erections and masturbation. To use the expression coined by Berlin, these drugs reduce "sexual appetite."

Berlin (1983) described another approach to reducing testosterone, the use of a gonadotropin releasing hormone agonist (GnRH). The drug that has been most often used in the USA with sex offenders is leuprolide (Lupron). The advantages of Lupron over the more commonly used anti-androgen (Provera) include fewer side effects and greater potency when it comes to decreasing testosterone. The major disadvantage is that Lupron, at least at the present time, is much more expensive than Provera.

A major addition to the anti-androgens for treating sexual offenders is the group of antidepressants classified as selective serotonin reuptake inhibitors (SSRIs). Reduced serotonin has been associated with a wide variety of psychiatric problems, including most impulse control disorders, suicide, major affective disorders, anxiety disorders, panic disorder, consummatory disorders (such as alcoholism), obsessive-compulsive disorder and aggressive behavior. The SSRIs increase serotonin, and the biological basis for the use of these drugs with sex offenders was provided in a series of papers by Kafka (e.g., 1995, 1997a, 1997b, 2003) and others during the 1990s.

In summary, drugs used to treat sex offenders fall into two categories: (1) the anti-androgens, such as Provera and Lupron, and (2) the SSRIs, such as Prozac, Zoloft, and Paxil.

These drugs are most helpful in treating sex offenders who are highly preoccupied with sexual thoughts and fantasies and those who report a high sexual drive or high total sexual outlet. In addition to their high sexual drive and often atypical or paraphilic expression of sexual urges, these individuals may also have low self-esteem, social anxiety, social skills deficits, low grade anxiety, and depressive symptoms. For these reasons, a combination of an SSRI with an anti-androgen may be most effective for those sex offenders that present with high sexual drive coupled with an affective disorder.

Expert competency must include a working knowledge of those drugs commonly used with sex offenders. Working knowledge includes awareness of (1) the principle on-label indications for these drugs, (2) side effects associated with these drugs, (3) the pharmacodynamic properties of these drugs, and (4) to a much lesser extent the pharmacokinetics of these drugs. Comorbid diagnoses may produce complex poly-pharmacy. Awareness of potential interactions between the anti-androgens and frequently observed medications used to treat other disorders (e.g., major affective disorders) is part of expert competency. In addition, familiarity with the recent literature on the efficacy of both the anti-androgens and the SSRI antidepressants is critical. There is a substantial empirical and theoretical literature on drug use with sex offenders. A rudimentary knowledge of this literature is essential. In addition, there are significant ethical issues that expert competency embraces. As noted above, for example, the principle anti-androgen used in the USA is prescribed off-label, requiring a detailed statement of informed consent. In addition, compulsory (mandated) use of drugs, occasionally referred to as "chemical castration," may raise possible Eighth Amendment issues. Acquaintance with these ethical issues is part of expert competence.

16.3 Transition from Basic Competence to Expert

Since most practitioners working with sex offenders have a Master Degree, transition from basic to expert competence typically begins with education – acquiring a doctoral degree. Beyond the acquisition of a doctoral degree and licensure, transition to expert competence requires hands-on work experience with parallel supervision, extensive reading, and attendance at professional workshops.

16.4 Summary

Establishing benchmarks for levels of competence in the relatively small niche of specialized practice with sex offenders is difficult given the apparent absence of prior efforts in this regard. We have attempted, nonetheless, to provide a preliminary set of recommendations, subject to the scrutiny and critical appraisal of our colleagues. This area of clinical practice is unique in at least two major respects. First, a substantial proportion of practitioners are Master's-level. Among ATSA's 2,049 clinical members, for instance, only 455 (22.2%) have doctoral degrees. Thus, over three quarters of ATSA's clinical members are MA-level practitioners. Thus, unlike most specialty areas of clinical practice wherein transition from basic to expert competence translates to training and supervision around new tasks or procedures, transition to expert competence for those providing basic clinical services to sex offenders usually means returning to school to acquire a doctoral degree. Second, since the "clients" are typically current or

former offenders, there is increased sensitivity to ethical issues, as well as occasional demand for services that are uniquely forensic, such as assessment of risk for recidivism and court testimony.

We hope our contribution prompts further discussion around appropriate guidelines for levels of competence for those working with sex offenders. Given the increasing number of clinicians entering this field, working with forensic clients under heightened conditions of ethical and legal scrutiny, it would seem prudent that this area of professional practice be legitimized with accepted standards of training and practice, delineated standards for competence, and some form of certification process that insures competent practice.

Special Topics

17 Geropsychology

Michele J. Karel · Gregory A. Hinrichsen

Abstract: Geropsychology is a growing area of practice within professional psychology. Due to the demographic imperative of an aging population, increasing numbers of psychologists will find themselves working with older adults, their families, and related care systems. They will seek to develop increased competence for work with this historically underserved yet rewarding and challenging clinical population. This chapter reviews the knowledge base and skill competencies for professional geropsychology practice, as defined in the Pikes Peak Model for Training in Professional Geropsychology. Foundational competencies (e.g., ethical issues, diversity, relationships) and functional assessment, intervention, and consultation competencies are defined and elaborated as applied to an older adult population. The chapter includes an overview of common late life clinical problems (e.g., depression, anxiety, dementia, alcohol and substance abuse), strategies for evaluation and efficacy of psychological interventions (e.g., for depression, anxiety, caregiver distress, behavioral problems in dementia, sleep problems), and settings of care for geropsychology practice (e.g., primary, long-term, and end-of-life care). The importance of interdisciplinary care and consultation skills is emphasized. Basic versus expert competencies for geropsychology practice are delineated; basic competencies are important for any psychologist working with older adults while expert competencies are important for psychologists who will serve as geropsychology educators, supervisors, and leaders. Essential components of a geropsychology training program are reviewed, while emphasizing that there are multiple developmental pathways to geropsychology competence. Resources for further information and education in the field are provided.

17.1   Overview

Professional geropsychology is the application of psychological and gerontological knowledge and skills in the assessment of and intervention with older adults and their families. Services are provided within a range of health care, residential, and community settings. Geropsychology is a growing area of practice within professional psychology. Its growth is due to the expanding aging population and associated health care needs, growing research base that informs geropsychology practice, increased opportunities for geropsychology training, and Medicare reimbursement for psychologists (He, Sengupta, Velkoff, & DeBarros, 2005). However, there are many fewer psychologists with the interest, training, and experience to serve older adults when compared with the need for geriatric mental health services (Qualls, Segal, Norman, Niederehe, & Gallagher-Thompson, 2002). To meet the needs of an aging population, most psychologists will need to develop basic competence to serve older adults, along with an increased number of geropsychology experts to provide education, training, and leadership in this field.

17.1.1 Geriatric Health Workforce Shortages

Geriatric health workforce shortages are projected across multiple professions, including medicine, nursing, social work, psychiatry, and psychology (Center for Health Workforce Studies, 2005; Institute of Medicine, 2008). Geriatric mental health care workforce shortages are of particular concern (Halpain, Harris, McClure, & Jeste, 1999; Jeste et al., 1999). Factors associated with the increased need for geriatric mental health services include rapid growth of the "oldest-oldest" population (those over the age of 85 years), with associated complex mental health needs related to chronic illness, dementia, and long-term care; the aging of the baby boom cohort, which has higher rates of mental disorder than the current cohort of older adults (Koenig, George, & Schneider, 1994); and the greater receptivity to mental health services among cohorts now entering older age (Gatz & Smyer, 2001; Jeste et al.; Qualls et al., 2002). Furthermore, most health care professionals receive relatively little training in providing care to older adults, and few professionals choose to specialize in geriatric care. Medicare reimbursement policies often do not give financial incentive to professionals to provide care to older adults (Center for Health Workforce Studies, 2005).

A survey of American Psychological Association (APA) members in 1999 projected that psychologists were meeting only about half the need for geropsychology services at that time, with little preparation for future needs (Qualls et al., 2002). The survey found that, while most respondents (69%) reported spending some professional time with older clients, only 3% devoted most of their professional work to geropsychology. Most had received very little formal training in geropsychology. For those who did receive training, it was on-the-job training (49%) or informal (76%). More than half (58%) felt that they needed more training to work competently with older adults.

17.1.2 Growth of Professional Geropsychology

The good news is that professional geropsychology, while still a relatively small specialty area of practice, has come into its own over the past few decades. It now has a robust research base, multiple scientific journals, defined competencies for practice, a training model, education and training opportunities at all levels, active professional organizations, and organized policy advocacy efforts. In 1998, the American Psychological Association created the Office on Aging, which coordinates efforts to improve Psychology's ability to meet the needs of older adults. The Office on Aging webpage is a substantial channel for information and resources related to geropsychology practice (http://www.apa.org/pi/aging/).

Efforts to define competencies for geropsychology practice and models of training for the field have been ongoing for almost 3 decades. To date, three training conferences have been held. The "Older Boulder" conference, held in Boulder Colorado in 1981, focused on graduate education in geropsychology (Santos & VandenBos, 1982). The "Older Boulder II" conference, held in Washington, DC, in 1992, attempted to define the knowledge base for professional geropsychology practice and outlined three levels of geropsychology competence: exposure, experience, and expertise (Knight, Teri, Wohlford, & Santos, 1995). After much effort by a Task Force spawned at the 1992 conference, the APA adopted and published the *Guidelines for Psychological Practice with Older Adults* (American Psychological Association,

2004). Twenty guidelines addressed six broad domains: attitudes; general knowledge about adult development, aging, and older adults; clinical issues; assessment; intervention, consultation, and other service provision; and continuing education regarding practice with older adults.

In 2006, the National Conference on Training in Professional Geropsychology convened in Colorado Springs. It produced the Pikes Peak Model for Geropsychology Training (Knight, Karel, Hinrichsen, Qualls, & Duffy, 2009). The Pikes Peak Model delineates attitude, knowledge, and skill competencies; provides a general model of training for the field; and makes recommendations for training at graduate, internship, postdoctoral, and postlicensure levels (Karel, Knight, Duffy, Hinrichsen, & Zeiss, in press; Qualls, Scogin, Zweig, & Whitbourne, in press; Hinrichsen, Zeiss, Karel, & Molinari, in press).

17.1.3 Pikes Peak Competencies for Professional Geropsychology Practice

Efforts to delineate geropsychology attitude, knowledge, and skill competencies were informed by broader efforts within professional psychology (Kaslow et al., 2004). The "Cube Model" conceptual framework that emerged from the 2002 Competencies Conference embraced the development of both foundational and functional competencies across a psychologist's training career (Rodolfa et al., 2005). The Pikes Peak geropsychology competencies build upon these professional psychology competencies. They define the specific attitude, knowledge, and foundational and functional skill competencies recommended for working with older adults. The Pikes Peak functional competencies focus on assessment, intervention, and consultation skills (Knight et al., 2009; Karel et al., in press).

This chapter outlines the knowledge base for understanding adult development, aging, and clinical geropsychology; foundational geropsychology knowledge and skill competencies; functional geropsychology knowledge and skill competencies in the domains of assessment, intervention, and consultation; settings for geropsychology practice; and consideration of basic versus expert competencies in geropsychology.

17.2 Knowledge Base for Geropsychology

17.2.1 Knowledge of Adult Development, Aging, and the Older Adult Population

The background against which psychologists provide clinical services to older adults is the larger field of gerontology. Gerontologists have studied aging through the lens of the major academic disciplines, and have given us a sense of what is normative for many older adults. Some theorists have tried to place later adulthood within the frame of the entire life span (Erikson, 1980; Levinson, 1978). Adult development and aging researchers have focused on how central themes or issues help us to better understand aging (Bengtson & Schaie, 1999; Birren & Schaie, 2005). Psychologists have played an important role in developing methodologies to study aging over time and to identify changes that are due to age per se,

rather than others factors that may covary with age, such as unique generational experiences that shape attitudes and behavior (Schaie, 2005). Demographics are important in the study of aging and reveal how population dynamics and structure shape societies and individuals. The fact that in the year 2030, 20% of Americans will be 65 years of age and older has substantive implications for the United States (Federal Interagency Forum on Aging Related Statistics, 2008).

Physical change is part-and-parcel of growing older. There are normative changes in vision, hearing, physical strength, and appearance that are experienced by older adults (Whitbourne, 1999). Familiarity with these changes helps the clinician to identify what is usual (vs. a disease process), and to make adaptations to professional practice that optimize clinical interventions and rapport (e.g., environmental changes to maximize hearing and seeing). Psychologists have had a prominent role in studying aging, including the relationship of age with stability and change of information processing, emotional regulation, mental abilities, and personality (Birren & Schaie, 2006). The social dynamics of the aging process have long been a focus of gerontological research, including social roles, family and marital relationships, friendship formation and continuity, and engagement in voluntary organizations (Binstock & George, 2006). In contrast to the negative and stereotypical views of older people, most enjoy reasonably active and fulfilling relationships with family, friends, and community (APA Working Group on the Older Adult, 1998).

An understanding of what is normative for older adults as a whole must be tempered by an appreciation of the diversity within this age group. A gerontological maxim is that "the older people get, the more diverse they are." Factors such as social class, race/ethnicity, disability status, sexual orientation, and place of residence interact with the aging process in ways that create unique vulnerabilities and unique strengths. Although a black woman who spent most of her life in the rural south and a white man living in a large northern city may both be 80 years of age, life experience, economic status, personal perspective, and a myriad of other factors will likely vary greatly.

17.2.2 Knowledge Foundations of Clinical Practice with Older Adults

While the majority of older adults live without functionally disabling physical or mental disorders, a minority do suffer from them. Knowledge of common problems experienced by older adults is a critical reference point for practicing psychologists. Most older adults suffer from one or more chronic illnesses, and take one or more medications. Up to one-quarter of older people meet criteria for a mental disorder. Mental disorders and symptoms are more common among older adults who have physical health problems. Though rates of most mental disorders are lower in older adults when compared with younger adults, older people are at much greater risk of cognitive impairment or dementia than younger people. For example, about 5% of people of 65 years of age and older have dementia and the risk for dementia doubles every 5 years. Older people are less likely to seek mental health services than younger people for varied reasons (e.g., generational attitudes, lack of access to services, financial barriers). Among those who do seek services, the most common presenting problems are dementia, depression, anxiety, and adjustment disorders. Older adults often have multiple problems including co-morbid physical and mental disorders (Zarit & Zarit, 2006).

Some mental disorders have unique presentations in later life and require careful evaluations. As noted, older adults often take one or more medications which may be associated with the onset of or clinical complication of mental disorders. Physical and social environments interact with physical and mental health problems of later adulthood. Physical environments that promote physical functioning (e.g., few stairs, bathroom grab bars, transportation options) and easy access to age peers and family will likely have a salubrious effect on emotional health (Lawton & Nahemow, 1973). Most older adults with physical or mental health problems have a web of family and social relationships which may be critical resources. However, the process of providing care to older adults with physical, emotional, or cognitive problems can be very stressful for family members and may erode their ability to provide care (Schulz & Martire, 2004). Geropsychologists appreciate that a full understanding of an older adult requires a substantive assessment of family and social supports.

17.3   Foundational Competencies

Foundational competencies for geropsychology practice are built upon foundational competencies of the "Cube Model" (Rodolfa et al., 2005). Foundational competencies are the underlying "building blocks" informing all professional psychology activity, and include: self-reflective practice, scientific knowledge and methods, relationships, ethical and legal standards, individual and cultural diversity, and interdisciplinary systems. The Pikes Peak Model has added two additional foundational skills for geropsychology practice that cut across functional domains: advocacy and care coordination, and the business of geropsychology practice. Further, the Pikes Peak Model defines the knowledge base that informs these foundational geropsychology skills and all geropsychology practice (Karel et al., in press).

17.3.1 Ethical and Legal Standards

The APA Ethics Code guides the professional behavior of psychologists working with older adults. Beyond the core ethical guidelines for this profession, psychological practice with older adults can raise complex ethical and legal dilemmas. Distinctive ethical issues arise particularly in working with older adults who are physically or cognitively disabled, increasingly dependent on others for care, or cared for in interdisciplinary health care settings (Karel, 2008).

When caring for frail older adults, there is often a tension between promoting an individual's right to make *informed* decisions for himself or herself, consistent with his or her values and beliefs, and the professional desire to protect individuals who are no longer capable of making informed decisions (e.g., regarding health care, residence, money management, driving). Older adults have the right to confidentiality (even if the family brought them for treatment, or if treatment team members want to know their clinical status) and privacy for psychological care (even if they live in a nursing home with little private space). Hence, psychologists who work with older adults should be alert to decision making capacity of older people while working to optimize their participation in decision making. Familiarity with laws and institutional policies regarding confidentiality, surrogate decision-making, advance directives, conservatorship, guardianship, end-of-life care, and elder abuse is also important (Karel, 2007; Mezey et al., 2002; Moye, 1999; Moye et al., 2007; National Center on Elder Abuse, 2008; Qualls & Smyer, 2007).

17.3.2 Cultural and Individual Diversity

The experience of aging differs across gender, generational, socioeconomic, ethnic/racial, cultural, linguistic, religious, disability, sexual orientation, gender identity, and geographical (urban vs. rural) statuses. Age has been an under-appreciated aspect of individual diversity, but a person's age alone tells us very little about that person. It is essential to acknowledge interactions between age and other aspects of diversity. Psychologists who work with older adults should be aware of the wide diversity among older adults. They should work to counter stereotypes about aging in themselves, their clients, client's families, and communities, and work in a culturally sensitive manner with a wide range of older adult clients. Cultural, ethnic, religious, and other individual differences very much inform older adults' values, attitudes, and beliefs regarding aging, disability, caregiving, medical decision-making, dying, and grief. These factors will also have an impact on choices and preferences in the course of geriatric health care (Administration on Aging, 2001; Hinrichsen, 2006; Karel, 2007; Xakellis et al., 2004; Yeo, 2001; Yeo & Gallagher-Thompson, 2006).

17.3.3 Multi/Inter-Disciplinary Teams

Many older adults are healthy, hearty, and may seek psychological services to address a circumscribed life problem. With advancing age, however, many older adults are at risk for multiple medical, neurological, psychiatric, and psychosocial problems. Increasingly complicated problems benefit from assessment and treatment from a wide range of professionals. In many geriatric health care settings, an interdisciplinary team evaluates the older adult and then devises a treatment plan that includes interventions by multiple team members (e.g., physicians, nurses, social workers, rehabilitation and occupational therapists, pharmacists). Geropsychology practice, therefore, requires an appreciation of the contributions of other disciplines to geriatric care and effective communication with other professionals (Fulmer, Flaherty, & Hyer, 2003; Zeiss & Steffen, 1996).

17.3.4 Self-Reflection

Self-reflection is the awareness of one's own biases, assumptions, or sources of discomfort that may influence professional behavior. Each psychologist has different personal and professional experiences that influence attitudes and feelings about aging and older people. For example, were grandparents present in one's childhood and, if so, were they a positive or negative influence? Were older family members active and productive until later years, or did they suffer disabling medical, cognitive, or emotional conditions? Did psychology training include exposure to older adults and, if so, what were those experiences like?

Self-reflection also includes evaluation of one's own competence to address the care needs of a particular patient, or population. Metacompetence is one's ability to accurately evaluate what one does or does not know, and guides professional development (Falender & Shafranske, 2007). Psychologists new to clinical work with older people must evaluate whether or not they can offer competent assessment or intervention services, and seek consultation, continuing education, and referral to other professionals when needed.

17.3.5 Relationships

In geropsychological practice, relationship competency refers to the ability to establish effective and empathic working relationships with older clients. Barriers include negative stereotypes of, personal discomfort with, or exaggerated respect for or, conversely, infantalization of older adults. Effective clinical work will be difficult without the ability to relate to older adults with respect, genuineness, appreciation for long lives lived, recognition of strengths as well as deficits, and adapting communication with respect to an individual's sensory, cognitive, intellectual, and emotional capabilities (Knight, 2004; Scogin, 2000). The ability to foster empathic and collaborative relationships with families, treatment team members, and other colleagues is also critical. Further characteristics of relationship competence include recognition of strengths and shared goals of various stakeholders, and effective negotiation of conflict.

17.3.6 Application of Scientific Knowledge

Psychologists who are relatively new to working with older adults may not have been exposed to the large research literature in adult development and aging, geriatric mental health, and gerontology. This research broadly provides information on effective and ethical geropsychology assessment and intervention. Geropsychologists should familiarize themselves with the scientific basis of normal versus pathological aging (Birren & Schaie, 2006), psychological assessment methods with older adults (Lichtenberg, 1999), and the growing literature on evidence-based psychological interventions with older adults (Gatz, 2007; Scogin & Yon, 2006). Psychologists acknowledge the strengths and limitations of the scientific knowledge base (e.g., there remains relatively little research on psychological interventions for very old or ethnically diverse elders).

17.3.7 Business of Geropsychology

A core foundational competency for geropsychology practice is the understanding of Medicare and Medicaid. Medicare is the primary insurer for adults aged 65 years and older. The 1989 Omnibus Budget Reconciliation Act recognized psychologists as independent Medicare providers, thus, significantly increased the ability of psychologists to provide mental health care to older adults. Further, in 2002, Medicare expanded coverage for psychological services to include assessment and intervention for health conditions (not only psychiatric illness), through the "Health and Behavior Assessment and Intervention" codes. State-funded Medicaid programs often cover co-payment fees for poor patients. Some older adults have private insurance policies that cover co-payments (Hartman-Stein & Georgoulakis, 2007; Karlin & Duffy, 2004; Karlin & Humphreys, 2007).

Psychologists who wish to provide services to older adults must, in most cases, become Medicare providers and be informed about coverage and appropriate coding, billing, and documentation for services rendered. Services must meet the criteria for medical necessity, and each encounter must be so documented (Hartman-Stein & Georgoulakis, 2007). The Centers for Medicare and Medicaid Services (CMS) contracts with fiscal intermediaries (FI), regional

insurance companies that develop local coverage/reimbursement policies for services and process claims. Psychologists who serve older adults will become well acquainted with the policies of their regional FI. The CMS website is a key resource for geropsychologists (www.cms.gov). In addition, the APA website (www.apa.org) and, in particular, the APA Practice Organization website (www.apapractice.org) are useful resources. Medicare regulations often change, and hence, it is important for psychologists to remain updated. Further, psychologists can play a critical role in policy advocacy to ensure adequate mental health care for older adults (Karlin & Humphreys, 2007; See APA Office on Aging, at http://www.apa.org/pi/aging/).

17.3.8 Advocacy and Care Coordination

Older adults face many barriers to accessing health and mental health care, as well as community-based and long-term care services. Service networks can be complex and fragmented, eligibility criteria may be difficult to understand, and telephone or physical access may be problematic for people who have trouble seeing, hearing, walking, driving, or comprehending or communicating clearly. Geropsychologists work to minimize these barriers to care. They recognize the importance of care coordination, continuity of care, and advocacy for older adults. Further, they coordinate care with family members, medical and social service providers, community agencies, and others. Advocacy and care coordination occur with consent from the older adult or from the surrogate decision-maker of the older adult with impaired capacity.

17.4 Assessment Competencies

Competence for psychological assessment of older adults builds upon general adult assessment competencies. These competencies include understanding the importance of a biopsychosocial conceptual framework to inform assessment, appreciation of reliability and validity of assessment instruments for the population at hand, and appropriate use of assessment results to inform recommendations and treatment planning. Distinctive issues for geropsychological assessment are normal versus pathological aging, comorbidities in older adults, and the critical role of environment and social context for an older adult's functioning. Furthermore, a lifespan perspective on psychopathology informs assessment, as various disorders have different baserates, phenomenology, and risk factors in older adults. Psychological screening and assessment tools may or may not be reliable and valid for an older adult population. However, increasing numbers of tools are being developed for use with older adults (Lichtenberg, 1999; Zarit & Zarit, 2006).

17.4.1 Fundamental Considerations for Geropsychology Assessment

Older adults referred for psychological assessment often present with a range of symptoms that can have multiple possible etiologies. For example, consider a 76-year old woman who complains of trouble sleeping, poor motivation, increased worrying, trouble concentrating, and increased forgetfulness. These symptoms might be attributed solely or in combination to

depression, anxiety, dementia, chronic pain, recent medical hospitalization for cardiac problems, medication side effects, alcohol misuse, caregiving stress, or other factors. Therefore, the initial list of "rule-out" diagnoses can be quite long. Assessment also includes attention to client strengths as well as deficits, the implications of medical and psychological problems for everyday functioning, the environmental and social context that may serve to enhance or pose barriers to optimal functioning and quality of life, and how assessment results may be translated into practical recommendations for the older client, family, and/or professional caregivers.

The Pikes Peak assessment knowledge-base encompasses the understanding of normal aging and psychopathology in late life, methods often needed to inform assessment of an older adult, limitations of some assessment methods, and contextual issues that may affect assessment results. Interdisciplinary assessment is often indicated. For many presenting problems (e.g., undue fatigue, confusion, depression), medical, medication, nutritional, or other organic causes should be ruled out. Psychologists need to be attentive to age and educational normative data when assessing older adults, and be aware of the limitations of tools not specifically normed with older adults, particularly older adults from ethnic minority and immigrant backgrounds. Further, it is important to be aware of individual and environmental factors that may influence assessment performance (e.g., sensory problems, limited literacy, medical conditions, noisy hospital setting with distractions).

Pikes Peak geropsychology assessment skills include the abilities to: (1) Conduct clinical assessment and differential diagnosis (e.g., common problems include depression, anxiety, grief, delirium, dementia, medication and physical disorders, and their effects on functioning); (2) Use psychometrically sound screening instruments for cognition, psychopathology, and personality to inform treatment planning; (3) Refer for neuropsychological, neurological, psychiatric, medical, or other evaluations as indicated; (4) Use cognitive assessments and/or neuropsychological reports to clarify clinical issues and inform treatment planning; (5) Evaluate decision-making and functional capacities (e.g., for managing finances, independent living, driving, and making health care decisions); (6) Assess risk (e.g., suicidality, self-neglect, elder abuse); and (7) Communicate assessment results to various stakeholders with relevant, practical, and clearly understandable recommendations, in tandem with consideration of confidentiality issues (Knight et al., 2009).

Several of these competencies warrant further discussion. Given rising rates of dementia with advancing age, it is important to screen for cognitive problems. While the large majority of older adults are cognitively intact, it is important to screen for possible cognitive problems and, if needed, conduct or refer for further evaluation. Signs of cognitive problems during a clinical interview include: difficulty recounting details of recent history, vague responses to questions, repetitive responses or stories, tendency to defer to a family member if present, marked distractibility, extreme tangentiality, or obvious confusion or disorientation. Tools such as the Mini-Mental Status Exam, the Modified Mini Mental Status Exam, or the Clock Drawing test are cognitive screening tools and are not diagnostic in nature. However, they can help to structure a screening and suggest whether further cognitive evaluation is indicated (Attix & Welsh-Bohmer, 2006; Cullen, O'Neill, Evans, Coen, & Lawlor, 2007; Ruchinskas & Curyto, 2003).

Another important geropsychology assessment competency is evaluation of older adults' decision-making and functional capacities. The following questions often prompt psychological assessment referrals: "Is dad still safe to live on his own?"; "Should my wife still be

driving?"; "My elderly patient is refusing recommended surgery, is he 'competent' to refuse the intervention?"; "Mom is making huge donations to local charities, is she really able to make these financial decisions?" Many psychologists, including geropsychologists, have not been trained to evaluate decision-making and functional capacities. While psychiatric, cognitive, or neuropsychological assessment results suggest implications for functioning, there is often not a direct relationship between a person's score on a memory test and, for example, ability to live alone. Functional assessment includes gathering an array of data from multiple sources; assessing an older adult's abilities to understand, appreciate, reason, and make particular choices; using decision-making or functional capacity tools; collaborating with other professionals; and appreciating the ethical and legal context for findings of compromised capacities. Psychologists with little training in this area should be cautious in providing professional judgments about capacities, particularly when an older adult stands to lose certain freedoms or legal self-determination (American Bar Association & American Psychological Association Assessment of Capacity in Older Adults Project Working Group, 2008; Moye, 1999; Qualls & Smyer, 2007).

Finally, psychologists working with older adults must be aware of risk issues in this population. Suicide risk is relatively high among older white men, particularly those who are depressed and physically disabled (Heisel & Duberstein, 2005). The practitioner is aware of signs of self-care problems, and emergent medical conditions among older adults. Assessment of an older adult's ability to complete activities and instrumental activities of daily living (and to what extent they can access supports to optimize these abilities) is important (Moye, 1999). Recognizing signs of emotional, physical, sexual or financial abuse, or self-neglect in older adults is critical (Mellor & Brownell, 2006; National Center on Elder Abuse).

17.4.2 Assessment of Common Late-Life Psychological Disorders

While it is beyond the scope of this chapter to provide a solid review on late-life psychopathology and geropsychological assessment, we highlight common psychological disorders in older adults and recommend relevant assessment tools.

Depression. There exists a large research literature on the prevalence, phenomenology, risk factors, assessment, and treatment of geriatric depression. A few points to keep in mind about the potentially distinctive characteristics of late-life depression are presented in this section (Alexopoulos, 2003; Alexopoulos et al., 2002; Qualls & Knight, 2008; Zarit & Zarit, 2006). Some depressed older adults present with relatively few affective symptoms, and instead of sadness, complain of problems with motivation, interest, energy, memory, and somatic discomforts. Subsyndromal or minor depression is common in older adults and is associated with increased disability; that is, clinically significant depressive symptoms may not meet the DSM-IV criteria for major depressive episode in many older adults. There are strong relationships between medical illness and depression, anxiety and depression, and dementia and depression, and differential diagnosis in these contexts can be challenging because the symptoms of these syndromes overlap significantly. There is increasing evidence that cerebrovascular disease and related risk factors, such as hypertension, diabetes, and obesity, pose risk for a late-life depression syndrome characterized by apathy, executive dysfunction, and psychomotor retardation. The onset of depression for the first time in late life may be a precursor to dementia.

Assessment of depression in older adults necessitates a comprehensive interview about the individual's history, the onset and course of symptoms, relationship to medical and other presenting problems, risk concerns, social supports, and so forth (Karel, Ogland-Hand, & Gatz, 2002; Snarski & Scogin, 2006). Depression screening tools, used in primary care, mental health, or long-term care settings, can be used to determine the need for more comprehensive evaluation (Arean & Ayalon, 2005; Edelstein et al., 2008), as well as to track treatment progress over time. For older adults, the Geriatric Depression Scale (GDS; Yesavage et al., 1983) has received the most research attention, and is a reliable and valid screening tool. The GDS 30- and 15-item versions, and translations into multiple languages, are available at the GDS website (http://www.stanford.edu/~yesavage/GDS.html). The Cornell Scale for Depression in Dementia is a clinician-administered scale useful for older adults with dementia (Alexopoulos, Abrams, Young, & Shamoian, 1988). Several other tools can be used with older adults, depending on the care setting and cognitive capacity of the older adult (Beck Depression Inventory-II, Center for Epidemiologic Studies Depression Scale; Edelstein et al., 2008). Assessment of suicidality is critical in the context of late-life depression, and several tools can help with this assessment (Edelstein et al., 2008).

Anxiety. Anxiety in late life is more prevalent than depression. Anxiety is frequently comorbid with medical conditions, depression, and dementia (Beck & Stanley, 2001; Kogan, Edelstein, & McKee, 2000; Seignourel, Kunik, Snow, Wilson, & Stanley, 2008). Generalized anxiety disorder is a common concern for older adults, as is post-traumatic stress disorder. A variety of anxiety assessment tools have reasonable psychometric properties with older adults (Edelstein et al., 2008). While a variety of tools may be useful (Beck Anxiety Inventory, State-Trait Anxiety Inventory, Worry Scale, Penn State Worry Questionnaire, Hamilton Anxiety Rating Scale), most also have some limitations when used with older adults (Edelstein et al., 2008; Wetherell & Gatz, 2005). The Geriatric Anxiety Inventory is a promising new tool to keep an eye on (Pachana et al., 2007). Ongoing research will guide the choice of tools that are most useful for different subgroups of older adults.

Dementia, Delirium, and Behavioral Concerns. Dementia assessment entails obtaining a thorough history of the onset and course of symptoms, medical evaluation and laboratory tests to rule-out reversible causes, brain imaging, and often neuropsychological testing (Lichtenberg, Murman, & Mellow, 2003). Therefore, dementia assessment is best coordinated with an interdisciplinary team. A critical diagnostic distinction exists between dementia and delirium. While dementia can have many causes (e.g., Alzheimer's disease, vascular disease), it is typically progressive and rarely affects a person's alertness until at the very late stages. Delirium is an acute confusion state that is transient and usually reversible, characterized by deficits in attention, disorientation, difficulty in thinking clearly, and fluctuating alertness. Delirium is common in the context of dementia, and needs medical evaluation to determine the underlying causes (e.g., infection, medication reaction) (Fick, Agostini, & Inouye, 2002; Inouye, 2006). Geropsychologists must be alert to signs of delirium in older adults, and seek medical consultation in these cases.

In addition to cognitive changes, dementia is often associated with a range of psychiatric and behavioral symptoms, such as depression, apathy, anxiety, agitation, delusions, hallucinations, wandering, repeated vocalizations, and others (Steffens, Maytan, Helms, & Plassman, 2005). Observational and caregiver report tools are useful in the evaluation of problematic behaviors in dementia patients, who may not be able to provide accurate reports about their own symptoms and behaviors. One particularly helpful tool is the Revised Memory and

Behavior Problems Checklist (Teri et al., 1992), in which caregivers rate the frequency of a range of behavioral and mood symptoms and the extent to which each of those symptoms upsets the caregiver.

Alcohol and Substance Abuse. Substance abuse disorders are often overlooked in older adults and their prevalence is expected to increase as the current baby boom cohort moves into old age. Age-related metabolic and brain changes make older adults more vulnerable to functional consequences of substance misuse, abuse, or dependence (e.g., alcohol, prescription medications including benzodiazepines and narcotic pain medications, nicotine, and illicit drugs) (Sorocco & Ferrell, 2006; US Dept of Health and Human Services, 1998). Psychologists must ask older adults about their use of prescription and non-prescription medications, as well as alcohol and other drugs, and be aware that "safe" drinking limits decrease with age (for adults over the age of 65 years, the recommendation is no more than one drink per day). Alcohol screening tools useful for older adults include the Michigan Alcoholism Screening Test – Geriatric Version (MAST-G) (Blow et al., 1992) and the Alcohol Use Disorders Identification Test (AUDIT) (SAMHSA, 1998). The Substance Abuse and Mental Health Services Administration Treatment Improvement Protocol (TIP) on *Substance Abuse Among Older Adults* is an excellent resource and is available online.

Other Issues. Additional important foci of geropsychology assessment include personality disorders, psychotic symptoms, grief, insomnia, sexuality, caregiving stress, a wide range of behavioral health concerns (e.g., smoking, obesity, inactivity), and multiple adjustment issues (e.g., retirement, family changes, residential changes). Readers are encouraged to seek information about the assessment of these issues in older adults. There is a growing research base related to all these domains, as well as many validated screening and assessment tools that can help in the evaluation of an older adult client.
