Preface

Fully qualified professional psychologists are expected to possess several competencies. These refer to professional knowledge, skills, and abilities gained through education and experience. Over the past several years, a number of competencies have been enumerated by professional bodies around the world, yet the nature of these competencies and how they are developed and maintained remains obscure. Statements commonly refer to broad domains, such as "assessment," "intervention," and "research" with the implication that many subdomains of competence are subsumed under each. The widespread commitment to the competence model brings a unifying force to professional psychology, yet it provides little guidance to educators, practitioners, and credentialing bodies in how to proceed with competency modeling or setting standards for achievement. Since competencies are developed, it is necessary to distinguish between basic and expert competencies. The basic level refers to clinicians who have completed an internship and some residency. A well-trained clinician should possess these basic competencies. Expert competencies are achieved by clinicians with additional training and experience and who work extensively with particular populations, techniques, or diagnoses. In much general writing, the distinction between basic and expert is lost and the readers are left to disentangle developmental levels and expectations themselves. An objective of this series is to clearly define these levels for the reader. In addition, the evidence base for psychological assessments and interventions is a critical consideration in judging competence. We have asked authors of the chapters to discuss the evidence relating to each practice presented in the series.

The purpose of this series is to provide definitions for each competency domain and provide detailed descriptions of the levels of competence and the developmental strategies for reaching each level. Volume I begins with the basic competencies of the clinical psychologists, and then the succeeding chapters present the competencies related to diagnosis and evaluation, research, and professional roles. These chapters follow a similar format: overview, basic competencies, expert competencies, and a summary. Volume II is devoted to the competencies associated with the interventions and treatments for adults and Volume III is concerned with the interventions and treatments for children and adolescents. In both volumes, we asked the authors to follow, whenever possible, a basic format of recognizing symptoms and assessment, maintenance factors, evidence-based treatment approaches, mechanisms of change underlying the intervention, followed by basic and expert competencies and how a psychologist transitions from the basic to the expert level. Certain topics required adjustment to this format, but even then the fundamental information is presented.

A large number of people contributed to the development of these three volumes. As the editors, our greatest debt is to the chapter authors who contributed considerable time, effort, and ingenuity to the books. We cannot thank them enough. Behind the scenes, Sharon Panulla at Springer rendered invaluable assistance to us. Our students, Blake Kirschner, Terri Draper, and Heidi Meeke, assisted us with the information gathering and the indexing of the volumes. Carole Londerée, our editorial assistant, is priceless. She organizes material, corresponds with authors, and keeps the editors on their toes. Thank you Carole for all you do.

About the Editors

Jay Thomas is Professor and Assistant Dean of the School of Professional Psychology at Pacific University. His Ph.D. is in Industrial and Organizational Psychology from the University of Akron. He holds specialty certification from the American Board of Professional Psychology (ABPP) in Industrial and Organizational Psychology and Organizational and Business Consulting Psychology. He is past President of the latter board and is on the Board of Trustees of ABPP. He has worked with clinical and counseling psychologists and students for since 1993 to improve their practice and training. Research interests include his organizational and industrial work in psychology with mental health, program evaluation, assessment, and outcome studies. Dr. Thomas' research and consulting team of students works with the Oregon State Hospital, Oregon Department of Corrections, Washington County Mental Health Court, and other institutions to create more effective organizations in the delivery of mental health services. He is the author of *Competency & Best Practice: Organizational & Business Consulting Psychology, Volume X of the Competencies in Psychology Specialties* and has edited a number of other books on mental health in the workplace, research methods, and personality and psychopathology.

Michel Hersen (Ph.D., ABPP, State University of New York at Buffalo, 1966) is Professor and Dean, School of Professional Psychology, Pacific University, Forest Grove, Oregon. He completed his post-doctoral training at the West Haven VA (Yale University School of Medicine Program). He is Past President of the Association for Advancement of Behavior Therapy. He has co-authored and co-edited 147 books and has published 226 scientific journal articles. He is co-editor of several psychological journals, including *Behavior Modification*, *Aggression and Violent Behavior: A Review Journal*, *Clinical Psychology Review*, and *Journal of Family Violence*. He is Editor-in-Chief of the *Journal of Developmental and Physical Disabilities*, *Journal of Anxiety Disorders*, and *Clinical Case Studies*, which is totally devoted to description of clients and patients treated with psychotherapy. He is Editor-in Chief of the 4-volume work entitled: *Comprehensive Handbook of Psychological Assessment.* He has been the recipient of numerous grants from the National Institute of Mental Health, the Department of Education, the National Institute of Disabilities and Rehabilitation Research, and the March of Dimes Birth Defects Foundation. He is a Diplomate of the American Board of Professional Psychology, Fellow of the American Psychological Association, Distinguished Practitioner and Member of the National Academy of Practice in Psychology, and recipient of the Distinguished Career Achievement Award in 1996 from the American Board of Medical Psychotherapists and Psychodiagnosticians. Finally, at one point in his career, he was in full-time private practice and on several occasions he has had part-time private practices.

Volume I
General Competencies

Basic Competencies

1   Competencies in Adult Clinical Psychology

Warren W. Tryon

Abstract: This chapter addressed the following background issues: evidence-based medicine, the empirically supported treatment debate, what constitutes evidence, and competency. The National Council of Schools and Programs in Professional Psychology (NCSPP) educational model was discussed including the following components: relationship, assessment, intervention, consultation and education, management and supervision plus research and evaluation. Six specific foundational competencies were considered including their essential components, behavioral anchors, and assessment methods that indicate readiness for practicum, internship, and practice. These foundational competencies include: reflective practice and self-assessment, scientific knowledge and methods, relationships, individual and cultural diversity, knowledge of ethical and legal standards and policies and interdisciplinary systems. The following six functional competencies were discussed: assessment-diagnosis-case conceptualization, intervention, consultation, research and evaluation, supervision and teaching, plus management and administration. Essential components with behavioral anchors and assessment methods that indicate readiness for practicum, internship, and practice were identified. What being expert entails was briefly discussed.

1.1   Overview

Clinical psychologists have been concerned about competency since formal training began but have differed with regard to what it means to be competent. Evaluating competency requires a context of what a clinical psychologist should know, and that is determined by the theoretical orientation and training model. Relevant questions include: How much science training should clinical psychologists have? How developed should their professional skills be upon graduation? Graduates seen as competent from one training model may be seen as marginally competent, if competent at all, from a very different training model. The history and theoretical foundations of clinical psychology (cf. Tryon, 2008a) support different views of competency. The American Psychological Association (APA) is a diverse organization that currently consists of 56 divisions. It should not be surprising that views on competency are similarly diverse. The APA Committee on Accreditation requires training, and presumably competence, concerning the following six bases: (1) history and systems, (2) biological, (3) cognitive and affective, (4) social, (5) individual, and (6) developmental. However, the Committee on Accreditation does not specify competencies that must be achieved. They leave each program to define its own training goals and evaluate the extent to which these goals are realized. It follows that programs based on contrasting training models will graduate students with different competencies. The "Competency Developmental Achievement Levels (DALs) of the National Council of Schools and Programs in Professional Psychology (NCSPP)" (http://www.ncspp.info/pubs.htm) are quite specific with regard to the knowledge, skills, and

attitudes that constitute competency to begin practicum, begin internship, and complete the doctoral degree but a comment made when the DALs were circulated by email minimized their impact by indicating that they are training guidelines that need not be adhered to and can be modified to meet program goals. This liberty to follow, or not, and to revise at will competency criteria increases rather than decreases the range of competencies graduates from clinical programs will have. The public interest requires more certain competency criteria.

Identifying and developing specific clinical competencies represents a major pedagogical change in the training of clinical psychologists. Such clinical focus has largely been brought about by schools of professional psychology. We shall see that their competency criteria involve evidence-based practice where evidence means scientific evidence (not just accumulated personal experience) although these matters have not been fully resolved. Before considering specific competency criteria we identify several background issues. Evidence-based medicine provides an important context in which to evaluate competency for clinical psychologists. The medical profession has only recently based its practices on scientific evidence. Clinical psychologists have only recently become interested in evidence-based practice, with a special focus on empirically supported treatments and principles. We conclude that clinical psychologists are ethically bound to best serve the public by using the best practices: i.e., practices supported by the best evidence. We consider the question "what constitutes evidence"? Then we directly address the question of what constitutes competency. An overview and more detailed presentation of the competency training model developed by the National Council of Schools of Professional Psychology (NCSPP), the most detailed model currently available, is provided. It specifies foundational and functional competencies at three developmental levels: readiness for practicum, internship, and practice.

1.2   Background Issues

1.2.1   Evidence-Based Medicine

At the dawn of time, societies authorized, and thereby legitimized, practitioners of the healing arts based on the need to care for the sick rather than on any special competencies demonstrated by them. Claims of special healing powers may have been made by practitioners but supporting evidence of effectiveness and/or competency was not required. Practitioners, including shamans, witches (pagan healers), priests, clergy, and physicians developed methods for treating sick people. These methods were handed down from generation to generation and established traditions of healthcare based on precedent and consensus rather than evidence of efficacy. Competency was defined and evaluated by senior practitioners who modeled approved methods and trained their apprentices accordingly. Questioning these methods was generally not well received. Eddy (2005) noted that until about 1965, it was widely believed that medical competency was insured by medical education, including medical school, internship and residency training, licensure, continuing education, and consultation with colleagues. Clinical judgment was considered sufficient to identify the best course of action, including testing and treatment decisions. Medical decision making was not studied nor was there any felt need to study it. Insurance coverage and medical necessity were reciprocally defined. If most physicians were performing a procedure, then it was considered to be medically necessary and should be

covered by insurance. On the contrary, evidence began to appear that questioned this view. Wennberg and Gittelsohn (1973) documented wide variations in health care occurring within small areas. When two physicians recommend different treatments for similar patients it is unlikely that they are both correct. Additional evidence surfaced showing that medical experts deemed some physician decisions to be inappropriate. All of this leaves aside the competency of individual physicians in their performance of these procedures. It is most unlikely that all physicians are equally skilled. Clearly some are more competent than others. No definition of competency has been agreed to and used to regulate the practice of medicine.

Eddy (2005) identified a second problem in the medical profession: i.e., the gap between science and practice. It was estimated that only 15% of medical practices were based on science. Physicians, like psychologists, frequently do not follow clinical practice guidelines derived from controlled research. This is especially disturbing given a report by Eagle et al. (2005) that 30-day and 1-year mortality rates are decreased when cardiologists follow clinical practice guidelines. Rello et al. (2002) reported that physicians do not consistently follow practice guidelines even to prevent ventilator-associated pneumonia. They further noted that "… the degree of nonadherence seems to be independent of the strength of the evidence in support of specific interventions that have been reported in previous trials" (p. 659). Cabana et al. (1999) asked "why don't physicians follow clinical practice guidelines?" and reported knowledge, attitude, and behavioral barriers against adopting clinical guidelines that are relevant to clinical psychology. Greenhalgh (2002) remarked on the conflict between intuition and evidence; a dialectic tension found in the debate over the role of empirically supported treatments in clinical psychology. Drake et al. (2001) reported that pharmacological and psychosocial interventions that are known to be effective are not widely offered in mental health settings. These authors reported "Research shows that education alone does not strongly influence the practice behaviors of health care providers" (p. 47) and they indicated that "Financial incentives and administrative rules and regulations must be aligned to support the implementation of evidence-based practices" (p. 52). Entering "why don't physicians follow clinical practice guidelines?" as a search term into Google Scholar yielded 5,860 hits thus revealing a great deal of discussion and concern regarding this important topic. The current "Competency Developmental Achievement Levels (DALs) of the National Council of Schools and Programs in Professional Psychology (NCSPP)" indicate that competent clinical psychologists use evidence-based interventions and cited the APA (2006) presidential task force report on evidence-based practice.

Eddy (2005) noted a related third problem, in that it takes years for the results of Randomized Controlled Trials (RCTs) to influence clinical practice. Some procedures that physicians took for granted to be effective were studied and found to be ineffective. I have not seen a figure estimating the percentage of psychological practices that are based on science. Herbert (2003) noted that "Despite important advances in the development and empirical evaluation of psychotherapies over the past three decades, the chasm between clinical practice and the scientific literature is as wide as ever" (p. 412). Few practicing clinicians use empirically supported treatments. They mainly rely on the traditions of care that they learned in graduate school and continue to do so throughout their professional career despite access to continuing education. Regrettably, some of these practices have been shown to be harmful (cf. Herbert, 2003). Lambert, Shapiro, and Bergin (1986) reported that as many as 10% of clients deteriorate during psychotherapy and end up worse off than when they began. Mays and Franks (1985) edited a book entitled *Negative outcome in psychotherapy and what to do about it.* Our ethical mandate

to do no harm requires that we discontinue these practices even if we were taught them in accredited doctoral training programs. For example, the theoretical construct of symptom substitution is without empirical basis thereby falsifying interventions and training practices based on, derived from, it (cf. Tryon, 2008b).

Eddy (1990) introduced the term "Evidence-based Guidelines" (EBG) to distinguish methods of medical practice based on evidence from methods based on subjective judgment and/or consensus. It is noteworthy that this recommendation resulted in substantial changes to cancer related health checkup guidelines issued by the American Cancer Society. EBG insisted that testing must reduce morbidity or mortality, medical benefits must outweigh risks, cost must be reasonable and comparable with expected benefits, and recommendations must be practical and feasible. Guyatt and Rennie (1993) first published the term evidence-based medicine. Eddy (2005) reported the history of how the medical community began to adopt evidence-based guidelines. This relatively recent effort to base medical practice on science seems inconsistent with the emphasis placed on chemistry, physics, and mathematics for pre-med majors and on the MCAT examination required of all applicants to medical schools.

Eddy (2005) identified a second type of evidence-based medicine that he termed Evidence-based Individual Decision Making (EBID). Whereas EBG is conducted by multidisciplinary teams using scientific methods to produce best medical practices, EBID is done by individuals using their own implicit and personal methods to make decisions about best medical practices. Eddy (2005) observed that EBID is what passes for EBM; not the more rigorous EBG. Eddy (2005) also provided several reasons for extending EBM to EBG. The author concluded that both EBG and EBID should be included in any comprehensive implementation of EBM. Guyatt et al. (2000) reported that beginning in 1992 JAMA published 24 User Guides for practicing clinicians. The American Psychiatric Association also publishes practice guidelines (http://www.psych.org/MainMenu/PsychiatricPractice/PracticeGuidelines_1.aspx); the American Psychological Association does not and seems unlikely to do so in the foreseeable future. Do psychologists who oppose basing clinical psychology on psychological science want physicians and dentists to base their professional practice on science?

In sum, the notion that medical care should be based on science is a very recent concept given the long history of medical practice in Western culture. This new idea is more easily stated than defined. Eddy (2005) reported that the most commonly cited definition of EBM is "the conscientious, explicit, and judicious use of current best evidence in making decisions about the care of individual patients" (p. 9). Epstein and Hundert (2002) noted that "there is no agreed-upon definition of competence that encompasses all important domains of professional medical practice" (p. 226). Agreement has still not been reached. Guyatt et al. (2000) recognized that evidence is never enough for clinical decision making but provides a solid basis for doing so thereby leaving room for valid individual differences of clinical opinion. Psychologists can build upon this base without adopting the medical model of disease/symptom formation. The scientific method is a disciplined and fruitful epistemology for moving from a lesser to a greater state of knowledge. Nathan and Gorman (2002) noted that "In the absence of science, opinion prevails" (p. v). Meehl (1997) pointedly stated that "Since clinical experience consists of anecdotal impressions by practitioners, it is unavoidably a mixture of truths, half-truths, and falsehoods. The scientific method is the only known way to distinguish these, and it is both unscholarly and unethical for psychologists who deal with other persons' health, careers, money, freedom, and even life Itself to pretend that clinical experience suffices and that quantitative research on diagnostic and therapeutic procedures is not needed" (p. 91). That

science may never fully guide clinical practice is not a sufficient reason to avoid the professional discipline imposed by evidence-based practice.

1.2.2 Empirically Supported Treatment Debate

Psychologists, like physicians, are divided with regard to basing their clinical practice on psychological science. Psychologists, like physicians, have developed their own cherished traditions of health care and seek to perpetuate them and the professional associations dedicated to their promulgation. While the practice of assessment in clinical psychology is rooted in psychometrics, psychological interventions of all types have largely emerged from clinical practice. During his 1909 lectures at Clark University, Freud proposed a theory of personality and psychopathology and offered a method of psychotherapy based on his personal clinical practice; not on scientific study. Tryon (2008a) referred to this as the "big bang of clinical psychology" because Freud's theory and therapy rapidly spread across American, then Europe, followed by most of the rest of the world. Freud's theory and therapy were soon modified into several schools of psychoanalytic thought and practice, which continue to develop largely outside of psychological science. Carl Rogers (1942, 1951) was arguably the first psychologist to subject therapy to scientific study. Eysenck (1952) alarmed psychologists when he reported that there was no scientific evidence that psychotherapies were more effective than no treatment. Lambert et al. (1986) reported that as many as 10% of clients deteriorate during psychotherapy and end up worse off than when they began. Mays and Franks (1985) published an edited a book on this issue. Professional freedom to practice in any way one chooses regardless of evidential support now came into conflict with the ethical principle of beneficence; to do no harm.

Psychologists also administer tests that impact decisions that influence the lives of millions of people each year. Once upon a time psychologists had full professional discretion over test selection. Professional training was considered adequate preparation for competent clinical practice. Unfortunately such professional discretion led to adverse results due to administration of unreliable tests and/or tests not valid for the intended purposes. Contemporary ethical standards that govern psychological testing (American Educational Research Association, American Psychological Association and National Council on Measurement in Education, 1999) clearly direct psychologists to only use tests with acceptable reliability that have been validated for the intended purposes of testing. Deviations from this practice are sometimes required in situations where a reliable test has not yet been validated on the population that the psychologist serves. Psychologists are then directed to proceed with caution and to fully inform the consumer about the issues and limitations involved. Concerns over the restrictions on the professional practicing of psychological testing were never loudly voiced. Resulting restrictions have not adversely impacted professional psychology. The ethical principles that govern psychological testing are more than guidelines that clinical programs can revise to fit goals of their chosen training model.

While the more general ethical standards that govern psychologists (American Psychological Association, 2002) do not similarly direct psychologists to only use interventions that have been shown to be effective, the recommendation to limit clinical interventions to empirically supported treatments (ESTs) can be justified on parallel ethical grounds. If ethical practice requires psychologists to limit their use of psychological tests to instruments with demonstrated

reliability and validity, then ethical practice should also psychological interventions to methods that have demonstrated efficacy and effectiveness. Perhaps a greater proportion of practice income derives from intervention than from testing in which case ethical constraints posed less of a burden for testing than for intervention. Nathan and Gorman (2000) discussed efficacy and effectiveness. *Efficacy* is primarily concerned with replication of treatment effects that exceed appropriate control conditions. The intervention must be sufficiently well defined that clinicians can be trained to consistently implement it across therapists and over time with well defined clinical groups based assessed on objective measures. *Effectiveness* is primarily concerned with feasible results that can be obtained in clinical settings. Studies that demonstrate efficacy and effectiveness also provide evidence that these methods do not produce harm. Whereas the American Psychiatric Association publishes Practice Guidelines based on empirical evidence (http://www.psych.org/MainMenu/PsychiatricPractice/PracticeGuidelines_1.aspx), the American Psychological Association does not. The "Competency Developmental Achievement Levels (DALs) of the National Council of Schools and Programs in Professional Psychology (NCSPP)" stipulate that competent clinical psychologists use evidence-based interventions. It is always possible to leave this matter to insurance companies to determine the services they will reimburse for and to lawyers who may sue clinicians for malpractice but this free market buyers beware guild approach is not necessarily in the public interest.

Arguments against limiting practice by empirical findings typically take one of three forms. One line of argument criticizes the short comings of existing research. Research samples are often monosymptomatic and unrepresentative of clinic samples which are typically comorbid. Therapy manuals require that the same procedures be used for every client within an experimental design condition which makes clinical practice rigid and unrepresentative. Research findings have not yet been shown to generalize across dimensions of diversity, including race, age, sex, and SES. While these criticisms are valid, they are not reasons to abandon outcome research and/or continue to prefer interventions that have even less empirical support. Limited positive results provide at least partial support for an intervention and indicate that it may not be harmful. Unstudied interventions may or may not be beneficial. They might even be harmful (cf. Herbert, 2003; Lambert, Shapiro, & Bergin, 1986; Mays & Franks, 1985).

Testimonials by clinicians and reference to common practice do not constitute persuasive evidence of efficacy or effectiveness. Eddy (2005) noted that some procedures that physicians took for granted to be effective were, based on controlled research, found to be ineffective. For example, bloodletting was once a common medical practice supported by clinical testimony. Benjamin Rush, a prominent physician and founding psychiatrist, advocated bloodletting to treat yellow fever. When patients survived, he attributed this outcome to the effectiveness of his intervention. When patients died he reasoned that they were too sick to be saved. Either way, clinical practice supported the efficacy of bloodletting in his mind. We now know that patients who survived most likely did so in spite of bloodletting; not because of it, and some patients who died probably did so because of bloodletting. How could such a brilliant and noted physician and psychiatrist as Benjamin Rush be so misguided by clinical evidence? How can clinical evidence be so misleading? At least six reasons that reflect common human foibles can be given. First, expectation derived from theory and reports of others psychologists can cause us to see what we want to see. Kunda (1990), a social psychologists summarizing research regarding dissonance theory, noted that "There is considerable evidence that people are more likely to arrive at conclusions that they want to arrive at …" (p. 480). This principle has an even longer history in clinical psychology. Intuitive biases are also at work. Second, Chapman (1967) defined

illusory correlation as "the report by an observer of a correlation between two classes of events which in reality *(a)* are not correlated, or *(b)* are correlated to a lesser extent than reported, or *(c)* are correlated in the opposite direction than that which is reported" (p. 151). Chapman and Chapman (1967) reported results of six studies demonstrating that undergraduates who were presented with Draw-A-Person pictures that were *randomly* paired with clinical symptoms rediscovered the same relationships that clinicians reported based on their clinical practice. Third, Tversky and Kahneman (1971) revealed that people have a belief in the "Law of Small Numbers," where they regard a small randomly drawn sample as highly representative to the population in all important ways. Clinicians typically draw inferences and make generalizations from small unrepresentative samples. Freud is an excellent example of this practice. Fourth, Tversky and Kahneman (1983) exposed a fundamental flaw in human reasoning. Whereas the probability of a conjunction [P(A&B)] cannot exceed either the probability of A or the probability of B, the authors reported that experts and lay people exceed this limit by using intuitive heuristics. Fifth, Meehl and Rosen (1955) noted that clinicians rarely consider the impact of base rates on cutting scores for diagnostic decisions despite their considerable importance. A further exploration of related factors that remain relevant today is Meehl's book entitled *Statistical versus Clinical Prediction.* Sixth, psychologists convicted of unethical practices sometimes claim, as part of their defense, that their clinical experience shows that many or most of their clients benefited from their treatment (cf. Koocher & Keith-Spiegel, 2008). Clinicians are people too and can see benefit where none exists and where others see harm. Considerable pseudoscience can be found in clinical psychology (Lilienfeld, Lynn, & Lohr, 2003) based on these foibles and others. Clinicians must either protect themselves, or be protected by others, from these human foibles by controlled research when making causal inferences.

A second line of argument against scientific research is that some interventions are too complex to be studied scientifically. Some interventions apparently cannot be adequately characterized by treatment manuals such that independent observers can verify that this therapy is being used. A corollary complaint is that some treatments aim to do substantially more than change behavior or reduce symptoms, and that these goals cannot be sufficiently described or characterized to enable the construction of reliable and valid outcome measures. Together these features preclude application of the scientific method. They appear to constitute applied philosophy. A crucial difference between science and philosophy is that scientific questions can be investigated and are potentially falsifiable by empirical data. Existential interventions share more with philosophy than science when they lack the defining element of falsifiability. Hence, convincing empirical evidence of efficacy or effectiveness of such interventions cannot be expected. The pertinent ethical question regarding consumer protection that arises is whether the inability to conduct adequate scientific studies constitutes a free pass such that these services can continue to be offered and reimbursed by third parties, especially if they are wide spread and have a long history within clinical psychology. Or, should the absence of evidential support call such practices into question given that while these interventions may be effective, they may also not be effective, and could be harmful (cf. Herbert, 2003; Lambert, Shapiro, & Bergin, 1986, Mays & Franks, 1985). For example, the failure of symptom substitution to occur undercuts the psychodynamic theory of symptom formation (cf. Tryon, 2008b). It also renders baseless the validity of interpreting physical symptoms as manifestations of psychodynamic conflicts.

A third line of argument concerns respect for diversity and resistance regarding limitations to professional practice. Our ethics code requires respect for diverse methods and models of clinical practice including professionals who practice from models different than one's own

(American Psychological Association, 2002). However, diversity can become problematic as follows. Arrange clinical practices along a spectrum that begins with the best methods at one end and moves through less effective methods to methods that clearly under serve the public, and finally to the other end of the spectrum characterized by unethical and illegal practices. Respect for diversity gives clinicians the right to under serve and/or poorly serve the public. Our profession draws the line only at unethical and illegal practices. Then it requires us to speak disapprovingly to the responsible clinician and possibly report their actions to the proper authorities. All other levels of clinical practice, including marginal practices that poorly serve the public, are accepted and protected under the principle that we value diversity and respect the right of other psychologists to practice anyway they choose.

A consequence of diversity is that a case can be made for "customary care" when enough professionals practice in a particular way regardless of what those practices are with the exception of unethical and illegal methods. Bloodletting once constituted customary medical care. Practitioners of all stripes can defend their actions on the basis that many other graduates of accredited programs provide similar services. More popular programs can graduate more psychologists and more strongly determine "customary care" regardless of how they train students. The Committee on Accreditation of the American Psychological Association evaluates programs based on the programs stated training model rather than on the degree to which best practices are taught. This policy accepts all professional training as equally valuable. It gives professional training programs the right to teach their students almost anything they choose including methods that under serve and/or poorly serve the public. Promulgating the DAL competency criteria as guidelines that can be revised by faculty to suit program goals further abdicates professional responsibility to provide the best possible care to the public. Practitioners who under serve their clients can cite their graduation from an accredited program, and cite other practitioners who graduated from the same and similar programs in support of their clinical practice; i.e., this is how I and many other clinicians were taught to practice by faculty at an accredited clinical training program. Should choice of professional practices remain completely unfettered? Should maintaining traditions of clinical practice be a primary consideration? Should the bar for competent clinical practice be raised above these self-serving concerns?

All three arguments against ESTs just discussed miss or minimize the central ethical issue, to provide the best possible care to the public (cf. American Psychological Association, 2002 and supporting texts e.g., Fisher, 2003; Koocher & Keith-Spiegel, 2008). The foundational competency for reflective practice and self assessment considered below requires one to be aware of the literature pertinent to treated cases to facilitate professional development in order to best serve the public. The foundational competency for professionalism considered below requires integration of science and practice. The three lines of argument against ESTs discussed above fail to grasp this ethical issue. Are we not ethically bound to provide the best practices that the profession has to offer? If so, then what evidence shall we base our clinical practices on?

1.2.3 What Constitutes Evidence?

The second foundational competency considered below concerns scientific knowledge and methods. Its three facets are: (1) scientific mindedness, (2) applied knowledge, and (3) scientific foundations of clinical psychology. The fourth functional competency considered below pertains to research and evaluation and consists of two facets: (1) taking a scientific approach

to knowledge generation and (2) application of the scientific method to clinical practice. Competent psychologists are therefore informed about scientific methods and principles and base their practice upon them. These competency concepts bear directly upon the practice issues discussed in the prior section. It seems that one cannot be competent except that their practices are based on scientific evidence.

Although we frequently speak of science as an end product it is a method. While it is easy to criticize the contemporary science products upon which to base the professional practice of clinical psychology, as Levant (2004), Peterson (2004), and others have done, including the polarizing effects of McFall's (1996) manifesto (see Beutler, 2004), such limitations should not excuse or exempt psychologists from the responsibility to substantiate their diagnostic and therapeutic claims with sound empirical evidence. These limitations should motivate us to provide better evidence rather than to revise our methods downward to suit the types of theories and practices that we prefer (see Kettlewell, 2004). Beutler (2004) noted that "Like the poor marksman who corrects his problem by drawing a bull's eye around whatever place his arrow lands, if science doesn't give us the answers we want to our questions, Levant would have us change the definition of science until it includes procedures that give us the answers we want" (p. 227). Such methods serve to defend present practices and waste resources that could be put to better use. Hypotheses and theories should be supported or undercut by rigorous evidence; this includes long favored theories and practices. Such change is difficult, especially for older psychologists. "Seasoned" professionals are more likely to be committed to past practices as a justification for how they have spent their careers than are their younger colleagues who are still in a formative stage. Resistance to change is a human trait that needs to be struggled with rather than defended. Diluting the scientific method to where subjective judgments by therapists and clients are considered equally probative with investigations disciplined by the rigors of experimental design and statistical analysis may serve to protect present interests of some practicing psychologists but will ultimately devalue and discredit our profession. Our professional ethics prompt us to provide the best possible services to the public and to strive to improve the knowledge base that underpins these practices rather than to defend preferred practices by pointing out the faults of those who try to do better. Their errors should not constitute a pass to those who do not try at all. The first facet of the second functional competency considered below concerns knowledge of interventions that can alleviate suffering and promote health and well-being. This includes being able to cite empirical evidence that supports one's choice of interventions. The first three facets of the second functional competency considered below concerning intervention includes knowledge of empirically-based best practices and their inclusion in treatment planning. Competent clinical psychologists therefore seek to use the most effective interventions available.

Nathan and Gorman (2002; pp. v–vi) identified six levels of empirical support. Type 1 studies are based on random assignment, blinded assessment, clear inclusion and exclusion criteria, reliable and valid diagnostic and assessment methods, and adequate sample size to provide sufficient statistical power to detect group differences. Type 2 studies lack one or some of the criteria for Type 1 studies but are better designed than Type 3 studies. Type 3 studies typically entail open treatment pilot investigations and case control studies where treatment information is obtained retrospectively from treatment completers. Type 4 studies include reviews with secondary data analyses. Type 5 studies include reviews without secondary data analyses. Type 6 studies include case studies, essays, and opinion papers. Evidential criteria for being certified as an empirically supported treatment recognizes the role of single subject research

designs (http://www.apa.org/divisions/div12/cppi.html, http://www.apa.org/divisions/Div12/journals.html, http://www.psychology.sunysb.edu/eklonsky-/division12/, http://psy.ed.asu.edu/~horan/ced522readings/div12/chambless98.pdf).

1.2.4 Competency

While competency has always been of concern to clinical psychology faculty members, clinical competency has been emphasized by faculty at professional schools of psychology. Discussions concerning what constitutes clinical competency have recently increased. Kaslow (2004) considered core and foundational competencies in professional psychology. A new journal entitled *Training and Education in Professional Psychology* began publishing in 2006. A special section of *Professional Psychology*, 2007, Volume 38, Number 5, was devoted to competency issues. Rubin et al. (2007) provided a historical perspective on the competency movement within psychology. Nelson (2007) also provided a historical perspective on these issues. Kaslow, Rubin, Bebeau, et al. (2007) discussed 15 general principles and derivative recommendations for the assessment of competence. Leigh et al. (2007) discussed competency assessment models with examples from nursing, dentistry, medicine, and psychology. Lichtenberg et al. (2007) discussed challenges encountered during assessment of competencies. Manring, Beitman, and Dewan (2003) considered ways to evaluate competency in psychotherapy. Barber, Sharpless, Klostermann, and McCarthy (2007) addressed the issue of intervention competency. They distinguished between adherence and competence. Adherence concerns the ability to deliver the treatment as defined in a manual written by its originators. Competence concerns the ability to distinguish when to and not to administer a treatment. Elman and Forrest (2007) considered a broad range of professional development; one that extends from trainee impairment to professional competence. Overholser and Fine (1990) discussed managing subtle cases of clinical incompetence, whereas Brown, Lambert, Jones, and Minami (2005) discussed identifying highly effective therapists in a managed care environment. Kaslow, Rubin, Forrest, et al. (2007) wrote about recognizing, assessing, and intervening with problems of professional competence. Further information is available at: http://www.psychtrainingcouncils.org/.

This chapter seeks to identify characteristics that make for a competent clinician. One approach is to train and assess for competency for administering reliable and valid tests and implementing empirically supported interventions. It is easier to train students to competently administer, score, and interpret psychological tests than it is to competently administer psychological interventions. Some years ago there were over 250 different therapies to choose from (cf. Wamphold, 2001); now there are likely more therapies. It is unlikely that each of these interventions is unique and different. The presence of common factors including a working alliance characterized by accurate empathy, positive regard, nonpossessive warmth, and genuineness, is now well recognized (Lambert & Bergin, 1994, p. 164). Some therapies are trivially different from others and may not need to be learned. For example, one could add an inert component to an otherwise effective treatment and it would work just as well and therefore would pass all requirements to be listed as an empirically supported treatment. Rosen and Davison (2003) referred to such therapies as "Purple Hat" therapies based on their example of having a client wear a purple hat while undergoing exposure therapy for a phobia. The problem here is that proponents of such a therapy could attribute success to wearing the purple hat, charge therapists for workshops on the proper use of the hat in therapy, and to purchase an

official purple hat. Rosen and Davison (2003) recommend that empirically supported principles (ESPs) be listed instead of ESTs. Tryon (2005) identified a possible connectionist mechanism for why desensitization and exposure therapy work. Tryon and Misurell (2008) formulated a dissonance induction/reduction principle and connectionist mechanism to explain why effective therapies work.

Epstein and Hundert (2002) discussed basic competency as it pertains to medical practice and concluded that competency consists of Evidence-based Individual Decision Making (cf. Eddy, 2005). They emphasized acquisition and use of knowledge, a holistic and integrative approach to health care, the development of a therapeutic relationship, and that competence takes time to develop. Sackett, Rosenberg, Gray, Haynes, and Richardson (1999) stipulated that "Evidence based medicine is the conscientious, explicit, and judicious use of current best evidence in making decisions about the care of individual patients. The practice of evidence based medicine means integrating individual clinical expertise with the best available external clinical evidence from systematic research" (p. 71). Adequacy of basic competency can be evaluated against such a criterion.

The advent of professional schools of psychology set the occasion for new discussions regarding basic clinical competency and required training. The National Council of Schools of Professional Psychology (NCSPP), which was founded in 1974 as a support group, first met to discuss core curriculum issues in the summer of 1988 just before the APA convention and led to a series of training conferences. The first book was entitled *Quality in Professional Psychology Training: A National Conference and Self-Study* (Callan, Peterson, & Stricker, 1986); it reported on the Mission Bay conference. The second book was entitled *Standards and Evaluation in the Education and Training of Professional Psychologists: Knowledge, Attitudes, and Skills* (Bourg et al., 1987). The third book reported on the Puerto Rico conference and was entitled *Toward Ethnic Diversification in Psychology Education and Training* (Stricker et al., 1990). The fourth book entitled *The core curriculum in professional psychology* (cf. Peterson et al., 1991) reported on the San Antonio conference. Part I of this book addressed the core curriculum and general considerations. The first chapter discussed background issues (Peterson, 1991). The second chapter provided a critical history of efforts to develop a competency-based core curriculum (Weiss, 1991). It was noted that clinical training has largely been content-based rather than competency-based over more than the last 40 years as illustrated by the following six bases required by the American Psychological Association for accreditation: History and Systems, and five bases of behavior: Biological, Cognitive/Affective, Social, Individual, and Developmental. Hence, moving to competency-based training and evaluation marks a major change. Webbe, Farber, Edwall, and Edwards (1990) discussed the need for and nature of the academic-scientific core curriculum. They noted that the need for an academic-scientific core curriculum derives from the view that clinical practice entails applied psychology which means applied scientific psychology. Whereas master's level training might be restricted to testing and treatment manuals, doctoral level training entails the creative and flexible application of findings and principles of scientific psychology.

1.3   NCSPP Educational Model

The emphasis on clinical competency by training programs that primarily seek to prepare its graduates for service delivery is particularly appropriate. This section draws heavily on the

results of conferences and committees sponsored by the National Council of Schools and Programs of Professional Psychology. The complete core curriculum in professional psychology was described by Peterson et al. (1991). Individual chapters and/or the entire text can be downloaded from http://www.ncspp.info/core.htm. Peterson, Peterson, Abrams, and Stricker (1997) reported on the National Council of Schools and Programs of Professional Psychology educational model which contains the following six facets: (1) Relationship, (2) assessment, (3) intervention, (4) consultation and education, (5) management and supervision, and (6) research and evaluation. A final version of the "Competency Developmental Achievement Levels (DALs) of the National Council of Schools and Programs in Professional Psychology (NCSPP)" (http://www.ncspp.info/pubs.htm) added diversity. We now briefly consider each of these facets.

1.3.1　Relationship

The standards state that: "Relationship is the capacity to develop and maintain a constructive working alliance with clients and includes the ability to work in collaboration with others such as peers, colleagues, students, supervisors, and members of other disciplines, consumers of services, and community organizations. The relationship competency is the foundation and prerequisite of the other competencies" (p. 391). The DALs identified professional demeanor regarding self and others, interpersonal connection, cultural adaptability, and ethics as facets of relationship competency.

Establishing a good working alliance is the first and arguably most important psychotherapeutic step. Meta-analytic reviews by Horvath and Symonds (1991) and by Martin, Garske, and Davis (2000) have clearly established an association between a positive working alliance and good outcome. Bordin (1979) articulated the following three components of the working alliance: (1) agreement of treatment goals by client and therapist, (2) agreement on how to achieve those goals by client and therapist, and (3) the development of a personal relationship between the client and therapist. Horvath and Greenberg (1989) developed a Working Alliance Inventory for both the client and therapist. Tracey and Kokotovic (1989) and Tichenor and Hill (1989) created a short working alliance form that Andrusyna, Tang, DeRubeis, and Luborsky (2001) used to study the factor structure of working alliance with Cognitive Behavior Therapy with 94 patients from the Jacobson et al. (1996) study. Two rotated factors were interpreted. The first factor concerned agreement and confidence; the degree to which client and therapist agreed on goals and methods plus confidence that this approach would be successful. The second factor concerned the personal relationship or bond between the client and therapist.

1.3.2　Assessment

Peterson et al. (1997) reported that the standards maintain that assessment is "…an ongoing, interactive, and inclusive process that serves to describe, conceptualize, characterize, and predict relevant aspects of a client. The assessment process uses a multimethod and multitheory approach that takes into account the sociocultural context and that focuses not only on limitations and dysfunctions but also on competencies, strengths, and areas of effectiveness. Assessment is a fundamental process that is involved and interwoven with all other aspects of professional practice. In recent years the emphasis of assessment appropriately has shifted from

a narrow focus on tests, individuals, and psychopathology to a more comprehensive approach addressing a broader range of clients and client functions" (p. 392). The DALs identified psychological testing as one of the four domains of professional competency.

1.3.3   Intervention

Peterson et al. (1997) reported that the educational model conceptualizes intervention "…as activities that promote, restore, sustain, and/or enhance positive functioning and a sense of well-being in clients through preventive, developmental, and/or remedial services" (pp. 392–393). They did not further identify which interventions have been shown to accomplish these goals. The DALs identified intervention planning, intervention implementation, intervention evaluation, and ethics as facets of intervention competency. This chapter addresses these considerations in the background section where we discussed the following issues: (1) evidence-based medicine, (2) empirically supported treatments, and (3) what constitutes evidence.

   Diversity.   The DALs require one to identify and understand dimensions of diversity including, but not limited to age, gender, ethnicity, language, religion, disability, sexual orientation, and socio-economic status. Issues of power, privilege, and oppression are fundamental. Knowledge, skills, and attitudes pertain to five domains: (1) understanding how students identify and understand themselves and others, (2) understanding constructs of power, oppression, and privilege, (3) understanding the scientific and theoretical base of diversity, (4) ability to provide culturally competent services, and (5) integrating diversity issues into ethical decision making.

1.3.4   Consultation and Education

Peterson et al. (1997) reported that educational standards maintain that "Consultation refers to the planned collaborative interaction between the professional psychologist and one or more clients or colleagues, in relation to an identified problem area or program. Psychological consultation is an explicit intervention process that is based on principles and procedures found within psychology and related disciplines, in which the professional psychologist has no direct control of the actual change process. Psychological consultation focuses on the needs of individuals, groups, programs, or organizations. Education is the directed facilitation by the professional psychologist of the growth of knowledge, skills, and attitudes in the learner" (p. 393). The DALs identified knowledge of evidence-based theories, models, and interventions, integration of research and evaluation, problem-solving and intervention, performing consultation and education roles and building relationships, and ethical and knowledge of professional practices as facets of consultation/education competency.

1.3.5   Management and Supervision

Peterson et al. (1997) reported that "The Standards define management and supervision as follows: Management consists of those activities that direct, organize, or control the services of psychologists and others offered or rendered to the public. It includes knowledge about the business aspects of psychological practice and the laws, standards, and regulations affecting

practice. Supervision is a form of management blended with teaching in the context of relationship directed to the enhancement of competence in the supervisee" (p. 395). The DALs identified (1) assuring client and organizational welfare, (2) training/mentoring, (3) evaluation/gatekeeping, (4) ethics, and (5) health care leadership and advocacy as facets of management/supervision competency.

1.3.6 Research and Evaluation

Peterson et al. (1997) stated that competency includes: "(a) designing and critiquing approaches to systematic inquiry, using qualitative and quantitative methods; (b) analyzing data, using statistics, both descriptive and inferential, univariate and multivariate as well as methods appropriate to qualitative data; (c) conducting a scholarly project on a meaningful problem, typically associated with professional practice in psychology, with a strategy of disciplined inquiry appropriate to the problem" (p. 400). Doctoral programs that grant the Ph.D. spend more resources developing these skills than do programs that grant the Psy.D. The DALs identified (1) critical evaluation of research, (2) conducting and using research in applied settings, and (3) ethics and professional competency as facets of research/evaluation competency.

1.4   Foundational Competency Benchmarks

The final report of the 2006 American Psychological Association Task Force on The Assessment of Competence in professional Psychology (http://www.apa.org/ed/competency_revised.pdf) provided a general background and discussion of relevant issues including credentialing and specialization. An American Psychological Association Work Group published a *cube model* of competency benchmarks that specifies the essential component, behavioral anchors, and assessment methods for evaluating readiness for practicum, internship, and independent practice regarding the NCSPP educational model introduced above (cf., Rodolfa et al., 2005). Criteria specifying readiness for practicum and internship pertain to basic competencies. The criteria specifying readiness for practice, including independent private practice, pertain to expert competency. I preserve this developmental sequence to enhance continuity. This document can be retrieved at http://www.psychtrainingcouncils.org/pubs/Comptency%20Benchmarks.pdf or at http://wsm.l Feb_2007.pdf. The remainder of this section relies heavily on the cube model. A revised version of the "Competency Developmental Achievement Levels (DALs) of the National Council of Schools and Programs in Professional Psychology (NCSPP)" approved at the NCSPP Summer Conference Business Meeting on August 15, 2007 can be retrieved from http://www.ncspp.info/pubs.htm. A separate short section concerning expert competency follows.

Pages 11–33 of the cube model (cf. Rodolfa et al., 2005) concern the following core *foundational competencies*: (1) reflective practice and self-assessment, (2) scientific knowledge and methods, (3) relationships, (4) ethical and legal standards and policies, (5) individual and cultural diversity, and (6) interdisciplinary systems. It is unclear if the order reflects importance or if all six functional competencies are considered to be equally important. An essential component and behavioral anchors are provided for each of the following three developmental levels for each competency: (1) readiness for practicum, (2) readiness for internship, and (3) readiness for practice.

1.4.1   Reflective Practice and Self-Assessment

This foundational competency concerns practicing within the boundaries of one's competencies and a commitment to lifelong learning, scholarship, critical thinking, and the development of the profession. It consists of the following three facets: (1) reflective practice, (2) self-assessment and self care, and (3) professionalism.

1.4.1.1 Reflective Practice

The essential component that indicates readiness for *practicum* is self-awareness and a willingness to critically examine one's positions and practices. Behavioral anchors include: critical thinking, problem solving skills, intellectual curiosity and flexibility and the ability to self-examine and disclose. Assessment methods include performance in seminars plus written papers and proposals, and faculty judgments. The essential component that indicates readiness for *internship* is a broadened self-awareness. Behavioral anchors include being able to articulate attitudes, values and beliefs on a variety of topics including issues of diversity and being able to see and understand how peers and supervisors see them. Assessment methods include direct observation of professional activities by a supervisor either live or recorded, use of peer and self-assessment instruments and faculty and supervisor evaluations. The essential component that indicates readiness for *practice* is spontaneous reflection used as a therapeutic tool. Behavioral anchors demonstrating readiness for professional practice include regular monitoring of oneself and actions, accurate awareness of strengths and areas in need of improvement, and an understanding of how to practice within ones scope of competence. Assessment methods include client, supervisor, peer, and self-evaluations.

1.4.1.2 Self-assessment and Self-care

The essential component that indicates readiness for practicum includes a knowledge of core competencies and the beginnings of self-assessment regarding competencies and an understanding of the importance of self-care in professional practice. Behavioral anchors include a willingness to consider one's own motives, attitudes, and behaviors as they affect other people, a basic awareness of the need for self-care, and an awareness of the required clinical competencies. Assessment methods include self, peer, and supervisor evaluations based on direct observation or from taped sessions. The essential component that indicates readiness for internship includes accurate self-assessment that derives from self-monitoring and a willingness to acknowledge and correct errors. Behavioral anchors include effective use of feedback, working on self-monitoring with supervisors, writing a personal statement of professional goals as a draft for the APPI application, systematically reviews one's professional development through videotape or other technology. Assessment methods include self, peer, and supervisory evaluations based on direct observation or review of videotapes. The essential component that indicates readiness for practice includes the ability to accurately critique one's own performance and to spontaneously self-correct as necessary. Behavioral anchors include systematically reviewing one's own performance and making changes in one's professional activities based on self-monitoring. Assessment methods include supervisor evaluations, a review of interactions with clients, and attendance at professional meetings.

1.4.1.3 Professionalism

The essential component that indicates readiness for practicum includes an initial understanding of what it means to be a professional and to begin thinking like a psychologist. Behavioral anchors include: being organized and on time, demonstrates appropriate personal hygiene and dress, membership in professional organizations, demonstrates the need to practice within one's competence and understands what the core competencies entail. Assessment methods include self, peer, and faculty judgments with an emphasis on consensual validation. The essential component that indicates readiness for internship is an emerging professional identity as a professional psychologist who uses the published literature and supervision for professional development. Behavioral anchors include attendance at colloquia, workshops, and conferences, can summarize relevant literature regarding assigned cases, documents case meetings in progress notes, actively participates in supervision, and demonstrates an awareness of the impact they have on clients. Assessment methods include self, peer, and faculty evaluations, attendance at colloquia, seminars, and professional meetings. The essential component that indicates readiness for practice is the ability to integrate science and practice as part of a consolidated professional identity. Behavioral anchors include continuing education to keep up with advances in the profession, contributing to professional organizations, and awareness of the impact one's behavior has on the public and their perception of professional psychologists. Assessment methods include supervisor evaluations, performance on comprehensive doctoral examinations, attendance at professional meetings, and multi-method review of client interactions.

1.4.2 Scientific Knowledge-Methods

This foundational competency pertains to one's ability to one's understanding of research methods, including methods of data collection/analysis, and the biological bases of behavior as well as the cognitive-affective bases of behavior. The educational standards distinguish three components: (1) scientific mindedness, (2) scientific knowledge, and (3) scientific foundations.

1.4.2.1 Scientific Mindedness

The essential component that indicates readiness for practicum is critical scientific thinking. Behavioral anchors include the ability to critically review scientific publications which includes evaluating their assumptions, methodology, results, and conclusions. Assessment methods include performance in courses and seminars, presentations by faculty and peer reviews. The essential component that indicates readiness for internship is the application of scientific values and methods to professional practice. Behavioral anchors include discussions concerning case formulations as case conferences and ability to critique related scientific literature. Assessment methods include faculty, supervisor, peer, and self-ratings. The essential component that indicates readiness for practice is the independent application of scientific methods to practice. Behavioral anchors include the habitual use of scientific methods and the willingness to present one's work to others for evaluation. Assessment methods include the Examination for Professional Practice in Psychology (EPPP), portfolio reviews, and supervisor evaluations.

1.4.2.2 Scientific Knowledge

The essential component that indicates readiness for practicum is understanding psychology as a science. Behavioral anchors include the ability to cite scientific literature in support of an argument and the ability to evaluate scholarly literature. Assessment methods include performance in undergraduate course work, performance in graduate courses and seminars, and faculty ratings. The essential component that indicates readiness for internship is knowledge of core psychological science. Behavioral anchors include a demonstration of such knowledge and respect for the scientific bases of behavior. Assessment methods include successful performance in course work and on comprehensive examinations. The essential component that indicates readiness for practice is additional knowledge of core psychological science. Behavioral anchors include a demonstration of knowledge of and respect for the scientific bases of behavior as a foundation for clinical practice. Assessment methods include performance on the EPPP exam, case presentations, portfolios, and supervisor ratings.

1.4.2.3 Scientific Foundation

The essential component that indicates readiness for practicum is understanding the scientific foundation of professional practice. Behavioral anchors include understanding the development of evidence-based practice, understanding core science issues regarding human behavior, ability to cite scientific literature to support an argument and the ability to evaluate scientific studies. Assessment methods include performance in undergraduate course work, performance in graduate courses and seminars, and faculty ratings. The essential component that indicates readiness for internship is an understanding of and ability to apply concepts of evidence-based practice (EBP: see background comments about this issue above). Behavioral anchors include application of EBP concepts to case conceptualization and treatment planning plus comparing EPB approaches with other theoretical perspectives in the context of case formulation and treatment planning. Assessment methods include self-assessments, supervisory ratings, direct observation of professional activities, and either live or recorded, and successful performance on comprehensive examinations. The essential component that demonstrates readiness for practice is knowledge, understanding, and independent application of scientific knowledge to clinical practice. Behavioral anchors include reviews of scholarly literature related to clinical work, application of EBP concepts in practice, ability to compare and contrast EBP approaches with other theoretical perspectives in case conceptualization and treatment planning. Assessment methods include self-assessment, review of cases at case conference, supervisor ratings, and direct observation of professional activities, either live or recorded.

1.4.3 Relationships

This foundational competency pertains to one's ability of relate effectively and meaningfully with individuals, groups, and/or elements of the larger community. This competency is seen to include the following four facets: (1) interpersonal relationships, (2) affective skills, (3) interdisciplinary relationships, and (4) expressive skills. We consider each of these facets next.

1.4.3.1 Interpersonal Relationships

The essential component of that indicates readiness for practicum concerns interpersonal skills. Behavioral anchors include listening with empathy to others, showing respect for other cultures and the experiences of other people, and openness to feedback. Assessment methods include performance and behavior in courses, examination of performance during interviews, and faculty, peer, and self-evaluations. The essential component that indicates readiness for internship regarding relationships includes the ability to form and maintain respectful and productive relationships with clients, peers, colleagues, supervisors and other professionals. Behavioral anchors include forming a good working alliance with clients and supervisors plus involvement in departmental, institutional, and/or professional organizations. Assessment methods include working alliance ratings by clients, supervisor and peer ratings, direct observation of professional activities by a supervisor either live or via video tape or co-therapy. The essential component that demonstrates readiness for practice includes the ability to develop and maintain a good working alliance with a broad range of clients, colleagues, and work within professional organizations and the community. Behavioral anchors include maintenance of satisfactory relationships with clients, peers, and faculty and the ability to manage difficult conflicted relationships with individuals and groups that differ significantly from one's self. Assessment methods include self-evaluations and 360 evaluations.

1.4.3.2 Affective Skills

The essential component that indicates readiness for practicum concerns a rudimentary level of those skills. Behavioral anchors include tolerance of affect in oneself and others, tolerance and understanding of interpersonal conflict, tolerance of ambiguity and uncertainty, an awareness of one's own inner emotional experience, and emotional maturity. Assessment methods include self, peer, and faculty judgments with an emphasis on consensual validation. The essential component that indicates readiness for internship is the ability to constructively mediate conflict, negotiate differences of opinion, and receive constructive feedback from others including individual and group conferences. Behavioral anchors include working collaboratively with others, demonstrating active problem-solving, making appropriate self-disclosures, accepting and implementing supervisor recommendations in a nondefensive manner. Assessment methods include self, peer, and supervisory evaluations, direct observation by a supervisor or co-therapist. The essential component that indicates readiness for practice is possession of advanced interpersonal skills and the ability to manage difficult communication/relationships. Behavioral anchors include seeking clarification, demonstrating understanding of diverse view points and acceptance and implementation of constructive feedback from others. Assessment methods include self, peer, and supervisory evaluations and the extent to which the person seeks peer consultation and participates in professional activities.

1.4.3.3 Intradisciplinary Relationships

The essential component that indicates readiness for practicum concerns interdisciplinary respect. Behavioral anchors include respect for collegial interactions and professionals who

operate from a different perspective than their own. Assessment methods include course performance plus self-peer, and faculty ratings with an emphasis on consensual validation. The essential component that indicates readiness for internship is knowledge of professional relationships, norms, and culture. This includes the ability to establish and maintain appropriate professional attitude and boundaries. Behavioral anchors include adherence to ethical standards and institutional policies and procedures. Assessment methods include self, peer, client, staff, and supervisory ratings. The absence of negative reports is especially important. The essential component that indicates readiness for practice relationships is a clear understanding of professional boundaries plus an appreciation of individual and group differences including respect for one's self and for others. Behavioral anchors include adherence to ethical standards and institutional policies and procedures. Participation in local and national professional organizations is another positive indicator of readiness for practice. Assessment methods include self, peer, client, staff, and supervisory ratings. The absence of negative reports is especially important.

1.4.3.4 Expressive Skills

The essential component that indicates readiness for practicum concerns expressive skills themselves. Behavioral anchors include the ability to effectively communicate one's ideas and feelings both verbally and nonverbally. Assessment methods include performance in course work and at evaluation milestones during training. The essential component that indicates readiness for internship regarding expressive skills is the ability to express oneself in a clear and articulate way. Behavioral anchors include verbal, nonverbal, and written skills plus an understanding of professional language. Assessment methods include performance during class and evaluations by oneself, peers, and faculty members. The essential component that indicates readiness for practice regarding expressive skills is the articulate and eloquent command of both language and ideas. Behavioral anchors include a written and verbal command of language that enables clear and effective communication with clients. Assessment methods involve case presentations and supervisor evaluations.

1.4.4 Individual and Cultural Diversity

This foundational competency concerns one's awareness and sensitivity when working professionally with diverse individuals, groups, and communities. It consists of (1) self awareness and (2) knowledge application.

1.4.4.1 Self-awareness

The essential component that indicates for readiness for practicum entails self-awareness, knowledge, and an understanding of one's own ethnicity, gender, sexual orientation, race, and socioeconomic status as dimensions of diversity that may contrast with other individuals. Behavioral anchors include demonstration of such self knowledge by being able to articulate how ethnic group values influence how one related to other people. Assessment methods include performance in class prior to practicum. The essential component that indicates

readiness for internship includes the ability to monitor and apply knowledge of one's self during assessment, treatment, and consultation. Behavioral anchors include being able to understand and monitor one's own cultural identity while working with others and to effectively use feedback during supervision about diversity issues. Assessment methods include congruence among self, peer, and faculty evaluations. The essential component that indicates readiness for practice is the ability to independently monitor and apply knowledge about yourself as a cultural being during assessment treatment, and consultation. Behavioral anchors include the ability to independently articulate, understand, and monitor one's cultural identity while working with others and to be able to profit from supervision. Assessment methods include congruence among self, peer, and supervisory evaluations.

1.4.4.2 Knowledge Application

The essential component that indicates for readiness for practicum entails a basic knowledge of and sensitivity to scientific, theoretical, and contextual issues as the relate to the professional practice of psychology. Behavioral anchors include a demonstration of basic knowledge of the literature regarding individual and cultural diversity and demonstrating an understanding of diversity issues as they impact all aspects of professional psychology. Assessment methods include performance in small group experiences, course work, and peer review in addition to self, peer, and faculty ratings with an emphasis on consensual validation. The essential component that indicates for readiness for internship entails application of knowledge with sensitivity to issues of individual and cultural diversity during assessment, treatment, and consultation. Behavioral anchors include demonstrating knowledge of and APA policies regarding individual and cultural diversity, demonstrating the ability to address issues of diversity in professional settings, working effectively with diverse clients and colleagues, and demonstrating awareness of the effects that discrimination and privilege have on one's self and others. Assessment methods include direct observation of professional activities by a supervisor including co-therapy or review of videotape, client satisfaction surveys, client no-show and drop-out rates, self, peer, and supervisory evaluations of the extent to which diversity issues are included in case conceptualizations. The essential component that indicates for readiness for practice entails the application of knowledge, skills and attitudes regarding dimensions of diversity to the delivery of professional services. Behavioral anchors include the ability to articulate an integrated conceptualization of how dimensions of diversity impact one's own behavior and the behavior of clients including the ability to make appropriate adjustments to one's practice including seeking consultation when appropriate. Assessment methods include self-peer, and supervisor evaluations regarding case presentations and other work samples.

1.4.5   Ethical-Legal-Standards-Policy

The essential component of this foundational competency includes the application of ethical principles and awareness of legal issues to professional activities of individuals, groups, and organizations and advocating for the profession in various venues. It contains three facets: (1) knowledge, (2) awareness and application of an ethical decision making model, and (3) ethical conduct.

1.4.5.1 Knowledge

The essential component that indicates readiness for practicum concerns basic knowledge of the Ethical Principles and Code of Conduct published by the American psychological Association (2002) plus a rudimentary knowledge of legal and regulatory issues as they apply to the professional practice of psychology. Behavioral anchors include demonstrating one's knowledge through coursework and pre-practicum seminars, demonstrating knowledge of child abuse reporting, HIPAA regulations, confidentiality, and informed consent issues through written tests and discussions. Assessment methods include course performance and evaluations of decisions made in hypothetical situations. The essential component that indicates readiness for internship concerns a working knowledge and understanding of the APA Ethics Code along with other relevant ethical and professional codes, standards, laws, rules, and regulations that govern the professional practice of psychology. Behavioral anchors include ethical behavior, successful completion of coursework in ethics and the legal aspects of professional practice, the ability to effectively identify ethical dilemmas, the ability to seek and receive supervision regarding the ethical and legal aspects of professional case work, and recognition of the limits of one's own understanding of ethical and legal issues. Assessment methods include self, peer, and supervisory assessments based on co-therapy and live or recorded observation of clinical work plus the successful completion of the ethics section of comprehensive examinations. The essential component that indicates readiness for practice entails the routine command and application of the APA Ethics Code and all relevant legal and professional standards and guidelines that govern the professional practice of psychology. Behavioral anchors include spontaneous and reliable identification of complex ethical and legal issues and the ability to suggest constructive ways to proactively address and/or prevent them. It also includes awareness of the obligation to confront peers and organizations regarding unethical conduct and to suggest ways of proactively dealing with such matters. Assessment methods include the EPPP examination, state and provincial jurisprudence exams, client feedback, self- and supervisor evaluations.

1.4.5.2 Awareness and Application of Ethical Decision Making Model

The essential component that indicates readiness for practicum is recognition of the importance of ethical concepts, informed consent, confidentiality, conflict due to multiple relationships, competence, and child abuse reporting. Behavioral anchors include student and instructor discussions in class and clinical venues. Assessments include performance in courses and during clinical intervention including self-, peer, and faculty evaluations. The essential component that indicates readiness for internship is to be able to make ethical decisions in response to a dilemma. Behavioral anchors include the use of an ethical decision-making model when discussing cases during supervision and the ability of readily identify ethical implications in cases presented by others as well as in one's own cases. Assessment methods include self, peer, and faculty evaluations concerning clients seen, successful performance on written comprehensive examinations and oral evaluations that entail analysis of hypothetical cases. The essential component that indicates readiness for practice is commitment to and integration of ethics into all aspects of one's professional work. Behavioral anchors include inclusion of ethical issues in professional writings and presentations, in research designs and the treatment of participants, in teaching and training activities, and in consultation. Assessment

methods include self, peer, and supervisor evaluations, performance on state and provincial jurisprudence exams, performance on the EPPP examination, and performance during mock ethical dilemma/vignettes.

1.4.5.3 Ethical Conduct

The essential component that indicates readiness for practicum is that the candidate displays ethical attitudes and values. Behavioral anchors include the desire to help others, openness to new ideas, honesty and integrity, personal courage, and a capacity to manage limits. Assessment methods include self-, peer, and faculty judgments. The student should be able to admit errors and value intellectual honesty. The essential component that indicates readiness for internship is that the student displays knowledge of his or her own moral principles and ethical values. Behavioral anchors include being able to articulate one's own moral principles and ethical values in discussions with peers and supervisors. Assessment methods include self-, peer, and supervisor ratings, successful completion of ethics courses and component of comprehensive examinations and the ability to make ethical decisions. The essential component that indicates readiness for practice is that the candidate can independently and confidently behave consistently with ethical and legal standards. Behavioral anchors include integrating ethical issues and principles into their practice and taking responsibility for continued professional development in relation to ethical and legal standards and policies. Assessment methods include self, peer, and supervisor ratings, absence of complaints, and a willingness to serve professionally in the ethics arena.

1.4.6 Interdisciplinary Systems

The essential component of this foundational competency includes identification and involvement with one's colleagues and peers. It also includes knowledge of key issues and concepts in related disciplines plus the ability to interactive constructively with other professionals. This foundational competency consists of four facets: (1) Understanding the shared and distinctive contributions of other professions, knowledge of key issues and concepts, and concepts related to the work of other professionals, (2) multidisciplinary and interdisciplinary functioning which includes understanding the differences and ability to function in both contexts, (3) understanding how participation in interdisciplinary collaboration and consultation enhances outcomes, and (4) developing respectful and productive relationships with individuals from other professions.

Understanding the shared and distinctive contributions of other professions, knowledge of key issues and concepts, and concepts related to the work of other professionals. The essential component that indicates readiness for practicum is that the candidate has a basic knowledge of the viewpoints and contributions that professionals in other fields have made and make. Behavioral anchors include demonstrating knowledge of and valuing the roles, functions, and services provided by other professionals. Assessment methods include course performance and the pertinent component of comprehensive examinations. The essential component that indicates readiness for internship is an awareness of the multiple and differing views, roles, professional standards, and contributions made by various professionals. Behavioral anchors include reports based on observations of behaviors while working with professionals from other fields. Assessment methods include self, peer and supervisor evaluations based on direct observation

such as during co-therapy. The essential component that indicates readiness for practice is an informed knowledge of the multiple and differing views, professional standards, and contributions that other professionals have and make. Behavioral anchors include the ability to articulate the role that other professionals provide and working successfully on interdisciplinary teams. Assessment methods include self, peer, and supervisory evaluations.

Multidisciplinary and interdisciplinary functioning which includes understanding the differences and ability to function in both contexts. The essential component that indicates readiness for practicum is a basic understanding of the difference between interdisciplinary and multidisciplinary. Interdisciplinary refers to what professions share; to their common ground; to modifying their respective approaches in order to be more effective as a team (see http://en.wikipedia.org/wiki/Interdisciplinary). Multidisciplinary pertains more to the separate functions of differing disciplines. Behavioral anchors include demonstrating knowledge of these differences. Assessment methods include performance in courses, evaluations, and comprehensive exams. The essential component that indicates readiness for internship is an understanding of strategies that promote interdisciplinary and multidisciplinary collaboration. Behavioral anchors include demonstrating knowledge of what is involved in such professional relationships. Assessment methods include self, peer, and supervisory assessments. The essential component that indicates readiness for practice is the ability to display skills that support effective interdisciplinary team communication and functioning. Behavioral anchors include demonstrating these skills in clinical and other professional settings. Assessment methods include self-, peer, and supervisory evaluations including members of other professions.

Understands how participation in interdisciplinary collaboration and consultation enhances outcomes. The essential component that indicates readiness for practicum is knowledge about how interdisciplinary collaboration can facilitate reaching therapeutic goals. Assessment methods include self-, peer, and supervisory evaluations. The essential component that indicates readiness for internship is demonstrating an ability to participate constructively on an interdisciplinary team. Behavioral anchors include effective consultation and cooperation with professionals from other disciplines. Assessment methods include self-, peer, and supervisory evaluations including members of other professions. The essential component that indicates readiness for practice is the ability to work effectively with other professionals to reach shared goals. Behavioral anchors include evidence of systematic collaboration with other professionals. Assessment methods include self-, peer, and supervisory evaluations including members of other professions.

Respectful and productive relationships with individuals from other professions. The essential component that indicates readiness for practicum is an awareness of the benefits of forming collaborative relationships with other professionals. Behavioral anchors include expressing interest in developing collaborative relationships and demonstrating respect for other professionals. Assessment methods include self-, peer, and supervisory evaluations in addition to performance in course work. The essential component that indicates readiness for internship is an ability to develop and maintain collaborative relationships and respect for other professionals. Behavioral anchors include the ability to communicate effectively with other professionals. Assessment methods include self-, peer, and supervisory evaluations based on live observation and/or co-therapy or videotape review. The essential component that indicates readiness for practice is the ability to develop and maintain collaborative relationships over time despite differences in perspective. Behavioral anchors include the ability to communicate effectively with other professionals and to appreciate their contributions. Assessment methods include self-, peer, and supervisory ratings including members of other professions.

1.5 Functional Competency Benchmarks

Pages 34–62 of the American Psychological Association Work Group's cube model concerns the following core functional competencies: (1) assessment, diagnosis, and case conceptualization, (2) intervention, (3) consultation, (4) research and evaluation, and (5) supervision and teaching. An essential component and behavioral anchors are provided for each of the same three developmental levels; readiness for: (1) practicum, (2) internship, and (3) practice (see http://www.psychtrainingcouncils.org/pubs/Comptency%20Benchmarks.pdf or http://wsm.ezsitedesigner.com/share/scrapbook/50/502062/Benchmark_Competencies_Document_-_Feb_2007.pdf). A related statement of "Competency Developmental Achievement Levels (DALs) of the National Council of Schools and Programs in Professional Psychology (NCSPP)" can be retrieved from http://www.ncspp.info/pubs.htm.

1.5.1 Assessment-Diagnosis-Case Conceptualization

The essential component of this functional competency includes the ability to assess and diagnose problems and issues associated with individuals, groups, and/or organizations. It includes three major facets: (1) diagnosis, (2) assessment, and (3) integration.

1.5.1.1 Diagnosis

The diagnosis facet of the assessment-diagnosis-case conceptualization functional competency consists of two components: (1) understanding normal and abnormal behaviors and (2) diagnostic skills.

Understanding Normal and Abnormal Behaviors
The essential feature that indicates readiness for practicum consists of basic knowledge regarding the range of normal and abnormal behaviors. Behavioral anchors include being able to describe normal development and identify DSM criteria for various disorders. Assessment methods include performance in course work and evaluations of clinical work. The essential feature that indicates readiness for internship is the ability to apply concepts of normal and abnormal behavior to case formulations and diagnosis. Behavioral anchors include being able to describe clinical disorders. Assessment methods include performance in advanced coursework and supervisor evaluations. The essential feature that indicates readiness for practice is the ability to diagnose and formulate treatment planning for cases. Behavioral anchors include the development of treatment plans that incorporate relevant developmental features and clinical symptoms. Assessment methods include supervisor evaluations.

Diagnostic Skills
The essential feature that indicates readiness for practicum is basic knowledge regarding diagnosis, case conceptualization and treatment formulation. Behavioral anchors include the ability to discuss diagnostic and case formulations in an informed way. Assessment methods include performance in coursework and clinical evaluations. The essential feature that indicates readiness for internship is the ability to systematically gather data to inform clinical decision making.

Behavioral anchors include preparing reports that include sufficient information upon which to base a clinical diagnosis. Assessment methods include case presentation and conceptualization plus supervisor evaluations. The essential feature that indicates readiness for practice is the ability to independently and accurately conceptualize cases based on assessment results. Behavioral anchors include the ability to administer, score, and interpret tests, independently prepare reports based on actual client material, and to formulate a case conceptualization. Assessment methods include self-, peer, and supervisor evaluations.

1.5.1.2 Assessment

The assessment functional competency consists of two components: (1) knowledge of measurement and psychometrics, and (2) use of methods which include interview plus tests and other measurements.

Knowledge of Measurement and Psychometrics

The essential feature that indicates readiness for practicum includes a basic knowledge of the scientific and theoretical basis of test construction and interviewing. Behavioral anchors include an awareness of the benefits of standardized assessment, knowledge of the constructs being assessed, and an understanding of test development including reliability and validity. Assessment methods include performance during coursework and clinical evaluations. The essential feature that indicates readiness for internship includes the ability to select assessment measures on the basis of reliability and validity. Behavioral anchors include the ability to identify appropriate assessment measures for cases seen at a practice site and consultation with supervision regarding the selection of said measures. Assessment methods include performance on the assessment component of doctoral comprehensive examinations and supervisory evaluations. The essential feature that indicates readiness for practice includes the ability to independently select and implement multiple methods of evaluation in ways that are responsive to and respectful of individuals with diverse backgrounds. Behavioral components include cultural awareness and sensitivity, knowledge of norms for different populations, seeking consultation to guide assessment and an understanding of the limitations of assessment. Assessment methods include reviews of test reports and case presentations, supervisory evaluations, and performance on the relevant section of doctoral comprehensive examinations.

Use of Methods

This competency consists of the ability to interview and to use tests and measurements. The essential feature pertinent to interviewing that indicates readiness for practicum includes knowledge of the models and techniques of clinical interviewing including administration of the mental status exam. Behavioral anchors include knowledge of both structured and semi-structured interviews, the mini mental status exam, goal planning relationship building, and treatment planning. Assessment methods include performance in coursework and supervisory evaluations. The essential feature that indicates readiness for internship includes knowledge of the principles and practices of systematic interviewing, data gathering, and the ability to integrate and interpret the data collected. Behavioral anchors include collecting accurate and relevant data from structured and semi-structured interviews and mini-mental status exams, the ability to write reports that synthesize these data, and consultation with supervisors. Assessment

methods include in vivo observations, and supervisory evaluations. The essential feature that indicates readiness for practice includes the ability to independently use the clinical interview to diagnose and formulate treatment planning. Behavioral anchors include collecting accurate and relevant data from structured and semi-structured interviews and mini-mental status exams and the ability to write integrative reports based on these data that culminate in a treatment plan. Assessment methods include in vivo observation and supervisory review.

The essential feature of the use of methods component pertinent to *tests and measurements* that indicates readiness for practicum includes basic knowledge regarding the administration and scoring of traditional assessment measures. Behavioral anchors include the accurate administration and scoring of assessment tools as part of coursework. Assessment methods include course grades. The essential feature that indicates readiness for internship includes awareness of the strengths and limitations regarding the administration, scoring, and interpretation of traditional and newer assessment measurements. Behavioral anchors include proper selection, administration, and interpretation of assessment tools and seeking appropriate supervision. Assessment methods include supervisor evaluations. The essential feature that indicates readiness for practice includes the ability to independently understand the strengths and limitations of diagnostic methods and to properly interpret the results for purposes of diagnosis and treatment planning. Behavioral anchors include appropriate selection of assessment tools, writing comprehensive reports that include limitations of assessment methods, and seeking appropriate supervision. Assessment methods include supervisory ratings of written reports and case presentations.

1.5.1.3 Integration

The integration functional competency consists of three facets: (1) site specific functions, (2) communication of results, and (3) integrated skills.

Site Specific
The essential component that indicates readiness for practicum includes knowledge of the similarity and differences in assessment methods across practice sites. Behavioral anchors include awareness of the need to select assessment measures that are appropriate to the client, assessment site, and primary problem. Assessment methods include clinical case vignettes. The essential component that indicates readiness for internship includes knowledge of assessment tools that are appropriate to one's training site. Behavioral anchors include the ability to select assessment tools that reflect the patient population being served at a specific practice site and seeking supervision. Assessment methods include supervisor evaluations. The essential component that indicates readiness for practice includes independent selection and administration of assessment tools that are appropriate to the practice site and to the assessment question. Behavioral anchors include independently selecting appropriate assessment tools. Assessment methods include supervisor evaluations of written reports and case presentations.

Communication of Results
The essential component that indicates readiness for practicum includes basic knowledge of measurements concerning different domains of functioning. Behavioral anchors include awareness to base diagnosis on multiple assessments and sources. Assessment methods include course performance. The essential component that indicates readiness for internship includes

being able to select appropriate assessment measures to answer diagnostic questions. Behavioral anchors include having done so and seeking supervision. Assessment methods include satisfactory performance on the assessment component of doctoral comprehensive exams and supervisory evaluations regarding report writing. The essential component that indicates readiness for practice includes the ability to independently select and use a variety of assessment methods and integrate their results into a written report that accurately evaluates the presenting problem. Behavioral anchors include the ability to interpret assessment results accurately accounting for the limitations of the evaluation methods used, the ability to provide accurate client feedback, and seeking supervision as needed. Assessment methods include supervisory evaluations of written reports and case presentations.

Integrated Skills

The essential component that indicates readiness for practicum includes basic knowledge concerning measurement across multiple domains of functioning. Behavioral anchors include awareness of the need to base diagnosis on multiple assessment sources. Assessment methods include performance in coursework. The essential component that indicates readiness for internship includes the ability to select appropriate assessment measures designed to answer specific diagnostic questions. Behavioral anchors include the ability to independently select and use appropriate assessment and diagnostic measures and seeking supervision on a routine basis. Assessment methods include the relevant section of doctoral comprehensive examinations and supervisory evaluations of integrated report writing. The essential component that indicates readiness for practice includes the ability to independently select and use a variety of assessment measures and to integrate the results into a report that accurately evaluates the presenting problem. Behavioral anchors include the ability to properly interpret assessment results taking into account relevant limitations of the evaluation method and the ability to provide understandable and useful feedback that is responsive to the client's needs, and to seek supervision when needed. Assessment methods include self-, peer, and supervisory evaluations of case presentations.

1.5.2   Intervention

The intervention functional competency concerns selection and application of interventions designed to alleviate suffering and to promote health and well being of clients, groups, and/or organizations. This functional competency consists of five facets: (1) knowledge of interventions, (2) intervention planning, (3) intervention implementation, (4) progress evaluation, and (5) skills.

1.5.2.1 Knowledge of Interventions

The essential component that indicates readiness for practicum includes knowledge of the basic scientific, theoretical and contextual bases of interventions and the value of evidence-based practice. Behavioral anchors include the ability to articulate the relevance of the science of psychology to evidence based practice including both its strengths and weaknesses for different populations and clinical settings. Assessment methods include course performance. The essential component that indicates readiness for internship includes knowledge of the theoretical and scientific bases of interventions. Behavioral anchors include writing a statement

of one's theoretical perspective, presentation of work with clients that demonstrates their understanding of evidence-based practice. Assessment methods include performance on doctoral comprehensive examinations, performance during case presentations, and supervisory evaluations. The essential component that indicates readiness for practice includes an ability to apply evidence-based practice in a clinical setting. Behavioral anchors include providing empirical support one's choice of intervention, demonstrating sufficient skill to implement the intervention, and writing a case summary that specifies the evidence that supports the chosen intervention. Assessment methods include performance during case presentations and evaluations by supervisors and clients.

1.5.2.2 Intervention Planning

The essential component that indicates readiness for practicum includes a basic understanding of the relationship between assessment and intervention. Behavioral anchors include the ability to state how intervention choices are informed by assessment results. Assessment methods include course work performance and faculty judgments. The essential component that indicates readiness for internship includes the ability to formulate treatment plans from at least one theoretical orientation. Behavioral anchors include the ability to state a theory of change, to identify procedures for bringing about that change, to writing a report of one's plan including the evidence upon which it is based. Behavioral anchors include the ability to describe a theory of change and procedures for achieving those changes, writing an understandable case conceptualization report, and successful completion of the intervention component of doctoral comprehensive examinations. Assessment methods include doctoral examination results, supervisory evaluations, and quality assurance reviews. The essential component that indicates readiness for practice includes the ability to independently plan and implement case formulations based on empirical evidence. Behavioral anchors include accurate assessment of the presenting problem with sensitivity to dimensions of diversity. Assessment methods include self-, peer, and supervisory evaluations and performance during case presentations and portfolio review.

1.5.2.3 Intervention Implementation

There are no essential components for this competency that indicates readiness for practicum. Students are not expected to be skilled in this regard at this stage of their training. The essential component that indicates readiness for internship includes the ability to implement evidence-based interventions with sensitivity to dimensions of client diversity and treatment context. Behavioral anchors include the ability to apply specific evidence-based interventions and write reports documenting the results of intervention. Assessment methods include supervisory ratings consistent with readiness for internship. The essential component that indicates readiness for practice includes the ability to implement interventions based on empirical evidence and to adapt these interventions where appropriate. Behavioral anchors include the ability to independently and effectively implement a variety of empirically-based interventions, to terminate treatment successfully, and to collaborate effectively with other care providers. Assessment methods include self-, peer, and supervisory evaluations, client satisfaction, and outcome measures.

1.5.2.4 Progress Evaluation

The essential component that indicates readiness for practicum includes basic knowledge of how assessments are conducted to evaluate progress and outcome. Behavioral anchors include demonstrating basic knowledge concerning available methods to assess the outcome of interventions. Assessment methods include course work performance and faculty judgments. The essential component that indicates readiness for internship includes the ability to evaluate treatment progress and to modify treatment planning as indicated by the results of outcome measures, especially when progress is slow or nonexistent. Assessment methods includes self-, peer, and supervisory evaluations plus results of assessment measures. The essential component that indicates readiness for practice includes the ability to independently evaluate treatment progress and outcome and to modify treatment planning and interventions accordingly. Behavioral anchors include the ability to independently assess treatment effectiveness and efficiency and the evaluate one's performance in the treatment role and willingness to consult as the need arises.

1.5.2.5 Skills

The essential component that indicates readiness for practicum includes basic helping skills. Behavioral anchors include demonstrations of these skills including emphatic listening and framing problems. Assessment methods include simulations and/or role playing in courses, self-, peer, and faulty evaluations. The essential component that indicates readiness for internship includes effective clinical skills. Behavioral anchors include the ability to develop rapport and a good working alliance with most clients, and the effective use of supervision. Assessment methods include case observations and presentations plus supervisor and client evaluations. The essential component that indicates readiness for practice includes effective clinical skills. Behavioral anchors include the ability to develop rapport and a good working alliance with a wide variety of clients and the use of good judgment about unexpected issues including crises and the effective use of supervision. Assessment methods include case observations and presentations plus supervisor and client evaluations.

1.5.3   Consultation

The third functional competency is consultation; being able to provide expert guidance and/or assistance as requested. Consultation consists of the following three facets: (1) addressing the referral question, (2) role knowledge, and (3) knowledge.

1.5.3.1 Addressing the Referral Question

No expectation indicates readiness for practicum. The essential component that indicates readiness for internship includes knowledge of and the ability to select appropriate assessment methods to address referral questions. Behavioral anchors include the ability to systematically collect data in a consultative role. Assessment methods include supervisor evaluations and performance on the relevant portion of doctoral comprehensive examinations. The essential

component that indicates readiness for practice includes the ability to select contextually sensitive assessment methods and other data gathering methods to address the referral questions. Behavioral anchors include clarifying and refining the referral question based on collected data. Assessment methods include supervisor evaluations and case presentations.

1.5.3.2 Role Knowledge

No expectation indicates readiness for practicum. The essential component of that indicates readiness for internship includes understanding how the consultant's role differs from that of other professional roles such as therapist, supervisor, and teacher. Behavioral anchors include the ability to compare and contrast the roles of consultant, therapist, supervisor, and teacher. Assessment methods include supervisor ratings and performance on the relevant sections of doctoral comprehensive examinations. The essential component that indicates readiness for practice includes the ability to determine which situations require consultation. Behavioral anchors include the ability to detect when consultation is appropriate and to be able to effectively shift among different professional roles. Assessment methods include consultee feedback and supervisor evaluations.

1.5.3.3 Knowledge

No expectation indicates readiness for practicum. The essential component that indicates readiness for internship includes the ability to identify and acquire publications pertinent to the consultee and their issues. Behavioral anchors include performance in relevant coursework and the ability to identify components of a consultation report. Assessment methods include performance in relevant coursework and supervisor evaluations. The essential component that indicates readiness for practice includes the ability to apply findings from published literature to both routine and complex cases as a consultant. Behavioral anchors include the ability to prepare useful consultation reports and to clearly communicate their contents to all appropriate parties. Assessment methods include case presentations, consultee feedback, and supervisor evaluations.

1.5.4   Research Evaluation

This fourth functional competency concerns the ability to generate and evaluate research that contributes to the scientific basis for professional practice and to evaluate the effectiveness of professional activities. This functional competency has the following two facets: (1) scientific approach to knowledge generation, and (2) application of the scientific method to practice.

1.5.4.1 Scientific Approach to Knowledge Generation

The essential component that indicates readiness for practicum includes critical thinking and scientific mindedness. Behavioral anchors include an understanding of the contribution that research makes to the professional knowledge base, an understanding that psychologists

evaluate the effectiveness of their professional activities, and an openness to inspection and evaluation of one's work. Assessment methods include coursework performance, self-, peer, and faculty evaluation with emphasis on consensual validation. The essential component that indicates readiness for internship includes the ability to apply research skills to evaluate principles and practices of professional psychology. Behavioral anchors include successful completion of master's thesis, doctoral dissertation, relevant section of doctoral comprehensive examination, and other research and scholarship activities. Assessment methods include comprehensive exams, research requirements, and faculty evaluations. The essential component that indicates readiness for practice includes the generation of knowledge. Behavioral anchors include engaging in research to answer a basic or applied question. Assessment methods include a review of manuscripts and/or reprints of publications and/or a portfolio review.

1.5.4.2 Application of Scientific Method to Practice

No expectation indicates readiness for practicum. The essential component that indicates readiness for internship includes the application of scientific methods to evaluate one's own professional practice. Behavioral anchors include discussions of evidence-based practices, data collection on one's own clients, and participation in program evaluation. Assessment methods include supervisor and faculty evaluations. The essential component that indicates readiness for practice includes the evaluation of outcomes. Behavioral anchors include evaluating progress and/or outcomes of professional activities. Assessment methods include supervisor evaluations.

1.5.5   Supervision and Teaching

This fifth functional competency consists of the following three major facets: (1) supervision, (2) teaching, and (3) management-administration skills. The supervision facet contains the following five components: (1) knowledge, (2) skills development, (3) awareness of factors affecting quality, (4) participation in the supervisory process, and (5) ethical and legal issues. We now consider each of these elements.

1.5.5.1 Supervision

The essential feature of the knowledge component of the supervision facet that indicates readiness for practicum includes a basic knowledge of what to expect during supervision. Behavioral anchors include demonstrating knowledge of supervision including student role and responsibilities, setting goals for supervision with respect to the practicum setting. Assessment methods include self-, peer, and faculty ratings, and performance in related coursework. The essential feature that indicates readiness for internship includes knowledge of the purpose, roles, and goals of supervision. Behavioral anchors include successful completion of supervision coursework, practicum placements, and relevant portions of doctoral comprehensive examinations. Assessment methods include course grades, practicum supervisor evaluations, and doctoral comprehensive examinations. The essential feature that indicates readiness for

practice includes understanding the complexity of the supervisory process including pertinent ethical and legal issues. Behavioral anchors include the ability to articulate a philosophy and/or model of supervision and to reflect on how this model is applied in practice. Assessment methods include peer and supervisor feedback.

There are no expectations regarding the *skills development* component of the supervision facet that indicates readiness for practicum. The essential feature that indicates readiness for internship includes knowledge of the literature on supervision and how clinicians develop into skilled professionals. Behavioral anchors include successful completion of supervision coursework and the successful completion of relevant sections of doctoral comprehensive examinations. Assessment methods include coursework and doctoral comprehensive examinations. The essential feature that indicates readiness for practice includes reflection regarding one's clinical relationships with supervisees and their relationships with their clients. Behavioral anchors include being able to clearly articulate how to use supervisory relationships to help supervisees more effectively treat their clients. Assessment methods include peer and supervisory feedback.

The essential feature of the *awareness of factors affecting quality* component of the supervision facet that indicates readiness for practicum includes a basic knowledge of and sensitivity to dimensions of diversity as they relate to supervision. Behavioral anchors include demonstrating a basic knowledge of the literature on supervision and how dimensions of diversity impact supervision. Assessment methods include performance during coursework and self-, peer, and faculty supervisor evaluations. The essential feature that indicates readiness for internship includes knowledge of how dimensions of diversity impact supervision. Behavioral anchors include discussions during case presentations, familiarity with the literature on supervision, understanding how privilege and oppression can arise during supervision, and completion of cases under supervision. Assessment methods include self-, peer, and faculty evaluations based upon supervisory experience. The essential feature that indicates readiness for practice includes an understanding of how dimensions of diversity impact the supervisory process and the ability to reflect on one's performance in supervision. Behavioral anchors include a demonstration of sensitivity to diversity dimensions during supervision over multiple cases. Assessment methods include self-, peer, and supervisor evaluations of case presentations.

The essential feature of the *participation in the supervisory process* component of the supervision facet that indicates readiness for practicum includes awareness of the need for honest and respectful communication during supervision. Behavioral anchors include a willingness to admit mistakes and to accept constructive feedback. Assessment methods include self-and supervisor evaluations. The essential feature that indicates readiness for internship includes observation of and participation in supervision with peers and faculty. Behavioral anchors include successful completion of supervision related coursework and the successful completion of relevant portions of doctoral comprehensive exams. Assessment methods include coursework and doctoral comprehensive examinations. The essential feature of that indicates readiness for practice includes the ability to independently provide supervision to others. Behavioral anchors include evidence of having provided supervision to advanced students, peers, and/or other providers. Assessment methods include reviews of video or audio tapes of supervision and feedback from the supervisee.

The essential feature of the *ethical and legal issues* component of the supervision facet of the that indicates readiness for practicum includes a knowledge of ethical principles of practice and a knowledge of pertinent legal and regulatory issues regarding supervision. Behavioral anchors include demonstrating an understanding of this knowledge as codified in the APA

(2002) ethics code. Assessment methods include performance in pre-practicum coursework and a practicum readiness interview. The essential feature that indicates readiness for internship includes a knowledge of and compliance with the APA (2002) ethics code and institutional standards and guidelines for the practice site. Behavioral anchors include behaving ethically, recognizing ethical/legal issues and dilemmas in clinical practice, and bringing these matters to their supervisor's attention. Assessment methods include direct observation of supervisees during service delivery, during case conferences, and during supervision. The essential feature that indicates readiness for practice includes a command of ethical, legal, and professional standards and evidence of their effective application. Behavioral anchors include spontaneously identifying complex ethical and legal issues during supervision and developing proactive solutions plus awareness of potential conflicts of interest that may arise during supervision. Assessment methods include self-evaluations and reports by supervisors.

1.5.5.2 Teaching Skills

This facet of the supervision-teaching functional competency concerns teaching skills. The essential feature that indicates readiness for practicum includes an awareness of contemporary theories of learning and how they impact teaching. Behavioral anchors include the ability to detect differences in learning styles and to provide appropriate learning experiences. Assessment methods include classroom observation and course evaluations. The essential feature that indicates readiness for internship includes knowledge of didactic learning strategies and how to accommodate individual differences in how people learn. Behavioral anchors include clear communication skills and accommodation to individual developmental differences. Assessment methods include observation of peer teaching sessions and observation and rating of one's didactic teaching class. The essential feature that indicates readiness for practice includes an evaluation of the effectiveness of learning and teaching strategies used. Behavioral anchors include demonstration of a strategy to evaluate teaching effectiveness of targeted skill sets, articulation of concepts to be taught and the research evidence that supports these concepts, and demonstrating a strategy to assess if learning objectives have been met. Assessment methods include observation and review of teaching in addition to course evaluations.

1.5.5.3 Management and Administration

This sixth and final functional competency consists of the following three major facets: (1) leadership, (2) management, and (3) effective program development.

Leadership

No expectation indicates readiness for practicum. The essential feature of that indicates readiness for internship includes a basic understanding of leadership and management. Behavioral anchors include an understanding of quality assurance procedures in the direct delivery of services and to understand the responsibilities, challenges, and management processes that are involved in quality assurance. Assessment methods include written quarterly evaluations and passing the HIPAA continuing education module. The essential feature that indicates readiness for practice includes a demonstration of leadership skills and abilities, business knowledge, and

management and supervisory skills needed for quality assurance. Behavioral anchors include the ability to develop a system for evaluating staff/employees, ability to communicate effectively with all parties, ability to provide direction to others, identify opportunities for quality improvement, and identify necessary resources to develop a business plan. Assessment methods include written quarterly evaluations and developing all necessary materials to comply with HIPAA in the Department of Developmental Services and/or OPA.

Management

No expectation indicates readiness for practicum. The essential feature that indicates readiness for internship includes a basic knowledge of and ability to effectively function within professional settings and organizations. Behavioral anchors include the ability to articulate organizational policies and procedures. Assessment methods include written quarterly reports and supervisory evaluations. The essential feature that indicates readiness for practice includes the ability to manage the direct delivery of professional services. Behavioral anchors include evidence that one can independently manage and evaluate the delivery of professional services and can respond promptly to organizational demands and can participate in the development of policies. Assessment methods include documentation of such activities and reviews by credentialing or by state, federal or private review boards.

Effective Program Development

No expectation indicates readiness for practicum. The essential feature that indicates readiness for internship includes recognition of one's role in creating policies, participating in system change and the management process. Behavioral anchors include discussions with supervisors and agency representatives. Assessment methods include written quarterly evaluations and supervisory evaluations. The essential feature that indicates readiness for practice includes awareness of principles of the OPA principles and policy manual. Behavioral anchors include being able to provide others with face to face and written evaluations and direction. Assessment methods include records of periodic reports of meetings with supervisees.

1.5.6   Becoming Expert

This chapter has taken the position that one must become expert prior to practicing professional psychology independently. These characteristics have been described in the preceding section that detailed foundational and functional competencies. Hatcher and Lassiter (2007) published a *Practicum Competencies Outline* that distinguishes three levels of competence, novice, intermediate, and advanced, with respect to two domains of functioning: (1) baseline competencies concerning skills, attitudes, and knowledge that students should have to be ready for practicum and (2) competencies that are developed during practica. These features are generally consistent with the characteristics outlined above for readiness for practicum.

Hatcher and Lassiter (2007) modified the definitions of five stages of professional developed introduced by Dreyfus and Dreyfus (1986) who modified material provided by Benner (1984). *Novice* is the first stage and is characterized by a limited knowledge and understanding of how to assess and intervene. The novice does not discern differentiate between important and unimportant information. The novice seeks and follows rules to guide assessment

and intervention. *Intermediate* is the second stage. Students at this level recognize important clinical features and can select appropriate interventions. *Advanced* is the third stage. Students display a deeper and more integrated knowledge of clinical patterns and appropriate interventions. They better integrate their professional practice with the science base of their profession. *Proficient* is the fourth stage. Pattern recognition and completion is prominent here. Pattern completion is the ability to reconstruct the whole given a part. The psychologist rapidly grasps the presenting situation as a whole rather than the sum of disparate parts. This holistic understanding facilitates decision making regarding diagnosis and intervention. *Expert* is the fifth stage. Pattern recognition and completion reaches a peak here. A psychologist at this stage no longer relies on rules per se but is guided by an intuitive grasp of the presenting situation and therefore rapidly focuses on the relevant factors and readily formulates treatment plans.

In general, beginners tend to be rule based and rule bound in their application of knowledge; following a more step-by-step approach whereas experts tend to be pattern recognizers and completers where they rapidly understand the situation at hand and apply their knowledge and skills accordingly. Assessment become increasingly "obvious" to the expert and intervention becomes increasingly "routine." Adaptation comes naturally to the expert. The pattern recognition/completion process becomes so automatic and rapid that it is difficult for the expert to explain what led them to their decisions. These skills are best learned by working with and observing clinicians who are already experts. Beginners who understand this phenomenon will be more tolerant of vague and/or complex explanations and confident that, with practice, they too will gradually develop this facility.

Ross (2006) discussed what is involved in becoming expert in a wide variety of fields. Baker, Horton, Robertson-Wilson, and Wall (2003) discussed factors in becoming an elite athlete. Both articles cited the Simon and Chase (1973) 10-year rule which maintains that it takes a decade of hard work to become expert in any field. The latter article also cited the Newell and Rosenbloom (1981) power law wherein the rate of change in performance is initially rapid during the early stages of learning and then slows down over time.

1.6 Summary

This chapter began by addressing background issues concerning evidence-based medicine, the empirically supported treatment debate, what constitutes evidence and competency. The competency-based approach to clinical training has been more fully developed by professional programs. The most elaborate specification being the NCSPP educational model whose components include: relationship, assessment, intervention, consultation and education, management and supervision plus research and evaluation. Six specific foundational competencies were considered citing essential components, behavioral anchors, and assessment methods that indicate readiness for practicum, internship, and practice. These foundational competencies include: reflective practice and self-assessment, scientific knowledge and methods, relationships, individual and cultural diversity, knowledge of ethical and legal standards and policies and interdisciplinary systems. The following six functional competencies were considered: assessment-diagnosis-case conceptualization, intervention, consultation, research and evaluation, supervision and teaching, plus management and administration. Essential components, behavioral anchors, and assessment methods that indicate readiness for practicum, internship,

and practice were identified. A brief discussion of what being expert entails followed. A final version of the "Competency Developmental Achievement Levels (DALs) of the National Council of Schools and Programs in Professional Psychology (NCSPP)" added diversity.

1.6.1   Trajectory of Acquiring Competence

The Practicum Competencies Outline published by Hatcher and Lassiter (2007) commented on the trajectory of acquiring competence. They noted that competencies are acquired at different rates with more complex competencies maturing latter than more basic ones. They expected that clinicians will move sequentially through the five stages reported above that they identified. The trajectory from being a beginner to being an expert seems to follow an exponential (log) course over the span of approximately one decade. The beginning stage entails the acquisition of many facts and specific pieces of knowledge. The middle stage entails connecting academic knowledge with clinical application. Observational learning based on working with experienced clinicians is especially valuable. Pattern recognition and completion increasingly describes the latter stage of professional development where skills are honed to a sharp edge.

2   Competencies in Child Clinical Psychology

Stephen D. A. Hupp · Jeremy D. Jewell · David Reitman · Monique LeBlanc

Abstract: The present chapter applies much of the discussion from the previous chapter to the unique aspects of providing clinical services to children, adolescents, and their families. For example, the 12 competencies of the "cube model" were designed to represent a broad overview of competencies within the field of professional psychology that could be applied to clinical work with adults as well as clinical work with children. On the other hand, clinical child psychology is a recognized specialty within professional psychology, and there are many differences between clinical work with adults and youth. Following a discussion of the importance of considering clinical child psychology as a specialty, this chapter relates the competencies from the cube model to the practice of clinical child psychology. Other competencies that have been specifically suggested for the clinical child specialization, as well as the subspecialty of pediatric psychology, are also considered. Thus, this chapter reviews and integrates three previous models of competencies, and this integration results in a description of 17 competencies divided into three broad domains including: a) conceptualizing psychological health, b) promoting psychological health, and c) scientific and professional issues. This chapter also describes the developmental progression of the clinical child psychologist from emerging skills to expert competencies. Some consideration is also given to issues related to training competence during graduate school, the predoctoral internship, and continuing education. Finally, the chapter closes with a discussion of the daunting challenge of the assessment of competence.

2.1   Overview

2.1.1   Specialization in Clinical Child Psychology

In the following chapter, we expand upon the construct of "competence" as presented in ❯ Chapter 1, Volume 1 and explore its application to the training of the next generation of clinical child psychologists. Clinical child psychology is a recognized specialty within professional psychology, and though there is considerable overlap between clinical adult and clinical child psychology, core competencies in clinical child psychology deserve unique consideration. The American Psychological Association (APA) Council in collaboration with the Commission for the Recognition of Specialties and Proficiencies in Professional Psychology (CRSPPP) formally approves new specialties in the field and offer the following definition of a specialty.

▶   A *specialty* is a defined area of psychological practice that requires advanced knowledge and skills acquired through an organized sequence of education and training. The advanced knowledge

and skills specific to a specialty are obtained subsequent to the acquisition of core scientific and professional foundations in psychology.

Although the specific dimensions of specialty programs may vary in their emphases and in available resources, every defined specialty in professional psychology will contain: (a) *core scientific foundations in psychology*, (b) *basic professional foundation*, (c) *advanced scientific and theoretical knowledge* germane to the specialty, and (d) *advanced professional applications* of this knowledge to selected problems and populations in particular settings, through use of procedures and techniques validated on the same (Joint Interim Committee for the Identification and Recognition of Specialties and Proficiencies (JICIRSP), 1995).

A specialty in clinical child psychology was considered as far back as in the 1949 Boulder Conference proceedings (famous for elucidating the scientist-practitioner model); however, by 1967, there were only four recognized specialties in psychology: clinical, counseling, school, and industrial/organizational (Drum & Blom, 2001). Roberts and Sobel (1999) discuss some of the obstacles of creating a child specialty. For example, many of those attending the Boulder Conference questioned the merits of distinguishing between clinical work with children and adults. In the decades following the Boulder Conference, the growing clinical and empirical literature concerned with children and families appeared to support the argument for a clinical child specialization. Still, when advocates petitioned for recognition of a clinical child psychology specialty in 1981, the application was denied for failing to establish the unique characteristics of clinical child psychology (Roberts & Sobel, 1999).

Contemporary arguments supporting a clinical child psychology specialty have converged on several points. First, it has been well established that clinical psychology has traditionally focused on adults, with child issues being ignored or added as a subspecialty (Roberts, 2006). For example, the oft-cited problem of extending adult diagnoses and treatments to children without appropriate developmental consideration continues to be of concern among researchers and clinicians. According to Pine et al. (2002), plans to address this issue and those concerning children and adolescents should be implemented in the next revision of the APA's *Diagnostic and Statistical Manual* (DSM). Roberts (2006) also describes the "adultcentrism" present in many clinical psychology programs and has previously argued that children's needs are largely underserved or poorly-served because of a lack of specialty training (Roberts & Sobel, 1999). Based on these arguments as well as an even more substantial body of clinical research with children (Lonigan, Elbert, & Johnson, 1998) and the development of clearer APA standards defining specialties (JICIRSP, 1995), clinical child psychology was finally recognized as a specialty in 1998.

Roberts (2006) suggests that movement toward increased specialization has "invigorated" professional psychology, yet also emphasizes the delicate balance between specialization and unification in psychology. Further, Roberts (2006) stresses the continued importance of a shared commitment to psychology's core professional and scientific foundations. Nevertheless, today there are 11 APA-approved specialties including behavioral, clinical child, clinical health, clinical neuropsychology, clinical (general), counseling, family, forensic, industrial-organizational, psychoanalysis, and school. Some of the specialties are based on the population served (e.g., clinical child), while others are based on a foundational theory (e.g., behavioral). Many professional psychologists fit into more than one specialty (e.g., a behaviorally-oriented, clinical child psychologist). Clinical child psychologists assume many professional roles, ranging from individual child therapist and parenting group leader to school- or hospital-based consultant,

and they also increasingly interact with a myriad of other professionals serving children (La Greca & Hughes, 1999).

The importance of fostering *developmental* competence has received especially high priority in recent reviews of the child specialization (Simeonsson & Rosenthal, 2001). A notable example of this emphasis is the addition of the term "adolescent" to the APA's Division 53 journal (i.e., *Journal of Clinical Child and Adolescent Psychology*) in 2001. The concern over developmental issues arises from the uneven rate and magnitude of physical and developmental change that occurs during early childhood, adolescence, and adulthood. For example, a child's first 2 years of life are characterized by developmental changes far more dramatic than those observed for young adults (or even adolescents) over the same 2-year period. Even to an untrained observer, the differences between a 12-month-old infant and a 36-month-old preschooler are obvious, while the 24-month gap between a sophomore and senior in college (or high school) involves developmental changes far more subtle. In this chapter, we focus on the training needs of persons working with infants, children, and adolescents, but we will use the term *child* unless specific distinctions are required.

Of the 11 specialties that exist today, significant overlap exists between clinical child, family, and school psychologists. Clinical child psychologists often work directly with the child, consult with parents, or conduct therapy sessions involving an entire family. While this coordination of multiple roles with children and families helps distinguish clinical child training from training in adult psychotherapy, such actions also blur the distinction between clinical child and family psychology (recognized as a specialty in 2002). The specialty of family psychology, however, tends to have greater focus on marriage therapy, occupational problems, and issues related to aging. The role of clinical child psychologists and school psychologists also overlap. Clinical child psychologists address school-related issues, such as homework readiness and organizational skills, as well as carry out classroom observations, and consult with teachers. School psychologists often conduct individual or group therapy on school grounds and may offer consultation to parents regarding behavior management issues that affect school and social behavior. Beyond differences in the settings in which clinical child and school psychologists typically work, school psychologists tend to focus more on psychoeducational assessments, monitoring the effectiveness of academic interventions, and help make decisions about educational placement. By contrast, clinical child psychologists are more likely to be involved in the diagnosis of psychopathology, the interventions for psychological disorders, and working with parents.

Though this chapter focuses on clinical child psychology competencies, it is notable that many authors have observed strong similarities between the competencies required of the many child-focused specialties (e.g., La Greca & Hughes, 1999; Roberts, Borden, Christiansen, & Lopez, 2005). As noted by La Greca and Hughes (1999), "[t]he overlap among the different child specialty groups is not surprising, given that a common set of societal and economic forces and scientific developments has influenced the delivery of psychological services to children and families across settings and specialties" (p. 444). Of special note is the relationship between pediatric psychology and clinical child psychology. Pediatric psychology has been described as a subspecialty of clinical child psychology. For example, APA's Society of Pediatric Psychology Task Force (Spirito et al., 2003) indicates "clinical child psychology is the foundation for developing skills and expertise in pediatric psychology" (p. 86), though the Task Force also acknowledges this description is "debatable" and that pediatric psychology also has foundations in clinical health psychology. Regardless,

pediatric psychologists assume many of the same roles as clinical child psychologists, and since pediatric psychology is not a recognized specialty at present, this chapter will include pediatric psychology under the clinical child psychology umbrella. In addition to the competencies noted in this chapter, the training of pediatric psychologists necessarily focuses to a greater degree on helping children and families cope with medical issues (e.g., dealing with a chronic illness, getting an operation, etc.) in residential hospital and outpatient settings. Recent trends in pediatric psychology have moved increasingly toward developing coping skills, resilience, and strength-based approaches identified with "positive psychology" (Roberts, 2005).

2.1.2 Competency Models

Recent attempts at defining core competencies in clinical psychology (adult and child) originated in the 1949 Boulder Conference, which enumerated two major competencies in psychology: science and practice. The integrated scientist-practitioner model was adopted by APA, but some have questioned its legitimacy. McFall (2006) describes the Doctor of Psychology (Psy.D.) degree as posing the first significant challenge to the scientist-practitioner model of clinical training. Psy.D. programs have emphasized the development of practice skills (e.g., assessment, interviewing, developing rapport, etc.), while traditional Ph.D. programs have continued to emphasize the development of research skills, with a more balanced focus on clinical skill development. Beginning in 1995, the Academy of Psychological Clinical Science challenged the scientist-practitioner model from the opposite direction, and has instead focused on the goal of preparing "clinical scientists." Defining core competencies in clinical child psychology may partly depend on which of these models are adopted. However, while varying in emphasis, all existing models allow for some attention to both the science and practice of psychology.

Several attempts have been made to formulate core competencies for clinical child psychologists (La Greca & Hughes, 1999 for a brief summary of historical events in the training of clinical child psychologists). In 1992, the National Institute of Mental Health (NIMH) assembled a group of mental health professionals in the Task Group to Refine Clinical Training Guidelines for Services to Children and Adolescents. This group reviewed the existing models of training with the goal of preparing a comprehensive set of guidelines for the training of clinical professionals working with children. Though the APA ultimately did not approve the resulting document, the committee's recommendations were published in Roberts et al. (1998). The Roberts et al. model includes ten competencies and has inspired other efforts including, Spirito et al. (2003), and the present chapter. All ten competencies introduced in Roberts et al. are listed in ❯ Table 2.1 and are discussed in greater detail later in this chapter. La Greca and Hughes (1999) note three general emphases in Roberts et al.: developmental theory and research, interdisciplinary and comprehensive care, and a multicultural perspective.

Building on the work of Roberts et al. (1998), APA Division 54 members (i.e., the Society of Pediatric Psychology) commissioned a task force to update and modify recommendations for the training of pediatric psychologists (i.e., Spirito et al., 2003). For the most part, the task force embraced the Roberts et al. competencies, with two additions. First, the task force added "consultation and liaison roles," with an emphasis on consulting with physicians

[a] Foundational competency.
[b] Functional competency.

and other health care professionals. Second, Spirito et al. added "disease process and medical management" as an additional training domain. Both of these domains are discussed in greater detail later in the chapter, and the Spirito et al. model is also summarized in ❯ Table 2.1.

In 2002, the APA convened a conference on competency (i.e., *Competencies Conference: Future Directions in Education and Credentialing in Professional Psychology*), resulting in the by now, well-known, "cube model" (Rodolfa et al., 2005). ❯ Chapter 1, Volume 1 thoroughly reviews the cube model. In contrast to the Roberts et al. (1998) and Spirito et al. (2003) efforts, the cube model proposed by Rodolfa et al. was intended to serve as a broad competency model for psychology, with each specialization being defined by its population, problems, setting, and theoretical orientation. Overall, the Rodolfa et al. cube model includes six *foundational competencies* (i.e., reflective practice/self-assessment, scientific knowledge and methods, relationships, ethical and legal standards/policy issues, individual and cultural diversity, and interdisciplinary systems) that theoretically form the groundwork for the later-developing *functional competencies* (i.e., assessment/diagnosis/conceptualization, intervention, consultation, research/evaluation, supervision/teaching, and management/administration). Conceptually, foundational competencies would be taught as part of didactic aspects of graduate education, whereas functional competencies (e.g., skills) would be best refined during the direct delivery of clinical services by practicing psychologists or trainees. Finally, the cube model includes five stages of professional development, including doctoral education, predoctoral internship, postdoctoral supervision, residency/fellowship, and continuing education.

2.2   Basic Competencies

Rather than simply applying the cube model to the clinical child specialization, we have attempted to integrate some of the unique features of the cube model with prior efforts by Roberts et al. (1998) and Spirito et al. (2003). We have included every competency suggested by each of these three models, though many of the competencies were in all three models. This integration resulted in 17 unique competencies. We also attempted to organize the competencies into three broad domains. The first competency domain was deemed *conceptualizing psychological health* and includes competencies critical in understanding the unique factors that shape the characteristics of the individual child or family. This domain includes competency in child, adolescent, and family assessment, as well as competency in several areas that influence case conceptualization (e.g., diversity issues). A well-informed case conceptualization is needed before psychologists can exercise competencies in next domain: *promoting psychological health*. The promoting psychological health domain includes competencies needed to foster meaningful psychological change in children and families. Competencies within this domain include specific skills involving intervention, prevention, and consultation, as well as being able to effectively integrate these competencies with other disciplines and within several service delivery systems. Finally, the *scientific and professional issues* domain includes the broader competencies needed to disseminate information and provides services. Competencies in this domain include research, teaching, and other competencies related to serving clients in private practice or other clinical settings. The integrated list of all of the domains, as well as the individual and shared facets of the three competency

models (Roberts et al.; Rodolfa et al., 2005; Spirito et al.), serves as the foundation of this chapter and is presented in ❯ Table 2.1.

2.2.1 Conceptualizing Psychological Health

2.2.1.1 Child, Adolescent, and Family Assessment

Regarding competency in assessment, Roberts et al. (1998) suggest that approaches should include: (a) psychoeducational and behavioral assessment from birth through age 21, (b) assessment with parents and other family members, and (c) consideration of sociocultural variables. Thus, assessment with children requires facility with a broad range of assessment techniques including both indirect and direct methods (Reitman, Hummel, Franz, & Gross, 1998). Moreover, competence in assessment includes broad skills in both acquiring the information needed for diagnosis, as well as gathering information needed for treatment planning (Reitman & Hupp, 2003). In distinguishing between these two roles of assessment, Scotti, Morris, McNeil, and Hawkins (1996) contrast the current structural criteria of the DSM-IV (American Psychiatric Association, 2000) with a functional analysis system in which greater emphasis is given to identifying target behaviors, using the assessment to inform treatment design, and evaluating the effectiveness of treatment. Roberts et al. describe this functional approach as being a problem-solving process in which hypotheses are tested during assessment and intervention.

Assessment in clinical child psychology typically involves multiple methods, including both indirect and direct approaches that aid in generating hypotheses. Indirect methods of assessment include clinical interviews and questionnaires. Interviews are often done with more than one person, and frequently with multiple people at the same time (e.g., a family). Depending upon the purposes of the assessment and age of interviewee, the skills required of interviewers may vary greatly. For example, competence in establishing rapport could vary across the age groups interviewed. Using questionnaires can also be more complicated in clinical child psychology. Clinical adult psychologists may employ a single measure with all adults seen in their practice. For example, the Minnesota Multiphasic Personality Inventory – Second Edition (MMPI-2; Butcher et al., 2001) can be used with adults 18-years old and up. By contrast, the Behavior Assessment System for Children – Second Edition (BASC-2; Reynolds & Kamphaus, 2004), a commonly used measure in clinical child settings, employs different forms for children (ages 8–11), adolescents (ages 12–21), and college students (ages 18–25). The BASC-2 also includes teacher and parent report measures. Thus, the clinical child psychologist must become familiar with similarities and differences between these variations of the same instrument.

Direct methods of assessment include psychoeducational testing and behavior observations. Clinical child and school psychologists have considerable overlap in the competency of psychoeducational testing which includes assessment of a child's developmental level, cognitive assessment, tests of achievement, or a combination of these methods. Behavior observations are another area of overlap for clinical child and school psychologists. While school psychologists are more likely to do classroom observations, clinical child psychologists are more likely to observe children interacting with family members. Observational data can be clinically useful, but it requires a higher level of effort to obtain than most interviews or rating scales. Moreover, while standardized analogue observations are sometimes conducted that may lend themselves to standardization, in vivo observations tend to be more idiosyncratic and occur in settings

(e.g., schools) that might limit the extent to which competence can be accurately assessed. While diagnosis is often one of the assessment goals, another goal includes determining function (Scotti et al., 1996). That is, clinical child psychology requires competence in determining the potential antecedents and consequences of maladaptive and adaptive behavior. Functional behavioral assessment (FBA) can be conducted through interview, questionnaires, and natural observations. Also, in the case of functional analysis, FBA is sometimes conducted through the psychologist observing behavior while purposefully manipulating antecedents and consequences.

Having chosen a subset of assessment techniques, the clinician is then faced with complex decisions about how to weigh discordant information and determine level of impairment (Reitman et al., 1998). As noted by many authors, we can offer little evidence-based guidance to users concerning how best to combine information from various sources. The task is complicated further when one considers the purposes of assessment, as some measures may be useful for differentiating diagnosis but greatly limited as measures of change (Mash & Hunsley, 2005). That is, assessment in clinical child psychology includes monitoring the effectiveness of the treatment (also called response to intervention). As one example, there are only a limited amount of times that a psychologist could administer some intelligence tests, whereas some other forms of academic assessment have been designed to be used more frequently. In addition to measuring changes in the child, some assessment tools have been designed to measure changes in others as well. For example, in a recent study, the Parent Instruction-Giving Game with Youngsters was used to monitor the effectiveness of behavioral parent training on both parent and child behaviors (Hupp, Reitman, Forde, Shriver, & Kelly, 2008). Parents and teachers are often also involved in keeping track of behaviors over time, and depending on the developmental level, the child sometimes self-monitors behavior as well.

2.2.1.2 Life Span Developmental Psychology (Normal Development)

Developmental considerations are important in both clinical child and adult psychology, but they are paramount in the former case. For children, similar behaviors (e.g., difficulty separating from a parent, temper tantrums, etc.) while typical in one phase of development are atypical in other phases. As discussed by Roberts et al. (1998), the clinical child psychologist must have a firm knowledge of developmental norms or benchmarks in many developmental areas including social, cognitive, emotional, behavioral, and physical domains. For example, a competency in life span development includes knowledge of major developmental milestones, such as walking, talking, and self-care. Later in development, sleep habits, social behavior, and cognitive abilities change markedly from infancy to adolescence. The life span development competency also includes knowledge of developmental issues characteristic of young adulthood and middle age as clinical child psychologists will often work closely with adults responsible for shaping child development. That is, multiple systems influence child development, and the training of a clinical child psychologist must focus on understanding the important relationships of the child. Bronfenbrenner's (1979, 2005) ecological systems theory includes family, school, peers, church, neighborhood, mass media, and cultural beliefs, and emphasizes interactions between these systems, such as the quality of communication between parents and the school. These systems affect children differently at different ages. For example, as children mature, they tend to spend more time with their peers, and less time with their parents. Thus, over time peers gradually have more influence on development (Arnett, 2007).

Determinations concerning the extent to which a given behavior can be considered "abnormal" and the degree to which such behavior results in "clinically significant impairment" (e.g., making a diagnosis) can only be made when competency in recognizing normal developmental processes is obtained. Some behaviors are so common in younger children that they are not considered diagnostic of clinical syndromes until later in development. For example, nighttime bed-wetting is a common problem in early child development. Thus, a child must reach 5-years old before enuresis can be diagnosed (American Psychiatric Association, 2000). Other behaviors in children require a time length that is not required in adults. For example, because transient fears of specific stimuli or situations (e.g., bugs, the dark, etc.) are very common in childhood, specific phobias cannot be diagnosed unless the duration of the fear exceeds 6 months (American Psychiatric Association, 2000).

2.2.1.3 Life Span Developmental Psychopathology

Competencies in life span developmental *psychology* (i.e., normal development) and life span developmental *psychopathology* (i.e., abnormal development) are complementary, but distinct competencies. A competency in life span developmental psychopathology includes knowledge of behavioral issues, mood problems, learning disorders, and developmental challenges across the life span, including into adulthood (Roberts et al., 1998). This competency requires a clear understanding of diagnostic comorbidities. For example, the importance of assessing for dual diagnoses in children with intellectual disabilities has been emphasized (Matson & Bamburg, 1998).

Many of the disorders in the *Diagnostic and Statistical Manual of Mental Disorder – Fourth Edition – Text Revision* (DSM-IV-TR; American Psychiatric Association, 2000) require onset before adulthood. For example, the criteria for mental retardation and separation anxiety disorder must be met before the age of 18. To qualify for a diagnosis of attention-deficit/hyperactivity disorder (ADHD), the individual must have shown some significant symptoms before age 7. Also, for children to be diagnosed with autistic disorder, they must evidence some impairment in either social behavior, communication, or play before age 3. For other disorders, important differences emerge in the diagnostic criteria for children and adults. For example, irritability can be substituted for depressed mood when diagnosing depression with children.

Though the DSM-IV-TR diagnoses typically avoid discussion of etiology, competent practice of clinical child psychology may be facilitated by such knowledge. Indeed, research in behavioral genetics supports both genetic and environmental influence for most disorders; however, the degree of heritability varies considerably from one disorder to the next. For example, the heritability of autism (Gupta & State, 2007) is considerably higher than the heritability of oppositional defiant disorder (Dick, Viken, Kaprio, Pulkkinen, & Rose, 2005). In fact, heritability plays a variable role even when comparing the different anxiety disorders (Kendler, Neale, Kessler, Heath, & Eaves, 1992). Interestingly, recent research suggests that the influence of genetic factors may vary across the life span (Gregory & Eley, 2007). Mechanisms of environmental influence may include such factors as classical conditioning, operant conditioning, and social learning processes and have, in most cases, shown that non-shared factors, unique to the developing child or adolescent, seem to contribute most to environmental variation (Plomin, 1990). Non-shared environmental influences may reflect parenting practices, but may to an

even greater extent involve peer influence, a child or adolescent's perceptions of the environment, or even relatively by chance the interaction between the developing child and the environment (Plomin, Asbury, & Dunn, 2001). By contrast, shared environmental factors linked to the social environment such as crime and poverty seem to play a more important role in the development of conduct disorder (Plomin, 1990).

2.2.1.4 Diversity Issues

Most recent models of competency include a multicultural component, including awareness and knowledge about multicultural issues and the skills needed to provide culturally and ethnically competent services. Psychologists and the families to whom they provide services are embedded in sociocultural frameworks. The groups to which people belong impact many aspects of functioning, including cognitive, affective, and behavioral development. The degree to which a given behavior is considered normal or abnormal must be evaluated within a cultural context. How families express problems, whether treatment is desired or sought, and what outcomes are preferred are also influenced by cultural norms (Johnson & Tucker, 2008).

The APA ethics code calls for psychologists to develop an understanding of how culture may affect psychological services and research, and the APA's recently published *Guidelines on Multicultural Education, Training, Research, Practice, and Organizational Change for Psychologists* (APA, 2003) points the way toward establishing this competence. However, multicultural competence is itself a multifaceted concept. While ethnic and racial diversity are commonly accepted elements of diversity, sexual orientation, socioeconomic status, religious affiliation, age, disability, and family structure may be other important dimensions. The picture is increasingly complicated as many of these areas of diversity intersect with or contribute to educational and health disparities that are known to affect physical and mental health (Sue & Sue, 2003).

Competence in diversity involves three components: awareness, knowledge, and skills (Hansen, Pepitone-Arreola-Rockwell, & Greene, 2000). Awareness of diversity issues is considered to be the first step in developing cultural competence. Clinical child psychologists should be aware of their own beliefs and values and how these factors influence their delivery of psychological services. Additionally, psychology as a whole is considered to have been shaped by a Western worldview (APA, 2003; Hansen et al., 2000; Johnson & Tucker, 2008). For instance, Western norms may convey that socially competent children are independent, assertive, and outgoing, while Asian cultures are often regarded as valuing conformity, behavioral inhibition, and dependence in children (APA, 2003; Chen, Rubin, & Sun, 1992).

The multiculturally competent clinical child psychologist is knowledgeable about the beliefs and practices of diverse groups and the way in which those beliefs and practices influence the effective practice of psychology (APA, 2003). Cultural norms also impact the definition of psychopathology, the interaction between the psychologist and family, and the assessment and treatment process (Johnson & Tucker, 2008). For example, gender and ethnic differences in assessment and treatment rates for ADHD have been demonstrated with researchers finding that Caucasian children are twice as likely to use stimulants as ethnic minority children, despite similar symptom profiles (Hudson, Miller, & Kirby, 2007). One study found that perceptions of ADHD-related symptoms were different among parents of African-American children and Caucasian children and screening instruments appeared to perform differently for the two groups (Hillemeier, Foster, Heinrichs, & Heier, 2007). Moreover,

African-American parents have reported fewer expectations about the effectiveness of treatment (Bussing, Gary, Mills, & Wilson, 2007). Knowledge about these factors can inform the development of ethnically appropriate assessment and treatment for ADHD in children.

Development of multicultural competence does not require the child psychologist to develop an entirely new set of assessment and intervention skills, but it is important to recognize that assessment and intervention may be more effective when cultural context is considered (APA, 2003). The competent psychologist uses appropriate assessment techniques and measures and considers culture and group norms when conceptualizing cases and planning treatment. For example, a culturally competent clinical child psychologist should examine the norms for psychological test instruments to ensure applicability to diverse child populations, attempt to establish rapport with the child and family in a culturally appropriate manner, address barriers to treatment, such as beliefs and stigma concerning psychological problems, and address communication differences (Johnson & Tucker, 2008).

2.2.1.5 Social Issues

Competent clinical child psychologists must be capable of recognizing, understanding, and influencing, when appropriate and feasible, social forces that affect families. Many of the challenges to successful development in childhood are related to the social environment (Bell & Luebbe, 2008). These social issues can include, but are not limited to, child abuse and neglect, witnessed violence, family disruption, homelessness, death, poverty, and lack of access to quality health care services. Negative social circumstances may directly affect psychological functioning but may also interfere with future development, placing the child at risk for future psychological problems and social or vocational dysfunction.

Child maltreatment and witnessed violence are examples of serious social issues facing children. Some children experience high rates of maltreatment, including sexual, physical, and emotional abuse, as well as neglect of children by caretakers. In 2006, child protective services investigated 3.6 million cases of child maltreatment with about 900,000 children classified as victims (Centers for Disease Control, 2008). Sadly, these data are thought to underestimate the incidence of child maltreatment (Wekerle, Miller, Wolfe, & Spindel, 2006). Moreover, children witnessed high levels of domestic or intimate partner violence as well as violence in their communities. A nationally representative study of adolescents found that 39% reported witnessing an act of serious violence in their lifetimes, such as witnessing someone being shot or hurt with a weapon (Kilpatrick, Saunders, & Smith, 2003). Some risk factors interact, as children who live in poverty are at higher risk for witnessing violence and being neglected. Although child maltreatment and witnessing violence are not psychological disorders, they have been linked to a plethora of negative psychosocial consequences, including aggressive behavior, conduct problems, depression, anxiety, and symptoms of posttraumatic stress disorder (Wekerle, MacMillan, Leung, Jamieson, 2008).

High rates of child maltreatment and violence exposure virtually guarantee that clinical child psychologists will have some contact with individuals and families who have experienced these events (Champion, Shipman, Bonner, Hensley, & Howe, 2003). A competency in social issues includes awareness and knowledge of the prevalence of maltreatment and violence exposure, comorbidity and associated features, appropriate assessment techniques, and a strong grasp of ethical and legal issues related to the criminal justice system, such as mandated

reporting. This competency also includes being able to incorporate social issues into case conceptualization and helping families obtain additional support services. Clinical child psychologists may enhance their level of competence by participating in prevention and child advocacy activities (Bell & Luebbe, 2008).

2.2.1.6 Disease Process and Medical Management

Around 10–15% of children experience chronic illness, and rates of certain chronic diseases, such as Type II diabetes and asthma, have increased substantially in recent years (Akinbami, 2006; Tarnowski & Brown, 2000; Wysocki, Greco, & Buckloh, 2003). As a result both pediatric psychologists and clinical child psychologists need to establish a basic competency in the general understanding of common pediatric illnesses, contemporary treatments for pediatric illness, knowledge of medical terminology (to facilitate communication between physicians and families), and common side effects of medication and other medical interventions used to treat chronic illness in children. To be clear, this competency is focused on the medical management of medical issues, whereas the medical management of psychological issues is later included in the *intervention strategies* competency.

Diabetes serves as an excellent model for establishing competence in disease process and medical management. The medical regime for children diagnosed with diabetes is complex and generally includes frequent self-monitoring of blood glucose, dietary control, exercise, oral medication, and insulin injections or pumps. Noncompliance with treatment for children diagnosed with diabetes is common and related to a multitude of factors, including patient and family knowledge, parental involvement, family communication, and developmental status (Chisholm et al., 2007; Dalewitz, Khan, & Hershey, 2000). Developmental status is important as adolescents, regardless of greater disease knowledge, are more noncompliant than children, possibly related to peer concerns and greater autonomy from parental control (Naar-King, Podolski, Ellis, Frey, & Templin, 2006; Thomas, Peterson, & Goldstein, 1997). Diabetes is also associated with increased risk of psychological problems, including depression, anxiety, and eating disorders (Kovacs, Obrosky, Goldstone, & Bonar, 1997; Vila, Robert, Nollet-Clememcon, & Vera, 1995). Finally, stress is thought to impact glycemic control and treatment compliance (Wysocki et al., 2003). Obviously, competence in disease management requires a diverse skill set, including helping children and families adjust to chronic disease, fostering adherence to treatment, teaching the child how to cope with pain or invasive procedures, and differentiating between symptoms associated with illness and those stemming from poor psychological adjustment (Roberts, Mitchell, & McNeal, 2003; Spirito et al., 2003). While it is clear that the full set of competencies noted above may be required for pediatric psychologists, it is less clear that these competencies are "core" requirements for all clinical child psychologists.

2.2.2 Promoting Psychological Health

2.2.2.1 Intervention Strategies

A competency in intervention strategies includes (1) selecting an appropriate intervention based on accurate diagnosis and/or functional assessment, (2) implementing the intervention,

and (3) making necessary modifications to the intervention plan, as needed. Regarding selection of interventions, the *Journal of Clinical Child and Adolescent Psychology* recently published a special issue on evidence-based psychosocial treatments (Silverman & Hinshaw, 2008 for an overview). This special issue reviews contemporary psychosocial treatments for autism, eating disorders, depression, phobic and anxiety disorders, obsessive-compulsive disorder, trauma exposure, ADHD, disruptive behavior disorders, and substance abuse. Of special significance is a final review that examines research on evidence-based treatments for ethnic minority children and adolescents (Huey & Polo, 2008).

According to Silverman and Hinshaw (2008), evidence-based treatment (previously called empirically supported or empirically validated treatments) reviews were prepared based upon criteria that were originally developed by an APA Task Force charged with identifying effective treatments in clinical psychology (Chambless et al., 1996). These reviews classify their respective treatments as well-established, probably efficacious, possibly efficacious, or experimental. The criteria for inclusion in the well-established category include (a) at least two well-designed group studies, (b) the studies were conducted by different research teams, and (c) the studies demonstrated that the treatment was superior to another treatment or placebo. Several interventions have been found to meet the criteria for being a well-established treatment; however, few interventions are regarded as having been disseminated adequately (Silverman & Hinshaw, 2008). In fact, Herschell, McNeil, and McNeil (2004) argue that the dissemination of evidence-based treatments has occurred more slowly for child clients than for adults.

For the evidence-based treatments, manuals have been developed to increase treatment integrity in research studies, and these same treatment manuals may be used by practitioners. However, one study found that approximately half of practicing psychologists reported they had never used a manual and did not have comprehensive knowledge of the content of manuals (Addis & Krasnow, 2000). To reduce dissemination barriers, Herschell et al. (2004) suggest that manuals must: (a) become more "clinician-friendly," (b) increase attention to developmental issues, and (c) allow for greater flexibility. Herschell et al. also suggest that graduate training programs should include a greater emphasis on evidence-based treatments. Additionally, Silverman and Hinshaw (2008) emphasize the importance of clinicians and researchers being aware of treatment mediators (i.e., how change is produced during therapy) and moderators (i.e., who is most likely to benefit from therapy and under what conditions).

In addition to psychosocial interventions, Kollins and Langberg (2008) present several arguments for developing clinical competency in pharmacological interventions for children. First, pharmacological interventions are on the rise. Second, there is considerably less research with children than with adults. Third, and related to their second point, knowledge of medication side effects, particularly very serious ones (e.g., suicidal ideation, cardiac problems, etc.), is of paramount importance. Fourth, some medication side effects mimic or diminish behavioral symptoms, which may complicate diagnosis. Finally, psychopharmacological competence may be valuable when clinical child psychologists participate in multidisciplinary settings or are needed to help clients make decisions about psychosocial treatments alone, pharmacological treatments alone, or combined treatments (Burns, Rey, & Burns, 2008). Because all but a few psychologists are barred from prescribing (Ax et al., 2008), this competency largely concerns itself with the clinical child psychologist's role as a consultant and client advocate (LaFleur & Northup, 1997 for an example in school psychology).

2.2.2.2 Relationships

The cube model presented in Rodolfa et al. (2005) includes relationships as one of the foundational competencies. Braswell and Kendall (2001) provide some insight into therapist behaviors that might facilitate different kinds of relations, suggesting that "a therapist must be able to teach in a playful manner and play in a way that teaches" (p. 250). However, a different teaching style may be required for teaching adolescents, and yet another skill set may be needed for parent or teacher consultation. Thus, the clinical child psychologist must often work toward developing an alliance with an adult while at the same time developing a bond with the child. Interestingly, while the therapeutic alliance has been well studied in the adult literature across several treatment modalities, far fewer studies have examined therapeutic alliance in clinical child psychology.

In one of the few studies examining alliance with youth, Kazdin and Whitley (2006) defined *alliance* as "the quality and nature of the patient-therapist interaction, the collaborative nature of that interaction on the tasks and goals of treatment, and the personal bond or attachment that emerges in therapy" (p. 346). Their study revealed that a stronger parent–therapist alliance was associated with improvements in parenting practices during parent management training. A previous study provided evidence that both the parent–therapist and child–therapist relationships were correlated with intervention gains and treatment acceptability (Kazdin, Marciano, & Whitley, 2005). Similarly, in a study of adolescents diagnosed with anorexia nervosa, early adolescent–therapist alliance was associated with early treatment gains while later parent–therapist alliance was associated with treatment completion (Pereira, Lock, & Oggins, 2006). Collectively, these studies support the contention that clinical child psychologists must often cultivate multiple supportive relations (e.g., the child, one or two parents, teachers) to maximize the likelihood of treatment success.

Research has identified some factors that have been associated with benefits in therapy. For example, facilitative and supportive comments made by the therapist predict treatment gains and parental cooperation during behavioral parent training (Harwood & Eyberg, 2004; Patterson & Chamberlain, 1994). Other factors that may influence alliance include gender and ethnicity. In a study of adolescents with substance abuse problems, Wintersteen, Mesinger, and Diamond (2005) found that adolescent–therapist alliance was higher when the adolescent and therapist were of the same gender, and matched gender was also associated with higher therapy completion rates. Similarly, adolescents were more likely to complete therapy when they were the same ethnicity as the therapist. This research suggests clinical child psychologists would benefit from knowledge about factors influencing alliance, as well as developing actual skills that promote alliance and minimize barriers to alliance.

2.2.2.3 Prevention, Family Support, and Health Promotion

Prevention has been a growing area of interest in clinical child psychology. Herschell et al. (2004) view prevention as an important and innovative area of focus for clinical child psychology training. Clinical child psychologists often see some symptoms of psychological problems even though the criteria for a particular diagnosis have not been met; thus, therapy often includes preventing some problems from developing into a disorder. Spirito et al. (2003) also emphasize the greater role psychology could take in disease prevention and helping

families promote resiliency in children. Weisz, Sandler, Durlak, and Anton (2005) present an integrated model of treatment, prevention, and health promotion in strengthening mental health with children. The model includes seven types of programs including three degrees of *intervention* (continuing care, enhanced therapy, and time-limited therapy) which may vary from long-term care to just a few treatment sessions. The model also includes three levels of *prevention* (indicated, selective, and universal). Indicated prevention involves programs designed for children demonstrating some significant symptoms without yet meeting the full criteria for a disorder. Selective prevention programs attempt to minimize risk factors in a selected group of children, while universal prevention programs focus on decreasing the effect of risk factors for every child in a particular population (e.g., the entire school). Finally, *health promotion* has "the goal of enhancing strengths so as to reduce the risk of later problem outcomes and/or to increase prospects for positive development" (p. 632). Thus, health promotion focuses more on building strengths rather than managing weaknesses. Like preventative medicine, preventive mental health care currently has serious limitations due to the current managed care system; however, preventative mental health care has the potential to ultimately have financial benefits for clients and the managed care system.

Weisz et al. (2005) indicate that there are over 125 prevention programs with good research support. These programs cover a broad range of issues with children including externalizing problems, internalizing problems, drug use, and other issues. Programs target children, parents, and teachers in many different settings (e.g., home, school, neighborhood agencies, etc.), and often the same program covers several types of prevention. For example, several variations of the Positive Parenting Program (Triple-P) have research support (Sanders, Bor & Morawska, 2007). Triple-P was designed to prevent externalizing problems as well as child abuse, and has five possible levels including: (1) a media-based universal prevention program, (2) a 1- or 2-session primary health care program, (3) a 4-session primary health care intervention, (4) an 8–10-session program for individuals or groups, and (5) an enhanced behavioral family intervention. Potentially, clinical child psychologists could implement this program for a variety of families with a range of problem severity.

2.2.2.4 Role of Multiple Disciplines and Service Delivery Systems

Bronfenbrenner's (1979) ecological systems model emphasizes the interaction between the individual and various levels of their environment that shape the individual's behavioral, social, and emotional functioning. Clinical child psychology training programs must also take into account these factors as they seek to promote interdisciplinary competencies needed to promote successful development. Borrowing from Roberts et al. (1998), La Greca and Hughes (1999) described this competency by indicating it "includes interprofessional, interagency, and family-professional collaboration, as well as an understanding of the roles and responsibilities of various service systems (e.g., educational, medical, public mental health, welfare) and disciplines (e.g., education, pediatrics and family practice, social work, psychiatry, law) in providing service to children, adolescents, and their families" (p. 440).

The value of multidisciplinary teams has been recognized by many professions, and some training programs in clinical child psychology have made formal efforts to facilitate these connections. La Greca and Hughes (1999) emphasize the importance of interdisciplinary training and the value of acquainting clinical child psychologists with the school administrators,

teachers, school social workers, and school counselors who play such an important role in children's lives. Knowledge of these disciplines "at a distance" is not sufficient, as ideally trainees should have working experience with these other disciplines through various collaborative experiences. Similarly, pediatric psychologists also serve on multidisciplinary teams in hospitals with a diverse group of other professionals. While most students will acquire cursory knowledge or obtain superficial experience with other professionals in these systems, those seeking specific specialization will require a great deal more practicum and internship experience, if meaningful competencies are to be achieved (Spirito et al., 2003).

2.2.2.5 Consultation and Liaison Roles

Clinical child psychologists often take the role as consultant, and this is particularly true for pediatric psychology (Spirito et al., 2003) as psychologists in hospital settings work closely with physicians to help deal with the psychological aspects of medical issues. Clinical child and pediatric psychologists also commonly provide consultation with families and within the school system by providing recommendations and facilitating communication between parents and teachers. While consultation is normally defined as a process by which one professional seeks another for assistance in solving some problem (in this case related to a child client), the role of liaison is somewhat different. That is, the primary role of a liaison is to provide communication between two separate systems. For example, a pediatric psychologist may work with a child who is recently diagnosed with lymphoma and requires long-term hospitalization. In this case, the psychologist might serve as a liaison between hospital staff caring for the child and the school personnel regarding the child's educational needs, any special education status, and school work that can be completed while in the hospital.

This competency is similar to the previously discussed competency (i.e., role of multiple disciplines and service delivery systems). The Rodolfa et al. (2005) cube model's distinction between foundational and functional competencies might be a good framework for distinguishing between these two types of competencies. That is, Rodolfa et al. define the *role of multiple disciplines* (i.e., interdisciplinary systems) as a foundational competency with the following definition: "Identification and involvement with one's colleagues and peers. Knowledge of key issues and concepts in related disciplines and the ability to interact with professionals in them" (p. 351). Alternatively, the functional competency of *consultation* is defined as follows: "The ability to provide expert guidance or professional assistance in response to a client's needs or goals" (p. 351). Spirito et al. (2003) also include both competencies and make a distinction between the training needs of these competencies. That is, for the competency in the *role of multiple disciplines*, Spirito et al. indicate that the primary training topic should be "experience on multidisciplinary teams delivering health care services" (p. 92), while the primary training topic for competency in *consultation* is described as "exposure to different consultation-liaison models and supervised experience providing consultation in health care settings" (p. 92). Thus, both models describe these as unique competencies.

With respect to theoretical models, while behavioral and cognitive-behavioral orientations toward consultation are most often reported by practitioners, mental health, solution-oriented, and systems/ecological models are also endorsed (Anton-LaHart & Rosenfield, 2004). One should also consider variations in the role of the consultant. Some consultants provide direct services to the "client," whereas others adopt an indirect approach. For example, client-centered

models of consultation often provide services to those working closest with a single child (Brown, Pryzwansky, & Shulte, 2006). By contrast, consultee-centered consultations, as well as systems or organizational consultations, provide services intended to benefit the broader population of clients served. For example, when working from a client-centered mode using a behavioral consultation theoretical model, consultants work directly with the teacher regarding a single child's misbehavior in the classroom (Noell, Witt, Gilbertson, Ranier, & Freeland, 1997). However, organizational models of consultation might focus to a greater extent on policy and procedural changes that require administrator input, such as adoption of a school-wide discipline program. Consultation in these examples may look quite different, and require knowledge of differing content as well as different process skills (Anton-LaHart & Rosenfield, 2004). *Content* refers to the knowledge base used by the consultant to lead a problem-solving experience. *Process* refers to the interpersonal processes as well as theoretically defined stages of consultation that dictate the "flow" of the consultation. Because knowledge is required prior to the delivery of consultative services, it stands to reason that consultation courses may need to occur later in a training program's curriculum as opposed to earlier (Meyers, 2002).

There are two other points that can also be made regarding the unique training needs for the consultative role. First, there are currently no ethical guidelines that address the specific ethical dilemmas that may occur during consultation. Rather, consultants must rely on the general APA ethical guidelines as they apply to other roles such as assessment and psychotherapy (Brown et al., 2006). Presumably, training in consultation is even more important than in other competency areas because of the apparent gap in the ethics code. Second, there is a need for specific practica in consultation (Atella & Figgatt, 1998). The status quo for most training programs is for students to acquire experience with consultation in practica in a haphazard and nonsystematic fashion. Alpert and Taufique (2002) discuss the need for practica sites and experiences whose role is specific to consultation, as well as the need for careful selection of such sites and supervisors.

2.2.3 Scientific and Professional Issues

2.2.3.1 Scientific Knowledge and Methods

The cube model distinguishes between two competencies directly related to science, including (1) scientific knowledge and methods, and (2) research and evaluation (Rodolfa et al., 2005). The first of these competencies, *scientific knowledge and methods* is described as a foundational competency and is defined as "the ability to understand research, research methodology and a respect for scientifically derived knowledge, techniques of data collection and analysis, biological bases of behavior, cognitive-affective bases of behavior, and lifespan human development" (p. 351). This competency includes understanding research design and statistics in an effort to make the psychologist an educated consumer of the research literature. In other words, psychologists need a thorough understanding of the strengths and limitations of research designs and statistical tests so that they can appropriately critique research in their field. Ideally, the psychologist will be able to distinguish between meaningful research that should inform practice versus research that has little value because of weak methodology.

Evidence-based practice is a broad term that encompasses every aspect of one's professional role, ranging from selection of reliable and valid assessment tools to staying abreast of

contemporary research on biological, cognitive-affective, and developmental factors that affect child development. Incorporating new information into one's case conceptualization represents a further challenge. Evidence-based practice also includes choosing treatments that are most likely to be effective for a given client and for developing an awareness of what factors promote or diminish their effectiveness. Over the past years, a series of important publications has informed the empirical goals of clinical child psychology. The evidence-based practice movement initiated in the mid-1990s (Chambless et al., 1996) has inspired two comprehensive reviews of the child treatment literature (Lonigan et al., 1998; Silverman & Hinshaw, 2008). Another comprehensive review was undertaken to explore the state of contemporary clinical child assessment (Mash & Hunsley, 2005). Collectively, these reviews reveal both substantial progress and significant barriers to delivering effective clinical services. Given the existing limitations of knowledge concerning "what works," the task of training and promoting continuing education is daunting.

2.2.3.2 Research and Evaluation

Research and evaluation is described as a functional competency in Rodolfa et al. (2005), and it is defined as "the generation of research that contributes to the professional knowledge base and/or evaluates the effectiveness of various professional activities" (p. 351). The extent to which this functional competency is a "core" competency for clinical psychology has been debated for over 40 years (McFall, 2006). Gaudiano and Statler (2001) provide a brief and insightful distillation of the debate between researchers and practitioners. Programs ascribing to the scientist-practitioner model (generally, those programs conferring the Ph.D.) often have greater expectations for students to be both informed consumers of research as well as active producers of research. On the other hand, programs ascribing to a scholar-professional model (generally, Psy.D. programs) generally emphasize the competency in scientific knowledge over competency in active research and evaluation.

Belar (2000) illustrates the symbiotic interaction between science and practice, arguing science is core to guiding the practice of psychology. At the same time, she argues that it is the responsibility of scientists to produce research that remains relevant to clinical practice. One recent mechanism for fostering better integration between research and practice may be through the application of the "clinical dashboard" (Daleiden & Chorpita, 2005). The clinical dashboard merges session-by-session information regarding the client's symptomology severity with a record of the therapeutic techniques employed in each session. In this way, the clinician is able to gauge the general effectiveness of therapy and can potentially estimate the effectiveness of particular techniques used in each session (Higa & Chorpita, 2008). Level-one research (Hawkins & Mathews, 1999) is another example of an attempt to make clinical research more relevant and more informative for practicing clinicians. Essentially, this approach only demands that data are collected on meaningful clinical outcomes, data are collected frequently, and data are used to foster changes in the treatment plan or conceptualization. Reitman and Drabman (1999) demonstrated this approach by using a simple, parent-completed, time-out record in the treatment of tantrums with an 8-year-old boy. During clinic sessions, time-out records were reviewed and the therapist graphed and shared this information with the parent. Decisions concerning how to respond to various forms of challenging behavior and goals for practice between sessions were developed from these in-session activities. It remains

to be seen whether teaching graduate students or professionals to apply such methods will foster better clinical outcomes than are presently being obtained in general clinical practice (Weisz, Jensen-Doss, & Hawley, 2006).

Clinical child psychologists may be involved in research and evaluation in multiple ways. Those pursuing careers in academia utilize a broad range of research abilities, including evaluating the psychometric properties of assessment tools, designing treatment evaluation research, and meta-analysis. However, even practitioners outside of academia can use functional research skills. For example, single-case research designs can be used to evaluate the effectiveness of treatments with individual clients (Morgan & Morgan, 2001). Finally, speaking to the larger issue of what scientists can learn from practitioners, Kazdin (2008) argues that one of the regrettable features of clinical psychology is how much knowledge is lost in clinical practice. That is, most clinicians gain a wealth of knowledge and experience that is rarely passed on to other psychologists in any systematic way to help other clients. While clinicians may share some of what they have learned to a few other clinicians (e.g., through supervision), this knowledge infrequently contributes to the accumulated knowledge of the field of psychology. Thus, Kazdin argues for more systematic ways of evaluating treatment outcome for all clinicians, so there is a mechanism for sharing knowledge gained from an accumulation of cases. This systematic evaluation might prompt more integration of clinical work and research.

2.2.3.3 Professional, Ethical and Legal Issues

Clinical child psychologists are required to adhere to the APA's *Ethical Principles of Psychologists and Code of Conduct* (2002). Licensed psychologists must also adhere to relevant state laws governing practice in their state. However, psychologists working with children face ethical and legal issues that greatly increase the complexity of clinical practice and do not affect those working only with adults. Issues such as confidentiality and informed consent, which seem rather straightforward when obtained in the context of adult psychotherapy, can be quite challenging for first-time family and child therapists (Sattler, 1988). Moreover, significant training and role play may be needed before novice therapists can be considered competent in this practice.

One area that highlights the complexity of clinical child training in this area is confidentiality. The Model Act for State Licensure of Psychologists (APA, 1987) outlines eight scenarios in which confidentiality may be broken. However, many of these scenarios are ambiguously described and may be difficult to apply to specific situations. For example, if a 14-year-old adolescent seeking therapy states to her therapist that she is planning on committing suicide, the ethical guidelines and model act clearly allow and require that confidentiality be broken. However, imagine that the same young woman tells her therapist that she is having unprotected sex and abusing alcohol. The therapist's duty to disclose this confidential information is guided by a number of factors, the first being the state in which they are practicing. States vary in how they handle confidentiality between children and therapists, and state laws also often lack clarity. Second, the therapist must consider whether the child sought therapy on his or her own without parental consent or whether the parent presented the child for treatment and signed a consent form. Other ethical and legal issues such as duty to report and neglect child abuse are also faced quite frequently by the clinical child psychologists. Given the incredible complexity of the legal and ethical issues surrounding the provision of services

to children, as well as the ambiguity of state and federal statutes, adequate training in ethical and legal issues is critical.

2.2.3.4 Supervision and Teaching

While explicit training in supervision skills has been regarded as critical (Barnett, Erickson Cornish, Goodyear, & Lichtenberg, 2007), steps toward making this a reality have only recently been taken. Arguments for explicit training in supervision arise from the observation that most graduates of clinical programs will, at some point in their career, supervise a junior colleague, and that many do so without formal training in supervision (Barnett et al., 2007). Competency in supervision first requires competency in psychotherapy and such training is typically at the center of graduate training in clinical child psychology. Indeed, competent supervision appears to require a complex skill set that is presently overlooked in most graduate training. Efforts are presently underway to delineate the specific components of this repertoire. Falender et al. (2004) describe the basic competencies necessary for supervision: knowledge, skills, values, social context overarching issues, training of supervision competencies, and assessment of supervision competencies (p. 778). However, this work is foundational, and training programs are currently not required by state accrediting agencies or the APA to adhere to this framework. One promising example of this kind of research is a recent review conducted by Hoffman, Hill, Holmes, and Freitas (2005) which examined how feedback is given in supervision, why some feedback is difficult to give, and the possible implications of not giving feedback to supervisees. One conclusion from this review was that difficult feedback is often related to the boundaries of supervision itself, and therefore training regarding supervision boundaries would be helpful.

Teaching is another role undertaken by clinical child psychologists. While many students in doctoral psychology programs have an interest in pursuing an academic career, most do not receive formal training in instruction (Wimer, Prieto, & Meyers, 2004). Wimer et al. (2004) review the literature on the scholarship of teaching, which indicates that overall the training for teaching in the field of psychology is cursory and inconsistent across programs, often lacks an assessment process to ensure adequate training, and lacks appropriate follow through when the student actually begins teaching. Wimer et al. also describe and review research supporting the acquisition of effective teaching skills, including seminars and coursework, "microteaching," videotaped feedback, and mentoring with regard to specific teaching skills such as syllabi preparation.

2.2.3.5 Management and Administration

Historically, managers and administrators in the field of clinical psychology have "risen up from the ranks" of their peers over time with little or no formal training related to their leadership position. Similarly, training programs often give little attention to the business skills needed to run a practice. While Rodolfa et al. (2005) include *management and administration* as a core competency requiring specific training, there are in fact very few programs currently that formally address this competency within the curriculum (O'Mahen & Sloan, 2006). Some recent graduates and faculty, within programs offering management and administration, with applied experience

(i.e., practicum or internship) have published descriptions of their framework (Campbell, Buhrow, & Liebscher, 2000; O'Mahen & Sloan, 2006; Zvolensky, Herschell, & McNeil, 2000). For example, a management practicum experience developed at George Fox University in Newberg, Oregon, details the training objectives and methods in the two broad areas of clinical management and administrative management (Campbell et al., 2000). Clinical management training objectives include practice-oriented skills such as clinical supervision, client case-load management, and training new counselors. The authors also present administrative training objectives that pertain to the systems or organizational level, including working with and developing constituencies, understanding organization funding, and developing programs and policies (Campbell et al., 2000). Zvolensky et al. (2000) similarly describe a 1-year graduate assistantship in administration in which the graduate student is mentored by the director of clinical training. The training objectives of this assistantship are broadly defined as acquiring the content knowledge and skills needed to function in the capacity of a director. The student acquires knowledge regarding training models, accreditation guidelines, policies, ethical guidelines, and broad social issues that impact the field. Additionally, the student is expected to gain experience and skill in organizational and administrative tasks, written communication, program review and evaluation, and understanding how to conduct oneself professionally in an administrative role.

2.2.3.6 Reflective Practice and Self-Assessment

Rodolfa et al. (2005) provide the following definition of a competency in reflective practice and self-assessment: "Practice conducted within the boundaries of competencies, commitment to lifelong learning, engagement with scholarship, critical thinking, and a commitment to the development of the profession." The notion that self-assessment might serve as a core element of clinical training is based on several assumptions. The first assumption is that no matter how specialized a graduate training program may be actual practice will require knowledge and skill that is even further specialized. The second assumption is that as one remains in the profession, new advances in the field will require continued education. State licensure renewal often requires some continuing education; however, this is not required in all states. The third assumption is that psychology's value will continue to expand into a number of other fields and markets, such as clinical health psychology (Belar et al., 2001), requiring one to apply self-assessment techniques in order to acquire the skill and knowledge to match these new opportunities.

While many have described graduate training as "learning how to learn," Belar et al.'s (2001) description of the need for graduate coursework in self-assessment perhaps exemplifies this idea best. These authors describe a template of self-assessment that goes beyond a student's graduate training and can be used throughout their professional career. This template addresses a number of questions that relate to prerequisite knowledge and skill in several core domains. For example, questions may consist of assessing one's knowledge of the biological bases of diseases and cognitive bases of behavior. This model is derived from the biopsychosocial approach and emphasizes the interaction between biological, cognitive, affective, and social processes as they relate to a client's physical and mental health. The authors also offer a number of resources (journals, handbooks, public policies, etc.) as well as activities (contacting relevant colleagues, performing literature reviews, creating peer learning groups, etc.) that can fulfill the ongoing training needs identified through self-assessment (Belar et al.).

2.3   Expert Competencies

The "Basic Competencies" section of this chapter is meant to be an inclusive grouping of the many competency domains suggested by Roberts et al. (1998), Spirito et al. (2003), and Rodolfa et al. (2005). However, it could be argued that some of the domains listed above are actually expert competencies. For example, *disease process and medical management* may not represent a core competency for all clinical child psychologists, but rather an expert competency for those specializing in pediatric psychology. Also, though most would agree that *scientific knowledge and methods* is a core competency necessary for all clinical child psychologists, some might argue that the *research and evaluation* competency is an expert competency for those taking positions in academia. Similarly, the *supervision and teaching* and the *management and administration* competencies could also be considered expert competencies, as these two competencies require that the clinical child psychologist be fairly competent in all of the other areas first.

There is a developmental progression relevant to all of the competencies discussed. That is, clinical child psychologists begin as novices and (ideally) develop increasing levels of competence, though perhaps at different rates for each competency. As noted previously, Rodolfa et al.'s (2005) cube model defines five stages of professional development for psychologists: (1) doctoral education, (2) predoctoral internship, (3) postdoctoral supervision, (4) residency/fellowship, and (5) continuing competency. Rodolfa et al. also suggest these basic stages could also be broken down into more discrete stages. For example, the first stage (doctoral education) is one of the stages where the greatest amount of change occurs. Ideally, competencies in clinical child psychology grow considerably throughout the doctoral education. First-year graduate students begin with a full course load and may obtain an initial practicum experience. Thus, early forms of training for most of the competencies include lectures, seminars, videotapes, directed readings, and other related course work (Spirito et al., 2003). Regarding applied experiences, Spirito et al. also endorse the "see one, do one, teach one" (p. 88) model. That is, training experiences in a practicum setting include observing more experienced clinicians at work and then being supervised while working with clinical cases. As students progress through doctoral training, they may also obtain experience in training more recent entrants to the program. By the end of their doctoral training, students typically have experienced a range of general courses, electives, and practica, and students in Ph.D.-granting programs have taken the lead on at least one major research project. Thus, significant development toward expertise occurs during graduate training.

The second and third stages presented in the cube model (i.e., predoctoral internship and postdoctoral supervision) represent periods in the training of clinical child psychologists where significant development may occur in a short amount of time. That is, the predoctoral internship lasts 1 year, and postdoctoral supervision and training typically lasts about a year or two. Additionally, most clinical child psychologists omit the fourth stage (i.e., residency/fellowship), but it does provide another possible opportunity for further development. The relative rapid progression through the predoctoral internship and postdoctoral supervision stages has been identified as a particularly important time for the training of clinical child psychologists. On this point, and in addition to their ten proposed competencies, Roberts et al. (1998) recommend that training programs provide "specialized applied experiences" for aspiring clinical child psychologists. Specifically, they advise that these experiences emphasize the ability of the psychologist to adapt by learning to work with children that vary in terms of age, ethnicity,

and clinical problems (e.g., internalizing, externalizing, and developmental problems), as well as children that are treated in diverse settings (e.g., such as clinics, schools, and hospitals) using varied assessment and intervention methods. They also suggest that the training experiences involve professionals from other disciplines, such as pediatricians, social workers, teachers, and other types of therapists. Furthermore, Roberts et al. emphasize that these specialized applied experiences be supervised by psychologists with competence in the aforementioned competencies. Thus, a critical feature of the Roberts et al. model is that a range of specialized applied experiences, with increasing independence, will promote the needed adaptability of the clinical child psychologist. Adaptability and independence are hallmark features of expertise.

The last stage of the cube model (continuing education) also presents opportunities for competency development (Rodolfa et al., 2005). This stage begins with the end of postdoctoral supervision (or residency/fellowship when applicable) and continues through retirement. Thus, the last stage may span 30 years or more. As should be evident from this chapter, there is no single universally agreed upon model of core competencies. Even if the broader field of professional psychology or the narrower field of clinical child psychology is able to reach a universally accepted model, there will come a time when that model is outdated due to advancements and other changes in the field. Similarly, even if a practitioner is deemed "competent" today, there is no guarantee of continued competence. This point is emphasized by Falender and Shafranske (2007), who describe competence as a dynamic, rather than static construct. The dynamic nature of competence will therefore require significant continuing education in clinical child psychology.

One issue that is not addressed by the cube model is competency as it relates to the granting of a terminal master's degree in clinical psychology. Hays-Thomas (2000) discusses some of the "pros and cons" of the terminal master's degree in psychology. On the con side, some believe that a master's degree is insufficient training for independent practice, and some authors view mental health care providers with a master's degree as a low-cost competitor to doctoral-level psychologists. On the pro side of terminal master's programs in psychology, there are several other types of professionals with master's degrees providing psychological services. For example, social workers, art therapists, and counselors can be licensed (and can independently bill insurance companies for psychological services), within their respective professions, with a master's degree. Therapists with a master's degree in clinical psychology, on the other hand, cannot be licensed as a psychologist in most states. Some proponents of terminal master's degree programs have argued the value of a specific license for master's level psychologists (Hay-Thomas, 2000). This debate is particularly relevant when discussing competencies. Should master-level therapists have the same basic competencies as a doctoral-level psychologist? If not, which competencies would be different? In many states, professionals with a master's degree in psychology can be licensed as a psychological associate (or with a similar title) but still need supervision from a doctoral-level psychologist. Thus, in these states supervision would be an important competency for the doctoral level but not the master's level.

As part of defining expertise, it is also important to consider how to assess basic and expert competencies. As recently as 2005, Roberts, Borden, Christiansen, and Lopez asserted "we chose not to delineate *how* competence should be measured. Instead, key principles and considerations were articulated as necessary for the development of processes and measures to assess trainees' and professionals' competence" (p. 356). Nevertheless, Roberts et al. make

a number of suggestions that could lay the groundwork for future efforts to evaluate the competencies assembled here. First, competency assessments should attempt to foster a link between formative and summative competence. For example, ongoing formative assessments of competencies should relate meaningfully to summative, "end stage" assessments of competence such as oral examinations or dissertation defenses in which the young professional is deemed to have "passed or failed." To facilitate this, important clinical values and attitudes must be assessed, while change in assessment, intervention, and therapy skills would also need to be monitored. Development of important clinical skills might be monitored by clinical supervisors on a weekly basis, whereas changes in attitudes and values could be measured programmatically on an annual (summative) basis. Unfortunately, the "best methods" for assessing the competencies presented here have scarcely been evaluated and might vary greatly depending upon the nature or type of skills being assessed.

Though Roberts et al. (2005) stop short of making specific methodological recommendations for the assessment of clinical child psychology competencies, they identify a number of potentially worthwhile approaches. Among their recommendations were "360-degree" assessments commonly found in business environments. Such evaluations typically involve "feedback" on performance from coworkers, supervisors, and subordinates. Another recommendation involves the use of "standardized patients," a method of competence assessment sometimes employed in medical school settings that might be very well suited to the evaluation of assessment and intervention competencies. A variation of the use of standardized patients may be the development of standardized "role plays" or "simulations" of clinical situations. For example, a graduate student could be asked to provide simulated feedback from a recent psychoeducational evaluation to an anxious parent. Other techniques for facilitating assessment of competence might involve the use of self-assessments and the development of clinical or research portfolios.

2.4   Summary

This chapter presented and integrated three competency models in clinical child psychology, pediatric psychology, and the broader field of professional psychology. Throughout the chapter, many distinctions between clinical child psychology and clinical adult psychology were made, and pediatric psychology was conceptualized as a subspecialty of clinical child psychology. There was considerable overlap between the three competency models, and an attempt was made to integrate the unique competencies included in each model. The integrated model included 17 competencies that were placed in one of three broad domains. The *conceptualizing psychological health* domain includes: (1) child, adolescent, and family assessment, (2) life span developmental psychology, (3) life span developmental psychopathology, (4) diversity issues, (5) social issues, and (6) disease process and medical management. The *promoting psychological health* domain includes: (7) intervention strategies, (8) relationships, (9) prevention, family support, and health promotion, (10) role of multiple disciplines and service delivery systems, and (11) consultation and liaison roles. Finally, the *scientific and professional issues* domain includes: (12) scientific knowledge and methods, (13) research and evaluation, (14) professional, ethical, and legal issues, (15) supervision and teaching, (16) management and administration, and (17) reflective practice and self-assessment. Although there is no

universally agreed upon competency model for clinical child psychology, this integrated group of competencies appears to be a promising way to foster continued conversation about child clinical training.

This chapter also included some discussion of expert competencies, though there has been much less discussion of expert competencies in the literature. Some of the basic competencies reviewed may be viewed specialized or expert competencies (e.g., disease process and medical management, management and administration) that may not necessarily be a core competency necessary for all clinical child psychologists. It is also important to note that some of the competencies have been described as *cross-cutting* competencies that can be integrated within all of the other competencies (Rubin et al., 2007). For example, the competency in diversity issues influences competencies in assessment, treatment, and research. In fact, none of the competencies stand alone. Any two competencies taken at random have an important relationship together, thus expertise might truly come from being able to integrate competencies. That is, assessment and intervention are two distinct competencies; however, expertise comes from being able to effectively use the assessment to design and modify the intervention. Furthermore, other influences shape both the assessment and intervention, such as developmental, sociocultural, interdisciplinary, and ethical factors that have been identified through research.

As clinical child psychology begins to address these competencies, much more attention will need to be devoted to the assessment of competency. For years, graduate programs, internships, and postdoctoral training programs have approached competency assessment idiosyncratically. Grades typically serve as proxies for content knowledge, and grades and feedback (sometimes written and/or oral) are typically given for practice and internship performance. High-stakes examinations such as clinical competency exams, and oral or written final examinations are also offered in many programs prior to formal acceptance for doctoral degree candidacy or prior to approval for the predoctoral internship. Research competencies are typically assessed indirectly through acceptance of research proposals and successful defenses of master's theses and doctoral dissertations. After graduate training, internship, and postdoctoral work, psychologists must also take the Examination for the Practice of Professional Psychology (EPPP) to practice independently. The EPPP covers several (but not all) of the competencies discussed in this chapter. A major limitation of the EPPP is that it assesses knowledge, but not the more functional aspects of service delivery (e.g., clinical skills). Also, after early career psychologists pass the EPPP, there is little if any way to assess professional competence.

Leigh et al. (2007) discuss possible models for the assessment of ongoing competence for practicing psychologists. Some of the possibilities include measures of: (a) knowledge, (b) decision making, (c) performance and personal attributes, and (d) practice-based skills and tasks. Though the need for continued assessment of child psychology competencies seems obvious, there seems to be little data to support this assertion. Do child therapist competencies erode? Do research competencies require updating? Should the profession allow for increased specialization (which would entail the loss of some competencies in favor or potentially, highly specialized competencies)? Interestingly, the answers to the questions posed above, require the adoption of what Roberts et al. (2005) called a "culture of assessment" to develop around the existing "culture of competence." Whether a culture of assessment develops will determine in large part how future debates about clinical competence in child psychology evolve.

3 Ethical and Legal Issues

Genevieve L. Y. Arnaut · Dave A. Hill

Abstract: The ability to identify, understand, and resolve ethical and legal issues is an important competency for clinical psychologists. In this chapter we provide basic definitions of this ethical and legal territory and provide a rationale for why every psychologist must pay careful attention to this area, including providing competent services as well as meeting a minimum standard of care as part of risk management. We next give an overview of basic competency in this area, based on the National Council of Schools and Programs in Professional (2007) and Assessment of Competency Benchmarks Work Group (2007) approaches to competency as a psychologist. Both approaches highlight the fact that ethical and legal issues are present from the very beginning of training in clinical psychology and that a developmental course in competence is expected. The models complement each other in that one offers a view of ethics and legal issues as a general foundational competency underlying all of a psychologists (or trainee's) activities, whereas the other model points to knowledge, skills, and abilities required in specific areas of practice. Subsequently, we consider aspects of competency that might be required of an expert (i.e., a psychologist entering professional practice): the ability to identify and sort through complex ethical and legal issues as well as to access resources for resolving these issues, and the application of one particular resource – ethical decision-making models – to resolve dilemmas.

3.1 Overview

Ethical and legal issues form part of the fabric of every clinical psychologist's daily activities, and the ability to identify and resolve these issues is an important aspect of professional competency. As such, ethical reasoning and judgment as well as knowledge of legal standards have figured prominently in two large-scale efforts to identify and provide measurable indices for competencies in clinical psychology: the Competency Developmental Achievement Levels (DALs) developed and approved by the membership of the National Council of Schools and Programs in Professional Psychology (NCSPP, 2007) and the Assessment of Competency Benchmarks Work Group convened by the American Psychological Association (APA) Board of Educational Affairs (Assessment of Competency Benchmarks Work Group, 2007).

In this chapter, we first provide some basic definitions of the ethical and legal territory we will be addressing. We then give an overview of the basic competency required in this area, based on the NCSPP (2007) and Assessment of Competency Benchmarks Work Group (2007) approaches. Subsequently, we consider aspects of competency that might be required of an expert: the ability to identify and sort through complex ethical and legal issues as well as to access resources for resolving these issues, and the application of one particular resource – ethical decision-making models – to resolve dilemmas.

3.1.1   Basic Definitions

According to the APA Committee on Professional Practice and Standards (2003), ethics "is defined as the rules or standards governing the conduct of members of a profession" (p. 595), whereas legal issues derive from "the body of rules governing the affairs of persons within a community, state, or country" (p. 596). Legal issues can be addressed through reference to state and federal statutes, state administrative regulations, and case laws. The primary resource for standards of conduct for psychologists is the APA's (2002b) Ethical Principles of Psychologists and Code of Conduct (referred to hereinafter as the Ethics Code). The Ethics Code contains five aspirational general principles (Beneficence and Nonmaleficence, Fidelity and Responsibility, Integrity, Justice, and Respect for People's Rights and Dignity). In addition, the Ethics Code contains ten ethical standards that are presented as obligations in the following areas: (a) Resolving Ethical Issues, (b) Competence, (c) Human Relations, (d) Privacy and Confidentiality, (e) Advertising and Other Public Statements, (f) Record Keeping and Fees, (g) Education and Training, (h) Research and Publication, (i) Assessment, and (j) Therapy.

An additional basic resource for psychologists with respect to specific areas of psychological practice is found in the practice guidelines (APA, 2002a). For example, available practice guidelines include the *Guidelines for Psychotherapy with Lesbian, Gay, and Bisexual Clients* (APA, Division 44/Committee on Lesbian Gay, and Bisexual Concerns Task Force on Guidelines for Psychotherapy With Lesbian, Gay, and Bisexual Clients, 2000), *Guidelines for Providers of Psychological Services to Ethnic, Linguistic, and Culturally Diverse Populations* (APA, Office of Ethnic Minority Affairs, 1993), *Guidelines for Psychological Evaluations in Child Protection Matters* (APA, Committee on Professional Practice and Standards, 1999), and the *Specialty Guidelines for Forensic Psychologists* (Committee on Ethical Guidelines for Forensic Psychologists, 1991). Such guidelines are aspirational rather than mandatory or exhaustive and were created for the purposes of education and information (APA, 2002a). A more exhaustive discussion of resources is provided below.

The ability to resolve ethical and legal issues is important for several reasons. First, as noted above, standards in the Ethics Code (APA, 2002b) represent obligations for psychologists. Indeed, the first standard presented in the Ethics Code, Standard 1, requires that psychologists resolve ethical issues. In the second standard, Standard 2.01a, Boundaries of Competence are discussed: "Psychologists provide services with populations and in areas only within the boundaries of their competence, based on their education, training, supervised experience, consultation, study, or professional experience" (APA, 2002b, p. 1063). Thus, at the risk of presenting circular reasoning, it is clear that psychologists are required by the Ethics Code to work within the boundaries of their competence, and as we will see below, one aspect of competence is knowledge of ethical and legal issues.

These professional obligations are closely tied to the second reason that psychologists must be aware of ethical and legal issues: Psychologists may be subject to unfortunate consequences if they are found through investigation to have violated ethical or legal requirements. A violation of a legal requirement may result in an action against the psychologist's license (Bennett et al., 2006). In Oregon, for example, sanctions listed in the relevant statute include the following: denial of a license to any applicant, refusal to renew a license, suspension of the license for a period of not less than 1 year, issuance of a letter of reprimand, imposition of probation with authority to restrict the scope of practice of a psychologist or to require practice under supervision, revocation of the license, or imposition of a civil penalty not to exceed \$1,000 (Oregon Revised Statutes, 2007). Violations of Ethics Code guidelines that are not codified in state licensing law can

nonetheless serve as the basis for a complaint and subsequent action against a psychologist's membership in APA or a state or provincial psychological association (Bennett et al., 2006).

Failing to follow a professional standard of care may also result in a malpractice claim (i.e., a psychologist could be sued in a civil court for monetary damages). Bennett et al. (2006) listed four essential components of a malpractice claim: (a) there must have been a duty between the professional and the client, (b) there must have been damage to the client, (c) the professional must have deviated from professional norms (referred to as reasonable standards of care), and (d) there must be a direct link between the professional's behavior and the damage sustained by the client.

Thus, as Bennett et al. (2006) noted, when a psychologist has a professional relationship with a client, he or she incurs a duty to use a reasonable standard of care. The Ethics Code authors (APA, 2002b) provided a definition for the term "reasonable" with respect to ethical standards: "[T]he prevailing professional judgment of psychologists engaged in similar activities in similar circumstances, given the knowledge the psychologist should have had at the time" (p. 1061). However, the authors of the Ethics Code addressed the relationship between the Ethics Code and civil liability as follows:

► The Ethics Code is intended to provide guidance for psychologists and standards of professional conduct that can be applied by the APA and by other bodies that choose to adopt them. The Ethics Code is not intended to be a basis of civil liability. Whether a psychologist has violated the Ethics Code standards does not by itself determine whether the psychologist is legally liable in a court action, whether a contract is enforceable, or whether other legal consequences occur. (p. 1061)

In spite of the absence of a direct link between the Ethics Code and civil liability, it certainly behooves the prudent psychologist to be aware of prevailing standards of care. Bennett et al. (2006) stated that the incidence of malpractice claims had been relatively stable over the 10 years prior to publication of their book; however, in that same period, the risk of a licensing board complaint had increased greatly. Although the authors noted that an exact calculation of the number of ethics complaints is difficult for a number of reasons, they provided the following estimate: About 1% of psychologists experience a licensing board complaint or malpractice claim annually. Van Horne (2004) found a comparable estimate in a survey of all licensing boards in USA and Canada. For each year from 1996 to 2001, complaints were filed (but not necessarily investigated) for about 2% of licensed psychologists each year. Fewer than 20% of complaints led to disciplinary actions against a psychologist.

Certain areas of practice appear to carry with them higher risk than others. Based on data from the APA Ethics Committee for the prior 10 years, Bennett et al. (2006) provided the following ranked list of the most common types of disciplinary actions by the committee:

- Sexual misconduct (adult)
- Nonsexual dual relationship
- Insurance/fee problem
- Child custody
- Confidentiality
- Practicing outside competence
- Inappropriate follow-up/termination
- Test misuse
- Termination/supervision

- False, fraudulent, or misleading advertising
- Sexual misconduct (minor)
- Inappropriate response to crisis

Clearly, most of these behaviors are addressed directly in the Ethics Code (APA, 2002b). Therefore, by acting in accord with ethical standards, many malpractice claims and complaints to licensing boards may be avoided. Along these lines, Bennett et al. (2006) noted that ethical principles are the foundation of good risk management, and ethical principles and standards can guide behavior in situations where laws do not. In the next section, we discuss what is involved in gaining competence in this area.

3.2   Basic Competencies

Having demonstrated why a psychologist is obliged to gain competence in dealing with ethical and legal issues, we now address how such competence might be defined and measured. To do so, we explore how two psychological associations with a stake in the training of psychologists have conceptualized skills needed for competent ethical and legal reasoning and behavior across various stages of training and practice in psychology, from the beginning of graduate practicum training to either graduation or the beginning of independent practice.

In the NCSPP (2007) model, ethical and legal reasoning is considered to be an integral part of each of the seven identified competencies (relationship, assessment, intervention, diversity, research/evaluation, management/supervision, and consultation/education), rather than a separate competency. In the Assessment of Competency Benchmarks Work Group (2007) approach, however, skill in the area of ethical and legal standards and policy is considered to be a foundational competency in its own right, on equal footing with five other foundational competencies (reflective practice/self-assessment, scientific knowledge/methods, relationships, individual/cultural diversity, and interdisciplinary systems). These foundational competencies are conceptualized as a necessary base underlying an additional six functional competencies involved in functions or tasks that a psychologist carries out (assessment–diagnosis–case conceptualization, intervention, consultation, research/evaluation, supervision-teaching, and management/administration).

It might be noted that individual schools are not required by APA accreditation standards to adopt either of these models and in fact may modify them or develop their own (APA, 2008). Thus, for example, the faculty at our school (Pacific University School of Professional Psychology) adopted the seven basic competencies identified by NCSPP but elected to break out professional and ethical knowledge, reasoning, and judgment as a competency in its own right. We now turn to a discussion of these two approaches.

3.2.1   The Assessment of Competency Benchmarks Work Group Approach

The Assessment of Competency Benchmarks Work Group (2007) identified three aspects of competency in addressing ethical and legal issues: (a) knowledge, (b) awareness and application of ethical decision-making model, and (c) ethical conduct. For each of these three aspects, the

authors then considered three developmental levels: readiness for practicum, internship, and entry into practice. At each developmental level, the essential component of each skill was identified, as were behavioral anchors and assessment methods. We consider each of the three broad areas of competency in ethical and legal issues in turn.

3.2.2 Knowledge

Not surprisingly, the APA Ethics Code and legal resources/requirements figure prominently in the knowledge required at each of the three levels. As one prepares for practicum, only a "basic knowledge" of the APA Ethics Code is required, along with a "rudimentary knowledge of legal and regulatory issues" (p. 25). This knowledge is assumed to be shown and measured in coursework and class discussion.

As one prepares for internship, a "working knowledge" (p. 25) of the Ethics Code and legal sources is desired, and this level of knowledge is now measured through behavior and not just coursework. For example, a student is expected to identify ethical dilemmas, actively consult with supervisors, and include ethical and legal issues in case conceptualizations. The student should also recognize the limits of his or her own competence. Such knowledge is assessed through self, peer, and supervisor assessment; direct observation; ratings from clients; and comprehensive examinations.

By the time a candidate is ready to enter independent practice, he or she is expected to have a "routine command and application" (p. 25) of the Ethics Code and other ethical, legal, and professional standards and guidelines. The practitioner should be able to identify and analyze more complex legal and ethical issues and proactively address them. In addition, he or she should identify potential conflicts in ethical and legal issues and be aware of the needs to confront peers or organizations when the need arises. Behaviorally, this readiness is measured through performance in the Examination for Professional Practice in Psychology (EPPP) and regional jurisprudence examinations required for licensure as well as through supervisors' evaluations, self-evaluations, and client feedback.

3.2.3 Awareness and Application of Ethical Decision-Making Model

Turning to decision making, as students get ready for practicum, they should be able to recognize the importance of basic ethical concepts relevant to initial practice (e.g., confidentiality and informed consent). As with knowledge, this ability is again assumed to be displayed and measured in classwork and discussions. As students prepare for internship, they should be able to know and apply an ethical decision-making model to specific dilemmas. This skill is demonstrated behaviorally in supervision and other aspects of practicum (e.g., presentations). Proposed measurements include self- and supervisor evaluations, comprehensive examinations and oral evaluations, peer cases in group supervision, and creation of hypothetical ethical dilemmas and resolution.

At the time of entry into practice, the practitioner should also show a "commitment to integration of ethics knowledge into professional work" (p. 26). This commitment is measured by the inclusion of ethics in professional writing, research, teaching, and training. In addition, the entry-level psychologist should have a strategy for seeking consultation for resolving ethical

and legal dilemmas. Competency is measured by supervisor evaluations, self-evaluations, performance in regional exams and in the EPPP, peer review of writings, performance reviews, and in mock vignettes.

3.2.4   Ethical Conduct

The final area of ethical and legal issues, ethical conduct, involves displaying "ethical attitudes and values" (p. 28) as one prepares for practicum. Behaviorally, this could include the following: desire to help others, openness to new ideas, honesty and integrity, personal courage, appropriate boundary management, and implementation of ethical concepts into behavior. Note that, with the possible exception of the final item on the list, these attributes do not necessarily refer to professional but may reflect personal ethical attitudes and values. Assessment occurs through judgment by faculty and peers and evaluation of behaviors by the program.

At the time of entry to internship, the student is expected to have become more aware of the underpinnings (i.e., the moral principles and ethical values) of the ethical attitudes and behaviors that should already have been displayed prior to practicum. Behaviorally, this skill is seen in the student's abilities to identify and discuss his or her principles and values as well as to discuss areas where personal and professional values meet. The student and the supervisor assess the student's proficiency in this area, and the assessment also occurs through comprehensive examinations and demonstrated behavior and decision making in professional activities.

Finally, ethical conduct at the time of entry into practice ideally incorporates independent and confident integration of ethical and legal standards with the other functional and foundational competencies. Behaviorally, this skill is demonstrated when the practitioner shows an understanding of ethical and legal standards when engaged in functional competencies, demonstrates that decision making in ethical and legal realms "informs and is informed by all foundational competencies" (p. 28), and takes responsibility for continuing professional development in this area. Assessment occurs through supervisor ratings and feedback from colleagues, and competence is also seen in an absence of complaints and "willingness to serve professionally in the ethics arena" (p. 28).

3.2.5   The NCSPP Approach

As noted above, in the NCSPP (2007) model, ethics and professionalism are included under each of the seven competencies rather than being discussed as a separate competency. As was the case in the Assessment of Competency Benchmarks Work Group (2007) model, three developmental levels are addressed: beginning practicum, beginning internship, and completion of the doctoral degree. The first two levels match the Assessment of Competency Benchmarks Work Group approach. The third level, completion of the degree, was selected rather than readiness for practice in recognition of the fact that independent practice in most states begins at least a year after graduation due to postdoctoral requirements for licensure. NCSPP programs only have oversight of students in an official capacity through graduation rather than through licensure.

In addition to breaking up competency according to three levels of practice, the NCSPP (2007) workgroups also identified separate knowledge, skills, and attitudes required for competency at each developmental level in each domain. Unlike the Assessment of Competency Benchmarks Work Group (2007) model, there are no specific behavioral assessment methods tied to the knowledge, skills, and attitudes. Presumably, the requisite knowledge, skills, and abilities would be assessed in practicum settings, coursework, and examinations at a minimum. Because a discussion of all of these competencies would be exhaustive, examples from two representative domains – assessment and relationship – will be presented.

3.2.6 Assessment Competency

Ethical knowledge with respect to assessment that is required to begin practicum includes basic knowledge of ethical assessment, familiarity with ethical issues and potential conflicts, and familiarity with external resources (including supervisors). By the time a student goes on internship, she or he is expected to have a more thorough knowledge of legal and ethical principles and guidelines involved in assessment and knowledge of potential courses of action. By the time the doctoral degree is completed, the student is expected to have a "refined and sophisticated knowledge of ethical and legal issues related to assessment" (p. 7).

Skills desired at the time of entry into practicum include the abilities to support decisions about actions, differentiate self from client needs, and use supervision constructively. At the time of internship, a student is expected to have the ability to identify potential legal and ethical issues and address these in supervision. By the time of graduation, the student should be able to apply relevant legal and ethical principles to the assessment situation, seek consultation, make referrals based on legal and ethical principles, and "delineate limitations of assessment data sources" (p. 8).

In terms of attitudes, the student beginning practicum is expected to have respect for relevant ethical standards throughout the assessment process. By the time of internship, the student should have a willingness to critically examine test results with respect to both diverse populations and normative data and to examine the applicability of ethical and legal issues within diverse populations. At the time of graduation, the student ideally should be able to integrate respectful attitudes and objectivity into an ethical professional identity and lifelong learning.

3.2.7 Relationship Competency

Ethical knowledge related to relationship competency that is required to begin practicum includes a "basic knowledge of ethics" (p. 15). By the time a student goes on internship, she or he is expected to have an understanding of legal and ethical requirements of the profession and "how they relate to developing professional relationships" (p. 15), as well as knowledge of common ethical dilemmas they might encounter in populations with which they have experience. By the time the doctoral degree is completed, the student is expected to have adequate knowledge of recent judicial and legislative decisions relevant to complex ethical issues in relationships as well as understanding of the complex nature of ethical standards and guidelines and of models of ethical decision making with respect to relationships.

Skills desired at the time of entry into practicum include the abilities to identify and discuss some ethical issues in relationships and to be "self-reflective" (p. 15) under stress and in several areas: power/privilege, motivation, manipulation, cultural difference, and systemic context. At the time of internship, a student is expected to have the ability to articulate some level of comprehension of legal and ethical requirements and how they relate to professional relationships, to identify ethical dilemmas and associated relational issues, and to self-correct "inconsistencies in verbal and nonverbal behavior and in use of power" (p. 15). By the time of graduation, the student should be able to apply relevant legal and ethical principles across a variety of situations involving relationship issues, with boundaries identified as particularly important in this regard; consistently demonstrate "appropriate use of power in relationships" (p. 15); appraise and adopt a model of decision making and apply it with "personal integrity and cultural competence" (p. 15); and seek and provide consultation with respect to relationships.

In terms of attitudes, the student beginning practicum is expected to value ethical behavior, basic self-care, care of others, and the role of training and the profession of psychology, as well as to respect the self, others, and the profession. By the time of internship, the student should recognize others' "autonomy and differences" (p. 16) and demonstrate respect for self and others and the profession, both verbally and nonverbally. At the time of graduation, the student ideally should value social justice, should have internalized both the Ethics Code and "sense of principled judgment" (p. 16) and be able to apply them as needed, and should value lifelong learning about relationships and ethics.

3.2.8 Comparing the Two Approaches to Competency

As one can see from the above descriptions, there are some basic similarities between the NCSPP (2007) and Assessment of Competency Benchmarks Work Group (2007) approaches. First, both work groups clearly saw the need to differentiate competencies according to professional development level, with the student/practitioner becoming more independent over time as well as developing more sophisticated analytic and decision-making skills. Implicit in this acknowledgement of the need to develop and refine skills over one's professional career is a recognition of the complexity of decision making in this arena. Second, both groups also recognized that competency in this area is multifaceted and requires a variety of knowledge, skills, and abilities that can be differentiated and assessed. Third, both approaches clearly refer to an ability to identify, access, and use resources for ethical and legal decision making and behavior. The Assessment of Competency Benchmarks Work Group explicitly referred to the Ethics Code as a resource, whereas the NCSPP group did not, but the Ethics Code would clearly be a resource that is appropriate in the NCSPP system. Finally, both approaches refer to the ability to use ethical decision-making approaches to assist in resolving dilemmas.

One can also see some basic differences in approach. Developers of the Assessment of Competency Benchmarks Work Group (2007) model conceptualized ethics as a foundational competency that has similarities across many domains of functioning as a psychologist, whereas the NCSPP workgroups conceptualized ethics as, at least to some extent, being specific to the individual domains of competency. As a result, the NCSPP guidelines include content specific to each competency area, whereas the Assessment of Competency Benchmarks Work Group competencies are more general. Thus, for example, in the NCSPP approach, relationship ethics stress issues of power and autonomy that are not explicitly identified in the assessment

ethics. Similarly, valuing social justice was identified as an important attitude for ethical professional relationships but was not identified for ethical assessment practice.

The differences in these approaches may to some extent mirror the curriculum in many professional schools. Thus, for example, licensing laws require that a separate foundational ethics course be taken by a candidate for licensure (e.g., Oregon Administrative Rules, 2008), and APA (2008) requires that students be exposed to current knowledge in professional standards and ethics in their graduate clinical psychology curriculum. Yet, it is also quite likely that the licensure applicant took courses in which he or she also learned specific ethics related to certain work settings or populations. Thus, an assessment course will typically include discussion of ethical standards related to the development and application of assessment instruments, and a forensics course would likely contain discussion of appropriate specialty guidelines relevant for forensic practitioners.

Is either of these approaches to competency in ethical and legal issues preferable? Without clear research to guide us, an answer to this question would rest primarily on speculation. However, a reasoned response might suggest that neither is necessarily superior; just as a standard curriculum would include a foundational ethics course and additional instruction in ethics for given applications and populations, we might also expect that the practitioner should have some foundational skills, knowledge, and attitudes that can be applied across many situations as well as knowledge, skills, and attitudes that lend themselves to resolution of ethical and legal issues involved in work with specific applications and populations. In addition, evolving areas of practice that are impacted by new technologies such as the Internet may necessitate discussion regarding how established standards and guidelines apply in new contexts. This endeavor would be aided by reference to foundational principles that cut across specific applications, but – as will be discussed more fully below – it may also necessitate standards and recommendations specific to this new technology as well.

The two models of competency presented describe the desired developmental course from initial graduate practicum training through the point of finishing internship and/or readying to enter independent clinical practice. In the next sections, we discuss what is involved in becoming an expert in the areas of ethical and legal decision making as the individual moves into independent practice. Based on the models of competency discussed above, we believe that some areas of commonality across the two models point to the knowledge, skills, and abilities required for expert competence in this area. Thus, we discuss the acknowledged complexity of ethical and legal issues and the need to access appropriate resources for resolution of dilemmas. In particular, we look in depth at the use of one particular resource: the application of ethical decision-making models to specific situations as a means of resolution.

3.3 Expert Competencies

3.3.1 Complexities of Ethical and Legal Issues

One of the fundamental skills involved in resolving ethical and legal issues is an ability to identify and understand the complex ethical and legal issues in the first place. Miller (2008) provided a clear framework for ethical and legal issues that may be used as a first step in approaching this complexity. The four broad ethical issues discussed in this framework were competence, informed consent, confidentiality, and multiple relationships. Within each broad ethical issue,

Miller identified several components; for example, the broad issue of competence was comprised of five more specific skills: (a) selecting relevant assessment methods and devices, (b) administering and interpreting each assessment device, (c) integrating assessment information into testable hypotheses and diagnostic formulations, (d) utilizing evidence-based treatments, and (e) monitoring treatment outcomes. Miller identified three primary legal issues of concern to practitioners: duties to the profession of psychology (including practicing within one's scope of practice and maintaining clinical records), duties to clients (treatment issues and protection of client confidentiality), and duties to third parties.

Miller's (2008) straightforward approach is a useful distillation that at first glance might suggest that ethical and legal considerations can be relatively easily separated and identified. However, a closer look at Miller's careful analysis of these issues suggests that in practice such separation may not be readily achievable or apparent. For example, Miller noted that confidentiality is addressed in Standard 4 of the Ethics Code (APA, 2002b) but also commented that there may be legal requirements or exceptions to confidentiality. Along these lines, as noted above, many states have adopted the Ethics Code as part of the laws or regulations governing the practice of psychology in that state. Thus, if one is acting in accord with ethical principles, one may also be acting in accord with statutes or administrative regulations, which then blurs the distinction between ethical and legal issues.

A second complicating factor in distinguishing ethical and legal issues is that the opposite may be true; that is, in some cases, the law may not look to or follow ethical standards but may in fact conflict with such standards. In other cases, one compelling legal doctrine or law may supercede another. For example, a psychologist who receives a subpoena directing him or her to appear in court – along with therapy notes – to testify in a client's divorce case has to balance the ethical standard of confidentiality and parallel legal standard of privilege with a direct order from the court that contradicts these ethical and legal standards. In such cases, Standard 1.02 of the APA (2002b, p. 1063) Ethics Code states as follows:

► If psychologists' ethical responsibilities conflict with law, regulations, or other governing legal authority, psychologists make known their commitment to this Ethics Code and take steps to resolve the conflict in a responsible manner. If the conflict is unresolvable via such means, psychologists may adhere to the requirements of the law, regulations, or other governing authority.

Although the focus in this example is on legal standards, it might also be noted that the example also raises potential ethical and clinical issues. For example, the clinician must consider the potential harm to the client that may ensue if the information were to be disclosed in a public forum rather than remaining confidential. In addition, harm to the therapeutic relationship may arise if it was the opposing attorney who had called the therapist as a witness; the client may feel betrayed if the therapist were to testify in a manner that even inadvertently provided support to his or her ex-partner's case. Alternatively, if it was the client's attorney who called the therapist as a witness, the clinician may risk harm to the therapeutic relationship by *not* testifying or by testifying in a manner that is viewed by the client as hurting his or her case; the client may feel unsupported or betrayed by the therapist and not return to therapy.

The above example hints at another problem: Ethical principles and standards themselves may lead to unclear or even incompatible formulations of appropriate actions. For example, Standard A (Beneficence and Nonmaleficence) states: "Psychologists strive to benefit those with whom they work and take care to do no harm" (APA, 2002b, p. 1062). Applying this

principle in the case of child abuse reporting, one could conclude that verified or suspected child abuse should be reported in all cases to ensure that the child is safe. On the other hand, the same principle could also lead to the conclusion that one should not report the abuse unless danger is imminent because it might disrupt the therapeutic enterprise and potentially destroy trust, thereby harming the client (and/or child if the child is not the client). For this reason, between 40% and 66% of psychologists have indicated that they had failed to report at least one suspected case of child abuse (Applebaum, 1999). Clearly, psychologists' judgment of what constitutes ethical behavior in this instance varies greatly. It may even vary for the same psychologist across different clients, different clinical scenarios, or different employment contexts or states.

Child abuse reporting is not the only area in which psychologists' behaviors may deviate from ethical principles. Pope and Bajt (1988) surveyed 60 senior psychologists to explore times when a psychologist intentionally broke a law or formal ethical principle so as to uphold client welfare or another value. The authors found that 77% of the respondents believed psychologists should sometimes violate formal legal and ethical standards for client welfare and other deeper values. In addition, a majority of the respondents (57%) acknowledged having done so: 21% had refused to report child abuse, 21% had illegally disclosed confidential information, 9% had engaged in sex with a client, 6% had some form of dual relationship with a client, and 6% had refused to make legally mandated warnings regarding dangerous clients.

Other evidence suggests that, in general, psychologists' behavior is in line with their ethical beliefs. Pope, Tabachnick, and Keith-Spiegel (1987) surveyed psychologists about their beliefs about, and compliance with, ethical principles. For only 4 out of 83 items did psychologists tend to report that they engaged in a behavior that was viewed as ethically questionable (measured in this study as a behavior engaged in at a frequency that was greater than the frequency of times the behavior was identified as unethical). The four areas were discussing a client (by name) with a friend, discussing clients (without names) with friends, unintentionally disclosing confidential data, and providing services outside areas of competence. For most other items, psychologists' behaviors were generally consistent with ethical beliefs. However, ethical beliefs were not always clear; indeed, 12 of the 83 items appeared to pose difficult judgments in terms of how ethical they were (e.g., accepting goods rather than money for payment, avoiding certain clients for fear of being sued, sending holiday greetings to clients, allowing clients to run up a large unpaid bill).

These results are in line with Pope and Vetter's (1992) findings relating to ethical dilemmas faced by APA members in their work. From 679 psychologists, 703 ethically troubling incidents in 23 general categories were obtained. The most frequent dilemmas involved confidentiality, followed by blurred, dual, or conflictual relationships with clients. Payment issues, academic and training dilemmas, and issues in forensic psychology were the next most common concerns. Clearly, confidentiality and relationships with clients have been noted as a consistent concern across studies, and these are the most common areas in which psychologists deviate from ethical principles if they are going to do so. We might also note that these areas were also identified by Bennett et al. (2006) in their list of the most common types of disciplinary actions against psychologists, cited above, again suggesting that following ethical standards is a useful risk management tool.

Quite apart from any blurring of ethical and legal boundaries in codified principles and regulations or in contradictions between or among law and ethics, confusion may also originate in the clinician's own understanding or interpretation of a case. Consider the following

scenario: A 15-year-old girl has been in individual therapy for depression and attempts at self-harm. She tells her therapist that she is pregnant by her 20-year-old boyfriend and plans to obtain an abortion. The law in the therapist's state requires that a minor under 16 obtain consent from her parents to have an abortion. However, the client tells the therapist that she lied about her age and obtained a false identification card that she has presented to the family planning clinic. Further, she does not want the therapist to disclose her pregnancy to her parents because she believes that her father will beat her. The therapist has evidence that the father has previously physically abused a younger sibling. Finally, laws in the therapist's state allow the youth to receive individual therapy without consent of the parents, with the understanding that the parents will eventually be brought into the therapy situation. Complex clinical, ethical, and legal issues of potential harm to self by the client, reporting of child abuse, knowledge of potential criminal behaviors, concerns regarding confidentiality, and providing services to a minor clearly need to be considered as the practitioner considers what constitutes ethical behavior in this scenario, as well as what legal standards apply, let alone what clinical interventions to employ.

3.3.2   Resources for Resolution of Ethical and Legal Issues

Scenarios such as those given above are not unusual in the day-to-day work of a clinical psychologist. The Ethics Code (APA, 2002b) and practice guidelines assist the practitioner by providing basic guideposts for navigating through such sticky situations, and reference to these standards and principles is an important first step in resolution of a dilemma. A resource such as Barnett and Johnson's (2008) *Ethics Desk Reference for Psychologists* can be particularly useful at this stage. After citing each ethical principle and standard, the authors supplemented the Ethics Code with a summary of the concepts and intent of each principle, identification of common dilemmas and scenarios for each principle, and practical suggestions. They also included a model for ethical decision making, a checklist for psychologists facing an ethics complaint, recommendations for high-risk situations, and a list of ethics resources.

Practitioners wishing to explore a particular area in more depth may also find it useful to refer to discussions or recommendations for a specific problem or dilemma. Thus, for example, in the professional psychological literature, one can find discussions of ethical and legal issues that are common in working with certain populations, such as ethnic minorities (e.g., Hall, 2001; Lee, 2006) or clients of varied sexual orientations (e.g., Hermann & Herlihy, 2006; Israel, 2007; Kessler & Waehler, 2005). One can also find guidance for a wide variety of work settings or roles, such as rural practice (Campbell & Gordon, 2003; Turchik, Karpenko, Hammers, & McNamara, 2007), supervision and training (e.g., Fly, van Bark, Weinman, Kitchener, & Lang, 1997; Hamilton & Spruill, 1999; Sullivan & Ogloff, 1998; Vasquez, 1992), and forensic assessment (Heilbrun, DeMatteo, Marczyk, & Goldstein, 2008). Finally, many authors have addressed areas that touch on specific ethical standards from the Ethics Code in more depth, such as multiple relationships (e.g., Campbell & Gordon, 2003; Younggren & Gottlieb, 2004), assessment (Cates, 1999; Rupert, Kozlowski, Hoffman, Daniels, & Piette, 2008), and confidentiality (Barham, 2007; Smith-Bell & Winslade, 2008). Clearly, this list is but a tiny sampling of a myriad of ongoing research and discussion in many areas of practice.

Such literature is important in a fast-changing world because new conundrums can arise at any time. For example, telephone therapy (Haas, Benedict, & Kobos, 1996) and Internet use

(Behnke, 2008; Naglieri et al., 2008) have created new ethical dilemmas. It is not always immediately obvious how established standards apply in these new contexts, and the literature provides a valuable resource for practitioners. In addition, resources such as APA publications and Web sites can also be helpful. For example, the APA Web site contains a specific statement regarding services by telephone, teleconferencing, and Internet formulated by the Ethics Committee of the APA (1997), in which it is noted thus:

► The Ethics Code is not specific with regard to telephone therapy or teleconferencing or any electronically provided services as such and has no rules prohibiting such services. Complaints regarding such matters would be addressed on a case by case basis. Delivery of services by such media as telephone, teleconferencing and internet is a rapidly evolving area. This will be the subject of APA task forces and will be considered in future revision of the Ethics Code. Until such time as a more definitive judgment is available, the Ethics Committee recommends that psychologists follow Standard 1.04c, Boundaries of Competence, which indicates that "In those emerging areas in which generally recognized standards for preparatory training do not yet exist, psychologists nevertheless take reasonable steps to ensure the competence of their work and to protect patients, clients, students, research participants, and others from harm."

In addition to the Ethics Code, practice guidelines, and psychological literature, one's colleagues (virtual or real) can also provide a substantial amount of support and wisdom. Web sites such as that established by Ken Pope (http://kspope.com/) have a wealth of resources with respect to ethics and legal issues. Continuing education can address ethical dilemmas related to specific work contexts, tasks, or client populations. In some states, formal work groups have been established. Along these lines, Knapp and Lemoncelli (2005) discussed the role of state psychological organizations in promoting ethical practice; in particular, they identified the Pennsylvania Psychological Association Ethics Committee, along with other committees, as assisting in that endeavor in their own state.

In our state of Oregon, an Ethics Committee similarly comprises one of the standing committees of the Oregon Psychological Association. This committee is composed of up to 9 practicing psychologists and 2 students, for a total of 11 members. Although when it was initially formed the committee made recommendations for adjudication of psychologists, it currently serves only a consultative function for psychologists, students, and the general public. An individual from any of these constituencies can contact the committee confidentially to seek input about a concern. The committee members help the caller identify the ethical issues inherent in the concern and provide advice about how to proceed. As a member of this committee, I (the first author) have found that one of the most common issues encountered is the caller's confusion about what the ethical issue actually is. Indeed, the committee members routinely spend time sorting out the ethical, legal, and clinical issues in any given scenario before offering any guidance. The facts that such a committee exists, is well-used (even by seasoned practitioners), and both callers and committee members grapple with identifying the appropriate ethical issues and sorting them out from other concerns attest to the complicated nature of such inquiries. It also reinforces the notion that ethical reasoning and knowledge of legal standards are lifelong developmental endeavors at which one can always become more competent.

In this section, we have identified sources of complexity in the analysis of ethical and legal issues, and we have pointed to some valuable resources for sorting through the complexity. It is interesting to note that Pope et al. (1987) found that the resources identified by psychologists as most helpful in resolving ethical dilemmas were colleagues, the APA Ethics Code, and

internship training, and the least helpful were identified as state and federal laws, published research, and local ethics committees. Whether this ranking remains current 20 years later remains an open question.

As noted by many authors (e.g., Barnett & Johnson, 2008; Knapp & VandeCreek, 2006) and in the NCSPP (2007) and Assessment of Competency Benchmarks Work Group (2007) conceptualizations of competency and successful resolution of legal and ethical issues are best guided by the use of ethical decision-making models. In the next section, we discuss several decision-making models that can be used both as a foundational way of conceptualizing ethical and legal issues as well as a model to apply to specific cases.

3.3.3   Ethical Decision-Making Models

As noted above, many resources are available to psychologists for resolution of ethical and legal dilemmas. Although the most basic resources – laws, the Ethics Code (APA, 2002b), and practice guidelines – provide rules and standards to guide psychology practice, they do not contain procedures or ways to make sense of all complex ethical, legal, and clinical issues. One approach that has been put forward to sort out these issues is the use of ethical decision-making models. Several models of ethical decision making exist in the ethics literature that may be helpful both for students to learn in the course of an ethics curriculum as well as for practitioners to apply in actual practice. We now examine how these models have been developed, compare their strengths and weaknesses, and evaluate their usefulness for clinical practice.

Several approaches to ethical reasoning have been proposed to guide the creation of ethical decision-making models. Principle-based ethics involves upholding moral principles, unless two moral obligations come into conflict. When this occurs, one moral obligation may be superior to another, depending on the situation (Knapp & VandeCreek, 2006). In the domain of medical ethics, Beauchamp and Childress (2001) identified four moral principles for practitioners to follow: justice, beneficence, nonmaleficence, and respect for patient autonomy. For psychologists, two other moral principles have also been suggested: fidelity and public responsibility (Knapp & VandeCreek, 2006). Compared to principle-based ethics, virtue ethics focuses on an individual's character and motives. This ethical theory may help psychologists deal with ethical dilemmas that evoke strong emotions (Knapp & VandeCreek, 2006). No matter what ethical theory psychologists prefer, ethical decision-making models can guide their actions in response to an ethical problem. We now describe the first of four models of ethical decision making presented in this section.

The Five-Step Model. Ethical decision-making models typically include several steps practitioners should follow when confronting an ethical problem. Knapp and VandeCreek (2006) described a five-step model for ethical decision making (shown in ❯ Table 3.1). Although this model can be used to make decisions stemming from different ethical theories, Knapp and VandeCreek focused on using the five steps in the context of principle-based ethics.

The first of the five steps, identify or scrutinize the problem, involves figuring out what ethical quandary or conflict is present (Knapp & VandeCreek, 2006). This could include taking note of Ethics Codes or laws that seem relevant, as well as what moral principles are in jeopardy. A psychologist might also determine the moral obligations he or she has to different people or groups in a given situation.

◼ **Table 3.1**

Five-step model of ethical decision making (Knapp & VandeCreek, 2006)

1	Identify or scrutinize the problem
2	Develop alternatives or hypotheses
3	Evaluate or analyze options
4	Act or perform
5	Look back or evaluate

In the second step, Knapp and VandeCreek (2006) propose that psychologists should come up with alternatives or hypotheses to resolve the ethical problem. To facilitate this process, psychologists need to be aware of cognitive and emotional factors that could help or hinder their ability to create solutions for ethical dilemmas. Being very rigid or emotional about a certain issue could lead practitioners to generate solutions that are not optimal for all people involved in a given situation. To assist the decision-making process, Knapp and VandeCreek also recommend that psychologists consult with colleagues or supervisors during this second part of the five-step model. Consultation is an essential element for ethical decision making that can help clinicians see issues from others' perspectives and become aware of their blind spots in different situations.

In the third phase of the process, psychologists should evaluate or analyze their options in a particular case (Knapp & VandeCreek, 2006). Once several options have been listed, psychologists should consider the advantages and disadvantages of each solution. These authors suggest that psychologists use their creativity to combine the best parts of the available alternatives into a new solution. This new integrative option should also be evaluated before it is implemented. In the context of principle-based ethics, the best option balances the moral principles involved in the ethical dilemma under consideration.

The fourth step in this model is to take action or complete the selected solution (Knapp & VandeCreek, 2006). In this stage of the decision-making process, the way in which a solution is put into place is also an important variable to keep in mind. When a psychologist acts to resolve an ethical conflict, decreasing harm to the moral principles involved takes a certain amount of skill. The authors also mentioned that even when a decision is reached, implementing the solution may not follow if the action continues to oppose what is thought to be the most moral or ethical response.

The final phase of the five-step model involves looking back or evaluating the option that was used to combat the ethical problem. Knapp and VandeCreek (2006) commented that this critical analysis should include an assessment of whether the decision has a chance of success and was made in an objective manner. In addition, the decision should be reached with no morally favorable option being accessible. Although this step normally puts an end to the ethical problem, sometimes evaluating the decision may point to other interventions being necessary.

The five-step model appears to have several strengths. First, it is easy to learn and can be supplemented with other steps for complex ethical dilemmas (Knapp & VandeCreek, 2006). Second, it includes a step designed to evaluate the success of the selected solution. This step may encourage psychologists to continually evaluate the outcome of the ethical decision-making process to benefit all parties involved and minimize harm to moral principles. Third, the five basic steps provide a framework for more lengthy and detailed models of ethical decision making that have been developed in more specialized areas of clinical psychology.

Fourth, this approach can be used to make decisions based on different ethical theories (e.g., principle-based or virtue ethics).

Looking carefully at the five-step model also exposes several areas in which it could be improved. In particular, this model has not been empirically tested in studies or surveys of professional psychologists. The current focus on evidence-based psychological practice suggests that ethical decision making should also be empirically analyzed in some way. Furthermore, in emergency or crisis situations, lack of time may prevent clinicians from being able to use a model that requires a certain amount of thinking and deliberation. Finally, reaching a solution with the five-step model seems to occur without identifying the individuals, groups, or organizations with a vested interest in the situation and who will be directly affected by the outcome.

The Narrative Model. The narrative model of ethical decision making is another alternative for psychologists to use when confronted with an ethical problem. This approach stems from previous literature on narrative ethics and feminist ethics (Sturm, 2002). In a narrative approach to ethics, ethical behavior and decision making are looked at within the entire context and personal experience of the lives of individuals and groups (Nicholas & Gillett, 1997). In particular, the ethical decision-making process includes negotiation for the values of the people involved (Hill, 2004). Narrative methods may also be helpful for psychologists to take the perspective of clients or other people affected by an ethical dilemma (Sturm, 2002). Understanding the point of view of others who are involved in an ethical conflict can be useful when the relevant stakeholders have less social or organizational power. Sturm contended that narrative ethics can assist psychologists in difficult ethical situations where human diversity factors (e.g., gender, ethnicity, class, sexual orientation) are involved. The narrative model of ethical decision making is shown in ⊙ Table 3.2.

Identifying the relevant clinical, legal, and ethical issues appears to be an appropriate first step to address any ethical problem. In many ethical conflicts, legal, ethical, and clinical issues are present and often meld together in ways that need to be sorted out before moving forward. The narrative approach deals with this aspect of ethical decision making directly and at the beginning of the process. The second step, to identify alternative courses of action, is very similar to the second part of Knapp and VandeCreek's (2006) five-step model described above. This phase of the process must happen before making a decision or taking action. The third step, to identify the relevant stakeholders in the situation, forces psychologists to look at the issues from the perspective of others. Using the therapeutic skill of empathy to broaden the view of an ethical dilemma may benefit all of the involved parties.

Sturm (2002) posited that using a narrative approach to help teach ethical decision-making skills has several benefits. First, the narrative method may help psychologists reflect on their own ethical values and principles. Second, perspective taking may assist practitioners in working with individuals from diverse cultural backgrounds. Third, psychologists working on interdisciplinary teams with other professionals may be able to use the narrative model effectively to discuss ethical problems in a group setting. Finally, the narrative approach may help clinicians

◼ **Table 3.2**

Narrative model of ethical decision making (Sturm, 2002)

1	Identify relevant clinical, legal, or ethical issues
2	Identify at least two alternative courses of action one might take in the case
3	Identify the relevant stakeholders

increase their cognitive flexibility when pondering ethical quandaries. In conjunction with Sturm's points, the narrative model's best feature appears to be taking the perspective of others and considering the impact any decision may have on all the people involved in the ethical dilemma at hand.

Along with the benefits described above, the narrative model has some disadvantages as well. The most glaring drawback of this model is that it stops short of taking action or implementing a decision regarding the ethical conflict. Although action may not be necessary in all situations, legal and ethical issues often require psychologists to make decisions to minimize harm to their clients. The narrative model also does not contain any procedure for critically evaluating the decision-making process or the subsequent course of action. This part of the process seems essential for psychologists in order to assess whether the ethical decision-making model they are using is working or needs to be amended in the future. Like the five-step model, the narrative model has not been empirically tested in the ethics literature. Future work should evaluate whether psychologists view the narrative approach as a valuable tool in the ethical decision-making process.

Forensic Psychology Model. In specialized areas of psychology practice, existing ethical decision-making models have been modified to apply to pertinent ethical situations. For example, Bush, Connell, and Denney (2006) added several steps to Knapp and VandeCreek's (2006) five-step model to address ethical decisions in forensic psychology. This forensic model has eight steps and is shown in ◉ Table 3.3.

Compared to the five-step model, these authors added three new steps to aid forensic practitioners in ethical decision making. Specifically, the second, third, and fourth steps of Bush et al.'s (2006) model are not included in the five-step model. The second step involves looking at the context and setting in which the psychologist is practicing. Depending on the organization or institution, a forensic psychologist may have obligations to different parties. These may include attorneys, the court, the trier of fact, and the examinee or patient (Bush et al., 2006). The third step of the model, to identify and use legal and ethical resources, is also new. Bush et al. go on to describe the available resources that forensic practitioners should use. Psychologists should first assess the fundamental ethical principles and values involved in a case, followed by a careful review of pertinent Ethics Codes and laws. These authors also recommend that practitioners examine published statements from professional psychological associations that clarify practice domains that are not covered by an Ethics Code. In addition, relevant research literature should be reviewed to assist in the decision-making process. Finally, consultation

◉ **Table 3.3**
Forensic psychology ethical decision-making model (Bush et al., 2006)

1	Identify the problem
2	Consider the significance of the context and setting
3	Identify and utilize ethical and legal resources
4	Consider personal beliefs and values
5	Develop possible solutions to the problem
6	Consider the potential consequences of various solutions
7	Choose and implement a course of action
8	Assess the outcome and implement changes as needed

with colleagues or ethics committees may be a valuable resource for figuring out ethical problems. The fourth step of Bush et al.'s model involves examining personal values and beliefs. In forensic psychology, issues often arise that have moral implications and can influence psychologists' decision-making ability.

Although designed specifically for forensic psychologists, the ethical decision-making model proposed by Bush et al. (2006) has several features that can be beneficial in many ethical dilemmas. Paying attention to the context and setting involved can allow psychologists to consider cultural factors that may be affecting the ethical problem at hand. Identification of different parties in a case also seems to add nicely to the five-step approach, as this is quite similar to the third step of the narrative model described earlier (identify the relevant stakeholders). Making use of ethical and legal resources to aid decision making is clearly a good guideline for psychologists to follow. In particular, Bush et al.'s suggestion to review relevant research literature fits very well with the professional psychology concept of research informing clinical practice. The idea that ethics committees can be a resource for consultation also stands out in the forensic model. As noted above, Ethics Committees of state psychological associations are often not adjudicative and can be consulted with ethical dilemmas.

Canadian Code of Ethics Model. In the APA (2002b) Ethics Code, there is no specific procedure for addressing ethical problems – only ethical principles and standards are included. Other national psychological associations have developed their ethics codes with guidelines for ethical decision making. For instance, the Canadian Code of Ethics for Psychologists (Canadian Psychological Association, 2000) contains 10 steps for ethical decision making to approach ethical issues that are difficult to resolve and may require extensive consideration. The entire model is shown in ❯ Table 3.4.

Many parts of the Canadian model overlap with the five-step (Knapp & VandeCreek, 2006) and narrative approaches (Sturm, 2002), but some additional steps warrant mention. The last two phases of the process include assuming responsibility for the consequences of the decision and taking action to prevent the ethical problem from happening again in the future (CPA, 2000). These two steps go beyond the last part of the five-step model (look back or evaluate) by using the ethical dilemma and subsequent decision in a positive way to address potential conflicts in the future.

Compared to the APA (2002b) Ethics Code, the Canadian Code of Ethics model of ethical decision making (CPA, 2000) provides much more specific information for psychologists concerning ethical conflicts. Although at first this may seem a bit prescriptive, the model does present one avenue for psychologists who are faced with a situation that is not clearly addressed by current ethical standards. For example, as noted above, in areas like Internet and e-mail communication in clinical practice, the current APA Ethics Code offers little guidance for psychologists. In these instances, ethical decision-making models may be helpful for psychologists to use. Before the model within the CPA Ethics Code is widely adopted, however, it does need to be empirically investigated to verify its effectiveness (Hadjistavropoulos & Malloy, 2000).

Comparing the Four Models. Across the four models for ethical decision making presented in this chapter, several themes are salient. All four models appear to have an initial step that includes identifying the specific issues that exist in a case. Another similarity between models is the development of alternative courses of action to address an ethical dilemma. Following this, the process involves deciding which alternative to pursue and then acting or implementing a decision. Most models also contain a step to evaluate the action afterwards and examine the effect the decision has on all parties involved.

◼ **Table 3.4**

Steps for ethical decision making (Canadian Psychological Association, 2000)

1	Identify the individuals and groups potentially affected by the decision
2	Identify ethically relevant issues and practices, including the interests, rights, and any relevant characteristics of the individuals and groups involved and of the system or circumstances in which the ethical problem arose
3	Consider how personal biases, stresses, or self-interest might influence the development of, or choice between, courses of action
4	Develop alternative courses of action
5	Analyze likely short-term, ongoing, and long-term risks and benefits of each course of action on the individuals and groups involved or likely to be affected (e.g., client, client's family or employees, employing institution, students, research participants, colleagues, the discipline, society, self)
6	Choose a course of action after conscientious application of existing principles, values, and standards.
7	Act with a commitment to assume responsibility for the consequences of the action
8	Evaluate the results of the course of action
9	Assume responsibility for the consequences of the action, including correcting negative consequences, if any, or reengaging in the decision-making process if the ethical issue is not resolved
10	Appropriately act, as warranted and feasible, to prevent future occurrences of the dilemma (e.g., communicate and problem-solve with colleagues, change procedures and practices)

One weakness of the models we discussed is the lack of empirical research that has been conducted on their effectiveness for practicing psychologists. In a review of the literature on ethical decision-making models, Cottone and Claus (2000) pointed out that empirically based models must be developed to advance the study of ethical decision making in the future. Despite the lack of research in this area, ethical decision-making models provide a starting point for psychologists who are faced with difficult ethical problems that cannot be resolved by reference to the APA Ethics Code alone.

3.4   Summary

We started this chapter noting that ethical and legal issues pervade the daily work of psychologists. The NCSPP (2007) and the Assessment of Competency Benchmarks Work Group (2007) competency models also drive home the important fact that these issues are present from the very beginning of training in clinical psychology and that a developmental course in competence is expected. Each model offers a view of what that developmental course constitutes and gives us a picture of basic competency in this area. The models complement each other nicely in that one offers a view of ethics and legal issues as a general foundational competency underlying all of a psychologist's (or trainee's) activities, whereas the other model points to knowledge, skills, and abilities required in specific areas of practice.

The third levels of the NCSPP (2007) and the Assessment of Competency Benchmarks Work Group (2007) competency models (end of internship and beginning of professional practice, respectively) hint at what is required for expert competence in this area. We have offered a discussion of advanced skills in this area, based on these competency models. In particular, we believe that understanding and acknowledging the complexities of ethical and legal issues so as to be able to identify the primary issues of concern, having an ability to access resources, and applying ethical decision-making models in particular will help the practitioner navigate this area.

4 Cultural Diversity

Martin J. La Roche · Michael S. Christopher

Abstract: In this chapter we present the theoretical and practical underpinnings of our culturally competent practice in psychology model. This contextually based model complements traditional clinical interventions by providing psychotherapists with a conceptual frame to guide culturally sensitive psychotherapy practice. To accomplish this goal we begin the chapter by providing an overview of the literature on cultural competence and describe several prominent cultural competency definitions, models, and guidelines. Second, we review individualistic, relational, and contextual interventions, and propose an integrative multidimensional approach in which we address strengths and weaknesses of these interventions vis-à-vis cultural competence guidelines. Third, we outline a three stage model with specific interventions that clinicians can use to enhance their cultural sensitivity in working with diverse clients. Derived from an integrative multidimensional approach, these three stages are: 1) addressing chief complaints and reducing symptoms, 2) understanding narratives, and 3) fostering empowerment. Fourth, we illustrate this approach with a clinical example and conclude with a discussion of the possibilities and challenges posed by these ideas as well as areas for future research.

4.1 Overview

Psychologists are becoming increasingly aware of the need for clinicians to be culturally competent in order to work effectively with diverse clients. This is exemplified by the emphasis on culturally sensitive intervention and treatment in the latest revision of the Ethical Principles of Psychologists and Code of Conduct (American Psychological Association [APA], 2002) and in the Guidelines on Multicultural Education, Training, Research, Practice, and Organizational Change for Psychologists (APA, 2003; hereinafter referred to as the APA Multicultural Guidelines). Inherent in these and similar guidelines is the message that "culture counts" (U.S. Department of Health and Human Services [DHHS], 1999, 2001). Despite this unified message, there is no general consensus within the field on exactly how to achieve this goal. Although several guidelines exist, there appears to be a recent shift in the way in which cultural competence has been conceptualized in psychotherapy to move beyond content (i.e., lists of issues that clinicians should consider when working with diverse clients) and focus more on process (i.e., fluid, practical ways in which this can actually be accomplished) (Lakes, López, & Garro, 2006; S. Sue, 1998).

Similarly, we view the common denominator of culturally competent practice in psychology (CCPP) as an emphasis on the integration of cultural contexts with specific strategies to guide the use of cultural elements effectively within interventions (Kazarian & Evans, 1998; La Roche, 2005; López, 1997). Therefore, CCPP complements other psychotherapies by adding a practical cultural-contextual perspective. Consistent with this goal, in this chapter, we will propose ideas to further organize and specify this contextual dimension within psychotherapy practice. To accomplish this, we start by reviewing several cultural competency

definitions, models, and guidelines, and offer our operationalization of CCPP. Second, we present a multidimensional approach that integrates key features of cultural competency models and guidelines for different clinical formulations, arguing that cultural considerations are an essential component of any intervention. Third, we describe specific interventions that clinicians can use to enhance their cultural competence by utilizing this multidimensional model. Fourth, we illustrate this approach with a clinical example and conclude with a discussion of the possibilities and challenges posed by these ideas. Overall, in this chapter, we aim to offer a practical process model for addressing a crucial though often neglected facet of mental health service delivery – cultural competence. Guarnaccia and Rodriguez (1996) noted the inadequate attention, both in practice and in the literature, devoted to conceptualizing culture within the development of culturally competent mental health services. Thus, before defining cultural competency and its implications, it is important to define culture and to discuss how it differs from – and is similar to – race and ethnicity.

4.2   Clarifying Race, Ethnicity, and Culture

Although race, ethnicity, and culture are very distinct from each other, they are often used interchangeably in the psychological literature, which can generate confusion and misunderstanding (Abreu & Gabarain, 2000; Betancourt & López, 1993). Race is often defined in terms of selected physical characteristics, criteria, or permanent human attributes (Betancourt & López, 1993). Historically, phenotypic attributes such as skin color and facial characteristics have been used to define racial groupings (e.g., Landrine & Klonoff, 1996). However, no psychological attributes or behavioral correlates can be inferred, given a participant's race (Helms, Jernigan, & Macher, 2005; Phinney, 1996). Some psychologists contend that race refers to biological characteristics of individuals as evidenced by their physical appearance (e.g., Rowe, 2002); however, race is a social artifact that has no biological evidence to support its existence (Bonham, Warshauer-Baker, & Collins, 2005). In fact, there is overwhelmingly greater genetic variation within a racial group than across racial groups (DHHS, 2001). Furthermore, using race as a psychological variable gives scientific legitimacy to a construct that has been used to perpetuate stereotypes that impose an oppressive sociopolitical hierarchy upon racial minorities within American society.

Ethnicity is a broader term than race, as it relates to the shared nationality, language, common values, beliefs, and customs of an identifiable group of people (Betancourt & López, 1993). It entails a person's identification with an ethnic group, which may be determined by genealogical ties or other socially related factors (Alvidrez, Azocar, & Miranda, 1996). In contrast to the identification of race, a person has some ability to define his/her own ethnicity; however, similar to the construct of race, ethnicity connotes a homogeneous and stereotypical understanding of an individual's cultural experience that cannot capture the complexity, vitality, and diverse nature of any experience. In addition, race and ethnicity are conceptualized as fixed and invariant attributes, thus overlooking the possibility that understandings and identifications may change.

Given any individual's complex set of changing experiences, we articulate a conceptualization of culture that is more suitable for individuals to define their own unique experience. Culture has been understood in many ways; however, we believe that Geertz's (1973)

definition of culture is particularly applicable, given its operational implications. Geertz defined culture as "an historically transmitted pattern of meanings embodied in symbols; a system of inherited conceptions expressed in symbolic forms by means of which men communicate, perpetuate, and develop their knowledge about and attitudes toward life" (p. 89). Consequently, culture is understood as an interrelated web of meanings that are dynamic, complex, and representative of a multifaceted experience, in which a person is understood first and foremost as a *homo symbolicus*, or meaning-maker. Meaning-making is a semiotic act in which persons not only relate to, but also create, a world and self of their own. Although these meanings reside in an individual's mind, they are inseparable from the sociocultural context in which they are created (Bruner, 1990; Shweder, 1995). Clearly, meanings vary greatly between and within cultural groups; however, members of any cultural group often construe themselves and the world in somewhat similar ways. Several conceptualizations of these common cultural characteristics have been offered. One of the most commonly used is D'Andrade's (1990) term *cultural models*, which consists of the representational and organizational patterns that make up the meaning system of any cultural group.

Geertz's (1973) definition of culture is applicable not only to racial, ethnic, and other minority groups (e.g., persons with a disability), but to all individuals. Consistent with Geertz's conceptualization of culture is the notion that meanings are fluid and flexible, especially when individual change occurs, such as migration or contact with different cultural groups (Berry & Kim, 1988; Carter & Qureshi, 1995). In addition, this socio-constructive definition of culture embeds individuals' experiences within their cultural contexts, making individuals' meanings inseparable from their cultures (Shweder, 1995) and highlighting the need to assess one's context. Furthermore, this definition assumes that individuals also have some influence in transforming their cultural context, not just passively experiencing the contextual influence on them (López & Guarnaccia, 2000), which is in stark contrast to traditional conceptualizations of culture.

A socio-constructive conceptualization of culture is also congruous with the APA Multicultural Guidelines' (2003) emphasis on "culture-centered" practices. Throughout the Multicultural Guidelines, psychologists are encouraged to use a "cultural lens" as a central focus of professional behavior. In culture-centered practices, psychologists recognize that all individuals, including themselves, are influenced by different environments, including their historical, ecological, sociopolitical, and disciplinary contexts. For example, a culture-centered approach acknowledges that behavior may be shaped by culture, groups to which one belongs, and cultural stereotypes including those regarding stigmatized group members (APA, 2003).

In CCPP, clinicians utilize culture-centered practices to assess and incorporate clients' cultural meanings or models throughout evaluation and treatment. From this anthropologically informed conception of culture, the integration of perspectives is not based on a presumed cultural difference or factor associated with the client from a specific ethnic or racial group (Lakes et al., 2006). Instead, it focuses on the process of defining the problem from both the therapist's and client's perspectives; the identification or construction of a presenting problem is a process that must be informed by both parties. In sum, contextualized and process-oriented conceptualizations of culture that do not depend on specific group membership offer a base for advancing an understanding of cultural competency in clinical contexts (Garro, 2003, 2005).

4.3   Definitions and Models of, and Guidelines for, Cultural Competence

There are a number of definitions of cultural competence. Davis and Donald (1997) defined cultural competence as the integration and transformation of knowledge about individuals and groups of people into specific standards, policies, practices, and attitudes used in appropriate cultural settings to increase the quality of services, thereby producing better outcomes. S. Sue (1998) defined cultural competence as "the belief that people should not only appreciate and recognize other cultural groups, but also be able to effectively work with them" (p. 441). López (1997) argued that the "essence of cultural competence … is moving between two cultural perspectives, that of the therapist and that of the client." Building on these conceptualizations, Whaley and Davis (2007) stated that cultural competence includes (a) the ability to comprehend the dynamic interplay between the heritage and adaptation dimensions of culture in shaping human behavior; (b) the ability to use the knowledge acquired about an individual's heritage and to use this knowledge to adapt existing treatments to maximize the effectiveness of assessment, diagnosis, and treatment for any given client; and (c) the ability to recognize how one's own cultural background, clinical orientation, and overall approach to therapy impact one's delivery of services across diverse groups.

In addition to specific definitions of cultural competence, several basic competency models have been developed to help instruct psychologists regarding how they can implement cultural competence into everyday practice. D. W. Sue et al. (1982) outlined one of the earliest and most influential models for specific competencies to be achieved in cross-cultural psychotherapy. Their three core competencies of beliefs/attitudes, knowledge, and skills have formed the foundation for many subsequent models (e.g., Arredondo, Toporek, Brown, Sanchez, & Stadler, 1996; Fowers & Davidov, 2006; Pope-Davis & Dings, 1995; D. W. Sue, Arredondo, & McDavis, 1992). In the D. W. Sue et al. (1982) model, beliefs and attitudes refer to the mindset psychologists have about ethnic and racial minorities as well as their responsibility to question their biases and stereotypes, develop a positive orientation toward multicultural perspectives, and recognize ways in which personal values and biases can affect cross-cultural psychotherapy relationships. Knowledge is the understanding that psychologists have of their own worldview, their specific knowledge of cultural groups, and their understanding of sociopolitical influences on cross-cultural relationships. Skills refer to the specific abilities that are necessary to work with racial and ethnic minorities (D. W. Sue et al., 1982; D. W. Sue et al., 1992).

D. W. Sue (2001) expanded the model to incorporate a multidimensional view of cultural competence that integrated three primary dimensions: (1) racial and culture-specific attributes of competence, (2) components of cultural competence, and (3) foci of cultural competence. The expanded model is based on a 3 (awareness, knowledge, skills) X 4 (individual, professional, organizational, societal) X 5 (African-American, Asian-American, Latino/Hispanic American, Native American, European American) factorial combination, which allows for the systematic identification of cultural competence in a number of different areas. Similarly, Constantine and Ladany (2001) expanded the three competencies to six in an attempt to broaden the conceptualization of cultural competence to include: (a) self-awareness, (b) general multicultural knowledge, (c) multicultural psychotherapy self-efficacy, (d) ability to understand unique client variables, (e) effective psychotherapy alliance, and (f) multicultural psychotherapy skills.

There are also a number of guidelines in place to increase the cultural competence of practicing psychologists, and to help ensure that students receive adequate training in cultural competence. Two of the most prominent sets of guidelines are the APA Multicultural Guidelines (2003) and the National Council of Schools and Programs of Professional Psychology (NCSPP) Competency Developmental Achievement Levels (2007). Both sets of guidelines are broad in scope while also offering specific suggestions for moving toward cultural competence. More specifically, the APA Multicultural Guidelines were developed to provide psychologists with (a) the rationale and needs for addressing multiculturalism and diversity in education, training, research, practice, and organizational change; (b) the basic information, relevant terminology, current empirical research from psychology and related disciplines, and other data that support the proposed guidelines and underscore their importance; (c) the references to enhance ongoing education, training, research, practice, and organizational change methodologies; and (d) the paradigms that broaden the purview of psychology as a profession. The APA Multicultural Guidelines address American ethnic and racial minority groups as well as individuals, children, and families from biracial, multiethnic, and multiracial backgrounds. Thus, the term "multicultural" in these guidelines refers to "interactions between individuals from minority ethnic and racial groups in the United States and the dominant European–American culture" (APA, 2003, p. 378).

There are six specific APA Multicultural Guidelines (2003) that are subsumed under five headings:

- Commitment to cultural awareness and knowledge of self and others
  Guideline 1: Psychologists are encouraged to recognize that, as cultural beings, they may hold attitudes and beliefs that can detrimentally influence their perceptions of, and interactions with, individuals who are ethnically and racially different from themselves.
  Guideline 2: Psychologists are encouraged to recognize the importance of multicultural sensitivity/responsiveness to, knowledge of, and understanding about, ethnically and racially different individuals.

- Education
  Guideline 3: As educators, psychologists are encouraged to employ the constructs of multiculturalism and diversity in psychological education.

- Research
  Guideline 4: Culturally sensitive psychological researchers are encouraged to recognize the importance of conducting culture-centered and ethical psychological research among persons from ethnic, linguistic, and racial minority backgrounds.

- Practice
  Guideline 5: Psychologists are encouraged to apply culturally appropriate skills in clinical and other applied psychological practices.

- Organizational change and policy development
  Guideline 6: Psychologists are encouraged to use organizational change processes to support culturally informed organizational (policy) development and practices.

Although only one of the guidelines (guideline 5) explicitly addresses the practice domain, we believe all six of the guidelines are instrumental for CCPP. As noted above, cultural awareness and knowledge of self and others (guidelines 1 and 2) are inherent in CCPP. Additionally,

teaching, mentoring, and supervision (guideline 3); evaluating the effectiveness of one's interventions (guideline 4); and taking an active role in shaping one's work environment (guideline 6) are all core activities of the practice of psychology, as well as CCPP.

Unlike the APA Multicultural Guidelines (2003) which focus primarily on practicing psychologists, the NCSPP Guidelines (2007) were established to provide a competency model of education and training of students for professional schools of psychology. Although cultural diversity is only one of the seven specific competencies outlined in the guidelines, it has been a primary agenda issue for NCSPP since its inception in 1976 (NCSPP, 2002). The NCSPP diversity competency requires the ability of students to identify and understand issues of individual and cultural difference (ICD), and issues of power, privilege and oppression. This understanding provides the foundation for all professional functions and activities, including assessment, conceptualization, intervention, consultation and evaluation approaches (NCSPP, 2007). The NCSPP cultural competency guidelines require an affirmation of the richness of human differences, ideas, and beliefs across various dimensions of diversity. Attention to social and cultural values influencing the profession as well as the development of awareness of ICDs and values within the practitioner are themes to be interwoven across all stages of training (Peterson, Coleman, Dobbins, & Boyce, 2002).

In terms of content, the NCSPP (2007) diversity competency is composed of five main domains of knowledge, skills and attitudes (KSA) related to individual and cultural difference: (a) multiple identities; (b) issues of power, oppression and privilege; (c) ICD-specific knowledge base; (d) culturally competent service provision; and (e) ethics. Each domain is operationalized by specific tasks and outcomes across the dimensions of KSAs (NCSPP, 2007). The first domain emphasizes an understanding of how students identify and understand themselves and others as having multiple identities, and how they use that knowledge in their professional activities. The second domain emphasizes an understanding of the constructs of power, oppression and privilege, the impact of these, and the psychologists' role in promoting social justice. The third domain emphasizes the ability to understand and critique the scientific, theoretical and applied ICD knowledge base, including an understanding of evidence-based scholarship and the appropriate application of research to diverse populations. The fourth domain emphasizes the students' ability to provide culturally competent services in all of their professional roles. The fifth domain includes students' ability to integrate an awareness of ICD into ethical decision making.

Overall, these definitions, models, and guidelines of cultural competence share several overlapping features. First, clinicians must be able to access any given clients' cultural perspective and then integrate it within her or his cultural perspective. Second, clinicians must be able to effectively relate to, or understand, clients from various backgrounds. Third, the cultural context must be integrated into treatment; this will also have an impact on the therapist, the client, and the relationship between them. A potential shortcoming of many of these models, however, is that the construct of cultural competence only emphasizes race or ethnicity, where recommendations are given for achieving competency in working with members of a particular group. As Lakes et al. (2006) suggest, the emphasis on racial and ethnic minority groups is understandable because the justification for cultural competence is based largely on the existence of disparities in the provision of relevant and effective mental health services to members of these groups. However, as noted above, a one-size-fits-all within-group approach is an essentializing view that may inadvertently promote group stereotypes instead of cultural sensitivity while failing to address individual needs (López, Kopelowicz, & Canive, 2002).

Therefore, we understand CCPP as a process in which the therapist develops an awareness of her or his own culture and clinical expertise, and subsequently enhances this information by allowing each client to express what is important for him/her about his/her culture, as well as his/her treatment preferences. This process fosters the development of a therapeutic relationship that is embedded within the client's and therapist's contexts as a means to offer the most effective treatment. As noted above, we espouse a broad, socio-constructive conceptualization of culture that can include (but is not limited to) race, ethnicity, disability, age, gender, sexual orientation, socioeconomic status, and geographical location, as well as the interactions between each. Similarly, it is important to note that in this operationalization, the client can be conceived of in broad terms that can mean individual, couple, family, group, or organization, or other numerous possibilities.

Before we proceed further, it is important to note that this particular understanding of CCPP emerged from several contexts, specifically from clinical work conducted with urban, low-socioeconomic, and culturally diverse communities in Boston and the evolving theories of culturally competent psychotherapy (e.g., López et al., 2002; D. W. Sue & Torino, 2005). The urban communities in which we have both worked – similar to many socioeconomically deprived neighborhoods – are plagued by crime, inadequate housing, poverty, deficient schools, and difficulties accessing medical services amongst a host of other problems. In working with clients in these communities, it became clear to us that it is insufficient to promote individual change (e.g., reduce depression or anxiety symptoms); social and contextualized change is also necessary if psychotherapy is to be effective in addressing the needs of marginalized clients. Therefore, based on our own clinical experience, in conceptualizing CCPP we also agree with others who have asserted that a shared goal of culturally competent psychotherapy is to bring about social change through clinical practice (NCSPP, 2007; Whaley & Davis, 2007).

4.4   A Multidimensional Conceptualization

A CCPP perspective assumes that human beings are complex, and therefore it includes a multiplicity of diverse and interactive characteristics that are better understood using a multidimensional approach. Each dimension can be understood as a level of analysis or perspective in which certain aspects of the psychotherapeutic process are either excluded or highlighted. The three perspectives or dimensions that will be highlighted in this chapter are: (1) individualistic, (2) relational, and (3) contextual. The individualistic level addresses the client's primary presenting issues; the relational perspective highlights the psychotherapeutic relationship; and the contextual level emphasizes the influence of the context on clinical understandings. Several additional dimensions could be constructed and effectively used within the psychotherapeutic process (e.g., spiritual, psychopharmacological); however, for the sake of parsimony, only three dimensions are herein underscored (La Roche, 2005). This multidimensional framework is also consistent with the evolving field of psychotherapy integration (Anchin, 2008; Norcross & Goldfried, 2005) where behavior is viewed as a result of a multiplicity of factors, and effective psychotherapy is predicated on the coherent integration of a number of aspects of a client's life (Gold & Watchel, 1993).

An exponential number of psychotherapeutic models have been developed since 1895 when Breuer and Freud published their *Studies on Hysteria*. Although current estimates on the

number of different contemporary models of psychotherapy begin at several hundreds, most put the number in the thousands (Stricker & Gold, 1993). CCPP attempts to make sense of this growing plurality of psychotherapeutic approaches by employing a multidimensional frame that allows clinicians to use, connect and integrate disparate formulations and consequently develop interventions in a coherent manner. It is argued that each dimension highlights certain issues, while others fade to the background. The dimension(s) being used have important clinical and cultural implications for the way psychotherapy is conducted. If clinicians become aware of the advantages and disadvantages of emphasizing each dimension, they will be more able to compensate for these shortcomings. Thus, some of the advantages and disadvantages of these dimensions are underscored as they are described. Clinicians are encouraged to think in multidimensional ways by questioning, testing, and enriching these formulations during the psychotherapeutic process and then exploring with their clients the applicability of each conceptualization. Ultimately, clients will decide which understandings and components of their cultural experience are more useful for them. This multidimensional framework is consistent with a recent APA Presidential Task Force (APA, 2006) elaboration on evidence-based practice in psychology, which is defined as, "the integration of the best available research with clinical expertise in the context of client characteristics, culture, and preferences" (p. 273).

CCPP is conceived of as a dynamic process in which client needs and the psychotherapeutic relationship are embedded within multiple, specific cultural contexts. As opposed to being restricted to the client's immediate context (as is often the case in individualistic treatments, for example, behavioral therapy), the cultural context is herein defined as the geographical space, historical time, and socioeconomic and political conditions in which the psychotherapeutic relationship occurs. Cultural contexts are not monolithic and homogeneous phenomena, but rather, dynamic and complex sets of interacting factors, which influence the psychotherapeutic process and can be altered by the psychotherapeutic relationship. Moreover, it is argued that the influence of the cultural context is consistently present, although often inadvertently, within the psychotherapeutic process. Some have suggested that the selective use of specific perspectives (e.g., individualistic, relational) is a result of sociopolitical, historical, and economic conditions (Cushman, 1995). However, we hope that the use of a multidimensional approach will offer a convergence of different perspectives, and a widening scope of understandings that will allow alternative explanations of the phenomenon to coexist by embedding them within the appropriate cultural context. One of the main implications of this approach is that as clients and therapists become increasingly aware of the influence of cultural and contextual factors, they will have more influence in constructing their lives. The central assumptions of the three underscored dimensions – that is, individualistic, relational, and contextual – will be highlighted, followed by a three-staged CCPP model.

The individualistic dimension is herein used to encompass all of the psychotherapeutic models and interventions that treat clients as independent, separate, and autonomous individuals with well-defined boundaries between observers, social contexts, and themselves. A common denominator among individualistic psychotherapies is that clients are the exclusive focus of treatment, while the client's and therapist's cultural contexts fade to the background. For example, classic psychoanalytic models emphasize the need to make clients aware of their unconscious, inner dynamics, while the therapist acts as a neutral blank screen onto which clients transfer their subjective experiences (Freud, 1933). Cognitive-behavioral therapists (e.g., Beck, 1967) identify specific maladaptive thoughts, behaviors, and schemas, and humanistic

clinicians use the client or self as the unit of analysis (Maslow, 1969; Rogers, 1961). Similarly, psychopharmacological interventions assume underlying biochemical processes (e.g., deficit in neurotransmitter activity) to explain symptoms (e.g., depression), while biologists search for genetic predispositions to clients' psychological problems. Although different individual attributes are highlighted by various theories (e.g., unconscious processes, biological predispositions) much of contemporary mental health treatment is characterized by an emphasis on the individual (Fowers & Davidov, 2006; Tseng & Streltzer, 2001).

Individualistic psychotherapies are often informed by the scientific method, which is generally considered the most reliable and valid way to glean objective data about a client (Kazdin, 2008; Task Force on Promotion and Dissemination of Psychological Procedures, 1995). Not surprisingly, empirically supported assessments and psychotherapies have flourished under the premise that randomized controlled trials are the best method to determine what treatments "work" (La Roche & Christopher, 2008; Sternberg, 2006). However, these treatments are often based on the assumption that science and the pursuit of knowledge are value-free, which inadvertently has not only obscured the possibility for therapists to explore their cultural assumptions (as suggested by all cultural competent models), but also clouded the political nature of its discourse (La Roche, 2005). Decontextualized and apolitical psychotherapy can de-emphasize sociopolitical factors (e.g., poverty, history of slavery) and may have unknowingly strengthened the status quo by supporting its underlying, dominant cultural assumptions (La Roche & Christopher, 2008). Similarly, psychologists who are seeking to be neutral and objective in treating their clients may be unaware of how their cultural biases can influence their services and confirm their own political agendas.

Most individualistic psychotherapies regard the psychotherapeutic process as occurring within an historical and geographical vacuum, overlooking many aspects of the macrocultural context (e.g., community violence or experiences of discrimination). For example, there is a paucity of psychotherapy research that addresses how the role of history and sociopolitical factors in mental health can compromise its effectiveness with marginalized groups for whom these issues can be more prominent (Comas-Diaz, 2006). Furthermore, as articulated in the APA Multicultural Guidelines (APA, 2003), despite goals of neutrality and objectivity, individualistic or mainstream psychotherapies may inadvertently pathologize certain cultural characteristics (e.g., collectivism = dependence/immaturity) and promote others (e.g., individualism = autonomy/maturity).

Given the limited scope of most individualistic models of psychotherapy, many therapists utilizing these treatments may neglect to consider cultural competence guidelines. For example, most individualistic psychotherapies do not encourage therapists to assess their own beliefs and knowledge of cultural issues; they are instead encouraged to remain neutral. The exploration of personal cultural assets/biases is a key component of most cultural competency models and guidelines (e.g., D. W. Sue et al., 1992). Furthermore, a neutral stance could be considered as a culture-specific expression of our mainstream society that may not match the expectations of many culturally diverse clients. Similarly, therapists who subscribe to an individualistic model are not asked to evaluate their own experience as a cultural being, and how this experience has impacted their life and how they view others (e.g., White privilege; McIntosh, 1988).

Additionally, traditional individualistic models of psychotherapy were derived in specific social contexts that may not have validated the humanity of members from marginalized groups, which can stifle psychologists' ability to adapt or create novel approaches to psychology that may better suit clients' concerns (Constantine & D. W. Sue, 2005).

In individualistic psychotherapies, treatment goals generally emphasize change within the individual rather than transforming the cultural context or their relationships within that context (La Roche, 2005). Cultural processes are addressed as individual variables, and socioeconomic and political problems are "interiorized" (located within the self). Consequently, clients may be implicitly blamed for these sociocultural problems. Moreover, individualistic psychotherapeutic models are at risk of assuming that clients' inability to adapt to the dominant culture excludes them from the benefits of the dominant culture; thus, clients are encouraged to cope or adapt to the majority culture, rather than to question or change it, and cultural minorities are encouraged to assimilate to the American culture. If change is defined solely in individualistic terms, then psychotherapy can only be viewed as an instrument to encourage clients to adjust to a society that often is not reflective of their values (Hall, 1997). To enhance cultural competence, psychologists must develop a basic understanding of sociopolitical influences on cross-cultural relationships; however, this is often neglected in individualistic psychotherapies (D. W. Sue & Torino, 2005).

The relational dimension focuses on the psychotherapeutic relationship as a whole, rather than on the client or on the therapist as isolated entities. Interactions amongst people prevail as the object of study, while splits between therapists and clients are considered artificial. Relational psychotherapies espouse the belief that the human mind is interactive rather than monadic, and that psychotherapeutic process should be understood as occurring between people rather than within individuals (e.g., Jordan, Walker, & Hartling, 2004). The relational dimension is composed of a number of psychotherapies, including (but not limited to) object-relations (Klein, 1955), interpersonal (Klerman, Weissman, Rounsaville, & Chevron, 1984; Sullivan, 1953), modern intersubjective psychoanalysis (Mitchell, 1988), narrative (Epston & White, 1992), and feminist (Brown, 1994) psychotherapies; all of these approaches underscore the interpersonal nature of psychotherapy.

While individualistic therapists are encouraged to minimize or control their own biases and prejudices (e.g., Beck, 1991; Freud, 1933), relational clinicians are conceived as part of the research field in as much as they are part of the phenomena being studied. Within the psychotherapeutic process clinicians' subjectivity is also included, and is used as an important tool to empathize and connect with clients. Therapists' experiences and countertransference enrich and inform their understanding of their clients' experiences (Gelso & Mohr, 2001; La Roche, 1999; Mitchell, 1988). Similarly, relational approaches espouse a view in which the therapists' objective and privileged standpoint is questioned, encouraging a more egalitarian relationship between client and therapist (Jordan & Surrey, 1983). Therapists are often concerned about developing relationships in which mutual and reciprocal influence is accepted and promoted, and empathy is a crucial tool for connection (Jordan & Surrey, 1983; Kohut, 1984). Narrative therapists (Angus & McLeod, 2004; Epston & White, 1992), for example, have described the psychotherapeutic process as a joint venture between therapists and clients, to edit, reframe, and co-construct narratives.

Relationships are crucial for psychotherapeutic change (e.g., Wampold, 2007); it is often assumed that if clients are able to change their interpersonal dynamics, they will achieve psychotherapeutic change. Although initial cultural competence models appeared to emphasize specific skills to enhance treatment of individuals from specific groups, more recent models also emphasize the importance of broader relational factors in therapy; particularly an effective psychotherapy alliance (Constantine & Ladany, 2001; Saldaña, 2001).

By addressing relational issues in therapy, these psychotherapy approaches lend themselves to being more culturally sensitive, because they invite discussion about differences and similarities between the therapist and client (La Roche & Maxie, 2003). This dialogue can create an atmosphere in which issues that are more relevant to patients (e.g., cultural or gender differences) are addressed rather than following a therapy manual. This allows the therapist to explore his or her own beliefs about cultural factors with the client, which is a seminal premise in the APA Multicultural Guidelines (2003, Guidelines 1 and 2). However, although relational psychotherapies underscore interpersonal issues, particularly within the psychotherapeutic relationship, they often neglect events that occur outside of the psychotherapeutic session. Many classic relational models, with a growing number of significant exceptions (e.g., Ballou, Matsumoto, & Wagner, 1992; Brown, 1994), seem to reduce culture to the intersubjectivity of the client and therapist (Miller & Stiver, 1997) or common patterns of interaction of specific cultural groups. Consequently, external socioeconomic and political pressures may be de-emphasized, and thus, important experiences such as a poverty and discrimination may be overlooked.

The socio-constructive dimension of cultural competence underscores the sociopolitical context in which the therapeutic relationship is embedded. It focuses on the idea that culture and society are essential in constructing one's experience of reality. Individuals and relationships are unknowable without an understanding that locates them within a cultural and historical context (APA, 2003; Cushman, 1995; Gergen, 1991). Some socio-constructive approaches include, but are not limited to, hermeneutics, post-modernism, community psychology, deconstructive approaches, cultural psychology, and some cross-cultural psychology models. Although some cross-cultural approaches emphasize individualistic or relational variables, most cross-cultural approaches are characterized by an understanding of culture as deeply embedded in the consciousness of all human beings, and central to all psychological functioning.

Socio-constructive theories hold that truth is not the result of rationally subjecting hypotheses to empirical tests, but rather the result of what emerges from a network of social agreements (Gergen, 1991). Thus, socioconstructivists assert it is not the "objective" world that determines scientific claims, but rather the social processes within science and society. For example, Cushman (1995) described psychotherapeutic models as expressions of complex sociopolitical, historical and economic interests. Within specific groups or historical eras, some constructions of "truth" or psychotherapeutic models are favored over others. As sociopolitical and economic conditions change, healing practices also shift (Cushman, 1995). Similarly, some cross-cultural psychologists (e.g., Moghaddam & Studer, 1999) have argued that cross-cultural psychology should pursue a social or normative understanding of clients, in which knowledge is treated as a set of agreements within cultural groups.

Claims about truth are intricately interconnected with the distribution of power within specific societies. Those groups to whom knowledge is attributed are generally granted the privilege of making decisions about what truth is and these determinations usually favor their own interests. The focus on power differentials in socio-constructive models is similar to NCSPP's (2007) diversity competency emphasis on issues of oppression and marginalization. Ultimately, socio-constructivists explain the decision to regard any set of behaviors or experiences as a psychological disorder rather than a medical disorder, a criminal act, or a response to an oppressive environment is not a scientific decision, but rather a political one. Such decisions are grounded in cultural and economic perspectives that arbitrate which behaviors are acceptable for a specific society (D. W. Sue & D. Sue, 2007). Similarly, in traditional psychotherapy,

many goals (e.g., individuation, insight) reflect Western values (e.g., materialism, individualism, heterosexualism), while alternative objectives (e.g., spiritualism, collectivism, homosexualism) may be devalued. Accordingly, in socio-constructivist therapies, clinicians and clients are encouraged to explore how their own questions, interactions, feelings, and even therapeutic goals may reflect larger sociopolitical, cultural and economic issues (Cushman, 1995; Helms & Cook, 1999; Helms et al., 2005). This is akin to the knowledge component of a number of KSA models of cultural competence, where knowledge includes the understanding that psychologists have of their own worldview and their understanding of sociopolitical influences on cross-cultural relationships (e.g., D. W. Sue, 2001).

As noted above, many individualistic psychotherapies conceptualize change as a process that occurs solely within the individual. Consequently, most treatment outcome measures are a reflection of individual change (e.g., self-esteem, insight, ego strength, increased self-control, decreased anxiety or depression, self-actualization), and most psychotherapeutic interventions aim to change or improve individuals, not their contexts (La Roche, 2005). Because psychotherapeutic interventions are located within a cultural context, change can also be reconceptualized to include cultural context transformations. Psychotherapeutic goals must be broadened to include not only individual, but also community-based prevention and change. To accomplish this expansion it is necessary for psychotherapy models to incorporate community-based treatment elements (see Marsella, 1998; Muñoz & Mendelson, 2005) and develop outcome measures that assess contextual changes (e.g., community empowerment). If psychotherapy is conceptualized as an agent to transform the cultural context, it will likely become more reflective of the needs of culturally diverse individuals who are often oppressed by the larger cultural context.

Consequently, socio-constructive psychologists and cultural competence models encourage therapists to seek knowledge that is sensitive to the client's political and socioeconomic needs, and helps encourage them to transform their cultural context. The primary difference between various cultural competence models seems to be the way in which the cultural context is defined. Earlier models described it more broadly and abstractly, while more recent approaches attempt to do so in experiential terms. The challenge is to find broad, encompassing terms (e.g., history, socioeconomic status (SES), etc.) that are also concrete enough to the therapeutic relationship. In addition to the client's immediate context, other historical contextual issues must be taken into account (e.g., systematic oppression, history of violence, and intergenerational trauma) in treatment (La Roche & Christopher, 2008).

Unfortunately, socio-constructivist efforts to contextualize the individual and group with respect to their cultural history may have minimized individual responsibility and relational issues (Miller & Stiver, 1997; Prilleltensky, 1999). For example, they may have at times focused solely on detrimental contextual conditions and overlooked clients' resilience. Furthermore, assuming general contextual characteristics about culturally diverse groups often minimizes individual differences and promotes cultural stereotypes. As several authors note (e.g., Fowers & Richardson, 1996; Prilleltensky, 1999; Ridley, 2001), some cultural psychotherapeutic models promote a separate set of psychotherapeutic principles and guidelines for culturally diverse clients other than Non-Hispanic Whites, and similarities between cultural groups are devalued. This further polarizes majority and minority groups into separate and opposing camps. Finally, it is important to state that although socio-constructive approaches have often emphasized the cultural context, these definitions are difficult to translate into concrete psychotherapeutic interventions.

4.5　Infusing CCPP into Individual, Relational, and Contextual Interventions

In an environment of changing complexity and a multiplicity of facets within the psychotherapeutic process, clinicians' interventions can become more effective when they are conceptualized using a multidimensional model. Emphasis on a dimension creates a perspective with specific advantages and limitations. Clinicians are thus encouraged to formulate client's issues using a multiplicity of conceptualizations. Clinicians can benefit themselves and their clients if they consistently explore and question their own assumptions (and the influence of those assumptions) upon their clinical work by, for example, wondering which variables, factors, or dimensions are regularly emphasized during the sessions and which are being overlooked or rarely discussed. Are the variables being underscored individualistic, relational, or contextual? Furthermore, are the psychotherapists' formulations emphasizing or overlooking any of these areas? If so, why? Are the psychotherapists' formulations consistent with the variables that clients are emphasizing? It is asserted that clinicians' enhanced awareness of these assumptions may increase their understandings of how highlighting each dimension may influence their clients' treatment and thus help them integrate different therapeutic strategies, all the while operating within a culturally competent framework.

Although clinicians can conceptualize multiple formulations simultaneously, only a limited number of interventions can coherently be conducted at a specific time and place. The following three stages are proposed: (1) addressing chief complaints and symptom reduction, (2) understanding clients' narratives, and (3) fostering empowerment. Each psychotherapeutic stage is a concrete, tangible translation of the dimension being highlighted. Addressing chief complaints, for example, is a demonstration of underscoring individualistic understandings; the socio-constructive dimension is operationalized through the empowerment stage. Each stage has a set of conditions that need to be met if clients are to move to the subsequent stage; however, once these conditions are met the psychotherapeutic process does not unfold on a stepwise, linear fashion. Psychotherapy may become cyclical and overlapping (in which clients and therapists focus simultaneously on several dimensions). The proposed model should not be viewed as a manualized psychotherapeutic cookbook, but instead, as a set of general guidelines that foster the practice of culturally competent psychotherapy. Although these stages are compatible with most types of psychotherapy, we encourage clinicians to consider the cultural ramifications of the particular conceptualization they are using (e.g., individual, relational, socio-constructivist) and how this interacts with the goals of CCPP.

Stage 1: Addressing Chief Complaints and Reducing Symptoms
The main goal of this first stage is to address clients' immediate concerns which often consist of problem solving and/or symptom reduction. To address clients' chief complaints, it is first necessary to understand these in an in-depth and culturally contextualized manner (Angus & McLeod, 2004; Kleinman, 1988; La Roche, 2002; S. Sue, 1998). This is crucial because worldview and life experiences may affect how clients present symptoms to therapists, the personal meaning of illness, their motivation and willingness to seek treatment and social support networks, and their perseverance in treatment (APA, 2003). An in-depth understanding of the client's chief complaints entails an exploration of the meanings of his or her essential narratives (La Roche, 1999; Lakes et al., 2006). At the end of the first session, it is useful to conclude with a mutually agreed upon set of psychotherapeutic goals between clients and therapists that will

allow them to understand what to expect from the psychotherapeutic process (S. Sue, 1998). As means to further orient the client to therapy, it is also useful to structure treatment and clearly articulate frequency and length of sessions and complete all necessary forms, (e.g., informing clients about the limits of confidentiality, arrangements with managed care companies, no-show policy).

As clients narrate their chief complaints, the consequences of these problems on their functioning should be explored, through a thorough, culturally-sensitive assessment. Consistent with Standard 9.02 of the APA Ethics Code (APA, 2002) and the APA Multicultural Guidelines (2003), multiculturally sensitive practitioners are encouraged to be aware of the limitations of assessment practices, including intakes, standardized assessment instruments, and diagnostic methods. Norasakkunkit and Kalick (2002), for example, found that commonly used measures of emotional distress (Beck Depression Inventory, Social Avoidance and Distress Scale, and Fear of Negative Evaluation Scale) incorrectly pathologized Asian-Americans for being highly interdependent and/or minimally independent. Similarly, members from different cultural groups may have preferred styles for reporting their concerns in the beginning stages of treatment. It has been found that some Asian clients prefer to first discuss somatic complaints (stomach pains, headaches – Kleinman, 2001; Ryder et al., 2008) rather than intrapsychic issues, while some Latinos clients seem to benefit more from discussions about their families or friends (La Roche, 2002). However, an increasing number of managed care organizations require the use of standardized, brief diagnostic and symptom tracking measures beginning in the first therapy session, despite questionable cross-cultural applicability of these scales. Relatedly, it is insufficient to obtain information solely about clients' functioning; it is helpful to inquire about their family and social environments through an ethnographic history, family geneogram, looking at family photographs, and asking about relevant "family stories" or cultural stories as well as exploring community resources and social networks (Kleinman, 1988). The APA Multicultural Guidelines (2003) encourage psychologists to avoid using instruments that have not been adapted for the target population, and they are also encouraged to use both pilot tests and interviews to determine the cultural validity of their instruments (Samuda, Feuerstein, Kaufman, Lewis, & Sternberg, 1998; S. Sue, 1999).

If clients report safety concerns (e.g. suicidality, homicidality, substance abuse, domestic violence) therapists need to become more directive and structured. Priority is given to ensuring safety and the need to establish effective precautions (e.g., detailing and rehearsing emergency plans, hospitalizations) cannot be emphasized enough. Depending upon the specific cultural beliefs that matter for most diverse clients (e.g., familism, spiritualism, allocentrism), it is often useful to identify clients' resources (e.g., extended family, church) as means to design a safety plan that is culturally sensitive (Christopher & Skillman, 2009). Clients' basic needs (e.g., food, shelter, health) also need to be addressed during the first stages of psychotherapy. These issues may be overlooked by culturally incompetent therapists, who assume that this is not within their purview. In many contexts, therapists can be extremely helpful in providing clients with some information on how to start meeting their basic needs (e.g., seeking social security benefits, on what to expect from their new culture, etc.). If these basic needs are not addressed, it may be difficult for psychotherapy to proceed to the next stages (La Roche, 2002; Maslow, 1943). It is important to note that the ways in which clients deal with these basic problems are also illustrative of the ways in which they construct their narratives and lives. Narratives are herein understood as the meanings or stories people make of their reconstructed past, present

and imagined future. These meanings can direct and organize peoples' affect, cognition, and behavior.

After clients describe their chief complaints, it is useful to explore their explanations of these problems in a culturally appropriate manner, inquiring about when the problem started, how it evolved, and wondering about why the client sought help at this particular point in time (Kleinman, 1988). Therapists should remember not only these explanations but also the words (narrative style and metaphors) with which clients formulate their problems (Epston & White, 1992; S. Sue, 1998). Therapists need to accurately employ clients' narratives as a means to enhance therapeutic communication. As clients describe their understandings, therapists start identifying variables that exacerbate problems as well as methods and situations that decrease them. This information is the foundation to design a therapeutic intervention that is consistent with clients' beliefs and narratives.

Often during the beginning of psychotherapy clinicians take a more active, objective, and structured approach. This expert stance allows therapists to teach clients to solve their problems. Consistent with culturally competent models that emphasize an awareness of power differentials, it is hoped that therapeutic relationships will evolve towards an egalitarian relationship or one in which clients are leading the therapeutic process, though this is rarely the case during the beginning stages of psychotherapy. Often, the power dynamics in the first sessions reflect those of the larger society in which therapists are constructed as the dominant figure and not following this cultural expectation too soon can generate anxiety and confusion. Furthermore, in the beginning stages of treatment, therapists and clients do not know each other so it is difficult to talk about intimate issues like relationships. Consistent with this initial expert stance is the delivery of psychoeducational information that normalizes or explains clients' conditions (e.g., muscular tension, stress) and the employment of behavioral directives (e.g., breathing exercises, improving diet, reducing caffeine intake). During this first stage, clients are often also interested in learning ways to regulate their affect; for example, clients seem to benefit from learning impulse control techniques or rehearsing relaxation techniques. Although cognitive behavioral therapy and behavioral techniques are clinically useful, they also often entail a power differential between therapists (the expert) and clients (the one with the problem) that needs to be acknowledged. The employment of these techniques is a unique opportunity to start exploring clients' experience with, and responses to, power differentials in their everyday life context. A growing awareness of these power imbalances within the therapeutic relationship is useful to understand how psychotherapy can mirror society's power dynamics.

As advocated by the APA Multicultural Guidelines (2003), in CCPP the meanings of important cultural characteristics such as race, ethnicity, gender, and religion should also be explored during the first stages of psychotherapy – particularly if they differ from the therapists' characteristics (La Roche & Maxie, 2003). The process of exploring and addressing cultural differences is not only a unique opportunity to explore the psychotherapeutic relationship, but also the influence the sociocultural context has upon this relationship (La Roche & Christopher, 2008; La Roche & Maxie, 2003). It is important that clients know they can discuss the influence of cultural differences (e.g., race, ethnicity, gender, sexual orientation, religion) from the onset of the therapeutic relationship. Although most clients may decide to discuss other issues first, the message conveyed is that cultural issues are relevant and that they can be discussed at any point.

The APA Multicultural Guidelines (2003) also clearly suggest that psychologists should not try to shape their worldviews to conform to those of clients, but rather that they have an

awareness of their own worldview, thereby enabling them to understand others' frame of cultural reference. It is hoped, however, that individuals can reduce the impact of possible negative and stereotyped cultural views through conscious effort. The first step is to recognize that such attitudes can exist and make an effort to communicate and work with members of the marginalized group (APA, 2003, Guideline 1). As clinicians, we can push back against these implicit prejudices by seeking out close and positive relationships or experiences with individuals from marginalized groups (Lehrman, 2006).

Similarly, from a CCPP framework clients and clinicians negotiate ways of working together that are mutually agreeable and likely to lead to positive outcomes. Clients can have strong preferences for types of treatment and desired outcomes, and these preferences are influenced by both their cultural context and individual factors. One role of the psychologist is to ensure that clients understand the costs and benefits of different practices and choices (Haynes, Devereaux, & Guyatt, 2002). Effective culturally competent practice requires balancing client preferences and the psychologist's judgment – based on available evidence and clinical expertise – to determine the most appropriate treatment. After clients' chief complaints have been met, many will decide to conclude psychotherapy, while others will articulate new goals. Sometimes, however, problem-solving is not enough. The underlying causes that triggered or exacerbated these problems may not have changed, making it likely that clients will relapse. For those clients who decide to remain in psychotherapy, it may be beneficial to explore their narratives in a more in-depth manner.

Stage II: Understanding the Client's Narrative
In this stage, client narratives and stories are explored with the goal of helping them to develop their own understandings and enhance awareness of their experiences. This narrative is an understanding that corresponds to their own experiences and goals, instead of one that is imposed on them by the dominant culture. The narratives clients construe of their experiences are the essential tools with which they view themselves, others, and the world. Clients are often unaware of how their society may have inadvertently scripted some narratives in their lives. Narratives are anchored in multicultural values that provide cultural group members with a menu of themes, symbols (verbal and non-verbal) and values (e.g., individualism, heterosexuality). Consequently, in some cultural groups certain narratives will be dominant, while others will be marginalized. It is important at this stage of treatment to articulate a central theme in most cultural competence guidelines: cultural differences in narratives and values should be seen as assets and not liabilities. Many members of culturally marginalized groups have continually had the message reinforced that their cultural beliefs – which often differ from the dominant culture – are somehow inferior or pathological. In CCPP, clients share their narratives and what is at stake for them in their local social world (Lakes et al., 2006).

As means for clients to develop their narratives, three goals are sought: first, to help clients identify some of the main themes in their narratives including their cultural values and how they relate to the dominant culture; second, to explore and question these understandings including those of the therapist, and; third, to accept, enrich and/or develop alternative models to understand their lives. A central objective of this second stage is to understand the clients' narratives as well as how they impact the therapeutic relationship, and how these narratives are located within the larger story. According to Mattingly (2008), when clinical encounters are successful it is because the practitioner and client are able to read each other well and/or create a shared narrative. Mattingly's idea is reminiscent of Winnicot's (1969) holding environment in

which the therapeutic relationship allows clients to cope with their anxieties. When clinical encounters are unproductive or unpleasant, significant mistakes are likely made in interpreting other's behaviors, or, as Mattingly stated, mistakes occur in narrative mind reading.

Although narratives are explored from the onset of the psychotherapeutic process, they are only explored in depth and in detail after two conditions are met. First, it must be ensured that clients are safe (e.g., not presenting psychotic symptoms, suicidal ideation, or domestic violence). Clients need to have some level of affect regulation to effectively cope with their daily stresses. Many clients may, for example, resume experiencing flashbacks or using substances after describing an experience of discrimination or trauma. Second, as noted above, clients need to experience the psychotherapeutic relationship as a "holding environment" in which they can trust the therapist and the psychotherapeutic process. These conditions can be met early in the process, but often they need to be revisited at different points in the therapeutic relationship.

The narrative review begins with a description of the client's life; they are encouraged to describe not only their current situations and the circumstances that led up to their current problems, but also the goals and experiences before the reported problems (e.g., family dynamics, community interactions). It is often useful to understand the meanings they have generated in response to significant life events. The central goal is to identify common themes about themselves, others, relationships, and the world (e.g., social injustices, socioeconomic inequities). Often when clients talk about injustices, it is important to not only involve the unjust events themselves and their own reactions (including thoughts and feelings), but also the responses of their significant others to these injustices or losses. Strengths and alternative ways of coping as well as cultural resources are explored. The therapist clarifies different perspectives, and shares the emotional burden of the injustices. When therapists validate and normalize clients' responses they share the burden of the injustices faced by clients through their empathic stance (Herman, 1992). A holding environment that allows clients to assimilate or retranscribe separate, divergent, and traumatic experiences is necessary for this process to occur (Horowitz, 1986).

Occasionally during this second stage clients construe therapists – regardless of their cultural affiliations – as members of the privileged or dominant group (La Roche, 1999). This transferential response may transform the therapeutic relationship into an adversarial one. The intensity of this conflict seems to be inversely related to the therapist's cultural similarity, including, for example, socioeconomic, gender orientation, skin color, religious background, language fluency, and educational level (La Roche & Maxie, 2003). Such transferential responses, particularly anger or frustration, need to be explored and validated. Within the holding environment of psychotherapy, clients can finally have an opportunity to articulate and further understand these feelings. Moreover, by talking about these experiences clients can also explore their own perceptions and feelings about dominant groups and society's power dynamics. This negative transferential response is a unique opportunity to address feelings of marginalization and discrimination because they are microcosms of larger social dynamics. Unfortunately, many clinicians respond to this questioning with a negative countertransferential tone that may be detrimental to the therapeutic relationship. In this phase of CCPP, the core cultural competence principle of an awareness of one's own cultural biases (e.g., D. W. Sue & D. Sue, 2007) is particularly helpful in preventing this from happening. Clinicians who are sensitive to their own cultural assumptions will more effectively prevent cultural stereotypes (e.g., African-Americans are angry and explosive) from being expressed countertransferentially (La Roche, 1999) and explore these intense negative responses. As clients become more able to question

therapists, they will gradually be able to question other social structures. Therefore, the therapy space can serve as a venue for marginalized clients to understand how their voices can influence not only therapists' views, but also the larger social world, rather than remaining silent and marginalized. This questioning is crucial for the empowerment process to unfold.

However, the narratives co-constructed within the therapeutic relationship are limited by the constraints of the setting. A strategy that may expand and challenge these narratives is to bring clients' partners, family members, and friends to the sessions or seek information from different contexts (groups or family therapy). This recommendation provides a method through which therapists can operationalize the APA Multicultural Guidelines (2003) and offer guidance for therapists to be informed of clients' contexts. In child psychotherapy, it is a must to glean information from different settings (family and school) and we also believe that it is crucial to do so when clients are from a different cultural background because of the importance of the family among members of many minority groups. Unfortunately, with adult clients the need to broaden and dynamize our perspectives by including a multisystemic ecological approach is often neglected. An additional way to explore the environment is through family pictures, news, or other contextual information that can be welcomed within the session. As clients describe their contexts, the application Google Earth™, for example, can be used for both clients and clinicians to visualize their comments within specific neighborhoods. The Internet and other technological tools have untapped potential within culturally competent psychotherapy. Similarly, therapists should recognize that culturally competent therapy may require nontraditional interventions and should strive to apply this flexibility in their practice (D. W. Sue & D. Sue, 2007; D. W. Sue et al., 1998). This may include inviting recognized helpers (e.g., community elders, folk healers, etc.) to assist in fostering the shared narratives process and in implementing sensitive interventions. The APA Multicultural Guidelines (2003) also encourage therapists to participate in culturally diverse and culture-specific activities and seek out community leaders, change agents, and influential individuals when appropriate, enlisting their assistance with clients as part of a total family or community-centered (healing) approach (Arredondo et al., 1996).

As clients become increasingly aware of their narratives, they also start questioning their applicability to different situations. Clients may discover that some narratives may be more applicable in some situations, while others are less useful. This questioning has the potential to open the client to consider alternative narratives that may have otherwise not been considered. As clients develop the capacity to revise and act upon these understandings and acknowledge how they are embedded within specific cultural contexts, clients may start feeling more empowered.

Stage III: Fostering Empowerment

The empowerment stage involves an awakening of social consciousness – a realistic awareness of one's sociocultural environment and experience – which gradually leads to a desire to transform oneself and one's context. A condition for empowerment to occur is the clients' awareness of the socioeconomic, historical, and cultural forces defining society. Only with this knowledge will they be able to alter their contexts. Thus, it is imperative that sociocultural issues be discussed within the therapeutic setting (La Roche, 1999). Some clients who have this sociocultural knowledge (and who do not have a high risk for relapse) will move quickly to the empowerment stage after developing a relationship with their therapist, without investing a significant amount of time in the first stages.

As clients narrate some of the injustices they have experienced while dealing with their socioeconomic environment (e.g., discrimination, sexism, economic inequalities, materialism), they realize they can refuse to conform to a marginalizing and oppressive status quo. This is particularly likely if they have challenged some dominant narratives or some of their clinicians' cultural assumptions. Social injustices can have paradoxical effects; the injustices that once hindered development and growth can now fuel the client's quest to overcome difficulties and new challenges. Their struggles are illuminated by new meanings and are often motivated by a desire to prevent others from suffering similar misfortunes and deprivations.

An increased social awareness may also enhance clients' abilities to perceive the complexity of social situations. They further understand that each social context has a distinct set of expectations and rules and that behavior may be understood differently in each context. This is particularly important with ethnic minorities whose experience is grounded in multiple cultural contexts, each influencing the way in which they make sense of the world. However, acknowledging the experiences evoked by each context is important, but not sufficient alone for change to occur. Clients can benefit if they explore and experiment with different behavioral strategies to intervene in their environments. It may be helpful to predict in advance that such experimentation may cause some anxiety and disappointment. However, these challenges may allow clients to develop a renewed sense of agency over their environment while fostering a reinvigorated sense of hope and power. Rather than seeking homeostasis, clients can proactively seek stimulation and new challenges.

During this stage, CCPP becomes more open-ended, less structured, and less frequent. Clients direct their treatment and the ways in which goals are pursued (e.g., meeting once a month to talk about social justice or relapse prevention techniques). Therapists offer feedback and ideas and will increasingly attempt to contextualize these suggestions as means for clients to identify possible cultural biases. Furthermore, therapists may also share some of their own views that influenced the psychotherapeutic relationship, making the dialogue between clients and therapists more genuine. For example, in the case illustration presented later in this chapter, the therapist acknowledged his lack of understanding of what it is to live in "the projects". The therapeutic relationship gradually becomes a collaborative partnership, far from the more directive stance described in the first stage. Similarly, the NCSPP (2007) competency standards underscore the importance of training psychologists to understand the constructs of power, oppression and privilege, their impact and the psychologists' role in promoting social justice, and as advocated by the APA Multicultural Guidelines (2003), psychologists are encouraged to engage in social justice work that derives from knowledge of contextual influences on various groups of marginalized individuals because this work can help foster an appreciation and respect for broader social and cultural conditions (Constantine & D. W. Sue, 2005).

As clients become more empowered, they may choose to end therapy. During termination clients need to review their achievements and challenges, the evolution of the therapeutic relationship, as well as their cultural contexts. Furthermore, therapists can genuinely share some of the ways in which the client has impacted him or her and the therapeutic relationship.

4.6   Clinical Illustration: Mary

At the time of treatment, Mary was a 55-year-old, unemployed, disabled, African-American woman who was seen therapy by one of us (ML). She was referred by Dr. R, her primary care

physician (PCP), who stated that "she was presenting with significant back pains with no structural damage," meaning that her pain was likely "psychosomatic." Mary, in contrast, explained that she was coming to therapy because Dr. R. had said "nice things about you" and that she had also heard that I "had helped many people." She hoped I could help her with her back pain. Mary explained that her back pain was so intense that at times she could not walk; often her back "burned" particularly during the morning. Burning back pain, Mary clarified, meant paralyzing and unbearable pain for long periods of time. When it "burned," nothing could stop the pain. Throughout the first sessions she repeated "nothing works." Furthermore, even though Mary believed her PCP was a "nice woman" she explained that "she can't do more for me." Although Dr. R. had explained that her back pain was not related to a general physical condition, Mary was persistent in her belief that her pain was due to structural damage.

Mary was a single mother of four children, one of who "died some time ago," and a grandmother of seven. Three of her grandchildren were currently living with her. Given her back pain, she had been classified by the state as disabled and had been receiving social security benefits for the last 4 years. She had worked at the counter of a store for over 10 years until her back pain intensified so much that she could no longer stand for extended periods of time.

As I proceeded to assess her mental status, she denied feelings of depression or anxiety, although at times she would cry for no apparent reason. She reported having frequent insomnia, fatigue, and occasional memory and concentration difficulties. Mary denied psychotic and manic symptoms, depressive episodes, panic attacks as well as alcohol and substance use. She reported having a good appetite and denied any significant relational problems with her family. Many of my initial questions were somewhat structured and directive. I was attempting to glean objective information – consistent with the individualistic dimension – that would suggest a Diagnostic and Statistical Manual of Mental Disorders (DSM-IV) (American Psychiatric Association, fourth edition, 1994) diagnosis. After reaching a tentative diagnosis of an undifferentiated somatoform disorder, I proceeded to further explore her explanations of her back pain.

Mary explained that her back pain began 4 years ago and I inquired if she remembered anything occurring at that time, and she could not. Mary continued to explain that she did not understand why the pain had started. However, I continued to address her chief complaint in accordance with her belief that it had a biological/structural component, while gradually exploring additional possibilities. Nonetheless, not understanding the causes of her pain made me fear that the psychotherapeutic process would be slow, and thus I stated that it might take a while to reduce the back pain and that I would have to get to know her and her medical history better before her back pain improved. To accomplish this goal I asked her if we could meet for weekly appointments and she agreed.

We also agreed that it was a good idea to read her medical chart and exams, and to consult with her doctors to attempt to have some understanding of her complex medical history. Concomitantly, she agreed to explore any daily activities that might be related to her back pain. Given that her back pain seemed to fluctuate during the day, I explained that she might find an activity such as talking with friends, watching television, or walking that could potentially diminish her back pain. She soon realized that the way she slept was related to her back pain and concluded "bad sleep equals bad pain."

Thus, we began working on behavioral strategies to decrease her insomnia. I taught her some sleep hygiene strategies (e.g., a consistent wake time) and encouraged healthy habits (e.g., encouraging her to walk, eat well, and reduce the number of cigarettes smoked per day). During this time, she used a behavioral chart and monitored her back pain fluctuations.

She identified antecedent thoughts/feelings/behaviors/situations that were related to her insomnia. Mary also explored what activities were useful to prevent a bad night. For example, she found that if she slept on a flat surface and went to bed at 11:00 pm rather than 9:30 pm she would sleep better.

At this early stage in treatment, although Mary had experienced some minor symptom relief, I realized that I had only explored individualistic issues and consequently only used individualistic interventions (e.g., CBT, psychoeducational strategies). Thus, I began to explore the influence of the therapeutic relationship and the cultural context. Mary immediately described how crime was rising in the projects in which she lived. She also explained how little she could buy with her social security check and how the projects were being taken over by new people, namely Hispanics. Mary quickly apologized, realizing that I was Hispanic. I rapidly thanked her for being honest and told her that it was okay to talk about these issues too. I told her that if psychotherapy was to be successful, we needed to talk honestly and freely. I also suggested that it might be hard to talk about these issues with someone from a different background, particularly given that Hispanics seem to be taking over the projects. Mary nodded.

As she gained increased control over her back pain, we further explored her narratives in more detail suggesting that we were in the second stage. I again inquired if anything significant had happened 4 years ago; "Not that I can remember" she immediately responded. However, her eyes welled up and within seconds cried "Tommy was shot! Oh my God, my Tommy!" After 15 minutes of intense sobbing she explained that she did not like to talk about Tommy. She explained that it was not only hard to stop crying, but "people are sick of my crying." However, all she really wanted was to talk about Tommy because she missed him so much.

During the following sessions, we repeatedly talked about Tommy. Mary described not only the day in which Tommy was shot at "Death Alley" – a corner in which drugs were trafficked – but also many memories of his childhood. By telling and retelling the details of Tommy's life and death, she explored many feelings that had been overwhelming her for the last 4 years. Mary traced her back pain to Tommy's murder. She described how her body had felt unbearably heavy and the intense burning pain that had overwhelmed her. Mary said "I wanted to scream, explode but nothing would bring my Tommy back, nothing works." In future sessions we talked about her experience of "nothing works" and soon identified several additional earlier experiences that seemed related to this hopeless feeling. Her father had abandoned her, she had experienced domestic violence, and living in poverty had severely limited her choices. Mary talked about how hard she had worked to move out but she had not been able to afford a house in a different neighborhood. In tears, she explained that "if I had been able to move, Tommy would be alive."

During the following sessions, Mary would cry for the first half an hour as she talked about Tommy; however gradually, the number of minutes seemed to decrease as she realized that she could in fact control her tears. She soon realized that one of her prominent narratives was that she was blaming herself for Tommy's death. Using a psychodynamic frame it could be said that her guilt was internalized and somatized; a CBT approach would focus on challenging Mary's maladaptive guilt. However, the common denominator of these individualistic models is that they would focus on changing Mary's guilt in isolation from her context. However, using the proposed multidimensional model, we also proceeded to explore the contextual conditions in which Tommy's murder occurred. It coincided with a summer in which violent deaths had increased exponentially in Boston. She remembered that 4 years prior the state of Massachusetts had experienced a significant fiscal deficit resulting in substantial cuts in social services.

Increasingly angry, she described how there were more young African-American men in jail than in college – a remnant of slavery in the US, she added. Furthermore, she noted that African-Americans were smoking more, had poorer health and were dying at earlier ages than Whites, not only because of health issues but also because of violent deaths. Although Mary had repeatedly reported being "hooked on cigarettes," this contextual awareness helped her to stop smoking. As she became more aware of the socioeconomic, cultural, and historic forces related to Tommy's death, she felt less guilty and less responsible for his death.

Six months after the beginning of therapy and about six sessions after she started talking about Tommy, Mary was again detailing feelings of pain and grief and I told her "I understand how painful it is." She angrily stared at me and said "Do you really understand? Have any of your children been murdered? Shot! No you don't understand! How can you dare say that you understand. No one knows what it is to lose a child until they lose one! You don't even understand what it is to live in the projects. You know, you can get shot any time, did you know that?" Nervously aware of my hasty comment, I hoped to transform my mistake into a corrective experience (Kohut, 1984) and nodded in an attempt to validate her anger towards me. Mary went on to explain the intense pain she felt when she realized that her son was shot – the unbearable burning pain that would not die. Mary then described how many people had started avoiding her because she was "crazy." Even her preacher had gotten tired of her and Mary was ostracized from her church for stating that she would kill her son's murderer and that she would never forgive him. She then proceeded to talk about many incidents in which she had been "put aside" and "discriminated by White and Hispanic folks." As the session ended, she seemed relieved.

During the beginning of the next session she seemed tentative and embarrassed. I thanked her for her honesty in an attempt to validate her comments and added "you know I have been thinking of what you said and I do think you are right. I do not know what it is to lose a child … even the passing thought of losing one of them is unbearable for me. I do not think I could survive as you have."

After a few minutes, she apologized for the angry tone in which she had "accused" me. However, I again attempted to validate her experience and thanked her for her honesty and explained "It's about time you show your anger. I think you have much to be angry about and you can clearly have the right to be angry at me" – attempting to acknowledge the relational dimension and my blunder, I then added – "but also anger toward all those people who have avoided you and even more so at the government that seems to be more concerned with making rich people richer than people living in the projects." My last comment attempted to include the sociopolitical and economic forces involved in Tommy's death. Mary explained that people were turned off by her anger and described how people at her church had stopped calling her not because of her lack of faith but because of her alleged craziness. I then assumed that she feared that I would stop seeing her because of her anger, thus I said "I don't think you are crazy, I think you have suffered much and I am glad we can talk about your anger, you have a right to be angry and it's about time it comes out!" Within the holding environment of the psychotherapeutic relationship I was not only attempting to validate her intense feelings of loss and anger, but also develop multiple understandings of her tragedy and grief.

After this incident she began to address gender and ethnic differences more openly with me. She described her resentment towards Hispanics and many men who had taken advantage of her. As she exposed this anger, it started to fade and she eventually began to make efforts to

meet some of her new Hispanic neighbors. Similarly, she started rehearsing different strategies to assert herself with people who were taking her for granted, like her daughters who assumed that she was responsible for babysitting her grandchildren at any time or day. Two of her daughters joined several sessions and informed me of Mary's improvements and continued issues (e.g., increased "selfishness"). However, Mary used these meetings as opportunities to practice her assertiveness skills. Gradually these family meetings became an opportunity for her family to openly talk about Tommy's death and continue the grieving process.

As Mary's symptoms abated, we agreed to reduce the frequency of the psychotherapeutic appointments, to once every 2 weeks. Soon thereafter Mary reported tearfully that another adolescent, a 14 year-old boy had been shot in "Death Alley". Her intense grief, anger and back pain instantly resumed.

After exploring, normalizing and helping Mary control the reemergence of her grief – partly by her enhanced understanding how the death of the adolescent had retriggered her past experiences of loss – we talked about what could be done to stop the shootings in her neighborhood. After one minute of thinking of what could be done to stop the violence, Mary decided to visit the mother of the teenager to provide her with the support she never got when she grieved over losing Tommy.

During the next session, Mary reported that she had not only met the mother of the 14-year-old boy, but also a handful of other mothers whose sons were murdered. She kept their telephone numbers and a few months later we started a group of grieving mothers within the health center. Instead of calling themselves a grief group they named it the "No B.S. Group." Mary was key in encouraging other mothers to participate. Several months later, this group was occurring within the projects and had more than six consistent members although often others would attend (one group consisted of 24 adults). The group members not only shared their grief, pains and frustrations, but they also gradually became interested in stopping the rapid spread of street violence within the projects.

During group meetings Mary had repeatedly underscored the fact that it was not the mothers' fault that their sons had been shot, but the influence of factors such as poverty, cuts in social programs, prevalence of drugs, and the war in Iraq. Instead of blaming themselves, group members started channeling their pain into concrete ways to transform their neighborhood; they invited professionals to speak about violence and volunteered for drug prevention programs. As experts in community violence started educating parents about what to do if their children had guns or if they joined gangs, several group members marched to "Death Alley" and talked with gang members.

Unfortunately, the "No B.S. Group" eventually stopped meeting after Mary's death. She was buried 6 weeks after being diagnosed with lung cancer. However, during Mary's last weeks she seemed to have reached a state of peace and grace. The last time I saw her alive, she said that Tommy was thanking me for the love I had given her. She described how Tommy was now holding her hand. As Mary's eyes shined, she stated she no longer had any fear or pain. Fearing it was the last time I would see her, in tears I thanked her – and maybe Tommy too – for her love and all I had learned with her.

Although the grief group dissolved shortly after Mary passed away, it had a lasting impact on its members and on the community during the time it existed. After her death, I met with her devastated family, and I continued to treat one of them in psychotherapy. This time, Mary's family openly grieved for her. At times, it seemed almost as though she was in these family sessions.

Much remains to be done to help the community in which both Mary and Tommy lived and died. It is our hope that these therapeutic recommendations may help this process.

4.7   Summary

The ideas sketched herein are in development and intended to complement psychotherapeutic models by elucidating the importance, as well as the complexity, of infusing culturally competent practices into the psychotherapeutic relationship. Specifically, we suggest that psychologists formulate clients' issues using a multidimensional model that includes the cultural context. Our aim was to present this multidimensional model while highlighting key features of cultural competency guidelines and models, arguing that cultural considerations are an essential component of any therapeutic intervention. All psychotherapies are anchored in multiple cultural contexts; thus, this model is not only applicable to racial and ethnic minorities but to all individuals. It is argued that each dimension offers a narrow range of understandings and options; however, the consideration of multiple perspectives opens the way to a fuller interchange of narratives and potentials. As clients and therapists become increasingly cognizant of different perspectives, they can chose to accept current ideas or create alternative ways of being and relating that are more consistent with their goals and needs. During the early sessions working with Mary, for example, I realized that I was only focusing on individualistic formulations (e.g., CBT, psychoeducation). Upon this realization, I proceeded to include her cultural contexts both within and outside of the psychotherapeutic relationship, which allowed Mary to contextualize her guilt and question the limitations of the psychotherapeutic relationship. By using the three described dimensions, Mary was able to broaden the meaning of Tommy's death, and this not only allowed her to cope with her grief but also empowered her to improve her community. It is, however, important to note that the proposed ideas have numerous limitations, several of which are addressed below.

A primary limitation in the developing area of CCPP is the lack of empirical evidence in support of cultural competence guidelines (Arredondo & Toporek, 2004; S. Sue, 2003). Despite the acknowledged need for mental health care to incorporate a cultural perspective, there are significant empirical and conceptual limitations to the study of cultural competence. Currently, there is no evidence that clinicians who adhere to a given culturally competent approach provide better mental health care than those clinicians who do not adhere to such an approach. Although it may be commonsense that experiences are embedded within cultural contexts, much research is needed to assess the specific links between clients' narratives and their cultural contexts (Lakes et al., 2006). Moreover, it is not clear if these ideas are helpful in healing clients or changing environments. Although the case presented here provides anecdotal evidence of the positive impact of including contextual issues in treatment, objective measures to assess clients' ability to change their environments are not currently available. Clearly, much research remains to be done to assess these ideas.

It is also important to place these ideas into a geographical, sociopolitical, and historical contexts. These are times in which economic markets are expanding across borders, fostering an interlinked, globalized economy in which business exchanges are coupled with an increased cultural awareness. It is not only that economic commodities are moving about the globe, but also cultural artifacts and ideas. As cars, cigarettes, and computers are imported and exported so are cultural values, ideas, and tastes. It is not surprising, then, within the

context of accelerated financial exchanges, an enhanced number of multicultural bridges are being built, which attempt to make sense of these contradictory set of voices, ideas, and products consequently implicitly supporting the growth of the prevalent global economic system.

Although consistent with socio-constructive perspectives, the proposed CCPP model aims to challenge oppressive social situations (in Mary's case to become more active in stopping street violence); however, an in-depth cultural questioning of this model should not be omitted because of this goal. On the contrary, it is necessary to be even more suspicious of the goals in the name of social justice, as they could potentially support different types of subjugation. For example, perhaps Mary's treatment could have focused more on the influence of advertisements and smoking on ethnic minority communities. By focusing on Mary's individual issues, was the influence of an inequitable socioeconomic context in which violence and health disparities are widening de-emphasized? Cultural competence models intend to bring questions like this to the forefront and let clients decide which issues are significant for them. Only through a profound and thorough analysis of the possible advantages and disadvantages of these ideas can we start to propose a more refined set of clinical guidelines that will transform our clients, ourselves, our clinical work, and our cultural contexts.

5 Relationships

Sandra Jenkins

Abstract: The therapeutic alliance, or working alliance, has been shown to be reliably predictive of therapy outcome. The therapy relationship is, conceivably, the most significant variable in the treatment process. This appears to be so regardless of theoretical orientation or treatment method. As an area research studies have focused on defining the construct, methods of measurement, issues of validity and reliability and development of proper research designs. While much work is still needed in all of these areas, consensus does exits that there is a high correlation between the quality of the therapy relationship and a successful conclusion to treatment.

   As would be expected, identifying the complex elements of the therapy relationship has been the subject of much examination in the literature. For the purposes of this chapter the components have been limited to the influence of: therapist/client variables, attachment styles, cultural variables, theoretical orientations, relationship congruence, alliance ruptures and the focus of relational analysis. Attention is also paid to crucial non-verbal elements.

   The overall quality of the relationship, e.g., whether or not the therapy participants are able to establish and maintain feelings of mutual trust, fondness and respect, is vital to the formation of a strong therapeutic bond. As is true in any relationship, the therapy alliance is an interactive phenomenon that is difficult to define and precisely measure, however, certain relational skills and competencies have been identified as essential to alliance formation. Basic competencies include self-awareness, empathic and genuine responding, maintaining relationship congruence and proper role boundaries, and interpersonal styles. Expert competencies include cultural competencies, knowledge of how to identify and repair alliance ruptures, negotiating treatment impasses, and how to utilize analysis of the relationship as part of the treatment. Case examples are offered to illustrate each of the Basic and Expert competencies.

5.1   Overview

Numerous research studies have shown that the *therapy alliance* is predictive of the outcome; in fact, no other variable has been found to be as significantly associated with treatment outcomes as therapy alliance. Meta-analysis studies have shown that treatment effect sizes have varied between 0.21 and 0.29 (Castonquay, Constantino, & Holtforth, 2006). Overall, studies have shown that the alliance consistently accounts for 4–26% of the variance (Lambert & Barley, 2002; Crits-Christoph, Gibbons, & Hearon, 2006; Hardy, Cahill, & Barkham, 2007). As Castonquay et al. put it, "although the size of the relationship is not large, it appears to be robust" (p. 272). No other treatment process variable has been so meticulously researched. A database check using "therapeutic alliance" as the key search term produced 3,350 citations of books and articles. Most of these citations were produced within the last 20 years or so. To underscore the significance of the therapy relationship, the therapeutic alliance has been shown to be highly correlated with treatment outcomes regardless of treatment modalities.

The emphasis on the alliance as an outcome variable began to emerge when it became clear, through numerous outcome studies, that different therapists, using the same treatment methods, consistently produced different results. It also became clear that no treatment technique was significantly superior to any other. The therapy alliance appears to be the only variable that remains a stable predicator of the treatment outcome across treatment methods, leading to the necessity to focus outcome inquiry on personal and interpersonal interaction variables (Horvath & Bedi, 2002).

As with any complex treatment method, defining elements of construct validity and reliable measurement can be an intricate process. There is still much work to be done to identify and sort out several key validity and measurement concerns (Safran & Muran, 2006). A comprehensive overview and examination of the research literature, conducted by Lambert and Barley (2002), noted that research efforts have focused on understanding why the alliance has been such a potent variable in treatment outcomes and in defining the construct. Many research studies have concentrated on identifying the crucial components. What is the treatment alliance? Researchers have generally tended to focus on certain cognitive, affective, and interpersonal components, but there is no current agreement about, let alone integration of, the necessary factors.

Cognitive components include those interactions that lead to successful, collaborative agreement for treatment goals, objectives, and techniques. Other cognitive elements include understanding and agreeing on mutual role and outcome expectations and the client's preferences for possible treatment modalities (Iacoviello et al., 2007). Affective elements that have been explored are mainly those posited by humanist models, i.e., empathy, genuineness, nonpossessive warmth, positive regard, and acceptance, etc. These affective elements have also been termed the "facilitative conditions." Interpersonal components include different interpersonal styles, therapist's credibility, and possession of adequate therapy skills. While there appears to be a consensus in the literature that these elements are important, researchers still disagree on the definitive list of elements (Lambert & Barley, 2002).

Measurement of the alliance also presents researchers with a complex array of instruments and statistical data, such that consensus about the list of reliable measures is lacking. Horvath and Bedi (2002) offer a historical overview of the research conducted with alliance instruments developed by several authors over a 20-year period. Drawing upon different theoretical orientations (e.g., humanist and psychodynamic), some 24 different instruments have been developed, but the most widely cited, or at least most focused upon by Horvath and Bedi, include, The Penn Helping Alliance (HA), the Vanderbilt Therapeutic Alliance Scale (VTAS), the Working Alliance Inventory (WAI), the Therapeutic Alliance Rating Scale (TARS) and the California Psychotherapy Alliance Scale (CALPAS). Perhaps the most widely used is the WAI, developed by Horvath and Greenberg (1986).

All of the existing measures are based on self-report items that have been recorded outside the actual therapy sessions. To date there is no in vivo method for measuring the alliance as it unfolds in the therapy work itself. This means that there is no way to measure the alliance as a function of the interactional relational situation. Independence of measurements has also produced the perplexing results that therapists and clients often do not rate the alliance in the same way or agree on the extent to which an alliance has been achieved (Wintersteen, Mensinger, & Diamond, 2007; Kivlighan, 2007). This has been explained as having to do to with the tendency of therapists to base their assessment of the relationship on their individual

training backgrounds, while clients may be largely influenced by their individual pretreatment expectations. There is no existing consensus to either explain such phenomenon or account for its impact on outcome studies.

Another problem is the fact that alliance ratings differ depending on when in the treatment process the measurements are taken. Two problems needed to be addressed. First, there was the real possibility that measurements taken toward the middle or end of the therapy reflected more accurately the client's satisfaction with therapy effects, or "reverse causation" (i.e., symptom relief was attributed to a successful therapy bond). This presented some problem with possible confounding of variables. Another phenomenon was the discovery of the "U" and "V" shapes, showing a high alliance rating, followed by a dip, followed by an upward incline in ratings. This "rupture-resolution" pattern suggested that a positive alliance formed early in the treatment relationship could be the product of a "honeymoon" effect, with erosions in the bond as the therapy became characterized by work expectations producing greater stress on the participants (Kramer, de Roten, Beretta, Michel, & Despland, 2008). Research conducted by a number of authors appears to have resolved both of these concerns by consistently demonstrating that obtaining alliance ratings at the end of the third and/or fourth sessions produces results highly predictive of outcomes.

While there is some overlap between constructs (i.e., most scales incorporate personal, affective, interpersonal, and collaborative components, the scales are essentially measuring different constructs, or assigning different weights to different components). Despite this fact, there is evidence of medium to high intercorrelation between the measures (0.34–0.82). The main problem is that without consensus on the constructs to be measured, the test instruments become a de facto way of selecting for, and defining, components. That is, the components become defined by whatever the instrument measures, rather than the other way around. This means that construct validity is still an important research problem (Horvath & Bedi, 2002).

Regardless of the problems with clarifying construct and measurement issues, the therapy alliance holds up as the single most predictive outcome variable. This is true to such an extent that it is now considered an area for psychotherapist training along with training in specific therapy modalities. As awareness of the connection between the *relationship context* and treatment outcomes has increased, professional associations have begun to focus on relationship skills as crucial to professional training programs.

The American Psychological Association (APA) convened the *Competencies Conference: Future Directions in Education and Credentialing in Professional Psychology* in 2002. The conference resulted in a set of competency domains deemed important to graduate training and these included relationship/interpersonal skills, among others, that are considered necessary for adequate professional functioning (Hatcher & Lassiter, 2007). The membership of The National Council of Schools and Programs in Professional Psychology (NCSPP) approved the *Competency Developmental Achievement Levels (DALs)* in 2007. Among the NCSPP competencies, *relationship competency* is acknowledged as fundamental to all other competencies (i.e., assessment, intervention, diversity, etc.) (NCSPP, 2007).

Conceptually, if psychotherapy is a cognitive, behavioral, and affective journey toward happier and healthier functioning, then the psychotherapy relationship is the vehicle in which the journey takes place. The general meaning of the word relationship is the connection of two or more things or parts belonging or working together (loosely referring to Webster's dictionary). Connection implies interrelatedness, where each part impacts or affects the other. Human

connection implies a sense of meaning or mindfulness. Relationship can be broadly defined (e.g., my various personal, social, and professional relationships are all meaningful long-standing relationships, but the same is true of my relationships with a tree in my backyard and my relationship with my dog).

Generally speaking, two aspects comprise the therapy relationship, the "real" relationship and the "professional" relationship. The *real relationship* in psychotherapy is the more informal bond that exists when any two or more persons connect. The real relationship is shaped by individual characteristics such as personalities, interpersonal styles, values, expectations, and demographic features (i.e., age, gender, ethnicity, education levels, etc.). The real relationship acts as the foundation or backdrop for the professional relationship. The *professional relationship* is shaped by more formal structures such as treatment methods, length, and number of appointments, assessment measures, and legal and ethical standards. Each relational aspect, real and professional, coexists simultaneously to form the quality of the therapy relationship, otherwise referred to as the *treatment alliance* (Gelso et al., 2005).

The therapy *relationship* and therapy *alliance* are terms that are often used interchangeably. The therapy relationship usually refers to all of the relational aspects of the therapy situation. Any interpersonal interactions occurring within the treatment context can be part of what is meant by "the relationship" and these interactions can be separated into two components: emotional/affective and role/professional components. Professional roles include interviewing, assessment, testing, diagnosis, charging a fee, setting goals, interventions, assigning homework etc. All of these behaviors occur within an interpersonal interaction between the client and the therapist according to their respective roles in the treatment context. The relationship is also shaped by the extent of emotional bonding as well as designated professional role behaviors (i.e., the feelings that each person feels for the other and how they each feel about their respective roles). The formation and development of the relationship are dependent on the contributions of both the therapist and the client. Both contribute certain expectations, goals, desires, and personal history characteristics to the process of engagement (Meissner, 2007).

The therapy alliance is formed by mutual engagement in the therapy relationship. The term "therapeutic alliance" is usually refers to the quality of both the affective and the professional role bonding between the therapist and the client and the resulting establishment of an agreed upon commitment to the therapy work. Alliance aspects include the extent to which the therapist and the client are able to collaboratively agree on a focus or goals for the treatment, and the degree to which they are both able to establish positive or hopeful feelings about working together. The alliance can also be defined by the extent of mutual trust and respect that is established between the two and the amount of openness and candidness with which the two participants communicate with one another (Samstag, 2006).

It is true that researchers are only beginning to focus on specifically defining the fundamental components of the therapy alliance, as well as the key concepts in the development of the therapy relationship. While much remains to be done in this area, some themes are repetitive enough in the literature that certain "agreed upon" elements can be identified.

5.1.1 The Therapy Relationship: Frequently Cited Elements

Some commonly cited elements emerge while perusing the literature and reflecting on my own clinical practice perspectives. Therapist and client variables are obvious elements. Essentially,

there is little disagreement that therapy works best when both participants are interpersonally competent or adequate to do the job. Much attention has also been paid to other variables including attachment styles, cultural variables, theoretical orientations, relationship congruence, alliance ruptures, and the focus of analysis (you, me, or we).

5.1.1.1 Therapist and Client Variables

Research has shown that certain therapist and client characteristics contribute to the formation of a strong therapeutic alliance. Every practitioner and client brings his or her own personhood to the treatment situation. We all have our own unique personalities, interpersonal styles, values, relationship needs, expectations, hopes, and capacity for intimacy. The treatment relationship is created out of the attributes and characteristics that the two participants bring with them to the therapy relationship. Interpersonal difficulties and developmental deficits on the part of either or both participants can prevent the formation of an alliance and subvert success of the treatment (Crits-Christoph et al., 2006).

On the therapist end a positive alliance is indicated by the therapist's enthusiasm for working with the client, faith in his or her ability to be an effective therapist, and taking a keen interest in the client's progress. The therapist's personal abilities and qualities such as warmth, empathic attunement, genuineness, compassion, and flexibility are associated with the development of a strong, stable, and effective alliance. Research studies show that therapist characteristics associated with obstructing or weakening the alliance include rigidity, hostility, and inappropriate professional behaviors (i.e., poor boundaries, inappropriate self-disclosure, or inadequate skill levels) (Clair & Prendergast, 1994).

Corresponding client behaviors contributing to a positive alliance include regular session attendance, open disclosure of problems, receptivity to therapist's input and interventions, follow-through with home work assignments, psychological-mindedness, and enthusiastic participation in the therapy. Another crucial client variable that has been identified is the client's expectation that change will require taking on his or her share of the responsibility for change. Conversely, client characteristics such as avoidance, withdrawal, hopelessness, and rigid opposition to adhering to the therapy structure are associated with poor alliance and treatment outcomes (Liotti, 2007).

The therapist's ability to be attentive and attuned to the client's affective and cognitive expressions is crucial to the formation of a strong alliance. Nonverbal expressions should also be attended to with careful scrutiny. A commonly held belief among researchers is that our bodies communicate with each other in a particularly powerful fashion. Of interest among the physical gestures are body postures, the eyes, the mouth, the lips and hands. Also having a strong influence are the nuances communicated by the tonal qualities of the voice, e.g., pitch and volume. It should also be stressed that cultural norms must be taken into account when assessing the appropriateness of nonverbal behavior (Safran & Muran, 2000; Wallin, 2007). Respectful body postures and eye contact norms differ remarkably from culture to culture. As will be discussed at greater length in another section, the competent therapist is well informed about diverse cultural norms and standards.

As a supervisor of graduate student trainees, I watch a large number of therapy videotapes. I ask students to tape the first session with each client. I especially like to watch the first few minutes of a therapy session videotape with the sound turned off, so that I can focus exclusively on

the nonverbal nuances. How does each person (therapist and client) enter the room? Where do they sit? How do they "hold" themselves? Do they sit up straight, slouch, cross their legs, fold their arms, etc.? Is the body rigid, flexible, stiff, or expressive? Is there eye contact and is the eye contact appropriate (e.g., is the contact maintained at meaningful intervals and for the right length of time, etc.?). What cannot be readily viewed on the videotape are three vital nonverbal messages (i.e., the expression of the eyes and mouth and pitch of the voice). These messages are softer, more subtle, and highly personal. Eyes and mouth convey a wide range of emotions and attitudes. The intimacy of these expressions is sometimes so powerful that words are less adequate.

5.1.1.2 Attachment Styles

Each practitioner has her or his personal history. More importantly, we each have our individual attachment and bonding histories, starting in infancy. There is evidence that attachment styles beginning with our parent–child attachments have impact on the formation of the treatment relationship (Barber et al., 1995; Horner, 1998). The longevity of the total dependence of the human infant on caregivers has resulted in the evolution of infants with strong attachment instincts. Infants display a predisposition to readily seek bonding with others (Mitchell, 1988; Liotti, 2007).

When caregivers offer adequate attention, protection, emotional and physical comfort, and empathic attunement, infants form a secure bond with the caregiver. Securely bonded infants show distress when the caregiver departs, but can be easily soothed upon his or her return. Insecurely attached infants display two notable patterns. In one pattern the infant shows distress when the caregiver leaves, but cannot be readily soothed when the caregiver returns. In another example, the infant exhibits little, if any, signs of distress when the caregiver departs, and shows little interest when the he or she returns. Securely attached infants also show an ability to play and move about independently more so than their insecure counterparts. These attachment patterns have been termed: secure, ambivalent, and avoidant, respectively.

Depending on whether we formed secure, insecure, ambivalent, or avoidant attachment bonds with our caregivers, we subsequently adopt a positive or negative adult interpersonal stance. Our experiences in relationships with our caregivers become internalized as mental representations of the self, the other, and the self-in-relation to the other. These internalized representations function mainly on an unconscious level to shape our interpersonal attitudes and expectations. Adult interpersonal functioning is based on *internalized working models* of childhood attachment patterns (Wallin, 2007).

Meyer and Pilkonis (2002) have identified four empirically supported adult attachment styles based on early attachment patterns: *secure*, *preoccupied-ambivalent*, *dismissing-avoidance*, and *fearful-avoidance*. Secure attachment is associated with consistently nurturing caregiver attention. Secure individuals expect to be comforted and gratified by relationships and they believe that they are worthy of the comforting provided by attentive partners. They also recover better when their trust has been violated by actively seeking comfort in other relationships. Preoccupied-ambivalent attachment is associated with inconsistent caregiver attention (e.g., the child is given nurturing care at times and is neglected at other times). Preoccupied-ambivalent adults are preoccupied with anxieties and issues of trust. On the one hand, they yearn for comforting relationships but they are also fearful, especially of rejection, from prospective partners. Dismissing-avoidance attachment is linked to a caregiver style of consistent

lack of attunement and nurturance. Dismissing-avoidance individuals tend to maintain a posture of defensive distance from others and avoid committed relationships. Worst off are individuals who exhibit a fearful-avoidance style. Fearful-avoidance attachment patterns are associated with consistently neglectful and/or abusive caregivers. These individuals find it exceptionally hard to trust others. They are especially fearful of abandonment and are prone to develop symptoms of depression, including suicidal ideations, after a relationship breaks up.

Meyer and Pilkonis (2002) also examine the existing attachment style measurement instruments as well as research linking attachment styles to the formation of the therapy alliance and outcome studies. Two of the frequently used instruments are: the Adult Attachment Interview (AAI) and the Experiences in Close Relationships questionnaire (ECR). The AAI was constructed as a series of interview items covering a range of relational perspectives and attitudes and is used by analyzing the recorded narratives. The ECR is a questionnaire that inquires about adult romantic relationship histories. Examination of the relationship between attachment style measures and self-reports of the treatment alliance showed a weak convergence. The authors concluded that the different variable instruments (attachment styles and alliance measures) are not measuring equivalent constructs, meaning there is a lack of sufficient clarity about the connections between the two.

The therapy relationship is structured in a way that resembles child–caregiver roles. The therapist acts as a source of comfort, cognitive and affective bonding, and emotional regulation. It is, therefore, logical to assume that preexisting internal working models of interpersonal life and attachment styles will impact the therapy process. The authors reviewed several studies examining the relationship between attachment styles and therapeutic relationship. Cited authors examined in-patient attachment styles and outcome, attachment styles and formation of the alliance, and therapist attachment styles.

Results confirmed that patients with secure attachment styles functioned better during and after therapy, than did insecure patients. Dismissive-avoidant patients, however, showed greater relative improvement than did secure patients. Secure patients did show significant correlations with outcome than did insecure patients. The authors speculated that, despite their distancing styles, dismissive patients may have unexpectedly benefited from the prolonged connections formed with therapist during long-term psychoanalytic treatments.

Measurements of the alliance reports showed that secure patients formed stronger, more effective treatment alliances. Dismissive patients reported weaker alliance formation. Preoccupied patients reported highly positive ratings. The unexpected high ratings of the preoccupied patients was explained as resulting from the tendency of preoccupied individuals to be fearful of rejection, and thus they were anxious to please the therapist and present themselves and their treatment experiences in a positive light. Overall, more securely attached patients were able to form better therapeutic alliances, which were shown to be associated with more sustained improvements over time.

Secure attachment style therapists were more likely to handle relationship problems (i.e., therapy ruptures [see that section] more effectively than less secure therapists). Preoccupied therapists, presumably due to their fear of rejection, showed more treatment problems with difficult patients. Much of the research provides evidence that therapists do respond differently to patients depending on patient attachment styles. There was some evidence that another important therapist treatment factor was the tendency for anxious therapists to be less empathic with dismissive and fearful-avoidance patients. More research is needed to ascertain how therapists can best respond to different client attachment styles to optimize positive treatment outcomes.

5.1.1.3 Cultural Variables

The therapy relationship exists within a larger social, cultural, and political system. Cultural forces impact many aspects of the therapy relationship. The profession of psychotherapy is itself based on a culturally specific worldview. Historically, European middleclass cultural values shaped the norms and expectations for appropriate professional demeanor, dress, roles, settings, goals, rules, ethics and treatment modalities, etc. (Frew, 2008). For the most part, these same cultural values have determined mental health policies and practices throughout the country's mental health delivery system. How many African-Americans, American Indians, or Asian immigrants have served on state or county Mental Health Boards or policy-making Commissions, Managed Care Boards, etc., in any area of the country?

Culture and gender influence client help-seeking behaviors, as well as role and outcome expectations. It is unlikely that the therapy dyad will achieve enough congruence to form a successful working alliance, if cultural and gender influences are ignored or not properly incorporated into our practice. All practitioners, regardless of our own demographic backgrounds, need to be aware of our biases, including racial, gender, sexual orientation, and social class biases. Moreover, it is not ethical to attempt to deliver services to any group where our ignorance or biases toward that group will interfere with competent professional practices.

Much of the psychotherapy literature has spoken to the high dropout rates of ethnic minorities and lower SES clients. Racial and gender matching has been one of the possible solutions that has been proposed over the years. Indeed, several studies have shown that race and gender matching does have a positive effect on retention rates. Therapists and clients matched by culture, ethnicity, and gender tend to report higher numbers of therapy sessions. On the whole, there is evidence that female to female therapist–client matches do produce stronger alliance scores. Sue and Lam (2002) perused the outcome literature and found evidence that lesbian, gay, and bisexual clients (LBT) stated preferences for female therapists, regardless of sexual orientation of the therapist. Sue and Lam also point to the fact that there are fewer studies on SES and outcome than is true of any other demographic group, leaving little room to draw conclusions about SES therapist–client relationships, including retention rates and matching.

While better retention rates might imply a stronger alliance, therapist–client matching studies do not show evidence for higher therapeutic alliance scores. Alliance variables are inclusive of many relational aspects, such as therapist competencies and client treatment expectations, therefore, racial and gender matches may produce higher retention, but not necessarily a stronger treatment alliance.

Different cultural groups also have different perspectives on mental health than do most professional psychotherapists. This is especially true when ethnicity is confounded with lower socioeconomic status. In a study involving 25 lower class White, Black, and Puerto Rican clients, Alverson et al. (2007) found that each ethnic group was confronted with a different set of treatment alliance barriers within their treatment clinics. Using a qualitative research method, clients were interviewed within their own cultural neighborhood settings, regarding their mental health point of view (how they defined their illness) and their treatment service experiences.

White clients were the most self-disclosing, were more likely to talk about their feelings, and perceived their mental health problems in biomedical terms. Alliance barriers for White clients included therapists not listening to their stories and not giving them adequate encouragement.

Black clients were more inclined to feel stigmatized by mental illness and needed more privacy. Black clients felt systematically jeopardized by being assigned to group therapy with strangers, not including family members in their treatment and not being given adequate information about medications. Puerto Rican clients tended to believe that the origins of mental illnesses were biological or brought on by social and environmental causes. Puerto Ricans took special comfort in family ties and felt particularly disadvantaged if their families were omitted from the treatment process (Alverson et al., 2007).

Other authors have pointed out that cultural groups differ in their view of the proper role expectations for the psychotherapist. Some groups prefer the therapist to take a formal, highly structured, authority figure stance and can be disturbed, confused, or insulted by a therapist who assumes a casual, egalitarian position. Generally speaking, Asian and Hispanic groups tend to fall within this role preference norm. Yet other groups are especially put off by the expert, authority figure posture and feel "talked down to" by a dominating figure that may be perceived as threatening and demeaning. These cultures tend to feel especially vulnerable and cautious with therapists who cannot, or will not, connect on a more personal level and may experience "coldness" or distancing that negates forming a strong alliance.

Therapists must recognize these clients' cultural preferences and be prepared to be more open and assume an equal client–therapist stance (Vasquez, 2007).

Recognizing and admitting to our biases can be difficult. Most likely we have all been taught or exposed to biased thinking, values, and attitudes, but are not necessarily conscious of this fact. Several researchers have focused on the largely unconscious nature of racial bias. These studies have shown that while we harbor racially biased attitudes, we often feel ashamed to admit it, thus, Dovidio and Gaertner (2008) coined the term *aversive racism* to address racist cognitions operating outside of our awareness.

Biases in the therapy relationship can be expressed by the therapist's inability to provide adequate empathy, validation, and support for the client's painful racial, sexual orientation, social class, or gender experiences in a society where he or she can be exposed to hostilities and discrimination. Lack of empathy, lack of validation, or denial of the realities of discrimination is a behavior that has been termed *micro-aggressions*. A study by Constantine (2007) showed that counselor racial micro-aggressions explained 15% of the variance of failures in the therapeutic alliance. Well-meaning therapists can be guilty of displaying (including nonverbally) micro-aggression attitudes such as *color blindness* or *blaming the victim*, which amount to denial of real situations of racial bias and their painful consequences.

Unfortunately, alliance barrier difficulties may not be addressed properly in therapy situations where culture, gender, and sexual orientation conflicts exist. There is evidence that clients may not feel comfortable confronting bias when evident in the therapist's attitudes. By definition, the therapist is in a superior role and power position and clients may not want to risk offending them. Nor is it easy for clients who may have histories of abandonment, child abuse, rejection, or social/political discrimination to risk making the therapist angry. Thus, many tend to keep their concerns to themselves and instead withdraw, passively resist, or drop out of the therapy (Constantine, 2007; Vasquez, 2007).

More importantly, clients are often not alone in having difficulties confronting or addressing diversity conflicts. After many years of teaching diversity courses in three graduate schools, it is clear to me that many students have real hesitation in talking about diversity issues. Many White students feel particularly at risk talking openly about racial matters, either in class or with their ethnic minority clients. White students have often expressed concerns that they will

be viewed as racists, if they unknowingly say "something offensive." Some White students have reported that they prefer to avoid racial and social class topics because thinking about these topics can provoke uncomfortable feelings of guilt or shame.

Others have reported that they were taught to avoid many diversity topics, regarding them as "taboo" or off-limits, at least in public or professional settings. Still others were raised to believe that the proper nonracist, "politically correct" attitudes were positions of "color blindness," where a person's race (or gender) should not mean anything and that everyone should only be viewed as individuals. Unfortunately, many crucial diversity topics are believed to be too "sensitive" or too prone to cause unpleasant interpersonal conflicts and altercations and are, therefore, simply not "safe" to approach and it is smart to avoid them. These beliefs and perspectives collide with openly and deliberately addressing diversity issues in the therapy process because previous learning has taught students that to do so would be inappropriate, "risky," "painful," or "unprofessional." Obviously, these attitudes will have lasting impact on any therapy situation. The therapy process will be at best seriously limited, or worse, the process will inevitably stall or come to a premature halt.

Perhaps the most difficult thing for any therapist is to examine how our own demographic realities affect our practice. How am I affected as a person, and subsequently as a professional, by my ethnicity, gender, age, sexual orientation, social class, religious beliefs, lifestyle choices, etc.? It is not likely, as much as I might want to think so, that these personal, social, and political statuses have no effect on how I relate to my clients and how I perceive and evaluate their problems and behaviors. This is a professional issue that goes beyond bias; it is a matter of worldview and how we are each shaped by how we were taught to see the world and see ourselves in the world. Moreover, I need to recognize what I was taught. More importantly, we all operate, consciously or not, from a set of learned values that are integral to our worldview and lifestyles. What are my values? What life choices do I systematically validate and endorse (Pedersen, Crethar, & Carlson, 2008)?

It is also a matter of knowledge or ignorance about the worldview of our clients. How much time have I actually spent with people who are different from me (i.e., persons from a different race, sexual orientation, or social class)? How does my ignorance or lack of familiarity affect my work with a client from a social background that is foreign to me? Why am I so ignorant about certain groups in the first place? Is my ignorance a form of micro-aggression, that is, I consciously or unconsciously avoid educating myself about different social groups in order to maintain a social/political distance from them?

It can be quite amazing how many well-educated people maintain ignorance about the different social groups in our communities. A few years ago, I was assigned to supervise an intern in our training clinic. One day she reported that one of her clients was Jewish. I asked her how often and in what ways the client had commented on this fact. Her answer indicated that the client's Jewish ethnicity was centrally important to her identity and worldview. I then asked the intern how much she knew about Jewish beliefs, traditions and history, and she replied that she knew almost nothing. I then instructed her to get to a library and check out books on Jewish history and traditions and begin reading up on the subject before her next meeting with her client. The intern stated that she would do this, but was puzzled about why that was necessary. I then informed her that she was currently practicing in an unethical manner to provide treatment to a client about whom she knew very little and could not, therefore, offer competent psychotherapy services. I also wondered why her ignorance about her client was so acceptable to her. Was she distancing herself from her client in other, perhaps more meaningful ways?

I made a mental note to myself to observe her videotapes more carefully for signs of lack of empathy and, indeed, that was what I found. Consequently, I altered my work with this intern toward helping her become more aware of relational issues in her therapy work.

The best solutions for diversity problems in therapy, put forth so clearly by Vasquez (2007), is for every therapist to take his or her responsibility seriously for greater self-awareness, openness to identifying and refuting his or her biases, learn the appropriate evidence-based treatments for different groups, and prepare themselves to include these topics in their discussions with the clients. We need to be capable of appropriate empathic responses and, moreover, we need to be willing to advocate for social change that will eliminate discrimination in all of its forms. It should be recognized that failing to take these steps leaves us at risk for being unethical, as well as ineffective practitioners.

5.1.1.4 Theoretical Orientations: Theoretical Orientations and Definitions of the Alliance

Different theoretical orientations have approached conceptualization of the therapy relationship differently. That said, it is important to note that the most practicing clinicians of any theoretical persuasion would agree that the alliance is essential for forming a collaborative and effective treatment. Generally, diverse orientations differ in two ways. First, there are different views as to the extent of the emphasis placed on the role of relationship in application of treatment methods and techniques. Second, there are variations in the manner in which the therapist is expected to respond to the relational material presented in the treatment dyad. In other words, how does the theory define and utilize the alliance in each treatment model, and in what prescribed manner does the therapist incorporate the alliance into his or her intervention strategies and techniques?

5.1.2   Psychodynamic Relational Treatment Strategies

Relational components have featured fundamentally throughout various psychodynamic treatments, especially in *psychoanalysis* and the more contemporary models. Freud posited *transference* as the key defense mechanism through which clients attributed their unconscious relational perceptions about significant others, especially parents, onto the therapist. By relating to the therapist in this way clients revealed their deeper feelings, anxieties, needs and wishes concerning parents and the relational dynamics associated with the parent–child relationship. Problems originating from early parent–child relationships are likely to become entrenched into painful and self-defeating interpersonal patterns, or *repetition compulsions*, where a set of rigid thoughts, feelings, attitudes, and behaviors persist throughout a wide range of social encounters and situations, making it hard for individuals to find lasting satisfaction in adult life (Goldman & Anderson, 2007).

The client's unconscious interpersonal problems usually gain expression when the client experiences *negative transference*, where feelings of hostility and anxiety are projected onto the therapist. For example, the therapist is perceived by the client as a "cold," "hostile," or "rejecting" person who should not to be trusted. Clients express these negative projections in all manner of ways (e.g., they might withdraw, accuse, attack, or become evasive, etc.).

By identifying, confronting, and interpreting the transference, the therapist engages with the client to bring to light hidden problems relating appropriately to authority figures and other significant persons. Unresolved interpersonal difficulties especially those concerning issues of trust, power, sexual gratification, self-esteem and intimacy needs, etc., can be brought to light within the therapy context, so that the client comes to understand the real origins and nature of his or her difficulties. This process of opening the unconscious to conscious awareness is called *insight*, which is the main goal of psychodynamic therapies. Insight eventually allows the client to resolve his or her unconscious compulsion to repeat painful and traumatizing childhood relational experiences, allowing for successful development toward mature adult functioning (Meissener, 2006).

Countertransference is the therapist counterpart to the client's transference. Countertransference refers to the cognitions and emotions that the therapist experiences in relation to the client. Feelings of affection, anxiety, inadequacy, excitement, praise, rejection, anger, frustration, etc. are all considered to be possible projections on the part of the therapist onto the client. In classical theory, countertransference is seen as a possible hindrance to the therapist's ability to function properly. When challenged by the client's negative transference, the therapist's first job is to remain objective. The proscribed therapist stance is one of removed distance to allow the client, as much as possible, to project onto a "blank screen." That is, therapists deliberately keep their own personal responses in check so that the client can fully express and explore his or her transference-inspired emotions and reactions without the interfering effects of the countertransference. In this way, it is possible to rely on the transference as an accurate source of information about the client's relationship history.

Thinking about both transference and countertransference has been modified over time. In contemporary schools of psychodynamic thought, such as *object relations* and *intersubjective* approaches, the relationship takes on a central role in the treatment modality. Transference and countertransference are both utilized in a more direct and integrated way than in classical, traditional methods. The countertransference is viewed as a valuable and intricate tool to be used as both a source of information and a part of intervention techniques. The relationship (i.e., the cognitive and affective responses of both parties to one another) is a crucial element in the analysis (Bollas, 1987; Ogden, 1993; St. Clair, 2004).

The client's transference is viewed as an unconscious attempt to join with the therapist in an *enactment* or repetition of the traumatizing or frustrating interpersonal relationship patterns and themes. It is assumed that the therapist's cognitive and affective responses (countertransference) to the client are in counterpart with the client's affective experiences. The therapist must try to be fully aware or make the best attempt at full awareness of his or her own authentic experiencing of the client's affects and behaviors. He or she needs to be aware of his or her own affective responses such as anger, hurt, anxiety, despair, frustration, etc. as possible clues to the client's internal affective and relational world. Once the therapist becomes awarene, he or she then responds to the client in a spontaneous and genuine here-now *engagement* that is designed to bring to light the unconscious relational meanings imbedded in the enactment (Ehrenberg, 1992; Mitchell, 1988).

5.1.3   Humanist Relational Treatment Strategies

Humanist therapists rely on a firm belief in the ultimate goodness of most human beings. Human beings are all born with the capacity to mature and function in ways that promote

happy, healthy, individuals contributing in positive ways to their society. Interpersonal problems begin when we are denied the proper caretaking, cherishing, and permission to become our natural true selves. Our natural relational development is then distorted and sacrificed to adjust and accommodate to destructive environments. A major sacrifice is the loss of authenticity and awareness about the realities of our true perceptions about us and others. Instead, we learn to suppress our true feelings, needs, and personal goals (Frew, 2008).

As articulated by Rogers (1961), humanist therapies focus on a *phenomenological* perspective, that is, the focus is on the development of human consciousness and awareness as it unfolds in the therapy relationship. The treatment emphasis is on increasing connections between therapist and client, in order to heighten awareness of here-now realities of the client's experience. The therapist concentrates on creating a relationship that nurtures and encourages each client's unique experience and perspective to find full awareness and expression. The curative aspects of this relational environment consist of assisting the clients to increase their connectedness to previously unknown aspects of themselves (cognitions and affects) and decrease the emotional and cognitive distance between themselves and the therapist.

The humanist perspective posits that certain therapist values and attitudes are prerequisite to a positive treatment outcome. First, the therapists must be as open as possible to the experience of both themselves and the client. *Openness to awareness* of the self and the other is a primary stance that opens the therapist to the next requisite attitude (i.e., *understanding*). The therapist strives to understand the clients' unique *personhood* with their own individual strengths, values, needs, goals, weaknesses, attributes, etc. Given this position of respect for understanding, and striving to understand, the client's uniqueness, the therapist necessarily assumes an attitude of *acceptance*. The client is accepted, as completely as possible, as the human being he or she is, with no presumption on the therapist's part about imposing his or her own values, desires, and goals onto the client. Put another way, the therapist does not presume to direct the client's growth, goals, or purposes (Ramsay et al., 2005; Frew, 2008).

The techniques employed are intended to increase awareness and bring to consciousness relational realities revealed within the therapy process. A major tool used to accomplish this goal is *empathy*. Therapists' active empathic responses are a cornerstone in aiding the clients to become increasingly aware of their true feelings and thoughts. Empathy encourages trust but, moreover, it establishes the therapy relationship as a vehicle for trust, acceptance, and understanding.

Another set of indispensable humanist attitudes is *warmth and compassion*. The therapist must have the capacity to feel compassion for the client's painful cognitions and affects. Compassion allows the clients to feel a sense of safety and *positive regard* that encourages opening their most vulnerable experiences and feelings to the therapy process. Finally, but perhaps most important, the therapist must be *genuine*. If the therapist is not honest and open about his or her own experience, the client can hardly trust in the process. It should also be noted that sound and prudent judgments are called for to preserve the therapeutic focus and insure that an atmosphere of mutual respect is maintained. Therefore, self-disclosures on the part of the therapist must be consistent with appropriate clinical roles and purposes.

Client-centered therapists challenge themselves and their clients to explore as fully and as honestly as possible the feelings and cognitions that are present in the moment-to-moment experience of the treatment context. The therapist maintains self-awareness, genuine and appropriate self-disclosures, and strives to accept, empathize with, and understand the client.

It is also important that the therapist maintains an attitude of acceptance of the feelings being expressed, without the intrusion of inhibiting value judgments. There are no "bad" or "wrong" feelings, only bad or wrong behaviors. It is extremely important that the therapist believes this, rather than attempt to encourage or collude with the client to censure or suppress feelings that he or she has been taught to fear or deny. As the client experiences the therapist's active empathy a sense of being understood and validated replaces feelings of loneliness and despair. As the client experiences the therapist offering empathy and understanding, the client begins to listen more accurately to themselves and connect to suppressed feelings and experiences. In a growth fostering, freeing, and validating relationship, clients tend to move toward greater awareness and better functioning (Rogers, 1961; Frew, 2008).

5.1.4   Cognitive-Behavioral Relational Treatment Strategies

Historically behavior therapy (BT) and cognitive-behavior therapy (CBT) models rejected concepts of unconscious motives as having anything to do with explaining observable behaviors. Instead what was embraced was the position that behaviors are motivated by environmental consequences that reinforce or increase the likelihood that particular behaviors will be repeated or maintained. Behavior change required the therapist to teach the clients to change the reinforcing cognitions and behaviors and their behavioral consequences and thus, change their unwanted *target behaviors*.

It was also noted, however, that clients tended to do better if they engaged in all aspects of the treatment (e.g., came to sessions regularly and diligently completed all homework assignments). In this respect, the importance of the therapy alliance was seen as a "necessary, but not sufficient," component of the change process (Hardy et al., 2007). While it was not clear that therapist behaviors such as empathy, positive regard, compassion, and understanding had any empirically supported impact on therapeutic outcomes, it was assumed that these skills needed to be included in the therapist's repertoire in order to support the alliance. Relationship building skills, however, were not emphasized in BT and CBT training and treatment, because they were considered "micro-skills" and were left to introductory basic skills courses. As research showing the high correlations between the therapy alliance and treatment outcomes has continued to accumulate, BT and CBT treatment models have begun to change. Indeed, Hardy et al. concluded that empathy accounted for 7–10% of the variance of cognitive-behavioral treatment (CBT) outcomes and that empathy was more essential for successful CBT outcomes than any other treatment model, although the reasons for this were unclear.

In the early 1990s Kohlenberg and Tsai (1991) developed *functional analytic psychotherapy* (FAP), a CBT treatment that emphasizes the relational aspects of therapy. Taking note of the potential therapeutic benefits of what psychodynamic theorists called *transference*, Kohlenberg argued that the client's here-now responses to the therapy process and the therapist were useful in correcting maladaptive cognitions. In-session cognitions termed *clinically relevant behavior* (CRBs) are useful in helping clients become aware of their here-now cognitions in interpersonal situations. In the FAP-enhanced CBT approach or *FECT* the clients learn to be aware of their CRBs and to notice how these cognitions are occurring throughout different interpersonal situations and how CRBs may be reinforcing their negative interpersonal behavioral consequences.

In FECT, the therapist must first be aware of his or her own emotional responses to the client's in-session behaviors as clues to maladaptive cognitions (*internal behaviors*) leading to maladaptive external behaviors (CRBs). Next, the therapist distinguishes between in-session behaviors that are the source of problems (CBR1s) and confronts those using CBT cognitive techniques. The therapist then interprets other interpersonal problems in the client's life as stemming from, and similar to, the in-session CBR1s. As the clients learn to recognize their CBR1s and how they occur within the therapy, the therapist then notices and reinforces in-session behaviors that represent improved functioning (*CBR2s*). FECT uses the therapy relationship as an in vivo learning tool. The combination of refuting CBR1s and reinforcing CBR2s eventually enhances the therapy bond and helps the clients learn better interpersonal functioning throughout their relationships (Kohlenberg, Kanter, Bolling, Parker, & Tsai, 2002).

5.1.5 Relationship Congruence

As in any relationship, the therapy process unfolds in a developmental sequence of stages and phases from the beginning to the middle and, eventually, the endpoint. In the beginning phase each participant brings his or her own set of preconceived notions and expectations as to how the relationship should be conducted in order to realize desired relationship roles, goals, and outcomes (Patterson, Uhlin, & Anderson, 2008). Relationship *congruence* makes the relationship "feel right" to both parties. Prescribed roles and how they are played are a major aspect of relationship *role congruence*. Each role has its own *demand characteristics*. The therapist has a set of role requirements and so does the client. In order for the therapist to do his or her "job," the client must fit with a set of client-role demands. On the other end, if the client is to get his or her role needs met the therapist must fit with a set of therapist-role demands. In a *congruent* relationship, the demand characteristics are met by both individuals (Lichtenberg et al., 1998).

The beginning or opening interactions are characterized by a series of participant maneuvers designed to influence the other toward behaviors that satisfy or fit with each participant's particular set of individual expectations, hopes, and desires. Put another way, each attempts to control the process of defining and determining the nature of the relationship. A negotiation unfolds as each tries to assume control over the situation. In any relationship, negotiations can be complex or relatively simple, subtle or straightforward, quickly resolved or protracted. Issues of power and control are conveyed by the therapist in how they articulate the therapy structure (e.g., the session appointments, fee structure, therapy work expectations, etc.). The clients convey their expectations in terms of how they present their history, complaints, problems, symptoms, and relational requirements.

The goal of the negotiation is to achieve congruence with each other. Participants feel satisfied with the negotiations when the relationship is defined in a way that promises satisfaction of their expectations. Therapy work cannot actually begin until relationship definitions have been successfully negotiated and an alliance formed. If relationship congruence is achieved, the participants can proceed with the establishment of a gratifying collaborative alliance. They will probably be successful in agreeing on mutually satisfying ways of working together (e.g., reach agreement on treatment goals, role expectations, and methods for eventually achieving desired outcomes).

When there is no fit, or a poor fit, or where there are primary disagreements, the relationship will become *incongruent* and will be experienced as frustrating, daunting, threatening,

or unsatisfactory by both participants (Lichtenberg et al., 1998). Mutual frustrations may motivate both to continue the negotiation process hoping for congruence at some point. If further negotiations fail to result in conciliation, it is likely that the relationship will stall or dissolve.

In my clinical experience, clients often start the negotiations over the phone, asking questions, or perhaps, refusing to answer my questions. The indicators of relationship congruence or incongruence are quite recognizable in the first phone conversation. In some situations, I determine when it is best to refer the potential client and never agree to see them. Once the client has entered my office, however, we are on "my turf" and I usually expect to take the lead in opening the more formal, structural negotiations. I begin to assume control by setting the frame (e.g., informing the client about my practice structure, such as fees, and asking them to fill out and sign forms and take psychometric tests, etc.). It is particularly noteworthy if a client does not allow me to make all of the opening moves in our negotiations, but instead, insists on taking control by continuously talking, refusing to fill out forms, or take tests, etc.

One important aspect of relationship definition and congruence is the establishment and maintenance of proper role *boundaries*. In all role demand situations, the professional practitioner must maintain the proper role congruence, including when interfacing with the larger community or ecosystems. No therapy relationship has ever operated in a vacuum. Ecosystems operating within the therapy relationship include third-party payers, psychiatric referrals, legal constraints on confidentiality, research projects, student training and supervision, and procedural policies inherent within professional settings (e.g., community agencies, hospitals, etc.). In any of these situations the practitioner must consider role demands such as smaintaining confidentiality, or to what extent outside intrusion is warranted or necessary (McWilliams, 2004).

Whenever relationship incongruence is ignored or is allowed to persist, satisfying professional goals becomes difficult and successful outcomes are jeopardized. In some circumstances, for a variety of reasons, the therapist is unable to adequately fulfill his or her role demands and relationship incongruence becomes the norm in the relationship. When clients assume too much control over the interactions, the role demands of both the therapist and client can be seriously compromised. Under those circumstances, the participants cannot fulfill their role obligations and the therapy will likely go astray. Such is the case whenever boundary violations of all sorts (e.g., inappropriate needs, including sexual desires) are allowed to erode the therapy process (Reamer, 2001).

5.1.6 Alliance Ruptures

Much attention has been paid to recognizing, repairing, and working with ruptures in the therapy relationship. Traditionally, any behavior on the part of the client that hindered or disrupted the therapy process was thought of as *resistance*. Clients who did not cooperate with therapist interventions, or who refused to accept the therapist's interpretations, were deemed to be at odds with, or obstructing, the helping relationship that they had sought out in the first place. Such seemingly paradoxical client behavior led to much frustrated speculation as to why clients tended to behave that way. Many therapists have been trained to persuade clients to a more cooperative stance or, failing in this attempt, to end the therapy. From a relational point of view, it becomes possible to strive to understand and engage with such behaviors rather than

seek to overcome them. Interpreted from a relational framework, resistance behaviors are viewed as another form of expressing some meaningful interpersonal problem (Stark, 1994).

All relationships, no exceptions, will have some conflict inherent within them. Quite simply, no two people will always see eye to eye and to think so is naive, if not ludicrous. *Ruptures* refer to any conflicts, barriers, and impediments occurring within the therapy process. When conflicts occur in the therapy, relationship problems can develop in the treatment work itself. Therefore, the therapist needs to be prepared to address these conflicts as they arise. Ruptures occurring early in the therapy relationship can lead to premature dropping out, difficulty setting and sticking to goals, vital information kept from the therapist, and so forth and so on. Ruptures occurring later in the process can lead to missed sessions, coming late to sessions, ending sessions early, or not paying the fee, etc. (Safran & Muran, 2000).

Many therapists have experienced unexpected shifts and changes in the therapy work. How many of us have thought the therapy work was proceeding well only to have the client hint, or indeed state, that he or she did not feel anything positive was happening, or express some disappointment with the rate of progress? Or the client who makes it clear that he or she doubts that we have the competence to help them. Or the client who begins to miss or skip sessions, or simply "no shows" for no apparent reason? Or the clients who for some dubious, "out of the blue" reason decide they want to severely cut back on the number of sessions (e.g., they only want to come twice or once a month).

These are fairly obvious signs of some relationship breach that should make us wonder if we are on the same wave length with that client. Many other, not so obvious, client behaviors can be taken as signs of relationship ruptures. Clients who will not talk about important or substantive material, clients who expect the therapist to play a directive/responsible role while they assume a passive/helpless stance, clients who lose the train of thought, or quickly change the topic from some important thought or feeling, or clients who are too confused or too ambivalent to adequately address some important problem, etc.

Prolonged trends in these behaviors will ultimately frustrate both to the point of ending the therapy or stall out the process into what is called a therapeutic *impasse*, meaning that progressive movement toward a successful outcome has essentially ground to a halt. When the process is "stuck" in an impasse, the situation can be likened to a marriage that has become mired down in bickering, with neither side winning nor losing, but each continuing through an endless series of stalemates. Therapy session content tends to repeat itself and take on a déjà vu quality (e.g., "haven't we been here before," "why can't we move on from this," "will we ever resolve this problem and move on?"). Therapists and clients both eventually feel a sense of pessimistic defeatism as they each spin around the same process/content territory over and over (Mitchell, 1997; Bromberg, 1998).

Once I had a client who habitually had some, beyond his control, circumstantial difficulty or crisis arise at regular intervals in the therapy process. After two or three successive sessions, he would call and report that he could not make it in because his car was not working, or he had to leave town to take care of his mother, or his ex-wife called and could not find a baby sitter so he had to cancel to take care of his child, or something had come up at work, or he had a sore throat and had to stay in bed, etc. He was always very apologetic, worried that I would become impatient, hoped I would understand and then he would promise to see me next week and then the whole thing would begin again. Eventually, this predictable pattern became frustrating and tiresome. Obviously, we could never achieve sustained momentum toward therapeutic change, if this kept up.

In a classical model the questions would be how to confront or interpret the resistance or the negative transference, to bring the client to insight or to at least stabilize him into the process in some consistent fashion. In a relational model the questions become quite different. "What is he trying to tell me and why is he trying to tell me about it in the context of our therapy relationship?" "What is it that he experiences and do I 'get it'?" "Why is there no other way to convey it, or is this behavior the best way he can convey it?"

Relationship conflicts originate with early interactions with significant others. The goal is to better understand the relational realities motivating the interpersonal transactions expressed in the therapy context. Learning to recognize and effectively utilize the relational meanings expressed in ruptures and impasses is one of the crucial relationship skills that a therapist has at his or her disposal.

5.1.7   Focus of Analysis (You, Me, or We)

As the therapist formulates an intervention usually he or she analyses the client content (what the client has spoken about) first and then focuses the intervention on the client (i.e., he or she comments on, or interprets the client's affective, cognitive, or behavioral messages). This type of intervention is at the *one person or you* level of analysis. Classical psychodynamic therapy was developed as mainly a *one person – you* level of analysis focused on the client's transference responses to the therapist. Another level of intervention is when the therapists focus their analysis on themselves (i.e., analyzing their own affect, cognitions, or behaviors). The therapists might then decide to include their awareness of their own experience as part of the intervention. This type of intervention is at the *one person or me* level of analysis. In classical models, the *one person – me* level is focused on the *countertransference* responses of the therapist. When the therapy intervention combines both levels, the intervention is then focused at the *two people or we* level of analysis.

Drawing on developments in attachment theory, psychodynamic models began to change toward thinking of the therapy relationship and the attachment bonds created between clients and therapists as the means for therapeutic change. In the same way, the client creates a view of the therapist based on transference, so does the therapist have his or her own relationship history activated in countertransference responses to the client. As times have changed, contemporary psychodynamic therapy has shifted the focus to an *intersubjective* framework or the *two people-we* level of intervention (Stark, 1999; Safran & Muran, 2000).

Mitchell (1988) used the phrase *relational matrix* referring to the intersubjective concept of the confluence of the self, the other, and the transactional patterns between the two. The relational matrix is largely unconscious and built upon internal representations of others, or *objects*, and our experiences of objects from our relational past. In the intersubjective model it is assumed that our behavior is largely motivated and determined by the dynamic between the interconnections that we form with others. Analysis of these relational matrixes and the interactions through which they find expression become the main focus of therapeutic interventions in two-person models.

Any interactions taking place in the therapy context are the cocreations of the subjective experiences of both the client and the therapist creating a moment-to-moment dynamic. Clarifications, confrontations, and interpretations are aimed at the relational intersection between the client and the therapist, not just at the client. Examination of the interactions

themselves leads to identification of interpersonal patterns that clarify the deeper issues, goals, and motivations for the client's behaviors in and out of the therapy context (Ehrenberg, 1992; Bromberg, 1998; Stark, 1999).

5.2   Basic Competencies of the Clinician

The basic competencies required to develop a strong therapy alliance are the same set of skills necessary to develop any healthy, constructive relationship. Basic skills promote formation of the professional relationship that is capable of providing the conduit for therapeutic change. All of the "basic" skills are actually a complex array of behaviors that can be, at times, daunting to apply and may take years of practice to master. After many years of practice, it is clear to me that many of our clients have never experienced the growth-enhancing benefits of a healthy intimate relationship, predicated on mutual trust and respect, and honest sharing of perspectives, feelings, and needs. The literature and my own clinical experience support the following list of basic skills: self-awareness, empathy, genuineness, maintenance of relationship congruence, and appropriate interventions for different attachment styles. Professional training must equip practitioners to engage with clients on many levels of awareness and responding.

This section (and the next section) will offer case examples from my own practice experiences. The chosen clients represent some commonly encountered relational challenges. Many clients present relationship problems stemming from attachment styles developed in childhood. Examples of working with clients exhibiting preoccupied-ambivalent, dismissive-avoidance and fearful-avoidance styles will be offered to demonstrate some interventions that have proven useful in forming the right relationship connections.

The therapist must be constantly aware of his or her own moment-to-moment cognitive and affective responses and experiences. This may be harder to do than it would seem, especially when we experience negative feelings for our clients. Allowing ourselves to be fully aware of strong negative, or positive, feelings for clients can be a threatening experience for some therapists. Many therapists are trained that strong emotions are a potential threat to maintaining objectivity and proper boundaries. This is unfortunate, since emotional responses and reactions are normal aspects of any relationship. Normal human emotions cannot be eradicated but can only be suppressed, manipulated, or distorted, and none of these options leads to healthy relational functioning. For some therapists exerting control over their own emotions is substituted by attempting to control the emotions of the client (i.e., avoidance of threatening affects as a mutual collusion).

For example, I recently received a phone call from a student in our clinic. She was obviously upset after a recent encounter with a male client. During their session, he had strongly stated that he was romantically and sexually attracted to her. As a student in her first year of graduate training, she felt completely unprepared for this behavior and dissolved into a state of confusion and intense anxiety. When I asked her to recount her feelings during this episode, she was unable to do so and could only repeat her concern that she had "handled the situation right." I pointed out that apparently she had become so anxiety-ridden during this encounter that she had dissociated from her emotional reactions and that was not helpful to her or her client. By becoming panic-stricken about how to "handle it," she had missed vitally important information that her emotions could have provided. For one thing, the client obviously knew that she was a novice therapist and might not, therefore, be adequately experienced or prepared to

effectively "handle it." This behavior on his part suggested issues of narcissistic power needs and, on a deeper level, issues of hostility and safety regarding relationships. After explaining this possible interpretation of his behavior, she was able to access feelings of fear and anger that his behavior had provoked, and began to see the therapeutic importance of staying attuned to her emotions.

Combinations of active empathic listening and genuine responding are basic tools in any therapy relationship. The capacity to attune to, and comprehend, the feelings of the other person is the fastest route to establishing a trusting bond in the therapy environment. Empathy requires listening to the affective parts of the client's verbal statements as well as paying attention to accompanying nonverbal affective messages. When the therapist responds he or she makes some statement that corresponds to the client's feelings, thereby letting the client know that his or her feelings were heard and understood.

As the clients experience empathy and acceptance they can explore and connect to previously unknown or unacceptable aspects of the self. They begin to feel less alone, less alienated, less confused, and less self-doubting. They begin to feel, perhaps for the first time, a sense of connection, clarity, and improved self-esteem. They begin to make different and better decisions and judgments in a variety of situations with a fresh sense of confidence and trust in themselves. They feel stronger in their ability to take control of life choices and situations.

A female client (preoccupied-ambivalent style), approaching middle age, had achieved a great deal in her career. Yet, she was filled with anxiety and sometimes dread when she was confronted with anger or antagonism from coworkers, many of whom she supervised. She also suffered from depression and severe self-doubt. Despite all that she had achieved, she was not sure that she was good enough, smart enough, or wise enough to deal with interpersonal altercations. She was always afraid that she would "be the one who is wrong" and get blamed for causing a problem. After several months of therapy, and much emphasis placed on empathic responding to her feelings, she began to see things differently.

As she recounted stories of clashes with coworkers, I responded empathically to her feelings of anger, sadness, fear, shame, loss, etc. Eventually she experienced being known and understood and she felt less like a peculiar and unknowable pariah, a feeling she had endured since adolescence, growing up in an emotionally abusive family that moved around the country a great deal. She now began to feel that her thoughts, feelings, and desires had some validity and normalcy. One day, she talked about how she was planning to handle a particularly sensitive power struggle with a hostile coworker. She outlined how she would assert herself with the worker and if that did not succeed she was ready to ask her to resign. When I commented that her plan seemed well thought-out and appropriate, she said: "You know, I always knew that I was smart, but I was afraid to be smart, but now I'm ready to be *deliberately* smart, does that make sense?" I assured her it did indeed make sense.

The therapist must also be willing and able to respond in genuine and authentic ways to any interaction with a client. This can also be difficult at times. Honest and open responses can indeed be risky in any relationship, and many therapists worry that they will inadvertently be "too blunt" or straightforward in a manner that will cause irreparable harm and damage to their clients. Yet, without the firm shared knowledge that we are capable of genuine responses, it is impossible to establish any lasting trust. Trust is so essential to the development of a healthy, thriving relationship that it is difficult to imagine a successful therapy outcome without it. At times it becomes absolutely essential to establish trust, safety, and respect with regressive clients who challenge and threaten reasonable rules of civility and courtesy.

A young female client (fearful-avoidance style) who was struggling with childhood sexual trauma became quite agitated during one of our sessions, as she recalled the devastation of past abuse situations. At one point, she became so enraged that she got up from her chair and threatened to "destroy this office and everything in it." It did not feel like an idle threat or gesture; she appeared to be on the verge of actually breaking something. I realized that this situation called for a suitably honest and genuine response that would have the effect of establishing me as someone who could be trusted and respected and at the same time assert the rules of our relationship congruence. It also seemed obvious to me that this behavior was meant to be provoking and I was being "tested" to see how I would respond.

It was working. I became aware of a sense of violation and feelings of anger. I very quickly stated: "You will not harm anything in my office, nor will you even threaten to, or you will leave and never come back." She promptly stopped her threats and studied me carefully for a while. Then she said in a sincere voice, "I'm sorry, I won't do that again," returned to her seat and resumed the session with an appropriate and nonmenacing demeanor. Four years of therapy produced good results, but it would not have been possible if the relationship had not been carefully protected from the corrosive effects of destructive enactments.

The practitioner must always consider the question of "who is in charge," who is defining the relationship, and is the relationship consistent with the roles we are assigned? Clients usually expect that our greater expertise and experience dealing with life problems will equip us to take charge of the therapy work, in whatever manner is culturally appropriate and mutually respectful. Clients also tend to join with the therapy better if they are also responsible for the successful outcome of the process. While relationship congruence is a cocreation, maintenance of role congruence is principally the responsibility of the therapist. For instance, it is not in keeping with the proper role relationships to engage in social, economic, or political roles with our clients. I also avoid giving advice about personal lifestyle choices, relationship commitments, financial problems, medical problems, legal problems, etc. I try to remain completely free of any roles with clients other than "therapist."

One of my clients (preoccupied-ambivalent style) was a student who was struggling with what to do with himself once he graduated. Toward the end of the treatment, which had gone very well, he continually asked me for ideas about possible future career paths. I resisted offering him any advice. Instead I repeated my stance (i.e., "all I do is therapy"). He became quite anxious and agitated at times and doubted he would make the right choices for himself. When he became agitated, I would reassure him that I thought he was a very bright young man and would be successful at any number of possible careers, and the only thing that mattered to me was his future happiness with whatever he chose.

Regardless of what I said, he persisted. He was obviously, with some desperation, trying to renegotiate the rules and roles of our relationship. Our relationship was no longer congruent. I was receiving weekly messages from him that he felt frustrated and disappointed by my refusal to offer him what he needed from me. I began to wonder about the rightness of my position. Was I being too rigid? Was I overly strict in my role boundary definitions? What would it hurt if I gave him "a few suggestions?" Despite the evidence to the contrary, had the treatment actually failed?

Yet, something else nagged at me. I realized that I did not want the responsibility for providing him with help to select a career. I worried about his lack of belief in himself. I also did not feel good about his lack of imagination or his lack of faith in a process that can clearly take some time to bring to fruition. I decided to take seriously that he needed some helpful guidance

and suggestions from me, but I also needed to be true to my own beliefs about my proper role. I decided it was best to try and serve both interests.

The next session brought more of the same persistent pleas for "just a few ideas, because he was graduating soon and just wanted some idea of where to start." I answered by telling him that I did have two suggestions for him. "First, stay as open as possible and second follow your heart." I added that I was convinced that if he did those two things, in time, the right path would present itself. He responded with disappointment, "That's all?" Yes, that was all I felt I could honestly offer him, but I truly believed every word of it and hoped it would help. He was not only disappointed, but defeated. He resigned himself to the fact that I was not going to offer what he felt he needed most, so he stopped asking.

We parted amicably, he honestly appreciated the good things that had transpired and he was prepared to accept that he could not have everything he had hoped for (i.e., helpful career ideas). I did feel some concern that I had ultimately let him down and I was certain he knew this as he tried to reassure me. A year went by when I received a phone call from him. He said, "I thought you would want to know, I found it." I was genuinely grateful and excited when I said "Yes, I would, what, what did you find?" He reported that he had spent a year worrying about what he wanted to do, but my advice to "stay as open as possible and follow his heart" had stayed in his mind. One day he was in the park with a friend walking their dogs when it hit him … animals. "I've always loved animals, my whole life I've loved animals, I want to be a vet!" It was indeed one of those life-changing "eureka" moments. He had applied to veterinary medicine school and had been accepted and was eagerly planning to begin his newly found career path.

5.3 Expert Competencies of the Clinician and Transition from Basic Competence to Expert

Basic competencies serve as the foundation for more advanced treatment work by promoting the formation of a strong treatment alliance. Once an alliance has been formed, it can be put to use by providing information and interactions that heighten the therapeutic benefits. Expert competencies include becoming culturally competent, identifying and repairing relationship ruptures and impasses, and working at the proper level of analysis (i.e., you, me, or we). Advanced relational treatment skills involve using the relationship as an integral tool in the treatment itself. In other words, the therapist treats whatever is dysfunctional in the relationship. The goal is to achieve a breakthrough from enactments, or unconscious repetitions of painful relational patterns, to an engagement where mutual, authentic sharing opens up new opportunities to experience genuine intimacy.

Many practitioners justifiably think of cultural competence as a basic skill, since it is unethical to practice without it. For relational purposes, however, the subtler implications of application require more advanced skill sets. Cultural *competency* skills, which go beyond cultural *sensitivity* skills, can be strengthened by training beyond the average one course degree requirement. Advanced competencies can be acquired through practical classes, internships, and residencies that focus on diversity training. It has been my experience that many people underestimate the difficulty of practicing at a truly competent level of cross-cultural skills.

The following case illustrates this point. An African-American male client (dismissive-avoidance style) sought treatment because he was stressed at work and experiencing a sense of

anger and resentment with his coworkers on a level that struck him as irrational and debilitating. Eventually, he became concerned that his attitudes were costing him a lot of personal happiness in life. He also had been through a string of girlfriends and always wound up thinking that the women he became involved with were lacking in their caring for him and were too insistent on commitment and marriage. Essentially, he lived the emotionally empty life of a loner. He had worked very hard to educate himself and lift himself from his working class family background. He had succeeded in becoming a successful professional in an important city agency, but found that persistent feelings of anxiety and anger were robbing him of taking pleasure in achievements and success.

When therapy began we mapped out a plan for improving his mood and his desire to start dating appropriate women. He began enthusiastically. In no time, however, it became clear that he was not inclined to follow-through on any of the planned efforts for change. An obvious relationship rupture was developing. On top of this, he was often very late to our sessions. Many times he was at least 10 min late, but 20 or even 30 min late was not that unusual. He would call if he became aware that he would be late, because something was detaining him at work, and he did have to drive a fair distance to my office through rush hour traffic, so I made an effort to be patient and accepting. It was, after all, his therapy time and we had agreed that I would not compensate him by going over the time allotted, or at least, "not much" over that time.

Despite my efforts to be patient, his constant lateness combined with his lack of follow-through began to annoy me. I also became aware that his conversation was consistently along the same themes and lines (e.g., he was angry at someone at work, he was lonely, and he felt trapped by his lack of energy to do anything about anything). We were now clearly in a relationship impasse. I became increasingly frustrated and disillusioned. Finally, I began to examine more deeply how my own responses were contributing to the ruptures and impasses.

One thing that became clear to me was that I had assumed an attitude that his lateness was probably a "cultural thing." That is, as a Black man he was inclined to be casual about time. I also assumed that he was expressing anger toward his office mates due to their subtle racist behaviors, and indeed he had pointed to some clearly racist incidents. Though none of these incidences was career threatening, I could empathize with how difficult it was to be Black in his work setting. Another thing that became apparent was that I was not sure how to help him get past his refusal to do the therapy work. That is, I had no methodology or techniques in mind that I thought would succeed in breaking us both free of these trapped, "stuck" feelings.

It was time to rethink some things. First, it occurred to me to ask myself if I thought of him as "White" not Black, or "female" not male, would I have a different feeling about his behavior? Instead of a "cultural thing," I immediately began to interpret his lateness as an expression of severe anxiety and ambivalence, for which I felt some empathy and sympathy. It did not take long to also realize that I had not considered the possibility that his anger with coworkers was not the central theme, but the enactments being conducted within the therapy relationship. Was his lateness and lack of follow-through messages about feelings of habitual relational anger, loneliness, anxieties, and inadequacies? Moreover, I began to see that I had neglected to take advantage of the opportunity to address these issues within the therapy context. Why? Was I colluding with him? Were these issues that I had some anxiety about addressing with him?

In our next session, I began to address the therapy relationship and how we had both allowed our work to become stagnant and stymied by inconsistent follow-through and a

reticence to address our feelings about our work with each other. He was genuinely surprised and taken aback by these comments, but he also seemed to find this new approach provoking and challenging. He was also honestly unclear about what I meant and wanted to know what I expected of him. I told him that I expected us to talk about it. For instance, why was he so often late and what, if anything, did he intend to do about it? At the very least I thought it was important enough that we needed to discuss all of the possible reasons why he was so consistently late to our sessions.

For many weeks we continued to try and talk about his behavior, but with very little success. The conversation would usually drift back toward his usual comments about people at work, his girlfriends, etc. Finally, one day, as some clients are prone to do, he initiated the breakthrough interaction. He came late as usual. When he entered the office, we both chuckled, something that, for some reason, we had each done many times as he entered the room. On this day though he sat down and asked me, "why did you laugh just then when I arrived?" his tone was obviously confrontative, angry, and accusing. I began to feel anxious and a little vulnerable. Now it was my turn to feel taken aback. "What do you mean?" I asked, not sure what was going on because he had never acted this way before. "I mean how you laughed just then, why did you do that?" I answered truthfully that I was only barely aware of having done it and that I honestly had no idea why I had done it. He looked at me skeptically and then I realized that this was a new relational behavior and that it might be vitally important to examine it carefully.

I told him that I would give some thought to his question and let him know when I thought I had an answer. I thought I could do this while we went on with our session, then I invited him to get on with whatever else he wanted to talk about while I thought it over. He agreed. Toward the end of the session, I believed I had it sorted out and told him was I ready to give him my answer. He seemed eager to hear it.

First I asked him to tell me why he had asked about my laughter. He said it was because of how it felt, so he wanted to know what was going on. I asked him to tell me how it had felt to him. He responded that it felt like I was "laughing at him." I said that I had thought so, that he seemed to feel "put off" or "put down" by my laughter. He agreed that he had felt that way. I then stated that I had concluded that my laughter had indeed been a message to him, but not one of ridicule. What I was aware of feeling was that every time he was late I had the feeling that his commitment to the therapy work was tenuous and not sincere. I believed my laughter was an expression of the anxieties I felt about how insecure our relationship felt to me and my confusion about how seriously I should take our work. He studied me for a long time and then he nodded and said, "I've heard this before, other people, like some of my girlfriends, have said the same thing about me, that I never seem to be serious about my commitment to things and that they get the impression that I could leave at any time."

After this "breakthrough" from enactment to engagement, he became more willing to talk about painful relationship experiences in his childhood and within his family. From then on little attention was given to his work relationships, yet those relationships began to improve. He was more inclined to be on time, or closer to on time. He began to focus more consistently on more deeply personal and meaningful topics from week to week. Toward the end of therapy he stated that he had learned more about himself than he had ever imagined. He felt less anxious, angry, and depressed, but he was still not sure what he wanted to do where women were concerned.

Careful attention should be paid to all client nonverbal behaviors. Many times during therapy sessions, the first, and perhaps only, evidence of emerging feelings are nonverbal signals.

Client nonverbal signals are often unconscious, or barely conscious, indicating presence of thoughts and feelings with deep-seated origins. Facial expressions and gestures such as smiles, frowns, grimaces, widening of the eyes, and raising of the eyebrows can speak volumes. Positioning of the torso, arms, legs, hands, and feet can signal numerous affective responses, rejoinders, and attitudes. Voices soften or amplify depending on the sensitivity and urgency of the subject matter. These can be fairly obvious displays of affect. Therapists need to be aware of subtler cues, many of which are expressed unconsciously, but convey a host of important relational messages.

One of my clients (preoccupied-ambivalent style, with some dismissive-avoidance features) is very extroverted and outgoing. She often enters the office in a "get down to business" manner and begins to hold forth on the past week's events. It is not hard to know what she is thinking or feeling, because she seemingly has no problem expressing herself. She has good social skills and confidence in her competencies. For several weeks I assumed that she was open and receptive to my interventions, because she never argued or objected. I also noticed, however, that she never commented on my inputs. After I had made them, they seemed to get "filed away" somewhere and never revisited unless I brought it up again. I also began to notice that sometimes when I made comments she would look down slightly. Once I noticed that, although she did not look down, her eyes seemed to "glaze over" softly.

When I commented on noticing these gestures she rejected, for the first time, my observations as inaccurate. She insisted that she "didn't do that and, if she did, what was I trying to make of it?" I persisted. I told her that she seemed to "not take me in" and I was beginning to feel that my comments had little impact on her, since she never incorporated them into her ongoing thoughts or what she elected to talk about. She continued to resist these notions and I observed a slight expression of annoyance or impatience, which I also commented on. Again she had no idea what I meant or why it mattered, but she said that she "would think on it," thereby signally it was time to bring this topic to a halt.

Several sessions later I noticed the same nonverbal responses to my remarks and again I had the distinct feeling that was I being "shut out." I stated that she appeared to be shutting down and shutting me out, like she did not want me to comment on what she was saying. She seemed exasperated and said in a harsh tone of voice, "well it's just that I had some things I really wanted to talk about today, and you are interrupting me!" I responded by saying, "I get that this seems useless and intrusive to you, but in my judgment it's important. I think we should talk about it, it affects our work. We can talk about it later if you want, but someday we need to talk about it." Realizing that I ultimately intended to push the issue, she relented and said with more annoyance, "okay, what?" I repeated my observations of her nonverbals and the subsequent feelings that I associated with them and asked her to speak to why she thought she did those behaviors whenever I had something to say or some observation to make? Could it be that she was telling me to "back off" or "butt out?"

At this point she was silent and looked down again, but this time looking downward felt different, this time it felt like she had "gone inside" to give the question some deep thought. I had finally connected. After awhile she signed and looked up. She then said in a voice that was now slightly shaky, "I don't know what it is, but I get really upset and annoyed when you are right. I can't stand it! And lots of times you are right, but I'm not ready to hear it, I mean I don't want to deal with some of that yet."

Once this important connection was made I realized that we were now on a very different relational footing, and I had no problem telling her that I would "back off" and wait for her to

tell me what she was ready to deal with, and asked her to do that, so I would know. A new and stronger partnership was established. Rather than unconsciously thwarting my well-intentioned interventions, she could now consciously inform me about her needs and desires for how to best help her. After that conversation I noticed that she continued to look down when I spoke, but much less often and for a much shorter duration. Slowly she was letting me in and allowing me to have an impactful presence in her inner process.

Another case illustrates the complexity of working at different levels of relationship dynamics by encouraging clients to speak directly to the relational struggles embedded in the enactment. I am always particularly interested in relationship breaches involving money, since paying the fee is both a highly personal as well as professional role requirement, it can often become a venue where numerous relational difficulties express themselves.

By responding in an authentic and spontaneous manner, the client is encouraged to respond likewise, and thereby find her way to the deeper relational meanings in her behavior. At times she noticeably struggles with the enactment dynamics as she tries to sort out what is real (the real relationship) from what is not (the negative transference). Eventually underlying feelings, long suppressed out of her awareness, begin to surface. She also finds these newly emerging feelings quite baffling and is uncertain about how to express them. At the end of this session it is clear that she has stepped onto a new relational territory integrating, probably for the first time, internalizations of past painful dynamics into the present relational context. In this new context, her painful repetitions can become fully aware to her and then become fully explored and understood, altering what is internalized as the process evolves.

A 23-year-old female college student client (preoccupied-ambivalent style) came for therapy seeking reasons for why she felt depressed and why she did not have a relationship. At the time of this session (middle of the first year of therapy), she has not been paying her bills. I deliberately begin the session with a forthright confrontation of the relationship rupture.

- ► T: So when exactly are you going to catch up on this bill?
- ► C: I'm still waiting for that check to come, it hasn't come yet.
- ► T: So in the mean time are you willing to pay something on the bill?
- ► C: I'm going to pay the whole thing off as soon as the check comes. I've been doing some thinking about this. You were asking me why I have a bill I can't pay. I did think about that. You were right, it seems like there is some reason that I have to think on more.
- ► T: So what did you think, what did you conclude?
- ► C: Well, I'm still doing it. Still spending $ on things I don't really need ….(begins to list them)
- ► T: So why do you think you do that?
- ► C: I don't know! I just don't seem to be able to stop myself. I don't know why I do! (Long pause)
- ► C: I think I do it because I'm depressed. I get depressed and then having toys makes me feel better. It doesn't last, later I feel bad, but for awhile at least, I feel better.
- ► T: I'm not buying it.
- ► C: You're not buying it? You're not buying what? Why are you not buying it?
- ► T: You told me you were on medications for your depression. In fact, didn't I ask you to be evaluated to see if you really need the medications and didn't you flat out refuse because you didn't want to feel depressed? So how can it be about you feel depressed or so depressed you would feel compelled to spend $?
- ► C: (Slouching down onto the couch, thinks for a long time) Okay, I see, if the meds eliminate my depression, how can depression be the reason?

▶ T: Right.

▶ C: (Thinks awhile longer) I guess, yes, it seems like there is some other reason. I don't know what it is, but yes, I sort of feel it, I feel that there is something else.

▶ T: Could the reason have something to do with me or us? Is the reason about our relationship?

▶ C: (Smiles, looks away) Well, that's funny you should say that.

▶ T: How so?

▶ C: Well, I thought that you probably thought that. I think I'm beginning to catch on. I knew you would think it was something like that.

▶ T: So what is it? What is the reason you don't pay your bill, or spend your $ on that?

▶ C: I don't know, honest, but okay maybe it is about us, but I don't think it's you. I mean, not you, you don't have anything to do with it. Does that make sense?

▶ T: Yes it does. But finish the thought, even if it doesn't make sense.

▶ C: Well okay. I don't know how to say this, it seems awful, but I don't think I want to pay you. That sounds terrible doesn't it? (Looks away again). But it is true. I don't want to pay you all this $! I have no idea how long I'm going to be here, needing therapy or if it's going to do any good at all.

▶ T: And so years from now, you are afraid that years from now, you will have gotten no better, but would have made me richer regardless. And your only hedge against that is to not pay me.

▶ C: Yes! That's right! It sounds real terrible, but that's it. I can see that happening and I would feel like a fool. Like I had been bad.

▶ T: This is interesting how you tie all of these fears into our relationship.

▶ C: Yes, I suppose so. I feel stupid saying these things, but it is the reason I don't want to pay you. What assurances do I have? How do I know that it isn't all just for you?

▶ T: The truth? You don't.

▶ C: (Long pause) And if it is just for you, then where am I? What am I going to have, when you are tired of me needing you, you could just say no more, or something and then I'm completely out, aren't I?

▶ T: What assurances do you want?

▶ C: That I matter, that it's not just for you.

▶ T: Why those assurances?

▶ C: (Long pause) Because sometimes I feel helpless to control things. I don't even know what you really feel about me.

▶ T: Why does that matter?

▶ C: It matters because then I would know where I stand and if you are going to give me the boot or not, maybe at the wrong time, maybe when I need you the most.

▶ T: So, if I say I love you, then you would feel safe and secure?

▶ C: (Another long pause) I'm confused now. What were we talking about?

▶ T: We were talking about love and assurances.

▶ C: Were we?

▶ T: Yes.

▶ C: Well, okay, sometimes I feel a lot like how I felt in my last relationship, since then, I feel I have to be extra careful, about needs and all, and the helplessness that … I hate this, why do I pay you for this?!

▶ T: When you feel helpless you need to be reassured.

▶ C: Yes, but now I have forgotten what I was saying (Begins to cry). What was I saying? (Pushes back the tears)

▶ T: What made you so sad just then?

▶ C: (Shrugs) I don't know, something to do with being put out or dumped out and there's nothing you can do about it. But it does feel like something just happened, like something just got shaken loose or shaken out.

At this juncture the client and I had a renewed sense of trust and respect for one another. We also had something that we did not have before, a deeper level of analysis of the problems. She was also now more open and available for exploring the more vulnerable parts of her relational injuries and traumas. She did indeed begin to pay her bills, although she now talked about the sense that it represented her ability to trust me and believe that I could have her best interest at heart. Within a few months, she got a dog and began to address her loneliness. Within another few months, she began a relationship, which lasted for over a year, and she felt hopeful that she was ready to make the effort to seek intimate connections.

5.4   Summary

Numerous research studies conducted over at least 3 decades have produced convincing empirical evidence that the therapy relationship is predictive of outcome. Outcome studies consistently show a medium to high relationship between the quality of the therapeutic alliance and the positive results across treatment modals and methods. Relational factors such as therapist' personal qualities of empathy, compassion, acceptance, understanding, etc. were once thought of as "common" or "nonspecific" variables, but no longer. Due to the preponderance of empirical research, relational factors have been redefined as mediator variables. As such, it is now imperative to include relationship competencies as part of professional training for all practitioners. Every theoretical orientation needs to train practitioners to integrate relational components into treatment methodologies.

Much remains to be done to clarify and define the construct and the essential components. Part of the difficulty is the identification of the many possible variables that impact an interactive phenomenon and the complexities of measurement inherent in such a process. Different alliance instruments have been developed, with the working alliance inventory (WAI) becoming the most widely used. Use of the WAI at the third through fifth sessions has been shown to eliminate confounding between symptom reduction and the correlation between early alliance formation and subsequent treatment outcomes.

The construct itself (i.e., the "therapy alliance") is yet to be concisely defined. Different authors and test instruments used different components and criteria. Despite this fact, some alliance promoting elements have been commonly cited. Positive therapist contributions include: self-awareness, genuineness, empathy, compassion, acceptance, flexibility, attentiveness, promoting the establishment of collaborative treatment goals, and adequate therapy skills. Therapist must also have adequate skills in cultural and demographic factors, maintenance of role congruence, and recognizing and addressing relationship ruptures, and therapeutic impasses.

Evidence also supports the importance of understanding and taking into account pretreatment, client, and therapist variables. Some evidence suggests that client expectations and preferences concerning treatment methods have some impact on self-report alliance ratings. Another important pretreatment variable is the interactive effects of the attachment bonding histories of both participants. Secure attachment styles versus insecure styles have been shown to affect adult interpersonal functioning. Therapists need to be cognizant of their own attachment styles, as well as their client's, in order to establish effective therapeutic bonds.

Relational orientations such as object relations and intersubjective and functional analytic psychotherapy approaches have developed contemporary treatments predicated on using the therapy relationship as a main source of assessment and intervention. Analysis of interactions occurring within the relationship context offers clients insight into long-standing dysfunctional interpersonal patterns. Object relations and intersubjective approaches hail from a psychodynamic orientation. These orientations assume that curative factors are based on the internalization of new and healthier mental representations of interpersonal relations and motivations. Functional analytic psychotherapy is a cognitive-behavioral orientation. In this model, it is assumed that reinforcement of more adaptive interpersonal behaviors acts as a corrective factor. In any case, increased awareness of dysfunctional interpersonal patterns allows clients to formulate more satisfying and healthy ways of connecting to others.

6 Translating Science into Clinical Practice

Thomas L. Sexton · Christopher W. Hanes · Jeremy C. Kinser

Abstract: In this chapter, we propose a developmental framework of competencies for the integration of science and practice. We believe a shortcoming of traditional competency models stems from the tendency to view science and practice as distinct entities that need to be linked rather than addressing their dialectical relationship. We argue that competencies for translating science into practice must acknowledge the inexorable link between the two. To accomplish this conceptual shift, we articulate the knowledge, attitudes, and skills necessary to define competencies pertinent to the realization of the scientist-practitioner. Four primary attitudes outlined include scientific mindedness, curiosity about how things work/what works, acceptance of ambiguity, and embracing the dialectical nature of science and practice. Core domains of knowledge identified include an understanding of scientific methods, familiarity with clinical intervention research, understanding the role of evidence based practice, and specification of clinical practices. We also propose skills necessary for the translation of science into practice. Skills include assessing scientific findings, consuming research through a levels of evidence lens, practicing research based clinical intervention protocols, and becoming a local scientist. We believe these three domains encompass both basic and expert competencies that are necessary for learning, developing, and functioning as a profession within the scientist-practitioner paradigm.

6.1 Overview

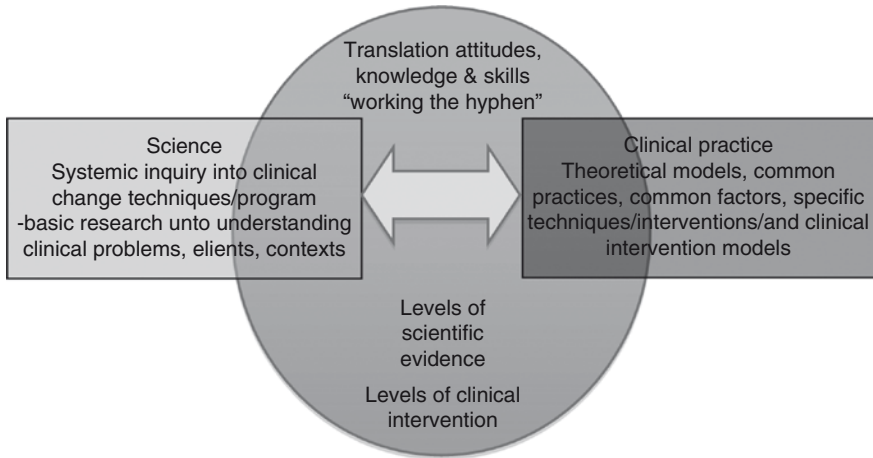
The identification and adoption of core clinical skills and abilities have long been the goal of the professionalization of psychology. The competencies approach (Bieschke, Fouad, Collins, & Halonen, 2004; Kaslow et al., 2004) is built on the idea that if the core abilities and related behaviors are identified we can better chart the appropriate course of professional development, create standards to judge the development of professionals, and measure the core skills of those practicing the profession. Core competencies and the standards for training and practice that evolve from them involve the knowledge, skills, and attitudes that allow for learning, developing and functioning of a profession. For psychological practitioners, competencies point out the "common" and "core" abilities needed to practice professional psychology. For training programs, accreditation bodies, and licensing groups, core competencies provide guidelines and training standards that provide curricular and training direction, points of evaluation, and entry-level standards. In all these ways, competencies play a critical role in the evaluation, identification, and training of professional psychologists. Thus, identification and use of accepted competencies of a profession have a wide-ranging impact in influencing treatment decisions and clinical decision making of practitioners both now and in future generations of professionals.

This chapter focuses on identifying the core competencies in an unaddressed area of professional psychology: the *translation* of research and science into clinical practice. Research and practice competencies are not new (Bieschke et al., 2004). Most often these approaches focus on discrete research and practice competencies leading to listing and identifying those that capture either the research/science or the practice domains. Few previous efforts have focused on the specific components required to successfully "translate" science into practice.

Attention to the "translation" between science and practice is important, given the central role of scientific research in the understanding and practice of the wide range of activities that fall under the umbrella of professional psychology. Furthermore, identifying the competencies that *link* science and practice has become particularly important given the ongoing and sometimes contentious debate between science and practice in psychology. In fact, the "gap" between science (research in particular) and practice is no less evident today despite the increases in research, the rise of evidence-based clinical protocols, and the increase in clinically relevant research methods (Alexander, Sexton, & Robbins, 2002; Sexton, Alexander, & Mease, 2004). The debate takes many forms. For many, the science of psychology is seen as over simplified, clinically irrelevant, and unable to account for the unique nature of clinical practice (Westen, Novotny, & Thompson-Brenner, 2004). For others, the practice of psychology is viewed as undisciplined, lacking a systematic approach, and based on principles and approaches that are more traditional than a verified and dependable fact. With the development of evidence-based practices (EBPs) and EBP guidelines, the disconnect between science as developed through research and as developed through practice has grown even more extreme in recent years (Kazdin, 2008; Westen et al., 2004).

We approach this chapter with the view that "translating" science into practice requires a particular set of competencies that focus on how one can move the knowledge of science into the daily clinical practice of psychologists. In fact, we suggest that what is missing is not a more complex list of abilities, knowledge, and attitudes in either research or practice but instead a focus on the linkage or the "hyphen" that connects the practitioner with the scientist (scientist-practitioner). As such, we suggest that integrating science and practice in psychology requires a conceptual shift away from viewing science and practice as distinct domains and toward one that considers these seemingly different domains of the work of a clinical psychologist as activities that occur together and exist in a dialectical relationship with one another. We suggest that science and practice are, in fact, different sides of the same coin: each bringing a unique perspective to understanding the same process of client change. Thus, both the accumulated knowledge of methodologically sound and systematic science and expertly conducted clinical practice are necessary and neither is sufficient to bring the best available treatments to the clients who seek the services (Sexton et al., 2007). Considered in this way, science and practice in psychology not only go hand in hand but are critical for the success of one another and have the potential to help overcome the continuing gap between the domains of research and practice.

Our goal in this chapter is to take a competencies-based approach to the science-practice "hyphen" by identifying and describing the attitudes, knowledge, and skills that facilitate the translation of the science of clinical psychology into the practice of clinical psychology (see ❯ Fig. 6.1). To provide a foundation for the discussion, we first create a context by reviewing the apparent difficulties in translating science into practice by considering the role of science in the practice of clinical psychology, the scientist-practitioner model. We then focus

◘ **Fig. 6.1**
Science–practice "dialectic"


on the core attitudes (scientific mindedness, openness, and acceptance of ambiguity) and knowledge (understanding the scientific method, clinical intervention research, EBPs, and specification of clinical practices) needed to move the scientific findings of clinical intervention research into clinical decisions making. Based on these core attitudes and knowledge areas, we identify the linking skills necessary to translate science into practice. In each area, we address the basic and expert competencies and the developmental trajectory between the basic and expert competencies within the levels of science as well as within clinical practice. Finally, in each area we provide concrete case examples and descriptions of each of the competencies and how they vary by level of scientific and clinical complexity.

6.2   The Role of Science in the Practice of Clinical Psychology

Science has always been a central part of psychological practice. Like all other professions, the scientific process is viewed as a set of inquiry methods that produce systematic knowledge, which extends beyond the individual, cultural, and personally bound perspectives of clients, the clinical process, and the basic understanding of the person. The embodiment of science in clinical practice is the scientist-practitioner model, a central core of training and practice of psychology since its inception (Committee on Training in Clinical Psychology, 1947; Raimy, 1950). This model espouses and aspires for the integration of science and practice, and is relevant to both new professionals entering the field and seasoned practitioners. According to Belar and Perry (1992) the goals of the scientist-practitioner model are critical thinking and bridging the gap between scientific foundations and professional practice. Jones and Mehr (2007) identified three vital assumptions at the core of the scientist-practitioner model. The first is the expectation that psychologists will develop the requisite knowledge and skills to create and consume scientific knowledge, developed through the methods of clinical research to facilitate effective psychological services. The second assumption is that research is necessary in order to develop a knowledge base of successful practice. The third assumption is that direct involvement in

clinical practice and research activities interacts in a manner that contributes to the study of important social issues. In short, the ideal realization of the scientist-practitioner model is a professional who is directed by systematic scientific methods for the development and enhancement of practice, with the best interest of the client as the primary focus (Jones & Mehr).

In reality, being a "scientist-practitioner" is not easy. It is assumed that the findings from various types of process and outcome studies and wide-ranging types of studies of clients, therapists, and the clinical change process can be integrated into clinical decisions made by a practitioner. The successful scientist-practitioner must have the attitudes and knowledge of both a scientist and practitioner, who can consume the broad and vast knowledge of science to find guidance in the clinical process. Thus, translating science into practice assumes a very complex set of research and clinical knowledge and skills that are put to use in clinical decision making. Furthermore, with the continuous growth in research findings a practitioner is no longer able to stay informed on current research by reading a few journals each month. In fact, estimates are that it would take 627.5 h each month to stay up to date with all relevant research (Walker & London, 2007). To be successful, the scientist-practitioner needs to be able to translate the language of research in a way that answers and informs questions about their practice. To do so, they must have an understanding of what research is helpful, how to consume it well, and how to understand its limitations. In the following section, we approach this by suggesting "levels of intervention" and "levels of evidence" as the knowledge base for the successful translation of science into practice.

6.3　Becoming a Scientist-Practitioner

The long-standing research–practice gap and the current debates and controversies in the field surrounding the use of evidence-based treatment and science-based treatment protocols suggest that, while a noble aspiration, true realization of the scientist-practitioner model has been elusive and largely unrealized as a central model in clinical psychology. Instead, many professionals have come to identify themselves as *either* scientists or practitioners. This split is actually quite understandable. Scientists generally focus on the nomothetic (group and similarities) level of information while practitioners have a more ideographic (individual and unique) focus. Over time these different areas of primary focus have increased the difference between the scientist-practitioner roles. The increasing research–practice gap has even given rise to calls to redefine the central "scientist-practitioner" model of training in psychology established at the Boulder Conference on Graduate Education in Clinical Psychology in 1949 to be more focused on scholar-practitioner or educator-practitioner (Committee on Training in Clinical Psychology, 1947; Raimy, 1950).

We suggest that the practical difficulties in being a "scientist-practitioner" who can successfully translate science into clinical practice are not because science does not go into practice or practice into science but instead it is the manner in which these two domains are linked together or the "hyphen" between science and practice, which is the problem. In this case, the grammatical form of the hyphen represents the critical issue in translating or linking the knowledge from science and practice into systematic decision making. Considered in this way, it is the process of translating between these domains that has not been well defined either in terms of the conceptual models with which to consider the evidence of science, in regard to practice, or realized in the competencies that may accompany these. Thus, it may be that a new

model (e.g., scientist-educator, etc.) is not what is needed but instead a more comprehensive definition, identifying and describing the basic and expert competencies of translating science into practice is what is missing. We approach this by using two primary conceptual "levels of evidence" and "levels of practice" models that "link" and help move information between these domains in a way that results in better overall treatment. ⊙ Figure 6.1 illustrates the primary domain of interest for the sections that follow.

6.4   Competencies to Translate Science into Practice

Professional competencies are often divided into three broad domains: knowledge, skills, and attitudes (Kaslow, 2004; Kaslow et al., 2004). Attitudes are the core beliefs, principles, and mindsets upon which specific knowledge necessary to understand science, research, specificity of treatments, and the levels of scientific evidence rests. Specific skills to use, access, and apply different sources of knowledge are found in both core attitudes and knowledge. Thus, each is inexorably linked. The Scientific Foundations and Research Competencies Work Group of American Psychological Association (APA) have taken steps toward identifying how psychologists can practice scientifically (Bieschke et al., 2004). The Work Group suggested five primary competencies: (1) access and apply current scientific knowledge habitually and appropriately; (2) contribute to knowledge; (3) critically evaluate interventions and their outcomes; (4) practice vigilance about how sociocultural variables influence scientific practice; and (5) routinely subject work to the scrutiny of colleagues, stakeholders, and the public. Although helpful, these competencies unfortunately do not address what is needed to successfully *translate* science into practice. Instead they represent an aspiration or ways in which clinical psychologists would "work" if they were scientist-practitioners. We suggest that for research to be "integrated" into practice different levels of science must be linked to corresponding levels of systematic practice and the specific needs of the client.

　　Within the domains of attitudes, knowledge, and skills there are different levels that practitioners may possess. Basic-level psychologists have a knowledge of, and ability to, work with and within the attitude, knowledge, and/or skills in a fairly simple way. Expert psychologists have all the foundations possessed at the basic level but with the ability to think and work complexly with the situations presented to them in research or clinical practice. In later sections, we describe the developmental trajectory and evolution from basic to expert knowledge in the intersection between science and practice. It is important to note that there is not a distinct list of what an expert and a beginner should know. In each of these domains, there are varying degrees that represent basic-, or entry-level competencies, and expert levels. In other words, experts often possess the same attitudes that someone at a basic level may have; however, they differ in their ability to apply that attitude, knowledge, or skill to particular situations, in the complexity and depth in which they use the competency. Instead there are differing degrees of breadth and utility of knowledge. Instead of a "list" of competencies for the beginner and the expert, we suggest that the differences lie in the complexity, flexibility, and creativity in one's ability to approach problems of clinical practice with the attitudes, domains of knowledge, and skills to translate research and science into that work.

　　In each section below, we describe the major construct (within the domains of attitudes, knowledge, and skills) and then describe the two poles of basic and expert mastery of the attitudes, knowledge, and skills necessary to match different levels of science and be linked to

corresponding levels of systematic practice and the specific needs of the client. Rather than lists of discrete competencies we describe the domains (attitudes, knowledge, and skills) that are critical in this translation process for clinical psychologists. The description represents the explanation of the attitude, the knowledge needed, and the skills required to do this translation. We suggest that approaching this task in a descriptive way best explains and fits the principles and understanding of competencies and allows them to be presented in a way that can be used in clinical practice. In the final section, we address the developmental progress between basic and expert competencies by providing specific examples.

6.5   Core Attitudes of Translating Science into Clinical Practice

The translation of research into practice begins with the core attitudes that provide an infrastructure for more specific knowledge domains and skill sets. Attitudes are difficult to specify in behaviors because they represent the manner in which either the researchers or the practitioners approach their subject and the general assumptions with which they approach their task. We suggest four primary attitudes that contribute to the translation of science and practice: (1) a scientific mindedness to both research and practice, (2) an essential curiosity about how things work and what works as well as an openness to new explanations and theories, (3) an acceptance of the inherent ambiguity and evolutionary nature of what we know about practice and research, and (4) a willingness to embrace the dialectical nature of science and practice. Despite the fact that you cannot "do" an attitude, we suggest that without these attitudes it will be difficult for any corresponding knowledge or skills to function as mechanisms for translating science into practice. Thus, these are critical core beliefs, principles, and attitudes of the scientifically practicing psychologist.

6.5.1   Scientific Mindedness

Bieschke et al. (2004) introduced the idea of a scientifically minded psychologist. The scientifically minded psychologist approaches clinical practice by accessing and applying the current scientific knowledge appropriately, consistently, and even habitually. More specifically, the scientifically minded practitioner becomes a local scientist (Stricker & Trierweiler, 1995) desiring to know the outcomes of their work, subject their work to study from others, and show what they do to colleagues, stakeholders, and the public. This means that they continually ask: "What do I know about this type of client, this type of problem, and this clinical context?" When working with a client, the practitioner with a scientific mind asks: "How did that work?" "What was the outcome of what I tried?" and "What more might be done?" This type of psychologist continually asks: "What are the sociocultural variables that might come into play?" "What impact does the context have?" and "What systematic knowledge might be available to use in finding a successful practice?"

   A clinical practitioner is also a scientifically minded psychologist who approaches clinical work in a systematic and intentional manner that is at the same time client-centered and clinically responsive. Scientific mindedness in clinical practice involves habitually questioning assumptions, developing potential hypotheses, and accessing the necessary relevant information. When psychologists demonstrate scientific mindedness it means that with each clinical

question the practitioner asks: (a) what are the main issues in the topic; (b) what are the different theories or perspectives on this question; (c) what factors have empirical research found to be involved; and (d) what is the most reliable and valid information available? To do this, the psychologist must set aside biases and preconceptions, avoid the temptation of superficial answers, and consider what the theories and research say. In a sense, it is as Tracey and Glidden-Tracey (1999) suggested, the logical argument of reasoning to a conclusion that might be the most critical step in the research process. We suggest that the same is true for the practice process – the critical need to "reason" to a clinical decision based on clinical experience, existing scientific knowledge, and considering the client, context, and situation at hand.

6.5.2 Systematic, Open, Complex, Curious, and Objective

Science acquires its knowledge through systematic observation, inquiry, and experimentation. The assumption is that "objective" research leads to theoretical hypotheses, which then lead to further observations and experimentation. In making these observations or inquiries, it is important to control all other factors that may influence research findings and potentially mislead us in drawing our conclusions. Openness is important because results may not always support the practitioner or the researcher's belief about the "cause." Thus, the most accurate scientific knowledge and the most useful practice information is produced through systematic, thoughtful questioning and inquiry, where the results are considered in an open way, even if the outcomes challenge the core beliefs of either the researcher or the practitioner. In this way the translation between these domains is built on the attitudes of questioning, critical thinking and open-minded skepticism based on a curiosity to understand. All assertions, speculations, and theories must be empirically tested, and the scientific evidence about them evaluated by objective and knowledgeable researchers before being accepted as valid.

The attitude of systematic inquiry is a central one for both research and practice. In the research domain, being systemic means that the psychologist follows the methods of scientific inquiry in order to produce reliable and valid results. In practice, being systematic means that the psychologist approaches the task of working with clients in a thoughtful and well-planned way moving from comprehensive assessment to purposeful intervention. A systematic attitude is an attitude shared by efficient practitioners and researchers in that both must develop hypotheses about their task (client change or studying a clinical phenomenon) and constantly question and reevaluate their hypotheses as the process of clinical or research work moves forward.

The attitude of openness described here is inherently a personal, cultural, and theoretical consideration. Each cultural and theoretical orientation brings a set of biases that shape observations and affect findings and the degree and specificity with which evidence may be integrated into practice. Researchers and practitioners have particular perspectives of their culture, class, and gender, shaped by their culture's sociocultural, historical, philosophical, religious, gender, and class experiences and beliefs. They have particular beliefs about clients, clinical change, and the definition of "successful" outcomes. Such beliefs are not inherently problematic but they do limit the awareness of other perspectives, beliefs, and explanatory alternatives for clinical or research questions. Without openness, beliefs of researchers and practitioners can bias both research and the application of research in practice. Open-mindedness also means being skeptical of common sense and personal experience. Researchers must try hard to set aside their

personal beliefs and attitudes, and the limitations of their culture and gender, as well as their theoretical perspective, to carry out objective, unbiased research. In addition to monitoring and setting aside one's own biases, the open-minded researcher should when possible be transparent about the potential biases that may impact his or her work. This entails articulating one's own biases in addition to attempting to set them aside. This can be difficult for "black-and-white" thinkers, who are looking for clear, simple, factual answers to memorize for the exam! In fact, as knowledge develops, understanding of clients, practice, and context grows more, not less, complex. The regulation and articulation of one's own biases allows for more objective and open exploration in both research and practice contexts.

6.5.3 Acceptance of Ambiguity

Ambiguity is an inherent part of psychological practice and research. The work of clinical practice is complex and the process of knowledge development through science is evolutionary. Thus, there are limitations of the degree to which science can translate into clinical practice depending on the question and the area of interest. The current research evidence is not complete and constantly changes as more is known, theories are confirmed, and principles are overturned. Any knowledge base is inherently one in motion that will change over time. In addition, there is much that science has yet to discover or may never discover about the complexities of practice. In some areas of practice there is clear evidence that could guide practice. In other areas there is no treatment model that fits common clinical needs. Thus, if psychologists are to be able to translate research into practice they must be able to have an appreciation for science as a dynamic and continuous process knowing that what is known today will change and develop over time. This would suggest that keeping up with this domain requires not only the ability to deal with ambiguity but requires being a "lifelong learner" constantly developing and adding new information based on systematic inquiry to make better clinical decisions.

Furthermore, it is important to know that even in the best of circumstances knowing what is "effective" in the practice of clinical psychology is complex. Determining the "best" treatment requires consideration of not only whether empirical evidence exists but also the extent, utility, and clinical significance of the evidence. Unfortunately, no degree of clarity or specificity can overcome the inherent ambiguity and difficulty in creating and applying clinical practice guidelines. Consequently, no set of practice guidelines can ever produce a clear and inarguable "list" or easy decision and there can never be a system that is simple to use, that produces clear-cut policy, service delivery, and clinical guidance. In the end, even with systematic practice guidelines the process of determining "what works" will be difficult, complex, and seem at times ambiguous.

We suggest that this represents the complexity of clinical practice rather than anything inherently flawed in clinical practice guidelines. It is, however, important to note that the inherent ambiguity of the knowledge base of science is sometimes difficult to accept and for many undermines their faith in the scientific process. It is not uncommon to hear, "science just can't study real things" or "one study tells this while another one says something different." The attitude of accepting this ambiguity helps both the practitioner and the researcher to respect the current limits of scientific knowledge while at the same time knowing that with more study, innovative research methods, and continued knowledge development many of the "holes" in the research knowledge will be filled. Translation of research finding that may vary widely in

their methodology and knowledge of approaching the task of practice in a research-based way requires accepting the ambiguity as a natural and hopeful part of good practice and one of the exciting elements of the profession.

6.5.4 Embracing of the Dialectical Nature of Science and Practice

What often gets lost in the traditional discussion of research vs. practice, specific models vs. common factors in practice, and evidence-based or practice-based evidence is that the goal of both science and practice in clinical psychology is the same: providing the best available treatment with the highest probability of success to the client experiencing a particular clinical problem. As noted in the APA Task Force, and many of the EBP guidelines, the best treatments are ones that are both scientifically sound and clinically relevant. Considered in this way, science and practice are one and the same. Each brings a different approach to the goal. Each produces a different type of knowledge essential in helping a client. Thus, they are two different sides of the same coin. The core element of "embracing" this dialectic (Alexander, Sexton, & Robbins, 2002) is an attitude necessary to bring knowledge and skills together to help clients and improve practice.

The "dialectic" approach means that both researchers and practitioners are able to inherently know that the question is not whether these enterprises (research/science and practice) go together but how does each inform the other with the specific issue or problem at hand. This approach also means that the competent clinical psychologist stands above many of the "either-or" struggles that often occur between researchers and practitioners and instead looks to see what and how existing, relevant, and available scientific knowledge can be apply to and be used in particular problems or issues at hand.

For scientists and practitioners these core attitudes represent the manner in which they seek information and go about fulfilling their professional roles concerning their particular area of interest. For purposes of clarity, we will present examples related to both domains of the profession. These examples will be structured in a way that one can easily identify the contribution of the aforementioned attitudes as necessary for translating science into practice within the context of problems that individuals in the profession often encounter. We will discuss the process of addressing two domain specific problems and where relevant will highlight the specific attitude at work. We will begin by discussing a situation in which a scientist has been requested to address an area of need.

Implementing the Attitudinal Competency: A Case Example. A researcher has been presented with a grant that tasks him or her in identifying and reporting what works in helping the at-risk adolescent populations. In line with a scientifically minded attitude, the researcher first attempts to identify the main issues related to working with at-risk adolescents. This includes potential modalities such as individual therapy, family therapy psycho-education as well as the major factors related to adolescents such as peers, family, school, autonomy, etc. After identifying the main features related to the focus of the research, it is imperative that the researcher acknowledges his or her own biases. This is an example of the attitude of openness, complexity, curiosity, and being systematic. In line with this attitude, the researcher would need to acknowledge his or her biases related to the field. For example, the researcher may be accustomed to thinking of research problems through a cognitive behavioral lens with a preference for individual modalities of treatment. This perspective has the potential to impact the way he or she

addresses the focus of research on a given topic. In addition, familiarity with the existing research using cognitive behavioral techniques and/or familiarity with the population of inter- est has the potential to bias one's pursuit and synthesis of new information by artificially nar- rowing the scope. When wedded to a modality, paradigm, and/or clinical familiarity in such a fashion, the researcher has inherent limitations on the potential questions, assumptions, and conclusions that he or she may derive. After the researcher has identified his or her bias toward cognitive behavioral thinking and has made an effort to regulate this bias in a transparent fash- ion, he or she is ready to ask important questions pertaining to at-risk adolescents. This researcher goes to the literature and actively adopts a scientifically minded attitude, which would focus his or her to relevant literature related to theories, interventions, and previous research studies on at-risk adolescents. While addressing these areas the researcher would also take steps to maintain an open attitude. This is essential as he or she must remain both critical and skeptical while also being open-minded regarding the information obtained from the at- risk adolescent literature. The risk here is not effectively navigating the disparity between open- mindedness and skepticism. Because this researcher has identified his or her biases in a transparent manner, there is less of a potential for his or her biases to fuel skepticism or active confirmation of preexisting beliefs. Hence, there is a tension between the open and critical stances that must be navigated when determining what is useful in the literature.

After a thorough examination of the literature, this investigator identifies two potential areas of research that may be helpful in addressing at-risk adolescents. One is an individual cognitive behavioral treatment and other is Functional Family Therapy (FFT), a family-based intervention for working with at-risk adolescents. As the researcher further explores these potential lines of research he or she finds that the cognitive intervention has less support for working with the at-risk population relative to FFT. Because of his or her earlier consideration of his or her biases, he or she is able to look past his or her desire to focus on a cognitive treat- ment and focus on the more promising FFT line of research. Up to this point the researcher has demonstrated some of the basic attitudinal competencies a researcher needs in researching in such a way that is translatable to practice. After identifying the method of treatment the researcher hopes to study, he or she may answer his or her questions in a number of ways depending on the current level of evidence related to the topic of interest. Given that the grant aims at identifying what works with at-risk adolescents it is likely that at some point the researcher will engage in relative efficacy or effectiveness studies. In other words, the researcher will want to examine the treatment in a practical context in order to note how well it actually works with a realistic sample. Depending on the results from this study (or series of studies), the researcher will adjust how he or she further studies the topic. There is an iterative process between science and practice where they simultaneously inform one another. The two con- structs share the same goal of attaining scientifically sound and clinically relevant change.

This highlights the researcher's attitude that recognizes the dialectical nature of science and practice. The final attitude that the researcher must demonstrate is one that accepts or embraces the ambiguity associated with the researcher process. First, he or she must understand that what works, in this case FFT, is complex, dynamic, and continuous. It is never complete. It is important the researcher recognizes that no particular research finding ever "seals the deal." Even if he or she satisfies the criteria set forth in the grant there will always be more questions to answer related to how one should work with at-risk adolescents. Moreover, the researcher must adopt an identity as a lifelong learner. This too has to do with accepting ambiguity. He or she must remain open to other literature findings in this area as what worked when he or she

set out at the onset of the study may be bypassed by new state of the art findings. Thus, he or she must know when it is time to change questions or research foci. Again, this has to do with his or her evaluating his or her biases and maintaining an open mind that renders him or her capable of shifting his or her focus when the literature suggests it is necessary. Thus, the process of studying the construct can begin anew as the researcher adopts a scientifically minded attitude as he or she examines whatever the new treatment may be.

Similar to the process put forth by the researcher in the previous section, a practitioner will utilize the same method in working with clients, which further underscores the dialectical nature of science and practice. For example, a practitioner has completed an intake with a client who presents with severe depressive symptoms. The practitioner faced with this new client wants to find the best way to intervene with the client's presenting issues and guide ongoing clinical decision making. This practitioner readily acknowledges his or her affinity for cognitive behavioral techniques, but, however, understands the necessity for accessing the literature to find how best to intervene with this depressive client. The process of clinical decision making requires that the practitioner identifies key factors that are related to the clinical context as well as explore the existing literature base for guidance given these specific factors. Following a scientifically minded approach, the practitioner first identifies the main factors that will potentially influence treatment including the client's presenting symptoms, contextual factors, treatment history, clinical intuition, and sociocultural variables, among others. These factors are likely to play a key role in all decision-making processes and this systematic approach, representative of scientific mindedness, requires this identification. In addition, the practitioner following an open-minded approach to the clinical process will need to acknowledge his or her own biases related to treatment in terms of treatment modality preferences, theoretical persuasions, clinical and research familiarity, and the interpersonal impact that the client may have on the practitioner. Identifying these potential biases is imperative as they can artificially narrow the manner in which the practitioner reviews the literature. In the example, the practitioner readily acknowledges his or her tendency to favor cognitive behavioral techniques and this could lead to an overvaluing of this paradigm within the literature base at the exclusion of other potential treatment options.

Given these prior steps, the practitioner can now formulate potential hypotheses and clinical questions related to how best to intervene with the client. The challenge here for the practitioner is finding a way to navigate the tension between being open-minded about new possibilities and research while also being skeptical about research findings. The goal is for the practitioner to find the most reliable and valid information to guide clinical decision making given the specific context, presenting issues, and other important factors. Following the review of the literature, the practitioner is able to find three potential interventions that have been empirically supported when working with depressive populations including cognitive behavioral therapy, solutions-focused group-based therapy, and client-centered therapy. Up to this point the practitioner has demonstrated some of the basic attitudinal competencies one needs in translating science into practice to inform clinical decision making.

The following steps in the process represent more advanced areas that require that greater flexibility and specificity be incorporated. After identifying the methods of treatment the practitioner feels appropriate given the presenting issues, the practitioner needs to make an informed decision on how best to intervene. This decision embraces the dialectical nature of science and practice as clinical decision making requires both the identification of current best practices while also considering specific clinical factors including client's presenting issues, contextual

issues, clinical intuition/judgment, and other contributing factors. The practitioner decides that given the nature of the client's presenting issues and the associated factors and the existing literature, he or she will utilize a cognitive behavioral approach to intervening with the client. Clinical decision making based on what works given the literature is complex. What works now will change and be expanded upon in the future. Further muddying the water is the ambiguity associated with what works questions. The nature of the literature base is one of being dynamic, continuous, and never complete. This requires the practitioner to embrace the ambiguity associated with clinical decision making and the notion that this process is an iterative one that requires repetition and adjustments on an ongoing basis to best guide clinical decision making.

6.6   Knowledge of Translating Science into Clinical Practice

Like attitudes, there are core domains of knowledge that facilitate the transfer of science to practice. Both basic and expert psychologists need to know about the scientific method, clinical intervention research, EBPs, and specification of clinical practices. These knowledge domains allow for the successful translation across and between science and practice. In the sections below, we describe each of the knowledge domains. In a subsequent section, we more specifically differentiate between basic and expert knowledge. In both cases, our focus is on the knowledge domains that will facilitate the use of science in practice.

6.6.1   Understanding Scientific Methods

The scientific method is one "way of knowing" that has the potential to inform psychologist in ways that other methods do not. Rather than authority (ways of knowing based on experts/ theories), personal experience (it is because it was for me), or a-prior beliefs (everyone believes this), science is a way of knowing that uses systematic methods to establish reliable and verifiable knowledge (Tracey & Glidden-Tracey, 1999). More specifically it is systematic inquiry, organized discovery, and the verification process that is aimed at developing knowledge over time (Sexton & Alexander, 2002). As a method science is nothing more than a set of assumptions and rules about collecting and evaluating data. Explicitly stated rules and assumptions allow for standard and systematic ways of inquiry. By being standard they are intended to reduce bias and produce knowledge that is more reliable and valid.

"Research" and its accompanying methods are the processes by which scientific knowledge is developed. The scientific method is a set of "rules" or procedures to systematically gather information in a manner that is reliable (it can be replicated) and valid (it represents what is intended to be studied). There are a range of research approaches that vary according to the topic of study. These approaches vary from controlled laboratory experiments to systematic observation, cognitive testing, surveys, and case studies. Each method has its advantages and disadvantages, which researchers and students must be aware of to evaluate the accuracy of the research findings. When appropriately using the methods of science and research, the appropriate question depends on stage of inquiry and the specific area of change in which you are seeking knowledge. Conversely, the choice of methodology and approach depends on the question being asked.

There are often competing epistemological approaches and methodological approaches to science which are viewed as different and almost as an "either-or." Rather than a specific type

(empirical/quantities vs. naturalistic/qualitative), the research process is actually just a systematic, inquiry-based, and knowledge-producing set of methods and skills. Research begins with a question of interest, requires a psychologist to be competent in forming operational definitions of key constructs, identifying variables of interest and their potential relationship, and using statistical techniques to answer question. The formulation of the research questions dictates the potential outcomes afforded by the scientific process. This understanding allows for the creation of useful and methodologically sound research that contributes to the broad scientific knowledge base and consumption of research when making clinical decisions. In the end, the particular type of research it is best depends more on the question than the inherent qualities of the approach.

6.6.2 Clinical Intervention Research

Methods of research can be applied to a vast array of different topics. Within clinical psychology there is a variation of the research process that is specific to the work of clinical practice. Clinical intervention research is the systematic study of the relationship between identifiable clinical practices (techniques, interventions, treatment problems) and client outcomes. Clinical intervention research is a systematic approach to understanding the practices, their outcomes, and the varying moderating and mediating variables that may affect the success or failure of different clinical interventions. This type of research is particularly useful for clinical practice because it focuses on what Wampold (2001) suggested are the "fundamental" questions of practice: (1) Does it, this intervention/technique/practice, work? (2) Where, with what, and for what does it work? (In which setting? With what "problems?" With what type of client?) (3) What about it works? (What are the clinical mechanisms that produce the change).

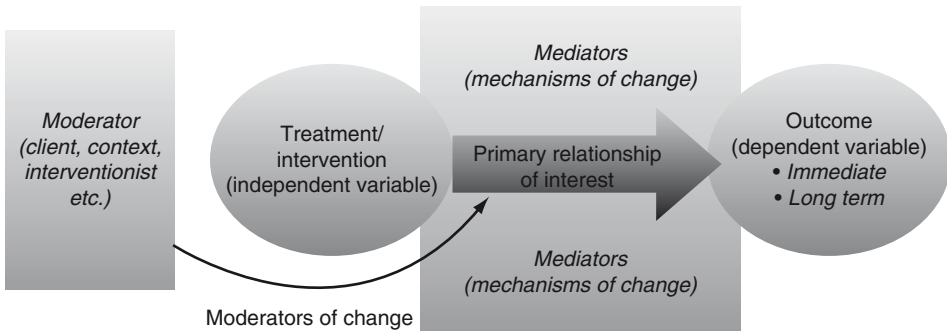
Types of Clinical Intervention Research. The domains of research described in the section above result from a range in types of methods. These methods are specific applications of the scientific method to the domain of clinical practice. Each of these types of research produces different information for different clinical questions. For example, outcome studies investigate the absolute (as compared to no treatment) and relative efficacy (as compared to a clinically legitimate alternative intervention) of an intervention or treatment program. Clinical trial studies (often referred to as randomized clinical trials [RCT]) are the result of randomized studies in which the emphasis is on high levels of internal validity, with some expense to ecological or external validity. RCTs are the traditional "gold standard" of clinical research and follow the same logic as similar studies used in medical research (Wampold & Bhati, 2004). Comparison trial studies evaluate interventions/treatments in relation to a systematically developed and relevant comparison intervention or treatment and are most helpful in answering questions about whether a program or intervention works, with whom it might work, and in which settings it might work. Comparison trials might not include randomization or many of the other strict methodological controls of traditional clinical trials.

Traditionally, outcome studies (whether clinical trial or comparison) are used in three ways. Efficacy studies answer questions about which treatments work under the most stringently controlled conditions. Efficacy studies have high methodological control, but are limited because they differ from actual clinical conditions. Effectiveness studies answer questions regarding the power of therapeutic interventions in actual clinical settings with conditions that replicate those that clinicians genuinely face. Although there may be decreased methodological

control (in the traditional sense) in these types of studies, they do have high clinical relevance. Effectiveness studies are often conducted in community settings at which it is not possible to match the high degree of experimental control of traditional efficacy studies. Finally, moderator studies address questions about which particular client, problem, or contextual feature moderates or affects the strength of the relationship between treatment and treatment outcomes.

Second, in addition to outcome studies, process-to-outcome studies link the conditions of therapy (preexisting and specific within-session processes) with the outcomes of clinical interventions. These studies help identify the mechanisms of action in evidence-based interventions/programs. Third, systematic case studies/N of one studies provide an ideographic view of clinical process. These studies are particularly useful for identifying the individual experiences of clients in the change process that might lead to better understanding of change mechanisms and outcomes. Fourth, qualitative studies consider the therapeutic change process from the perspective of an individual client/therapist/setting or in naturalistic settings of clinical practice. While limited in generalizability, these studies might provide evidence needed to understand processes within models or application sites. Fifth, transportability studies consider various issues related to the transportation of couple and family therapy interventions/treatments to the community settings where they might be practiced. Such studies might consider the contextual variables (therapist variables, client variables, organizational service delivery systems, etc.) that may either enhance or limit successful community implementation. While using similar methodologies as effectiveness studies, the focus of these studies is on the variables that potentially explain the contextual impact that may mediate the outcomes of established studies in community-based clinical studies. Sixth and finally, qualitative and meta-analytic research reviews contribute to understanding and identifying "common" elements, new treatment mechanisms, or differential results across studies. When an adequate number of model-specific process studies accumulate, within-model clinical change mechanisms can be identified or verified.

Moderators, Mediators, and Clinical Outcomes. The core of clinical intervention research is the integration of the various components of the scientific method with the specific elements of clinical psychology practice. The knowledge necessary to understand, create, and usefully consume the clinical intervention research requires understanding of the relationship between the primary variables (treatment and outcome) and the natural complexity of the moderator and mediator variables. Moderator variables are those factors of the client, the context, or the clinical problem that may change the relationship among the major variables of interest. For example, the gender or age of adolescents is a crucial variable to consider when testing treatments designed to change the involvement of that youth in the mental health system. Mediators are variables that provide a bridge between the variables of interest. In a sense, the mediators create the relationship of importance. For example, in a study similar to the one noted above, treatment programs for adolescents have an impact when the therapeutic relationship is considered. Without a measure of therapeutic alliance, many treatment programs are not related to any outcome. Thus, it is the alliance that provides the link in the complex formula between treatment and outcome measure. Clinical intervention research currently states that consideration of moderators and mediators is the standard because it allows the complexities of clients and the therapeutic process to be studied, thus, increasing the potential utility of the investigation. ❯ Figure 6.2 describes the relationship between the core elements of this type of research.

◼ **Fig. 6.2**
Clinical intervention research


6.6.3 Evidence-Based Practice

Over the last decade, evidence-based treatments have come to embody the intersection of science and practice. The increased use of research in practice is due to a number of forces, including the dramatic growth in the depth and breadth of clinical change research, the increasing call for accountability in clinical practice, as well as calls from consumers to identify treatments that are effective and reliable (Sexton et al., 2007). The EBP movement has resulted in a recent increase in the use of clinical intervention research in psychological practice. There are a number of clinical trials, local evaluations, and research reviews that suggest that EBP makes a positive difference to clients when it is delivered well (Aos & Barnoski, 1998; APA, 2005b). The advent of the EBP movement has thus served as a further catalyst for the translation of scientific knowledge into clinical practice. EBPs bring a systematic, scientifically minded, specific, and scientifically defendable program to practitioners by setting a standard for treatment intervention and program specificity, clearly articulating clinical protocols, and identifying quality assurance measurement.

This movement in psychology mirrors similar changes in other fields of clinical practice. For example, evidence-based medicine promotes the use of systematic research reviews for clinical decision making through "the conscientious, explicit and judicious use of current best evidence in making decisions about the care of individual patients" (Sackett, Rosenberg, Gray, Haynes, & Richardson, 1996). EBPs first appeared in clinical psychology when the Division 12 (Division of Clinical Psychology of the APA) established the Task Force on the Promotion and Dissemination of Psychological Procedures. Other efforts followed a similar process (e.g., Division 17: Counseling Psychology; Division 43: Family Psychology, Division 53: Society of Clinical Child and Adolescent Psychology, among others).

The common thread among these efforts is the use of scientific evidence as the primary basis for the determination of valid clinical treatment and preventive interventions. Regardless of the specific approach, evidence-based treatments and practice guidelines have emerged as a valuable component in clinical decision making and adds an important and necessary perspective beyond clinical experience. These works resulted in standards for clinical intervention research, the specification of clinical interventions, criteria for evaluating clinical research, as well as a *list* of effective psychological treatments (Chambless, 1996; Chambless & Hollon, 1998;

Sexton et al., 2007). In these ways, EBPs help identify attitudes, knowledge, and skills necessary to produce good outcomes for a specified client population.

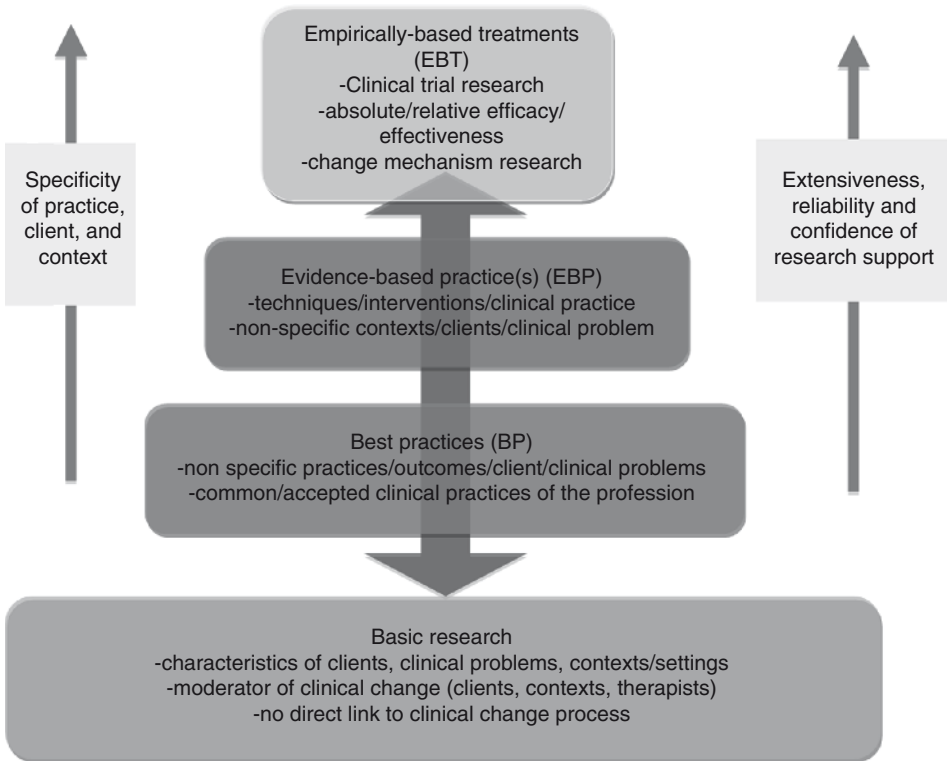
EBP and the resulting guidelines have also brought criticism. For example, Westen et al. (2004) suggest that the existing practice guidelines overstate the value of research, particularly in regard to the complexities of clinical practice. They suggest that empirical support is not a decision made between a limited set of "lists," but instead requires many types of evidence, as a way to account for the complexities of clients, therapists, and treatment settings in evaluating the research. They suggest that the current guidelines are limited because of the reliance on RCTs as the most legitimate source of scientific evidence.

To help further articulate the role of science and practice in clinical psychology, the APA charged a Task Force to study evidence-based treatments and develop a policy statement on EBPs (APA, 2005a). The Task Force concluded that research evidence should be part of clinical decision-making processes and that clinicians need to integrate the diverse forms of clinical trial research along with studies of client characteristics, practice contexts and clinical judgment to determine treatment decisions. The Task Force did not identify the specific attitudes, knowledge, and skills that facilitate that integration.

6.6.4   Specification of Clinical Practices

How well-defined intervention(s) and treatment(s) are is a central knowledge factor in translating research into practice. Well-defined treatments are a hallmark of scientific mindedness, critical to good research, and a central feature in clinical practice. The more specific the treatment the greater the likelihood that the treatment will be clinically useful with a range of populations and settings and that scientific evidence can be integrated into it. Thus, well-defined (or well-studied) treatments are more likely to provide the best treatment and the most relevant and specific clinical evidence to the clinical question of interest. Specification also can occur at the level of the clinical procedure and in the details and complexity of the procedure. Interventions are circumscribed clinical interventions that address a single or group of clinical change mechanisms and which may be embedded in a broader treatment plan and may exist alongside other interventions. These interventions "stand on their own" in the sense that they can be used appropriately in various treatment processes and methods; an example might be communication skills training. A broader and more comprehensive clinical intervention is a treatment model. Treatment models are comprehensive approaches to clinical treatment with systematic treatment plans, interventions, and theoretical principles and outcome goals that are designed to address a related category of clinical problems. Treatment models have varying degrees of specificity with which they address treatment outcomes, therapist issues (treatment fidelity, therapist variables), the therapeutic relationship, and variations amongst clients and their problems. These varying levels of specificity allow for process and process-to-outcome research that systematically investigates the clinical mechanisms proposed by the model. Interventions are likely to address specific therapeutic goals while treatment programs are more likely candidates for interventions for defined groups of clinical problems and clients (Alexander, Robbins, & Sexton, 2000).

❯ Figure 6.3 illustrates variations in treatment specificity from broad theoretical models to highly specific evidence-based treatment packages. Note that these are not mutually exclusive categories. EBPs are based, to varying degrees, on the common and core elements of

◼ **Fig. 6.3**
The levels of scientific evidence in clinical practice


psychotherapy integration (Sexton, Ridley, & Kleiner, 2004). In fact, any good evidence-based treatment model should be based on the core common factors of effective therapy. To be considered an EBP, the intervention/treatment model must include clearly demonstrated evidence of the following: (a) clinically meaningful problems being targeted and appropriately assessed; (b) coherent conceptual framework underlying the clinical interventions; (c) specific, core interventions described in detail with an articulation of the therapist qualities necessary to follow them; (d) process research that identifies how the change mechanisms work to produce positive change, and (e) outcome research that demonstrates the absolute and relative effectiveness of the intervention or program (Alexander et al., 2000; Kazdin, 1997).

Basic and Expert Knowledge. At the most basic-level psychologists need an understanding of the broad research that helps understand clients as well as a basic knowledge of the methods and approaches of research that help consume research in a way that the results fit or match the question at hand. Thus, there is a variety of different approaches that should be considered when evaluating empirically based treatments. The basic level requires the ability to know what research methods are more appropriate for addressing a particular question. To do so the scientist-practitioner needs knowledge of the specificity of research types and the specificity of treatment or intervention (practice). Levels of evidence represents the increasing specificity of research in accounting for treatment, intervention, client, and context, which are an inherent

set of moderators that are necessary to understanding what works, with whom, under what conditions (Paul, 1967).

No single standard of methodological excellence exists. Instead, the standard used to evaluate evidence must match the type of study. Furthermore, the standards applied to the evidence will change with time as the science of psychology improves. At a minimal level, high quality studies of clinical treatments should include: (a) clear specifications of the contents of the treatment model (e.g., treatment manual), (b) measures of model fidelity (therapist adherence or competence), (c) clear identification of client problems, (d) substantial descriptions of service delivery contexts in which the treatment is tested, and (e) the use of specific and well-accepted measures of clinical outcomes.

Expert knowledge includes the ability to differentiate between levels of evidence and practices and have a broad reach of the knowledge of each. For example, experts can distinguish between different types of research and the advantages and limitations of each; thus, they are better able to translate appropriately to practice. Experts know that different research approaches bring different perspectives that are essential to understanding the complexity of client functioning and therapeutic change. Furthermore, different research methods may be needed at different phases in the developmental evolution of a treatment intervention or program. Regardless of method or developmental phase, experts know that quality research is defined as a systematic inquiry process in which the study abides by the principles of the chosen method, the rigor of which is to be evaluated by an agreed-upon set of standards, and the information generated thereby is only used within the limits inherent in the methodological approach. Additionally, with different questions and in different developmental contexts, what constitutes the most appropriate research method is likely to change. The most telling criterion is whether the research method is the best available to answer the clinical question of interest, the research is done according to prevailing standards, and the evidence produced is used within the limitations of the method.

Knowledge allows experts to consume research and sort out different kinds of knowledge based on the methodological source. For experts, "evidence" is not the same. All research approaches do not produce the same type of evidence, and some evidence is likely to carry more weight in different clinical decision-making situations than others. For example, larger clinical trial studies might be most useful to determine the main approaches to use with specific clinical problems, while process studies with small sample sizes might provide more useful clinical guidance within a therapeutic approach, such as how or when a particular clinical strategy or technique might be best utilized.

Experts know the limits of the diversity of methods. Some hold RCTs as the most important research approach and clinical outcome standard. Instead we suggest that RCTs are a necessary but not sufficient approach to understanding, evaluating, and promoting effective practices in clinical psychology. Psychological treatments can be thought of as having various levels of evidence from the broad (does it work compared to no treatment) to the specific and clinically nuanced (why does this work in this situation with this person). Determining what are "good" treatments would be based on different methods matched to the "level" of evidence most appropriate. For example, in determining what works, RCTs provide a valuable tool to validate absolute and relative efficacy (Kazdin, 2006). However, once established, alternative approaches are necessary to answer the more "fine-tuned" and clinically rich questions. These methods may include case studies, matched control designs, and meta-analyses. Each method needs to be used when it fits the question at issue rather than used for its exclusive value. Moreover, each method should meet the established methodological quality and rigor.

In translating clinical intervention research to practice, experts also know the different knowledge produced by different types of research. For instance, absolute effectiveness evidence is a measure of the success of the intervention compared to no treatment. Such a comparison is useful in determining if an intervention can be considered evidence-based. Relative efficacy is the comparison of an intervention to a reasonable alternative (e.g., common factors, a treatment of a different modality, or a different intervention). Relative efficacy is critical to establish that a treatment is the best choice for a specific client or problem. However, when more fine-tuned clinical questions are of interest, Sexton, Alexander, et al. (2004) suggested the importance of contextual efficacy. Contextual efficacy is defined as the degree to which an intervention is effective in varying community contexts. This provides a critical dimension and a final level that focuses on change mechanisms within particular practices.

Implementing the Knowledge Competency: A Case Example. Continuing with the example of the clinical psychologist who has received a grant to explore what works best with at-risk adolescents, there are specific knowledge competencies he or she must demonstrate, both basic and expert, in order to fulfill the requirements of his or her grant. At the most basic level he or she must have knowledge of the scientific method. This competency allows him or her to formulate hypotheses, understand there are a range of methodologies available to him or her and how to carry them out, as well as how to interpret the data he or she attains. More specifically, he or she will need to have knowledge of clinical intervention research. This requires the ability to know what methods are appropriate for the specific questions he or she may wish to answer. At the more expert level, he or she will need knowledge of how different types of research can answer different types of questions while providing evidence that varies in value. For example, the more specific a study's findings, the more credit he or she might attribute to the information. Moreover, the methodology used will further influence how much he or she values different evidence sources. This researcher will understand that depending on the state of the current knowledge base he or she will want to ask questions that fill gaps. This knowledge relates to the specification of clinical practices. The more research informs practice the more the necessary questions will change. This in turn impacts both the questions and the methodology necessary for expanding the knowledge base. The researcher may find that RCTs show FFT and is the ideal intervention for working with at-risk adolescents relative to other interventions; however, he or she may need to expand on these findings by considering under what conditions the intervention is most effective.

Expanding upon the previous practitioner example, the above-mentioned knowledge competencies contribute to the process of clinical decision making for a clinical psychologist who is primarily a practitioner. Faced with the complexities of clinical work, practitioners can rely on the use of research as a means to understanding their clients, their problems, and the specific treatment options available. A basic competency associated with knowledge includes the active use of a systematic method for investigating clinical questions and formulating hypotheses about client issues. Given the depressive client presentation, a practitioner will formulate potential questions related to the client issues and how best to intervene as well as a means to investigate them in a reliable and valid manner. In the example, a basic understanding of research methods and types of evidence allows the practitioner to focus his or her efforts on community effectiveness research. This means that the practitioner has an understanding of the importance of considering treatment variables when consuming the literature in clinical decision making. The outcome at a basic level is guidance for the practitioner on how best to intervene with his or her depressed client. This usually takes the form of best practices as primary means of clinical decision making. The expert-level knowledge competency represents an extension of this

process with enhanced specificity and flexibility. This practitioner wants to know not only what works with the client given their presenting issues but also has questions related to what to do in the room. Expert-level practitioners illustrate their understanding of research methods and types of evidence by differentially weighing research evidence given their specific clinical question. This practitioner emphasizes the specifics of the depressive client and the community treatment center context as he or she knows that research and treatment factors impact the effectiveness of a given treatment. The practitioner is able to review the current literature with an understanding that specificity is needed and the existing literature may not be to the point of specificity desired. He or she uses this information to guide clinical intervention.

6.7 Skills of Translating Research into Practice

Skills are the ability to "do" and act within the attitudes and with the knowledge described above. The skills of translating research into practice described below focus on the "translational" aspect of the process. It is important to note that there are many specific research skills and practice skills needed to both produce research and do clinical work. The skills below represent ones that help translate the findings of the various types of research described above into clinical practice.

6.7.1 Accessing Scientific Finding

For the clinical practitioner the ability to access research is a central skill in the translation process. Accessing research means that the clinician knows where to go and how to look for information regarding clients, interventions, or outcomes of various clinical applications. The psychologist well versed in this competency is able to utilize the research in an ongoing fashion in his or her practice. This entails an understanding of how to access relevant databases and knowing the importance of quality of literature (peer-reviewed).

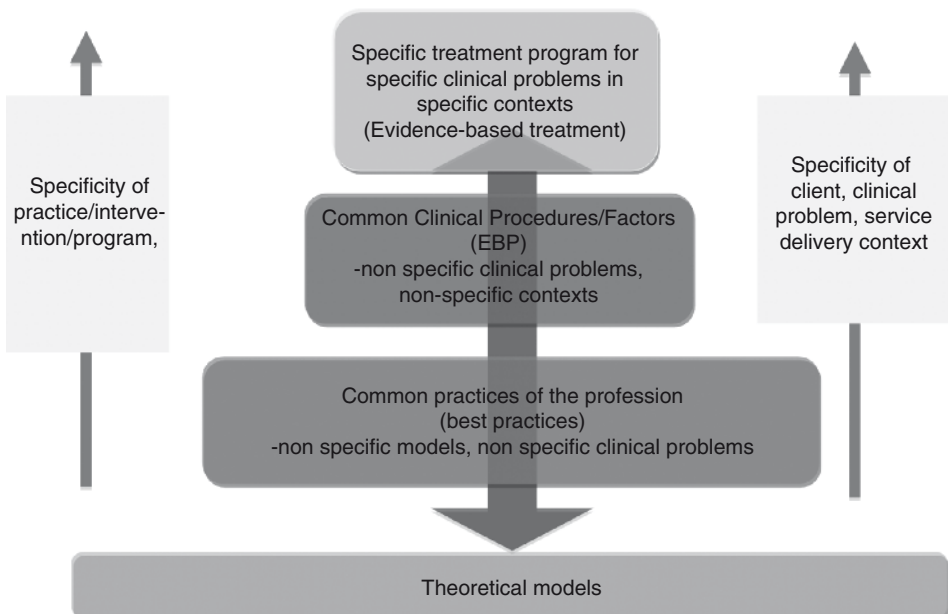
Accessing research knowledge begins with having a good question and knowing what it is you want to "translate" from the research domain. It is a specific question that facilitates accessing and ultimately finding information of interest. The question of interest is most helpful when it uses the knowledge of specification of clinical intervention and knowledge of the role of the variable in treatment/research (e.g., whether it is a moderator, mediator, treatment variable of interest or outcome measure). With a specific question in hand, the clinical needs to look to the correct type of research (outcome/process study) that is best able to answer their question.

There is a variety of sources of information to access. Accessing of information is efficient when the answers sought are found in the appropriate forums. For a practitioner, academic journals that publish empirical studies provide a wealth of information. However, depending on the specific question at hand, this may not be the most useful place for practitioners to access clinically useful information. For broad outcomes of general and specific treatments and clinical problems, it may be that review articles are the most useful. When it is specific clinical change mechanisms that are wanted, specific clinical studies may be most helpful. Accessing information is clearly enhanced through the use of computer-based searches (e.g., Psyc Lit). Professional journals focus on different types of research. *Professional Psychology Research and Practice*, for example, considers the translation of research into practice, while the *Journal of Counseling Psychology* is more

oriented toward publishing studies of specific and narrow questions of clinical intervention research. Receiving and reading journals that match to the typical questions asked by a particular clinician may also be useful. Professional books have a similar range of focus extending from theory to theory-based research. Regardless of the type of medium (computer search, journals, or books), it is the task of the consumer to match the specific question they may have with an outlet that is current, specific, and can provide answers in a way that has an empirical foundation.

6.7.2 Consuming Research: Clinical Utility Through Level of Evidence

For the translation of research-based knowledge to clinical practice, the knowledge of research must be consumed. That means that it must be taken in, absorbed, understood, and applied in practice. At the center of the ability to consume research evidence is the ability to match research findings to the clinical questions of the practitioner. As noted by Kazdin (2008), overcoming the practice/research gap and successfully translating research into clinical practice require more than just understanding the types of clinical intervention research. Sexton, Alexander, et al. (2004) in a review of the research in family psychology introduced the aforementioned "levels of evidence" approach to help make the different types of research more useful to translate into clinical practice. ❯Figure 6.3 illustrates the nested model of scientific evidence from basic research to empirically based treatments. Basic research focuses on understanding clients, context, clinical problems, issues of the therapist, among many others. The levels described in ❯ Fig. 6.4 are useful because they help the clinical psychologist differentiate

◼ **Fig. 6.4**
The levels of clinical practices


between research types and thus understand and use research in ways in which the research type fits the question or the interest of the psychologist. Each level varies by the specificity of the clinical intervention that is the focus of attention and the specificity of the client, context, and clinical problem. The methodological rigor needed to systematically and reliably conduct studies is also important to note. This is not intended to be a linear or hierarchical model but instead one that recognizes the importance and contribution of each tier.

Basic research is useful in "understanding" and forms a valuable foundation upon which systematic study of clinical change is based. This type of research is not one that can directly guide practice and is not a source to turn to when wanting to know how, when, and where to practice. Instead it is a useful guide and broad source of knowledge upon which to base additional study. A next, more specific level of evidence would identify a type or domain of practice. We designated this as "best practices" or those activities generally accepted by the profession as useful, helpful, and appropriate ways of approaching clients. Here, the study of research is focused on the process of clinical change. It is very likely that neither the practice nor the client or outcome is specific. Thus, outcomes with this type of research tend to be more general in their guidance.

EBP is a broader term that refers to clinical practice that is informed by evidence about interventions, clinical expertise, patient needs, values and preferences, and their integration in decisions about individual care (APA, 2005b). Kazdin (2008) has further articulated EBP as consisting of integrating evidence, clinical expertise, and patient considerations and then making a judgment of what to do. An example of EBP is cognitive behavioral treatment for a depression without contextual specificity. Clinicians may utilize cognitive behavioral treatment based on a combination of the notion that it generally has strong support in the literature coupled with their clinical experience and intuition as well as specific client variables in coming to a decision regarding treatment.

Research focused on specific intervention programs with specific clients in specific contexts is often termed evidence-based treatment. The research and utility of this type of work is very specific in identifying outcomes, processes, and clinical protocols. For example, an empirically based treatment for at-risk adolescents is FFT (Alexander & Sexton, 2003). This treatment model has been independently replicated and consistently yields significant results in a wide range of community-based settings. FFT provides a conceptual map for the practitioner that provides specificity, flexibility, and direction in treatment when applying this evidence-based practice. This top tier of evidence-based treatments consists of the treatments that have yielded significant empirical support using various research methods, usually focused on the use of RCTs during initial phases.

The value in the "levels of evidence" perspective is in how it can be applied in answering clinical questions and ultimately in understanding the potential value of clinical interventions. Instead of applying a single "research" perspective, a "levels of evidence" approach allows the clinical practitioner to successfully apply knowledge from diverse research methods. The "levels of evidence" view guides a practitioner in the process of matching their question with the type and "level of evidence" needed in order to make useful clinical decisions. For example, policy makers ask about what practices or treatment models to use, how to spend money, and what practices to promote regarding the pressing problems of the people and communities. These questions are probably best informed by broader "levels of evidence" that addresses absolute, relative efficacy/effectiveness, and transportation-based studies. For agency administrators, similar service delivery questions arise. For example, they may ask what practices to

use and whether they would be effective in their local setting. These questions are probably best answered by model/treatment studies of the moderators of clinical outcomes that involve much more of a context type of efficacy (does it work in this situation given these complexities, can it be transported to this agency?). Clinicians need to know what to do "in the room" and thus need a fine-tuned and specific level of evidence focused on the change mechanisms and their interaction with differences in client and setting. These questions are best answered by change mechanism and process-based research. The knowledge from diverse methods applied to the correct clinical questions provides the most comprehensive view of good clinical treatment.

6.7.3   Practicing Research-Based Clinical Intervention Protocols

Identification and dissemination of scientifically based treatments or interventions is only helpful if they can be implemented in "real life" community-based clinical settings. This critical skill of translating involves accurate assessment of clinical problems and client characteristics, matching available research on treatments, and the application of treatments to the client. Moreover, the accompanying clinical protocol needs to occur in a highly adherent way with the client. Thus, a psychologist with this competency should be able to administer a treatment while following its manual and maintaining treatment integrity. Moreover, this psychologist is capable of matching the manualized treatment to its intended target population within its intended context. The practitioner should have an understanding of the specific change mechanisms associated with the treatment and their theoretical underpinnings. At this level a psychologist understands the differences between an evidence-based treatment regimen and interventions that have empirical support. At the most basic level, this psychologist is capable of understanding a treatment manual and how it is meant to be applied.

6.7.4   Becoming a "Local Scientist"

The systematic inquiry of research and science is not the sole domain of researchers. Clinical practitioners may actually be the best located to conduct the systematic inquiry into the outcomes and processes at the center of clinical intervention research. Unfortunately, practitioners often do not collect information, use such information, or feel capable of conducting research. Stricker and Trierweiler (1995) coined the term "local scientist" to describe an approach for clinicians to move research into their practice. In this model, practitioners use their own practice to study profiles of service delivery, types of interventions, outcomes, and even process measures which, over time, accumulate to produce a "local" set of "evidence" for that practitioner in that setting. The difficulties of being a clinical practitioner cannot be underestimated, and the inclusion of local and individual evaluation has much to offer the practitioner. In addition, the skills and knowledge necessary to do so are those described above – the same ones that it takes to successfully translate science into practice (Stricker, 2002).

The practitioner who acts as a local scientist would systematically gather information in their own domain. For example, it may be that the practitioner adopts an outcome measure to determine pre (prior to therapy) and post (after therapy) levels of mental health, behavioral disorder, or healthy attitudes and behaviors. There are many easy and accessible measures of outcome that are easily integrated into practice. The service delivered to these clients could also

be tracked noting the number of times, the type of service, and the response of clients. Process measures, like therapeutic alliance, could also be measured during the course of treatment. An exemplary example of this work is that of Lambert et al. (1996) who used a simple, reliable, low-cost instrument to measure client systems frequently in therapy with the aim of providing the therapist with ongoing process information and outcomes. Percevic, Lambert, and Kordy (2004) have also developed a unique computer system to easily enter and track these assessments in such a way as to provide a number of critical therapeutic indicators to the therapist. In such a way, the clinician is able to demonstrate outcomes, be more accountable, and bring an attitude of scientific mindedness to individual practice. This is a true example of a scientist-practitioner.

Basic and Expert Skills. A practitioner with expert competencies is adept at navigating the literature base in ways that both utilize it and identify gaps within it. Specifically, this practitioner is able to utilize the existing literature base in a manner that addresses clinical issues while systematically navigating areas of weakness in the literature by identifying alternative relevant knowledge. While applying this evidence to practice, this practitioner remains critical and flexible.

A practitioner with expert competencies has the ability to navigate the literature in an adept manner while at the same time being able to differentially weigh the value of the evidence informing the empirically based treatment individually coupled with recognizing areas of less empirical support. This specificity translates to practice as the practitioner asks clinical questions that emphasize does it work, for whom, and under what conditions. The practitioner remains cognizant of the contribution of moderators and mediators in outcome studies and includes these in the process. When clinical presentation is matched with an appropriate empirically supported treatment, this practitioner is able to apply it in a flexible and clinically responsive manner while maintaining the fidelity of the treatment.

6.8 From Basic to Expert: The Evolution of Translational Competencies

Evaluating competencies from a developmental perspective is not a novel idea. The APA Assessment of Competency Benchmarks Work Group conceptualized the development of competencies as beginning during the earliest stages of professional training and progressing through more advanced stages over one's professional life span (APA, 2007). They suggested that the developmental stages progress through a readiness for practicum, internship, entry-level careers, and advanced training. Rodolfa et al. (2005) developed the Cube Model of Professional Competency which dictates the foundational and functional competencies within a developmental framework. They highlighted stages as advancing through doctoral education, internship/residency, postdoctoral supervision, residency/fellowship, and continuing competency.

These models, like most development-based competency models hold that there are certain skills that one acquires and hones at certain points in his or her professional career; moreover, these models indicate that the development of both clinical and research competencies is a lifelong endeavor. The APA Task Force on the Development of Competence suggested that a developmental perspective must undergird the assessment of competence (Kaslow et al., 2007). They suggested that there should be benchmarks and behavioral indicators associated with each domain of competence that provides descriptions of expected performance at each developmental stage. They further noted that earlier stages of development will reflect a more general simplistic approach while later stages of professional development will be more in-depth

■ **Fig. 6.5**
Evolution from basic to expert competencies

Specificity · Complexity ○ Flexibility ○

Developmental trajectory

and complex. Spruill et al. (2004) generalized Stuart Dreyfus' model of skill acquisition as depicted by Benner (2001) in the field of clinical nursing to clinical psychology. They articulated what a professional might look like at the beginner, advanced beginner, proficient clinician, and expert-level clinician stages of development. At the beginning stages, they suggest that professionals rely on basic principles and are rigid in their application of skills. As they progress, advanced beginners have a limited ability to generalize skills and begin to shift from rigid rules to more flexible guidelines. The proficient clinician demonstrates flexibility and well-understood principles. The expert-level clinician is the most flexible and can call on complex, specific interventions to address a wide range of situations.

We suggest that the developmental trajectory from basic competencies to expert competencies is less dictated by specific skill acquisition (although it is a part of development) and more focused on a professional's increasing ability to utilize his or her knowledge, attitude, and skill competencies with greater *specificity*, *complexity*, and *flexibility*. Thus, we agree with much of what Spruill et al. (2004) and Kaslow et al. (2004) suggested regarding the increased flexibility found in advanced practitioners. Much like other models of competency development, we argue that professionals should be lifelong learners and competency development never reaches a pivotal moment where one becomes "completely competent." Instead, scientist-practitioners will continue to develop, acquire knowledge, and learn how to incorporate that information with increased specificity, complexity, and in more flexible ways. Thus, moving from basic to expert is linked to moving through the developmental stages from being specific to being flexible and complex in attitude, knowledge, and skill (❯ Fig. 6.5).

6.9 Summary

In this chapter, we attempted to articulate a "competencies"-based approach to translating science into practice. As stated, development of competencies has become increasingly important in the professionalization of psychology. Competencies guide clinical training, establish standards for professional competence, and facilitate the measurement of professional standards. Rather than articulating a list of competencies for either science or practice, we focused on the often unaddressed integration of the two. Our approach recognizes the dialectical relationship between science and practice and their inexorable link. Thus, we believe the success of both science and practice is contingent on one another. Competencies outlined in this chapter are meant to facilitate realization of the scientist-practitioner by outlining the attitudes, knowledge, and skills necessary for the translation of science into practice. These three domains encompass both basic and expert competencies that are necessary for learning, developing,

and functioning as a profession within the scientist-practitioner paradigm. Furthermore, we believe it is important to take a developmental perspective when addressing the hyphen by recognizing the dimensions of specificity, complexity, and flexibility.

Diagnosis and Evaluation

7 Clinical Interviewing with Adults

Julie N. Hook · Elise K. Hodges · Daniel L. Segal · Frederick L. Coolidge

Abstract: Clinical interviewing with adults can be a complex and challenging process, particularly for the beginning clinician. In this chapter, we break down clinical interviewing skills into understandable steps and illustrate our points with a number of examples. In the initial considerations section, we help set the stage for starting the interview through a discussion of establishing rapport and goal setting, professionalism, and setting up the physical environment for the interview. We then review basic competencies or the fundamentals of the interview process, including opening and closing the interview, selection of questions and questions to avoid, paraphrasing, observing and listening to the patient, and self-awareness. Lastly we offer a review of expert competencies, which are aspects of the interview that are often more difficult to master. These topics include areas such as rhythm and timing of the commentary during the interview, prioritizing aspects of the interview, transference and counter transference, confrontation and interpretative remarks, dealing with difficult patients, and interviewing patients with diverse backgrounds. In all, this chapter provides a road map to help novice interviewers embark on their first interviews and offers guidance for the more skilled clinicians to hone and refine their skills.

7.1 Overview

Etymologically, the word *interview* stems from the French word *entreveue*, which means *meeting* (Hoad, 1996). At the most basic level, the clinical interview is a meeting, but is distinguished by its setting, context, content, and goals. Broadly construed, the clinical interview is the foundation of all clinical activity in psychotherapy and is typically the first encounter between the mental health professional and the patient. Although specific attention is often paid to the *initial* clinical interview, clinicians do not *complete* an interview and *then* start treatment – rather the clinical interview is an *ongoing* part of the psychotherapeutic process. Emphasis of this initial meeting is the commencement of a healing professional relationship. At the end of an initial clinical interview, the professional should be able to offer a summary understanding of the patient's problems, provide some feedback about the causes of the person's suffering (perhaps in the form of a tentative diagnostic impression), and present some initial directions for treatment.

Trying to manage the content and process of the interview can seem like a daunting task. However, with guidance and practice, clinical interviewing skills will develop and eventually become second nature. In this chapter, we first discuss initial considerations for interviewing, followed by a review of basic competencies and then expert competencies. We conclude with a summary of these important skills.

7.2 Initial Considerations

7.2.1 Basic Goals of the Clinical Interview

The main goals of the clinical interview are to: (1) develop a working alliance with the patient, (2) gather relevant data about the person and the types of problems he or she is experiencing, (3) determine an initial case conceptualization (also known as the clinical formulation), and (4) establish a mutually agreed-upon treatment plan or treatment contract. Arguably, the first goal of establishing rapport is paramount because, without development and ongoing nurturance of a positive therapeutic relationship, the acts of gathering information and conceptualizing the case are pointless if the patient does not return for ongoing treatment.

Basic and advanced texts on interviewing typically pay a great deal of attention and provide guidance to the process of developing and maintaining rapport (e.g., Othmer & Othmer, 2002; Sommers-Flanagan & Sommers-Flanagan, 2003). The thoughtful and sensitive use of basic attending, listening, and accurate empathy skills is the foundation for developing rapport. In their incisive analysis, Ackerman and Hilsenroth (2003) summarize several attributes of clinicians that facilitate development of rapport and the therapeutic alliance. Notable attributes include clinicians who are warm, caring, friendly, empathic, genuinely interested in the patient, respectful, supportive, and affirming of the patient. Other important attributes include facilitating expressions of emotions and the deep exploration of the person's problems, providing accurate interpretations as well as an activity level that matches the patient's preferences and expectations.

In addition to positive personal qualities of the clinician and use of basic clinical skills, Othmer and Othmer (2002) offer several helpful strategies for enhancing rapport. These include helping the clinician relax, putting the patient at ease, recognizing the patient's emotional pain and showing compassion, assessing the patient's insight and aligning with the healthier aspects of the patient, showing professionalism and expertise, establishing appropriate levels of leadership as the clinician, providing a suitable structure to the interaction, and balancing the multiple roles of the clinician.

Regarding the second goal of the interview, namely gathering relevant information about the patient and his or her difficulties, the challenge is to effectively do so while not compromising development of rapport. Information is typically obtained through an ongoing *dialogue* with the patient about the problems he or she is experiencing as well as the history and background, which serve to place the case in context. Clinical interviews vary widely in the degree of structure that is imposed on their flow and content. At one end of the continuum is the unstructured interview during which the clinician can proceed in any direction that seems reasonable, based on the clinician's personality style and therapeutic orientation and on the patient's nature and clinical presentation (Segal, Maxfield, & Coolidge, 2008). Clear advantages of this flexible unstructured approach are extensive opportunities for gathering a deep understanding of the unique psychology of the patient and empathizing with the patient to develop a strong therapeutic relationship (Segal et al., 2008).

At the contrasting end of the spectrum are semi-structured and fully structured interviews which conform to a standardized list of questions including follow-up questions, a standardized sequence of questioning, and a systematized rating of the patient's responses (Hook, Hodges, Whitney, & Segal, 2007; Segal et al., 2008). Clear advantages of the semi-structured

and fully structured approaches are increased coverage of some psychiatric disorders that might be overlooked in less structured interviews, enhanced ability to accurately determine whether specific symptoms are present or absent which is necessary for differential diagnosis, and reduced variability among the clinician's interviewers (and diagnoses) which improves reliability.

Regardless of how much structure is imposed on the clinical interview, it typically begins with an assessment of the patient's presenting problem or chief complaint (e.g., "What has been going on lately?"; "What kind of difficulties have you been experiencing lately?"; or "What brings you to see me today?"). The interviewer can then ascertain the nature of the complaints, including onset, duration, course, frequency, and severity, as well as the impact of these complaints on daily functioning. For example, if the patient says that he or she has come to the clinic due to "being depressed," the clinician should find out exactly what the patient means by depression, when the symptoms started, how often the symptoms affect him or her, how severe the symptoms have been, and how the symptoms detract from his or her functioning. Certainly, in this example, an evaluation of the full diagnostic criteria related to major depression will be an important aid in understanding the patient's difficulties.

After obtaining information about the presenting complaint, the interviewer should gather additional information about the patient's history. This will mean a review of some or all of the following: the patient's medical and psychiatric history, family medical and psychiatric history, developmental and educational history, social and relationship history including sexual functioning, use and/or abuse of psychoactive substances, work history, legal history, and leisure-time activities. During the interview, the clinician should also assess resources that are available to the patient. Areas for questioning may include strength of relationships with family or friends, quality of housing, ties to the community, religious beliefs, and state of finances. Understanding what resources the patient has in his or her environment will assist greatly in treatment planning and in obtaining a more holistic understanding of the patient.

Depending on the professional setting of the clinical interview, there is considerable variability in what topic areas are covered after the presenting problem and how thorough the evaluations are in each possible area. For example, if the clinician is working in a setting where there are only 30 min for the clinical interview, the clinician will need to determine the most essential areas to explore. In settings where more time is allotted, the clinician will have greater leeway to explore and evaluate each area in depth. No matter what the time constraints are, it is important to gather enough information to have a reasonably thorough understanding of the patient's problems and possible diagnosis and to offer the patient treatment options.

The clinical interview is often the first time the clinician and the patient have met, and the patient is typically asked to reveal detailed personal and painful information. As noted earlier, development of a working alliance is imperative in assisting the patient in feeling comfortable enough to relay this information. As such, clinicians should be aware of confidentiality, time management, and their professional presentation and caring demeanor, which all aid in the development of a working alliance.

7.2.2   Professionalism

Clinicians should keep in mind that many of the basic social interaction skills they have honed throughout their life will be useful in the clinical setting. However, it is equally important to

remember that a clinical interview is the start of a *professional* relationship that differs from casual social interactions. In a professional relationship, the patient is the focus of the interview and the professional sets the tone and guides the conversation. There is not an equal two-way exchange of personal information in a clinical interview as there may be in a typical social interaction.

Most people seeking psychological services are experiencing some level of emotional distress, may feel unable to cope, and are seeking professional help to reduce their distress (Frank, 1982). Therefore, the clinical interviewer should foster an environment of openness, allowing patients to freely express their thoughts and feelings (McWilliams, 2004). Indeed, it is the role of the clinical interviewer to gather information while creating an environment in which the patient feels comfortable to share.

A hallmark feature of a professional therapeutic relationship is *confidentiality* (American Psychological Association, 2002). Prior to the clinical interview, patients must be informed (e.g., verbally or in a written format) who will have access to their records. For unlicensed professionals, the supervisor or clinical supervision team will be privy to the information. Aside from these individuals, a patient's information is confidential with a few notable exceptions. Aspects of the clinical interview may be relayed to a third-party payer for reimbursement. If the patient is not his or her own legal guardian (i.e., a minor or an adult who is incapacitated), the legal guardian has access to the information. In cases where child or elder abuse is disclosed, confidentiality must be broken. Finally, when there is a duty to protect the patient from himself or herself (due to an imminent suicidal crisis) or when there is a duty to warn others (due to an acutely homicidal patient), the proper authorities should be notified.

Information gathered from the clinical interview should not be the topic of casual conversation under any circumstances. Even anecdotal de-identified information can be highly identifiable if the situation is distinct. Describing a patient during the course of a conversation with friends or colleagues in what may seem to be a private setting may actually include unintended listeners who can identify the patient's information due to the distinguishing features of the story. Novice clinicians may be more prone to discussing aspects of therapeutic experiences with friends or colleagues in inappropriate settings (e.g., restaurants, lounges, etc.). They may also be compelled to discuss patients in areas of the treatment center where other listeners may be present (e.g., at the front desk, elevators, hallways). Remember that confidentiality is the rule for information gathered in a clinical interview and not the exception, and respect for confidentiality is one of the elements in forging an open and honest dialogue.

Another crucial aspect of a clinical interview is *time management*. The professional is in charge of making sure that the appropriate content areas are assessed in a constrained amount of time. The typical clinical interview lasts anywhere from 30 to 120 min depending on the setting and nature of the problem. This means that the clinical interviewer has a finite amount of time to establish rapport, gather relevant clinical information, and determine a disposition for the patient. Therefore, if the patient is overly verbose or relays irrelevant stories, it is incumbent upon the interviewer to keep the patient focused.

Part of being a professional is looking like one. Although there may be latitude in interpretation of professional appearance, many clinical settings have dress codes to which the interviewer should adhere. For example, many hospitals have policies that do not allow open

toed shoes on inpatient units. Moreover, apparel that is flashy, revealing, or overly casual will not instill confidence in the patient and can damage rapport regardless of setting. Imagine a professional who wears flip-flops, jeans, and a ripped T-shirt. This presentation may make patients feel as though they are not being taken seriously and they may lose confidence in the professional. Dressing inappropriately can shift the focus off the patient and detract from the development of rapport.

Another aspect of being a professional is being *paid for service*. For new clinicians, this often feels awkward. It may feel uncomfortable for some beginning professionals who may not feel like they "are worthy" of being paid for the services they are providing. It may also be difficult to ask for a fee for service particularly if the patient is very distressed during the session. One of the best ways to feel prepared is to understand the agency's (e.g., hospital, clinic, private practice) policy on billing. That is, some clinics have office staff, who handle billing and the clinician is not overly involved. Alternatively, it may be the clinician's individual responsibility to collect fees or obtain payment for service. In either case, it is best to discuss charges, payment, and insurance issues prior to beginning the initial clinical interview. This way there are no surprises for the patient at any point during treatment and the patient is fully informed regarding financial obligations from the outset.

7.2.3   Supplies and Physical Setting

Supplies needed for a clinical interview are fairly basic. These include clean comfortable chairs, a clock, paper, and writing utensils. In a training clinic where the sessions are recorded, the clinical interviewer may also need to ensure that equipment is in good working order prior to the patient's arrival. During the interview, taking notes may be helpful in managing the information and keeping the interview on track. One important element of note taking is to do so in a limited fashion and unobtrusively to maintain appropriate eye contact with the patient. Staring at the paper during the course of the interview and not making eye contact will certainly damage rapport.

Another basic consideration that is often overlooked is ensuring that the physical setting in which the interview will take place is set up properly prior to beginning the interview. This usually entails making sure that there is ample seating for the interviewer and the patient. Some clinicians prefer to direct the patient where to sit. This way the patient does not have pressure in making this decision and the clinician is able to sit where he or she prefers. Specifically, some clinicians prefer a particular chair or sitting where a clock is easily seen. On the other hand, there are clinicians who allow the patient to choose a seat. In this situation, the clinician can see how the patient makes decisions and how quickly the patient makes them. In either case, it is important to keep in mind that when possible, the clinician should sit near the exit and not to have the patient blocking the egress. Should a patient become angry, agitated, unruly, or potentially dangerous the clinician should be able to exit the room quickly if needed. Personal decor in a treatment room, such as personal photos, generally should be kept to a minimum. These personal items may shift the focus of the interview to the clinician rather than the patient. Furthermore, this may lead the patient to formulating assumptions about the clinician that may damage rapport and impede the interview. To avoid this situation, keep room decorations neutral and nonpersonal.

7.3 Basic Competencies

In this section, *basic competencies* for clinical interviewing are reviewed. *Basic competency* refers to skills acquired through course work, clinical training, and supervised experiences and an ability to apply diagnostic and intervention skills across patients and settings (Hatcher & Lassiter, 2007). These include the opening and closing of a clinical interview, facilitating the narrative, and identifying points that can detract from the flow of the interview. We highlight the importance of patient observation and empathic listening. Nonverbal presentation and the clinician's self-awareness are also reviewed. Mastery of these basic competencies will assist the interviewer in gathering information about the patient while also building rapport.

7.3.1 Opening the Interview: The Introduction

The first step in any interview is the *introduction*, which is a preliminary exchange between the professional and the patient. Clinicians should introduce themselves by providing their full name and title and, if applicable, level of training (e.g., second-year graduate student; licensed psychologist) and for those in training, the name of their supervisor. The clinician should also confirm the patients' name and use the patients' surname when addressing them. For example, the clinician might say "It is a pleasure to meet you, Mr. Smith," rather than saying "Great, you could come in Joe." Though there are times it may be acceptable to greet the patient by his or her first name (e.g., if the patient is the same age as the interviewer), it is a good rule of thumb to allow the patient to make the indication to do so. For some patients, using their first name can be seen as impolite or unprofessional and ultimately damage rapport.

After the introduction, the clinician should provide an overview of the session so the patient knows what to expect, for example, "Mr. Smith, first we will review material so you are familiar with your rights as a patient. Then we will discuss a number of different things, including what brings you into the clinic today. At the end of the session, I will share with you my impressions of your situation and we will put our heads together to determine the best plan of action to help you. Please feel free to ask me questions as we go along." The introduction will typically include outlining limits to confidentiality (as noted above) and letting the patient know if the session is recorded. Depending on the clinic, setting, or situation, there may be other points that are highlighted in the introduction (e.g., paperwork to be completed, polices of the clinic).

7.3.2 Structuring the Session

To what extent should the clinician actively direct the flow and content of the interview? This is an issue of *structure*. Consider the example of a patient who during an initial interview spends a great deal of time describing his "Aunt Sally's lasagna" which seems tangentially related at best to the presenting problem regarding anxiety about his career path at work. To the extent the clinician allows the patient to focus on unnecessary, irrelevant, or unproductive topics in the session, not enough structure is provided.

On the other hand, consider the example of a patient who during the initial interview describes in depth her current feeling of despair and how she is coping with her recent divorce. To the extent the clinician interrupts this process and directs the client to switch topic (e.g., "Why don't you tell me a bit about your childhood before we get into your marriage?"), then too much structure to the interview is provided. The general rule of thumb is to provide the minimal amount of structure necessary for the patient to stay on productive lines of discussion. Beginning clinicians often struggle with either being too passive (and allowing the interview to flounder) or being too active (not allowing the patient the opportunity to participate fully in shaping the process), and either way, this can be viewed as an issue of structure.

7.3.3 Listening to the Patient (Active Listening Skills)

Being a good listener is an important skill to master. Typically, patients are coming for a clinical interview because they want help and the majority of them will be forthcoming with information. It is important for interviewers to listen closely to what patients are saying and allow them to speak freely and openly. Although this sounds like a fundamental concept, it is surprising how often what a patient says is not really heard or understood by the interviewer. At times, the symptoms or experiences that the patient is relaying are so foreign to the interviewer that it becomes difficult for the interviewer to fully understand. More frequently it is the case that the clinician's attention may have momentarily drifted due to anxiety or the clinician may not be listening intently because of being overly focused on the interview agenda (i.e., what he or she should say next).

Sitting back and letting the patient speak may feel too passive for some interviewers who prefer to be a bit more action-oriented. This can stem from anxiety on the part of the interviewer possibly due to being new to the interviewing process or because of time pressures. In either case, this urge can result in the interviewer interjecting at the first silent pause or interrupting the patient mid-sentence. These mistakes can detract from the cadence and flow of the interview and can make patients feel rushed or unimportant. Although there are times that the interviewer will need to interject to get the interview back on track, when and how this is done should be decided judiciously.

7.3.4 Observation of the Patient

A good clinician is a good observer of human behavior. From the first time the patient is seen, the clinician should begin to formulate some diagnostic impressions. The patient's clothing, accessories, body language, mannerisms, word choices, and manner of speaking (e.g., rate, prosody, and tone) can provide valuable clinical information. Imagine walking to the waiting room and seeing a patient for the first time. The patient is a young man who appears disheveled. He is slouching in his chair and staring at the floor. When greeted, he speaks so quietly that it is hard to understand him and he moves slowly to the interview room. From just these few observations, some initial diagnostic impressions are being generated. Some first thoughts may include depression or social anxiety. Now imagine that the next patient is agitated, moving all around the waiting room, seemingly unable to sit still. She speaks loudly

and rapidly to the office staff asking when her appointment will begin. She is wearing flashy clothing with heavy makeup and a lot of jewelry. For this patient, the clinician is likely thinking of different diagnoses, which may include mania or a histrionic personality style. These cases help illustrate how being a keen observer will be critical to formulating diagnostic impressions.

Observation skills should continue throughout the duration of the interview. How does the patient behave during the session? Does the patient make appropriate eye contact? Does the patient interact in an overly familiar way? Or does the patient seem excessively shy and have difficulty vocalizing concerns? Also, consider the patient who complains of one problem, but does not display these symptoms during the evaluation. For instance, a young woman says that she was reading about symptoms of attention-deficit hyperactivity disorder and is sure that she has it. She states that she cannot sit still in a chair and cannot focus on anything for longer than a minute. However, during the interview, the patient sits fairly motionless and is attentive for the entire hour. In fact, over the course of the interview, several fire engines went by the clinic with loud sirens and the patient did not appear distracted at all. This is valuable information for the diagnostic impression and should lead one to consider other areas for diagnostic evaluation.

Other characteristics to observe during the clinical interview include any remarkable physical characteristics, nonverbal behaviors, affect, and language. Remember the goal of the clinical interview is to gather information about the patient, and this information comes from observation, listening, and verbal communication.

7.3.5 Nonverbal Communication

Clinicians should also be aware of their own body language or *nonverbal communication*. It is best to have an open posture (arms and legs uncrossed), be physically relaxed, and lean in towards the patient, as appropriate. This sends a nonverbal message that one is interested and attentive to what the patient is saying. Make appropriate eye contact and place a clock in an area that can be seen unobtrusively. Use of video-recording, talking in front of a mirror, or interviewing a mock patient will all assist in identifying unwanted mannerisms.

Some nonverbal gestures can be quite helpful in conveying meaning. A head nod can convey an empathetic message of "I hear you and understand" although excessive head nodding may be distracting. Gesticulation can help when explaining a point, but excessive arm movements or inappropriate gestures can similarly be off-putting.

7.3.6 Open-Ended and Close-Ended Questions

In an initial interview, after introductions are made, the interview generally proceeds with an invitation to share, often in the form of an open-ended question. By definition, open-ended questions cannot be answered with simple fact or with a yes or no response and they encourage longer responses from the patient. Open-ended questions begin usually with "what," "how," "could," or "can." This type of question allows patients to elaborate and freely discuss what brought them to see the clinician. Examples of open-ended questions to start the interview

are: "What brings you in today?"; "What has been bothering you?"; "How can I help?"; "Could you share some of the concerns or difficulties you are having?"; or "Where would you like to begin?" Opening the interview with a gentle open-ended question allows patients to start on topics that they believe are most important. Patients are also able to share aspects of the situation, which they are most comfortable with until a greater degree of trust has been developed. It is possible that some aspects of a presenting problem could be missed or defensiveness increased if more directive questions were asked first.

Close-ended questions are those that require a yes or no answer (e.g., "Are you happy in your job?") or a simple fact (e.g., the date, someone's name). As such, they limit the patient's response and are usually not used in the opening of the clinical interview. Imagine opening the interview with a close-ended question, such as "Are you depressed." This type of question limits a patient's response to either yes or no and limits discussion of important aspects of the patient's presenting problem. It is possible that the patient is depressed, but the more salient issue may be the contributing factors to the depression or how the depression is manifested. It is not uncommon for patients to perceive one type of problem as more socially acceptable than another. For example, when making the initial appointment, the patient may have said that depression was the main complaint, when in actuality it was something else (e.g., difficulties with sexual functioning, a gambling problem). While open-ended questions will allow patients to express themselves more freely, using close-ended questions to start the interview can limit the patient's disclosure, hurt rapport, and make the clinician more prone to pursuing a less essential line of questioning (Marvel, Epstein, Flowers, & Beckman, 1999).

Throughout the interview, the clinician should use open and close-ended questions, but keep in mind there are strengths and weaknesses to both. Open-ended questions allow for individualized, unstructured, and genuine responses (Othmer & Othmer, 2002). In an examination of naturalistic interviews, Hopkinson, Cox, and Rutter (1981) found that open-ended questions with minimal interruptions allowed for more emotional expression than did close-ended questions. On the other hand, open-ended questions can lead to responses that are vague, lengthy, and incomplete. Some verbose, tangential, or confused patients may spend a lot of time detailing points that offer little to the diagnostic impression and use valuable time in the interview.

Close-ended questions are most appropriate for circumscribed topics (Othmer & Othmer, 2002). These questions allow for quick, precise, and frequently more reliable responses. When asking questions pertaining to the absence of symptoms, or questions pertaining to frequency, severity or duration of symptoms, close-ended questions work well (Cox, Hopkinson, & Rutter, 1981). The downside to close-ended questions is that they may elicit false-positive responses from patients and may make them feel less able to freely express themselves.

In sum, asking only open-ended questions would leave too much latitude for the patient and the interview would be too unstructured not allowing for all the relevant areas to be evaluated within the time constraints. Conversely, asking only close-ended questions can be time consuming on the interviewer's part (e.g., a long list of yes–no symptom questions), can thwart patients from freely expressing themselves, and can damage rapport. Therefore, after the initial open-ended question, it is advised to follow-up with a mixture of both open- and close-ended questions, depending on the subject area being assessed and the patient's ability to provide the relevant data.

7.3.7 Focusing and Clarification Questions

Throughout the interview, there may be times when important information is missing or is presented in a confusing manner. At these times, it is appropriate to ask questions aimed at focusing or clarifying information. *Focusing questions* narrow the conversation to specific details or topics and are usually open-ended in format. Examples include: "Tell me about your work history."; "Where did you grow-up?"; or "How did you deal with that?" Focusing questions are useful to fill in details and to understand topics in greater depth.

  Clarifying questions are helpful when a topic is ambiguous or vague. A clarification question will help the interviewer to explore the topic and to avoid erroneous assumptions. In fact, a clarifying question can make the topic more clearly understood to both the clinician and the patient. Examples include: "What is the worst thing that happened because of …?"; "What did you mean by …?"; or "Give me an example of …." Clarifying questions expand the interviewer's knowledge on the matter and they also convey a message that the interviewer is trying to understand the situation as much as possible.

7.3.8 Diagnostic Questioning

In most settings, it is important that clinical interviewers be able to ask questions of a diagnostic nature. As such, they should review and eventually become well versed in diagnostic criteria for the various mental disorders according to the *Diagnostic and Statistical Manual of Mental Disorders, fourth edition, text revision* (*DSM-IV-TR;* American Psychiatric Association, 2000). Certainly, it may not be possible to know the criteria for all of the mental disorders, but it is important for clinicians to review and familiarize themselves with the criteria for the most common ones. In the United States, anxiety disorders affect about 40 million adults per year and mood disorders affect about 20.9 million adults per year making these two of the most common types of mental disorders (Kessler, Chiu, Demler, & Walters, 2005). Because base rates for these disorders are quite high, it would behoove clinicians to begin by memorizing these. As noted earlier, some clinicians use semi-structured interviews to aid in diagnosis, but a basic knowledge of the diagnostic criteria for the common disorders is recommended regardless of how diagnostic questions are generated.

7.3.9 Assessing Aggravating and Alleviating Factors

When trying to understand the patient's presenting complaints, it is important to assess both *aggravating and alleviating* factors. For example, ask the patient: "Can you describe these problems at their worst?" or "How bad have those symptoms gotten?" The clinician should also ask if there are times that the symptoms have been absent or more tolerable. Along these same lines, ask patients if there are things that make the problem better or worse. Questions of this nature will assist in understanding the magnitude of the patient's current complaints.

7.3.10 Question Styles to Avoid

There are certain types of questions that should be avoided, as they can be confusing to the patient, make the patient feel uncomfortable, hurt the flow of the interview, and damage

rapport. *Double-barreled* questions are those in which the interviewer asks two questions at once. An example is: "Do you feel angry and sad?" With this type of question, the patient may not know how to respond or may feel confused. Furthermore, if the patient positively endorses this question, the interviewer does not know exactly what has been communicated (i.e., Is the patient angry? Is the patient sad? Or both?). Remember to inquire about one point at a time.

Similarly it is important to wait for patients to respond to one question before posing another. It is not uncommon for patients who are experiencing emotional or medical problems to take longer to respond than the interviewer may anticipate. Therefore, the interviewer should provide enough time for patients to adequately process their thoughts and respond. In addition, the interviewer should ensure that the patient understands the question by looking for cues to the contrary, such as a puzzled facial expression. If the patient appears confused, try rephrasing the question.

Biased questions should be avoided because they are frequently judgmental and based on false assumptions. Biases typically stem from prejudices, stereotypes, or generalizations from personal experiences. For example, a clinician's grandfather recently died and his grandmother has been very depressed since her loss. At a recent intake, the clinician met an older woman who was complaining of depression. The interviewer assumed that because the patient is older and depressed, she must have experienced the death of her spouse or some other type of loss and as such pursued this line of questions. The patient responded negatively to such questions because in this example the issue was not one of loss but rather poor social skills that left her chronically feeling taken advantage of by others. This example illustrates how biases can detract from building rapport. It is also important to remember that biases can be communicated in subtle ways (e.g., nonverbal communication).

The interviewer should avoid asking *leading questions*, which force the patient to answer in a particular manner. That is, by the way the question is phrased, it suggests that there is a desirable response. Examples of leading questions are: "So you are in great health then?"; "Don't you think your husband should be more supportive of you?"; "How much alcohol do you drink each week?"; or "No previous treatment that I need to know about?" This type of questioning is even more problematic in the case of the overly compliant patient (i.e., the *yes-sayer*), as the interviewer will likely obtain a great deal of false-positive information.

Another type of question that should generally be avoided are *why questions*. Asking *why* may put some patients on the defensive and may make some patients feel they need to justify themselves. In some cases, patients may not even be able to explain why they did something or why they feel the way they do, but may feel pressured to answer. Examples of why questions include: "Why would you have done that?"; "Why didn't you talk to your spouse about your feelings?"; or "Why didn't you just say no?" Instead of asking why, a more effective route might be to inquire about the causes of behavior by stating "Help me understand what you were thinking or feeling when you did …."

7.3.11 Paraphrasing and Reflection Statements

Although questions are an essential feature of the clinical interview, if patients are barraged with a litany of questions, they are more likely to feel that they are being interrogated rather than being interviewed. *Paraphrasing* and *reflection* statements are helpful in keeping the interview moving and on track without asking a question.

Paraphrasing will convey to patients that their message has been heard. In this technique, the interviewer repeats what the patient has said in an abbreviated form and using different words. Paraphrasing assists the patient in feeling understood and facilitates the narrative. For example, if the patient says "I am so tired of all this and should just give up. The more I work at getting things done the more troubles seem to develop," the interviewer could paraphrase saying "It seems like you are really feeling defeated right now, and that the harder you try, the more things come up."

Reflection statements address what the patient has said (verbally or nonverbally) and are typically used to highlight a specific point. A reflection statement, however brief, usually marks a specific feeling or statement, and thus can be divided into *reflections of feelings* or *reflections of content*. Liberal use of both throughout clinical interviews are advised. Reflection conveys a sense of empathy to the patient by sending a message that the patient is understood. With a greater sense of trust and rapport, patients will typically relay more detailed and personal information. As such, the clinician will gain a more accurate understanding of the patient's problem. For instance, if the patient was explaining her symptoms and said "I don't know how I felt, maybe anxious or afraid. All I know is that I wanted to get out of there," the clinician may reflect feelings that were expressed ("afraid") or highlight the end content ("get out of there").

Reflection and paraphrasing will assist in the flow of the interview. They can aid in the development of rapport as patients will feel that they are being understood. In turn, the patient may relay more information that will ultimately assist the interviewer in making an accurate diagnosis and disposition for the patient.

7.3.12 Transitions and Summaries

To maintain the flow of the interview as topic areas are switched, *transition* statements can be helpful. An abrupt change in topics can make the interviewee feel disjointed and can detract from rapport. When shifting topics, it is best to let the patient know what is going to happen. Examples of transitions include: "We have spent some time discussing what brought you in today. Now I want to switch gears and find out more about …" or "I have learned a lot about …. Now I would like to hear more about …." The goal of a transition statement is to let the patient know what is going to happen next and to keep the interview flowing.

Summaries are usually longer than paraphrasing and include a more detailed account of what the patient said, including the content and emotions described in the major line of questioning. Summaries when used judiciously in the interview will let the patient know they have been heard and also provide for the patient the opportunity to clarify points that may not have been understood completely. However, summarizing continuously throughout the interview is not necessary, as it may make the interview feel redundant. Summaries can also be used as a lead into a transition, where the interviewer recounts points made in one section of the interview and then introduces a new topic.

7.3.13 Avoiding Giving Advice (Despite the Temptation)

Although it is tempting to give advice to the patient, the clinician should generally not give advice or do so very sparingly. It is alluring for some beginning clinicians to give advice because

it may help the clinician feel like he or she "is doing something" as they are just beginning to learn about the intricacies of psychotherapy. Telling patients how to live their lives may also make some ineffective clinicians feel powerful. Although giving advice may help the clinician feel better, it is usually not very useful to the patient and in fact can be harmful to the patient. Imagine a young man who presents with significant anxiety about telling his parents that he is going to drop out of college. At the end of the interview, due to the patient's increasing agitation about what to do (and subsequent anxiety in the clinician), the clinician tells the patient to call his parents and tell them because he will feel better when it is over. The patient takes the advice and calls his parents. At the next session, the patient tells the clinician that this was a horrible decision – his parents have disowned him and never want to speak to him again. The patient blames the clinician for the bad advice and the therapeutic alliance is damaged if not ruptured entirely. Although it is possible that over the course of treatment the patient may have decided that informing his parents is the best decision, ultimately it is the patient, not the clinician, who should make the decisions on specific courses of action.

There may also be situations in which patients directly ask for advice. Examples include: "What do you think I should do? Should I call my parent's and tell them I want to drop out of school?" In this situation, remember that it is not the role of the clinician to tell the patient what he should do, rather these kinds of questions are ripe for exploration in treatment. How does the patient make decisions? Why is this particular decision so challenging? In these types of situations, it is best to respond empathetically and to educate the patient that you will help him decide, but not decide for him. Giving advice, even when it is asked for by the patient directly, prevents patients from having the opportunity to learn to make their own difficult decisions and accept responsibility for their actions. After all, it is the patient, and not the clinician, who has to live with the consequences.

7.3.14 Jargon and Commentaries to Avoid

Using overly technical or erudite words will detract from the development of rapport with the patient. Clinicians do not need to be grandiloquent or use multisyllabic words to make themselves sound more professional. Instead the clinician should speak clearly using words that will be easily understood taking the patient's education level and verbal skills into account. For example, instead of saying "The etiology of your complaints is idiopathic," the clinician should say "Currently, there is no single definitive cause of your symptoms, but together we will try to understand why you are having these symptoms right now." Talking in a language that the patient understands will enhance rapport and make the patient feel more comfortable.

There may be times when technical or psychological terms need to be conveyed to the patient. In these cases, ask patients if they understand the term and define the term if necessary (e.g., "It sounds like you are having lots of troubling thoughts you can't seem to shake. These are called obsessions. Have you heard that term before?"). Conversely, there may be instances where patients use psychological (or technical) terms. If this happens, it is typically best to ask patients what they mean specifically. If further clarification is needed the patient can be asked to provide an example of a behavior. It is frequently best to ask the patient to define a psychological term, as he or she may define the term differently than how a mental health professional would. Keep in mind that speaking to the patient straightforwardly and at his or her level will aid in building rapport.

The clinical interviewer should also avoid comments that are dismissive. Imagine a young woman who comes to a clinic complaining of depression because she was not invited to a party. The clinician says: "Well, that doesn't sound too serious." This comment is dismissive because it downplays the patient's perception. It would be better to reflect and acknowledge her pain and to discover why this event was so hurtful. It is also possible that there is something more to the story. However, with a dismissive remark, the clinician would have hurt rapport and the patient would not have been provided the opportunity to elaborate on the presenting problem because her concerns were minimized.

The clinician should also avoid frightening the patient, with commentary, such as "Well that sounds very serious!" or "That sounds bad. I have never heard of anyone having that experience." As the patient is looking for support, this type of reaction will hurt rapport and may unduly alarm the patient. Further if the patient's commentary is truly bizarre in nature, it is possible that the patient may have a psychotic disorder. It is best to get the information, support the patient, and empathize with the patient's concerns during the clinical interview. If the novice clinician is concerned, the clinician should express these concerns to the supervisor.

7.3.15 Responding to the Patient's Questions and Managing Self-Disclosure

How one responds to patients' questions depends on the level of training and types of questions being asked. In the beginning stages of training, student-clinicians should generally not offer diagnostic or disposition information without first discussing this with their supervisor. For example, if during an interview a patient asks "Do you think I have schizophrenia?," then student-clinicians should address the patient's feelings that are associated with the label, but delay answering the question directly until after a consultation with the supervisor has occurred. Questions of a pragmatic nature, for example about agency policies, should be answered directly (e.g., general agency questions such as concerns about billing, payment, or times the clinic is open) or the patient should be directed to the staff person who can answer these types of questions.

The issue of self-disclosure is often related to questions asked by patients because patients may ask clinicians to reveal personal information. Revealing personal details can switch the focus of the interview from the patient (where it rightfully should be) to the clinician. An inappropriate disclosure can also burden the patient. Beginning clinicians should generally keep self-disclosure to a minimum. One rule of thumb is to freely disclose details one would not mind seeing printed in the local newspaper, such as one's age, level of training and education, and the name of one's supervisor. Clinicians should be cautious about disclosing details of a more personal nature. When a personal disclosure is made, the clinician should be able to describe to the supervisor the reason why the disclosure was made, including the goal the clinician was trying to accomplish specifically by the disclosure. Clinicians should also ask themselves: "Could the goal have been accomplished in another fashion that does not carry the risks associated with self-disclosure?" If not, another general rule of thumb is to disclose feelings rather than facts. Should patients press for a self-disclosure (e.g., "Have you ever used drugs?"), it is advisable to reflect the patient's curiosity and try to understand what is behind the question, to illuminate the patient's assumptions or concerns about the clinician. It also helps to refocus the discussion back to the patient.

7.3.16 Self-Awareness

Effective clinicians must strive for self-awareness. According to Sommers-Flanagan and Sommers-Flanagan (2003), self-awareness refers to clinicians knowing how they affect other people and how other people affect them, being aware of one's physical, psychological, and emotional presence, and being aware of how one's own culture, social class, and background has shaped one's values. It is especially important to be able to recognize and understand one's own emotional reactions toward patients, as it may provide information as to what feelings the patient may typically engender in other people.

Be aware that one's self-perception may not match others' perspective. Understanding how one is perceived will assist in honing and refining skills as a clinical interviewer. Part of understanding one's stimulus value is understanding mannerisms. Particularly, decreasing verbal utterances such as "umms," "okays," or "like" will be of assistance. Also it is important to become aware of any unwanted nonverbal gestures. For example, tapping ones foot or fidgeting with a pencil can send the unintended message of being bored, disinterested, or anxious.

7.3.17 Final Summary and Ending the Interview

At the conclusion of the interview, the clinician should attend to the sensitive information that has been shared and may want to thank the patient for sharing personal, potentially upsetting experiences. The ending of the interview is also an opportunity to review important themes addressed and provide a final summary to the patient which recounts and highlights specific points including the presenting problem. An example of how to start the final summary is: "We have discussed a lot of information today. As I understand, your feelings of … have brought you into the clinic." After the summary is given, the clinical interviewer should let the patient know what to expect. It may be that the patient will be contacted within a specified amount of time with diagnostic interpretations and disposition recommendations, or in some settings, initial feedback may be given immediately and a mutually agreed-upon initial treatment plan commenced.

7.4   Expert Competencies

In this section, *expert competencies* for clinical interviewing are reviewed. *Expert competency* refers to a level of proficiency in the complex set of skills required for diagnostic interviewing, honed and refined through internship and postdoctoral training. These skills include a breadth of knowledge in psychopathology, personality theory, and how these factors interplay and impact the patient (Hatcher & Lassiter, 2007). In this section, rhythm and timing of an interview are reviewed followed by prioritizing in an interview, examining both explicit and implicit aspects of the presenting problem, offering interpretation and reassurance to the patient, recognizing transference and countertransference, and using confrontation. This section concludes with a discussion of dealing with difficult patients, understanding and appreciating diversity, making differential diagnoses, and using clinical formulations.

7.4.1 Rhythm and Timing

Clinical interviews have a pace or tempo. In the beginning phases, the verbal exchange of information tends to be a bit slower as the patient and clinician are developing rapport and trust. Over the course of the interview, the pace will wax and wane. For example, tempo can change by the topic area being discussed. If a topic is emotionally laden, the patient may speak louder and faster. Tempo can also change based on the interviewer. Therefore, clinicians should be conscientious to the speed at which they are talking and asking questions. It is usually better for the clinician to pace questions at a slower rate when asking about sensitive matters because the patient may feel rushed or uncomfortable if questions are asked too quickly. Clinicians who tend to speak quickly will find that they have to slow down their pace for many patients, and likewise clinicians who naturally speak slowly with long pauses may find that they need to pick up their pace in the clinical interview. When possible, the clinician should try to match the pace of the patient.

Although silent pauses happen naturally over the course of the interview, the clinician should be a keen observer to understand what is contributing to the silence. If the patient appears pensive or emotional, it is a good rule of thumb to wait rather than introduce a new topic, as the patient may be self-reflective or processing some of the topics that have recently been discussed. Interjecting at this moment will detract from rapport. However, if patients appear befuddled or confused, asking patients how they feel or rephrasing the last question may be necessary. Remember that during the interview, a momentary silent pause can feel like an eternity, but the pause has likely not even lasted a minute. When clinicians interject commentary during these pauses, it is usually more reflective of the clinician's anxiety rather than facilitating the flow of the interview.

Timing of transitions, interpretations, and statements in the interview can also add or detract from the flow and pacing of the interview. As the clinician becomes more experienced, appropriate timing of these points also develops. The clinician will typically know if a commentary has been ill-timed by the patient's confused or negative reaction (e.g., stopped talking, made a remark). Depending on the situation, the response of the clinician to his or her ill-timed commentary may vary. One strategy is to say: "Let me pause, back up for a moment, and rephrase that question." If the patient was distressed by the ill-timed comment, another strategy would be to address the patient's emotions. For example, the clinician might say: "I can see that comment was upsetting to you. Let's talk about that."

Flow and timing are important aspects of the interview process. This skill develops with time, practice, and supervision. The clinician should remember that mistakes in timing of interpretations or questions can happen. Although there are different ways to handle the situation, it is important to stay calm and relaxed.

7.4.2 Prioritizing

Prioritizing aspects of the clinical interview is frequently dictated by the setting in which the interview takes place, the amount of time available to complete the interview, and patient characteristics such as severity of symptoms, age, and mental status. How a clinician prioritizes questions in an interview will be a combination of these factors. Imagine working in a hospital inpatient unit or emergency room. In these situations, clinicians tend to see higher-risk patients

(e.g., suicidal patients) and patients with more florid psychiatric symptoms. Typically, priorities in these setting are to prevent tragedy (e.g., assessment of homicidal/suicidal ideation, intent, or plan) and to offer recommendations for treatment (e.g., admission to the hospital, consultation with psychiatry).

Certainly if patients present with a crisis situation, such as intense suicidal ideation, this should be prioritized in the interview process. There are several elements that clinicians should evaluate as part of a suicidal assessment (for a comprehensive review, see Dexter-Mazza & Korslund, 2007). The clinician should obtain information about suicidal thoughts, intent, and plan, as well as frequency, duration, and severity of symptoms. Simply asking patients about suicidal intent may not always be sufficient, and the interviewer may want to review the patient's beliefs about life and death. The clinician should also obtain information as to risk factors for suicide, including depression, feelings of hopelessness, alcohol abuse, limited social supports, self-injurious behaviors, and prior attempts. Indeed, prior attempts are known to be a significant risk factor for future suicide attempts and therefore, discussing whether a patient has attempted suicide previously is essential. If patients endorse having a plan, it is important to ask whether they have taken any steps in completion of the plan. The more detailed the patient's plan, in general, the greater the risk. Clinicians should also assess the patient's intention of carrying out the plan. If the patient denies intent to carry out a plan, the clinician should also discuss protective factors that contribute to safety and the presence of supportive family members or friends. In any situation where a potential duty to warn occurs, student-clinicians should alert their supervisors.

In an outpatient setting, if patients present with safety concerns, these need to be addressed first. However, when this is not the case, the clinician's priorities include gathering information to evaluate the problem, developing rapport with the patient, and offering disposition information. Similar to casual social interactions that have an implicit order, clinical interviews also have stages, which include an opening or introduction, an information gathering phase or body, and a closing or summary (Ivey, 1994; Shea, 1988; Sommers-Flanagan & Sommers-Flanagan, 2003). Although structure and format are essential to any interview, the more experienced interviewers tend to follow the patient's lead. These clinicians tend to be less rigid in their adherence to the order of introduction of topic areas. As clinicians become more adept at rewording questions, introducing new topics, modifying question order, and following patient's spontaneous verbalizations, clinicians can elicit more information as to the symptom origin, nature, onset, and severity and possibly uncover hidden contributors to symptoms (Wiens, 1991).

7.4.3 Implicit and Explicit Aspects of the Patient's Presentation

As clinicians gain experience with clinical interviewing, they will learn to evaluate both explicit and implicit mechanisms that contribute to the patient's presenting problem. That is, explicitly patients verbalize factors that contribute to their complaints, though the keen observer can also evaluate factors that the patient is not overtly reporting. Over the course of the interview, the clinician can identify coping mechanisms, underlying personality characteristics that maintain the patients' current state of being, and interpersonal processes such as insight, judgment, and frustration tolerance. For example, during the opening of the interview, some patients may not know how to respond to the first open-ended question (e.g., "What brings you

here today?"). These patients may appear uncomfortable, may be reluctant to speak, or may ask the clinician for advice on how to proceed. The more novice clinicians tend to *rescue* patients by providing an answer, whereas the more experienced clinician may use it as an opportunity to determine how patients tolerate lack of structure. Does the patient become angry or demanding? Does the patient respond by focusing on external or internal factors that are upsetting to him or her? Patients' reactions and responses can provide information about their frustration levels, tolerance, and coping strategies in the face of uncertainty.

Although it may be difficult to fully appreciate patients' interpersonal and personality characteristics during the initial interview, clinicians can form working hypotheses based on patients' description of past and present relationships, and the in vivo interaction with patients. Overall, evaluation of personality traits or interpersonal styles of patients is important, as these factors can contribute to the maintenance of the presenting problems. Understanding these will also assist in recommending treatment approaches.

7.4.4   Understanding and Utilizing Transference

Transference is a term that originated in psychoanalytic theory and is defined as the tendency for patients to *transfer* feelings onto the clinical interviewer that have been previously directed toward other important people in their lives (Freud, 1940/1949; Sommers-Flanagan & Sommers-Flanagan, 2003). Historically, Freud postulated that psychopathology resulted from unconscious conflicts between the socialized ego and libidinal impulses of the id. He purported that conscious awareness of these conflicts and related emotions are repressed, which is what maintains the persons state of being. *Transference* is the process whereby patients shift repressed feelings, emotions, and reactions onto the clinician. With a transference reaction, the patient's response to the clinician is typically in excess or does not fit with what would be expected based on the questions or topic of discussion (Sommers-Flanagan & Sommers-Flanagan, 2003; Waska, 2007). Although this kind of reaction may not occur at the start of an interview, over the course of the session transference may occur.

Interviewers should be prepared for patients who have strong emotional transference responses. Novice interviewers are often surprised when patients cry, yell, or laugh during the course of a clinical interview and the clinicians may feel uncomfortable, particularly if the emotions are directed towards them. It is important to keep in mind, however, that remarking on a transference reaction during an interview may not always be helpful. An ill-timed comment about transference can impact the therapeutic alliance and, as we have highlighted, maintaining the alliance should be given the highest priority in the clinical interview. Transference reactions can, however, provide the opportunity to explore deeper aspects of a problem by following up with questions, such as "Can you think of other circumstances when you have felt his way?" or "That seemed to really upset you, have there been other times that you felt like this?"

7.4.5   Understanding and Utilizing Countertransference

The term *countertransference*, like transference, stems from psychoanalytic theory (Freud, 1940/1949). It refers to reactions of the clinician toward the patient, which have little to do with

the clinical interview. Although in the past, countertransference was considered a breach of objectivity, current psychodynamic theorists view this as an important part of the therapeutic process (Waska, 2007). Understanding how or why a patient may evoke intense emotions can improve the clinician's self-awareness and subsequently improve interactions with future patients. For trainees in clinical psychology, this likely occurs during supervision and can be a valuable learning experience.

7.4.6 Interpretative Statements

Interpretation has been touted as one of the most important techniques in therapy and clinical interviewing (Craig, 2005). This technique involves bringing unconscious needs, drives, or motivations of patients into their consciousness. When done well, interpretation leads to emotional dialogue that provides new information to the clinician and patient (Hopkinson et al., 1981). However, use of this technique can be controversial depending on the theoretical orientation of the interviewer. Those who follow a strict Rogerian or humanistic approach may feel that it is best to discuss only topics expressed by the patient rather than interpret unexpressed attitudes, whereas psychoanalytic clinicians tend to believe that interpretation is essential to providing insight into underlying needs and personality characteristics of the patient (Pope, 1979).

If the clinician chooses to use this technique, interpretation should be carved out in a clear and empathic manner and offered to patients when they seem most ready to accept these statements. When interpretive statements are provided prematurely, patients may feel criticized or poorly understood, which can lead to opposition from the patient or premature termination of the interview (Allen et al., 1996, Othmer & Othmer, 2002). Four variables which lead to successful interpretation include: (1) *timing* which refers to relaying the interpretation when the patient is ready to hear the point, (2) *vantage point* which suggests that the interpretation should be made from the patient's not the clinician's point of view, (3) *scope* which refers to how narrow or broad the interpretation is, and (4) *impact* which refers to emotional impact of the interpretation on the patient (Othmer & Othmer). However, some authors (e.g., Allen et al.) suggest that the success or failure of interpretive statements depends on the strength of the therapeutic alliance. In any case, clinicians should be judicious and careful when offering interpretations (Craig, 2005).

7.4.7 Reframing, Reassurance, and Instilling Hope

Reframing is a technique that helps patients view their difficulties from another, more positive, perspective. That is, interviewers provide an alternative explanation to the cognitive distortions of the patient. By reframing negative views, the clinician can help reduce distress and promote cognitive flexibility. For example, if a patient stated "I never go out and no one ever asks me out," the clinician may say "Isn't it possible that no one asks you out because you don't leave your house?"

Most patients seek mental health services because they are experiencing some sort of distress (Sommers-Flanagan & Sommers-Flanagan, 2003). Therefore, over the course of the interview, *reassuring statements* can be used to convey empathy and understanding to the

patient as well as *instilling hope* that their situation can improve. Some patients feel concerned that no one else has had feelings or thoughts like theirs and they feel reassured through normalizing of their feelings. For example, if the patient stated that she felt anxious about her upcoming exam, a reassuring remark may be "A lot of people feel anxious before exams." Be careful, however, not to make global, vague, or false statements.

7.4.8 Use of Humor

For the clinician, the use of jokes or humor should be done sparingly and with caution, especially before a therapeutic relationship is solidly formed. Although the intention of the clinician may be to lighten the mood, a humorous remark is typically not appropriate during the course of an initial clinical evaluation. Patients may also use humor, sarcasm, or jokes during the interview. Frequently, this is done as a defense mechanism when the discussion becomes too emotionally laden. The clinicians' reaction to this should be dependent on the context of the situation. At times, the clinician may feel it is best to offer a smile or laugh, and at other times, the clinician may wish to offer an interpretation statement, such as "When you start to experience or discuss your very painful emotions, you always seem to joke."

7.4.9 Confrontation

Confrontation is a technique used to focus patients' awareness on their behavior with the expectation that they will modify the behavior. Confrontation can be difficult, as the patient might be resistant. This resistance may be subtle, such as avoiding the clinician's gaze, or more obvious, such as outright denial of the situation (Othmer & Othmer, 2002). To avoid damaging rapport, the clinician should have a clear understanding of intended usage of the confrontational statement. A well-timed and useful confrontational remark can provide patients with a clearer representation of how they are perceived and help to clarify distorted beliefs (Sommers-Flanagan & Sommers-Flanagan, 2003). For example, imagine a patient who angrily yells and waves her fists stating that she does not care if she gets into a particular graduate program. However, by the intensity of their emotional expression, it is clear that she in fact does care about this issue. In this example, a clinician may say: "Although you say you are unconcerned, I notice that you are raising your voice, look angry, and are waving your fists." Note that confrontation works best when a therapeutic alliance has been firmly established with the patient and when the clinician can provide strong evidence to support his or her statements. Further if gentle confrontational remarks are used, the clinician may need to repeat the point.

Not all clinicians support the use of confrontation remarks. For example, in motivational interviewing, confrontation remarks are not used because it is believed that these remarks can damage the therapeutic alliance (Rollnick & Miller, 1995). Using confrontational statements judiciously and sparingly may help in elucidating points in the clinical interview. A rule of thumb regarding confrontation is to "earn the right" to confront by first establishing a trusting and supportive relationship with the patient. Confronting too early in an interview or too strongly without earning the right to confront will usually result in a poor outcome.

7.4.10 Dealing with Difficult Patients

Although many clinical interviews are completed without difficulty, there are circumstances that can be unexpected or challenging. First, consider symptoms which may detract from the patient's ability to be fully engaged in the interview. For example, patients who are psychotic or highly intoxicated may be unable to accurately respond to questions. Other patients may not have adequate cognitive reserve to complete the interview or answer questions (e.g., developmentally delayed individuals). Depending on the situation, the clinician may need to refer the patient to an inpatient setting or obtain background information from a legal guardian or collateral.

Patients may also intentionally or unintentionally deceive the interviewer by not answering questions or by providing vague or inaccurate responses. If during the clinical interview, the clinician feels as though the patient is being deceitful, the clinician has a variety of options on how to proceed. In some cases, the clinician might use a confrontational remark, such as "I don't understand what you are saying. Can you give me an example?" Depending on the situation, there may also be times that the clinician chooses to end the interview.

Patients who are verbose and tangential can also pose difficulties to the interviewer. In a situation where a patient is overly talkative, the clinician should be empathetic to the patient's story, but gently interrupt them and state that there are other topics left to discuss. For example, it may be helpful to make a statement, such as "I can see that you are working very hard to give me as much information as possible, but I hope you do not mind if we also discuss other topics such as …." or "Let me pause you here for a moment and ask a bit more about …." Using more close-ended or focusing questions is frequently helpful with overly talkative patients. Conversely, when patients are laconic, terse, or reluctant to speak, it is helpful to acknowledge how difficult it must be for them to discuss the situation and make reassuring statements. The interviewer should also try being more directive in questioning and waiting through, at least some, silent pauses.

It is not uncommon for court-referred patients to be more resistant or less forthcoming than voluntary patients. In such cases, it can be helpful to acknowledge at the outset the circumstance that brought them to the interview, for example, "I understand that as a requirement of your probation that you undergo treatment. Can you tell me about the circumstances that led to this?" In this way, the clinician acknowledges the patients' potential reluctance as well as provides an opportunity for patients to explain their side of a story.

7.4.11 Treating Patients from Diverse Backgrounds

Clinicians should consider how cultural and demographic factors may influence aspects of the clinical interview including the working alliance, data gathering, and treatment planning. Although beginning clinicians are expected to be sensitive to issues of diversity including gender, culture, ethnicity, sexual orientation, and age, it usually takes time and exposure to diverse populations to develop competencies in multicultural interviewing and psychotherapy. A well-developed knowledge base about diversity issues and self-awareness of how these factors may impact oneself as a clinician are needed for advanced clinical work.

As communication with patients is critical for accurate diagnosis and treatment planning, one may question how diversity issues can impact the clinical interview. Research suggests that

matching the demographic characteristics of the therapist and the patient does not have a significant impact on therapeutic outcomes, but may increase the retention of some minority patients (Gray-Little & Kaplan, 2000). For this reason, it may be beneficial to match the characteristics of the patient and the therapist when possible, but this may not always be practical. As such, clinicians should do their best to be sensitive to the patient's cultural or ethnic backgrounds, and when needed, clinicians should educate themselves on the cultural backgrounds of their patients. In fact, pathologizing cultural and racial differences in symptom expression is thought to be the mechanism of overdiagnosis of serious disorders in some cultures and underdiagnosis of serious disorders in others (Suite, LaBril, Primm, & Harrison-Ross, 2007). Many international studies have reported that White patients are more often diagnosed with mood disorders, whereas African-American, Afro-Caribbean, and Latina patients are more frequently diagnosed with schizophrenia (Snowden & Cheung, 1990; Suite et al., 2007). Remember to keep in mind how race, gender, ethnicity, and culture influence one's beliefs about what is normal/abnormal or functional/dysfunctional and how these factors influence clinical interpretations.

Cultural differences may not only affect the clinician's perception, but can also influence how patients recognize, characterize, and describe their psychological symptoms (Neighbors et al., 1992; Sue & Sue, 2007). For example, Asian and African-American patients report a greater number of somatic symptoms compared to White patients (Lin & Cheung, 1999; Swartz, Landerman, George, Blazer, & Escobar, 1991). In some cultures, it is more acceptable to report physical symptoms than emotional distress; as such, psychological distress may be more commonly expressed as physical symptoms in these cultures (Lin & Cheung, 1999). Clinicians should also consider how culture impacts the trust or mistrust of healthcare systems. Specifically, minority patients utilize healthcare and mental healthcare systems less than White patients, and this difference has been attributed to minority patient's mistrust of the healthcare system (Suite et al., 2007; Whaley, 2001).

Clinicians should also be aware of how a patient's cultural experiences might affect his or her verbal and nonverbal interactions, including the tendency to be relatively passive in the interview or not make much eye contact which should not be viewed as a sign of pathology if the behaviors are consistent with patient's cultural scripts. In addition, patients from a markedly different cultural background than the clinician may report information and experiences that could be foreign to the therapist, and the therapist may unintentionally react in a way that detracts from rapport building (e.g., looks surprised). When cultural or ethnic differences between patient and clinician arise during the course of the interview, it is helpful to acknowledge the differences and work collaboratively to not make differences become barriers. Failure to acknowledge important differences can interfere with the development of the working alliance. Clinicians desiring more information about diversity issues in interviewing and psychotherapy should be aware that several excellent resources are now available (Aponte & Wohl, 2000; Clark, Anderson, Clark, & Williams, 1999; Neighbors & Jackson, 1996; Sue & Sue, 2007).

7.4.12 Diagnosis and Differential Diagnosis

While it is expected that beginning clinicians generate basic diagnostic questions and formulate a tentative diagnosis, it requires a more advanced skill to more fully appreciate the

complexity of psychiatric diagnosis and the process of differential diagnosis. There are a number of important benefits conferred by an accurate psychiatric diagnosis (Segal & Coolidge, 2001). First, diagnosis facilitates communication among professionals. Communication is enhanced when professionals share an understanding of disorders and their symptoms, in essence sharing a common language. For example, a clinician may state that a person has paranoid schizophrenia. Other professionals who are familiar with this diagnosis understand that this person may experience persecutory delusions, auditory hallucinations, as well as disorganized speech, catatonic behavior, and flat affect (APA, 2000).

Second, knowledge of disorders and symptoms helps clinicians organize their diagnostic thinking, essentially helping them to more effectively evaluate potential diagnoses that a patient may have. For example, if a patient presents with frequent crying spells, feelings of worthlessness, and overeating, a clinician may probe about the presence or absence of other symptoms of major depression (e.g., anhedonia, sleep disturbance, concentration problems, lethargy, suicidal impulses) to confirm or rule out the diagnosis.

Third, diagnosis plays an important role in the interface of clinical psychology with the legal arena. For example, mental health professionals are sometimes called to testify about a defendant's competence to stand trial or whether a mental disorder has impaired a defendant's judgment. In some cases, a diagnosis can help a severely mentally ill person who has committed a crime to be placed in a mental health facility instead of a prison. Also, neuropsychological evaluations are often conducted to determine the competency or ability of a person to make medical and financial decisions.

A fourth benefit of diagnosis is that, in many cases, it helps to determine appropriate treatments. Similar to the medical model in which a diagnosis of strep throat implies the known and successful treatment by a course of antibiotic medications, diagnosis in mental health can influence the type of psychotherapy or medication to be provided. There are now empirically supported psychotherapeutic interventions and processes for many specific psychiatric diagnoses (e.g., Castonguay & Beutler, 2005). For example, efficacious treatments for major depressions include cognitive therapy, behavior therapy, and interpersonal therapy, and these types of psychotherapeutic interventions as well as pharmacological interventions are frequently selected based on the formal diagnosis of the patient.

A fifth benefit of diagnosis is that it allows clinicians to bill for, and receive payment by, third-party payers (e.g., insurance companies) for the clinician's service. Typically, insurance companies require a diagnosis of insured persons before they will pay for evaluation or treatment. Finally, a sixth benefit of diagnosis is that it can be used to enhance research about the etiology, natural course, and treatments of mental disorders. Research on mental disorders would be impossible if people with the same diagnosis could not be accurately grouped together for study.

Differential diagnosis refers to the systematic way of discriminating among numerous possible disorders to identify specific ones for which the patient meets the diagnostic threshold. To be effective at the process of differential diagnosis, clinicians must have extensive working knowledge of the diagnostic criteria for the vast majority of mental disorders so that subtle distinctions between disorders can be evaluated in an interview. The text of the *DSM-IV-TR* provides information about how to discriminate similar mental disorders from each other. It also provides in the appendices decision trees and flow charts to aid in the process of differential diagnosis.

7.4.13 Clinical Formulation

Developing and honing a clinical formulation is one of the most challenging aspects of the interview. It can be difficult because patients' problems are often complex with many contributing factors. Throughout the interview, the clinician should be developing and testing hypotheses regarding differential diagnoses. Once the interview is complete, it is often helpful to list the most salient working hypotheses or preliminary diagnoses. Although most experienced clinicians assume they know the diagnostic criteria for a particular disorder, Aklin and Turner (2006) point out the high rates of misdiagnosis due to inadequate use of diagnostic criteria. Therefore, this list should include diagnoses that are probable and those that are possible. Next, the clinician should review all information obtained from the interview, including responses to questions, as well as observations and presentation of the patient.

In the clinical formulation, biological, psychological, and social/cultural contributors to the patient's symptoms or problems should also be reviewed. Biological factors include genetics, family medical or psychiatric history, prenatal development, or other general medical condition impacting patients' functioning. Psychological factors can include early childhood experiences, interpersonal processes, moods, irrational beliefs, or learned behaviors that are causing or maintaining the patient's symptoms. Social and cultural factors include current stressors, family environment, and consideration of the differences in expression of distress, such as reported somatic versus psychological symptoms (Aklin & Turner, 2006). Finally, the clinical formulation should also address patients' assets including their educational background, employment history, interests, skills, and abilities. This information will be important for patient treatment planning.

7.5   Summary

Although being a good clinical interviewer takes guidance and practice, the novice clinician should remember that the clinical interview at its core is a *meeting*, and we have all had this type of interaction. Remember the essentials of a clinical interview are confidentiality, professionalism, and preparedness. These qualities will assist in developing rapport with the patient, which will in turn assist in gaining a more thorough understanding of the patient's presenting problem and assist the clinician in diagnosis and treatment planning.

In the *basic competencies* section, we reviewed the fundamentals of interviewing, such as opening the interview, observing the patient, facilitating the narrative, and ending the interview. In the *expert competencies* section, we reviewed the more advanced aspects of interviewing, such as timing of interpretations, using confrontational statements, dealing with difficult patients, appreciating diversity, making differential diagnoses, and generating a clinical formulation. Where applicable, we also offered strategies and examples to assist in the clinicians' understanding of how to handle various situations. Through reading and practicing the competencies laid out in this chapter, we hope that both the novice and the more sophisticated clinical interviewer will gain ideas and ways to advance their skills. We also believe and hope that as existing models of competencies in clinical psychology (e.g., Hatcher & Lassiter, 2007; Kaslow et al., 2007; Rodolfa et al., 2005) are refined and more widely applied, training in professional psychology will be enhanced.

8 Clinical Interviewing with Children

J. Christopher Young · Julie A. Davidson · Alan M. Gross

Abstract: The aim of this chapter was to provide a comprehensive overview of clinical interviewing with children. The chapter details the basic clinician competencies essential for obtaining the requisite breadth and depth of necessary information for case conceptualization, diagnosis, and responding to the referral. Clinicians must possess an extensive knowledge of developmental trajectories and symptoms of psychopathologies and medical disorders commonly observed in children. Clinicians must also be prepared to recognize and address a range of cultural influences that include language barriers, acculturation, the involvement of the family, and additional factors that influence information provided by the child and family members. APA and DSM-IV-TR guidelines for cultural formulation and practice are discussed. Review and suggestions for employing developmentally appropriate language and question format are also examined. Last, considerations and methods for obtaining additional information from parents and teachers are reviewed. Following examination of these core skills, the chapter explores and outlines the administration of an effective interview. Suggestions are provided in the selection of interviewing format and instruments, discussing and establishing the bounds of confidentiality, and cultivation of rapport. Another section of the chapter highlights a group of expert competencies that clinicians who frequently work with children should possess. Strategies for interviewing children who are hesitant or opposed to participating in the interview are offered. The assessment of suicide risk and allegations of maltreatment and various forms of abuse (i.e., sexual, physical, verbal) are also examined in the expert competencies section. Last, factors and considerations associated with forensic interviewing are provided. The chapter concludes with suggestions for obtaining didactic and applied clinical experiences necessary for competent clinical practice.

8.1 Overview

The clinical interview is an essential tool in the provision of efficacious services and one that transcends specific areas of mental health services. The clinical interview is the process by which information is obtained about the client through direct communication with the client and relevant caregivers (Craig, 1989). The aims of the clinical interview are multifaceted and are often guided by the referral question or presenting problem. The information may be used for diagnosis, determination of appropriate services, and treatment planning (Aklin & Turner, 2006; Craig; Othmer & Othmer, 2002). In general, interviews include rapport building, mental status evaluation, historical or background information gathering, and identification of cultural considerations. When interviewing children, the clinician is presented with additional considerations that are unique to this group. Interviewing of parents and teachers, determining environmental contingencies (as related to problem behavior) as well as developmental

and family history additionally warrant consideration (Boggs, Griffin, & Gross, 2003; Logan, 1989). The clinical interview represents a method of acquiring extensive information in a brief period that will prominently influence diagnosis, case conceptualization, and treatment planning.

Research indicates that clinicians misjudge their clinical skills and may not readily agree with one another regarding diagnosis (Aklin & Turner, 2006; Miller, 2001; Miller, Dasher, Collins, Griffiths, & Brown, 2001). While disparate interpretations may be attributable to clinicians' varying consideration of cultural factors (Aklin & Turner; Garb, 1997) or variability in the information provided by the client, inconsistencies may also be attributed to the clinicians' professional competence related to the art of interviewing (Miller; Miller et al., 2001). Professional competence is a crucial issue in the practice of psychology and reflects both specific and broad abilities that are cultivated across one's career (Kaslow et al., 2007; Leigh, 2007).

Psychologists have attempted to specify needed competencies in the practice of the general psychological assessment (Krishnamurthy et al., 2004), yet the more specific tool of clinical interviewing has not received the same attention. It is clear that the clinician must cultivate skills in several core areas in order to effectively utilize the interviewing process, and the interviewing of children demands additional competencies unique to this group. The clinician must develop a working knowledge of the pros and cons associated with specific interviewing styles and formats, types of questions, interviewing environment, and circumstances that initiate the request for the clinical interview (Sommers-Flanagan & Sommers-Flanagan, 2002). The clinician must also have extensive knowledge of developmental trajectories, developmental disorders, and potential multicultural influences for accurate appraisal of symptom presentation (Aklin & Turner, 2006; Sharp, Reeves, & Gross, 2006). Last, clinicians should also consider how their own behaviors, beliefs, and biases influence interactions with the child and his or her family, the types of questions asked, and how symptoms are interpreted (Sommers-Flanagan & Sommers-Flanagan).

The principal goal of the clinical interview is the acquisition of information necessary for case conceptualization, diagnosis, and responding to the referral. This process of obtaining information is achieved primarily through discussion with the child and his or her parents. While these discussions may appear straightforward, obtaining accurate and quality information is often elusive and complicated by a number of factors. The purpose of this chapter is to delineate the skills necessary for competent application of this tool. Within basic competencies, this chapter will first review the requisite knowledge needed of the developmental process, diagnosis of developmental disorders and child psychopathology, and cultural factors. This will be followed by a description of effective communication with the child, parents, and teachers. The "Basic Competencies" section will concisely examine the components of the actual interview. Rapport building, negotiating concerns and discussions of confidentiality, interview structure, and interview content will be individually examined. Collectively, these areas of knowledge and skill represent the core proficiencies needed to competently perform the clinical interview with a child. Following an examination of basic competency skills, a review of additional factors and potential difficulties faced by clinicians when interviewing children and adolescents will be presented. The chapter will also outline a process for obtaining the necessary training and skills for competent practice.

8.2   Basic Competencies

8.2.1   Developmental Considerations

For optimal success in meeting goals of the interview (i.e., obtaining information related to possible diagnosis, assessment of factors maintaining problematic behavior, and treatment planning; Sharp et al., 2006) the child should be placed within the appropriate developmental context. Children grow and change rapidly. Clinicians who work with children must be aware of the normal progression of childhood development in order to quickly adjust the interview to the child's level. Knowledge of development will also guide selection of topic areas covered in the interview (Monaco, Rayfield, & Geffken, 1997).

Major areas of development include motor (i.e., fine-motor, gross-motor, and visual-motor integration), communication (i.e., verbal and nonverbal), cognitive ability (i.e., verbal and nonverbal reasoning, memory, executive functioning, general fund of knowledge), adaptive (e.g., feeding self, brushing teeth, toileting), and social (e.g., coping with stress, play behavior) skills (Morrison & Anders, 1999; Sparrow, Cicchetti, & Balla, 2005). For each area, the mean age at which skills are mastered by most children has been delineated. Additionally, the developmental trajectory of each domain extends beyond childhood through adolescence. For example, in the area of communication, most children can point to two to three body parts at 18 months, use two-word sentences at about 24 months, and can have a conversation at about 48 months. During late childhood and early adolescence, communication skills continue to evolve as children develop the ability to convey verbally complex ideas, as well as to use and to understand abstract expressions (e.g., metaphors, analogies, euphemisms). These examples use the mean age at which skills are typically observed, but a "normal range" for each skill is also empirically defined. The range of any developmental skill, however, is relatively large (Holmbeck, Greenley, & Franks, 2003). It is important that the clinicians understand that maturation and development do not occur in a systematic manner but rather appear as fluid transitions as new and more advanced skills and abilities are acquired (Morrison & Anders).

However, clinicians' knowledge of the age range for only major developmental milestones may not be sufficient. Other less commonly discussed behaviors may remain unnoticed by clinicians unaware of their significance. For instance, various behaviors may be indicative of a problem at one developmental level but may be normative at another. Typically developing children walk on their tiptoes around 7 months of age. However, the same behaviors exhibited in a 3-year-old may be a red flag to clinicians aware of their significance, as walking on tiptoes could indicate the presence of a Pervasive Developmental Delay.

Clinicians must also consider potential environmental influences that may prominently impact a child's developmental process (Morrison & Anders, 1999). Environmental insults can include dietary needs not being met (Morrison & Anders) and exposure to noxious chemicals (e.g., lead, mercury, harmful gases, household cleaners; Woodruff et al., 2004), as well as physical and sexual abuse and neglect (Wise, Wilder, & Brodhagen, 2007). Exposures to environmental threats often present in an array of behavioral manifestations and developmental delays. These include delays in meeting developmental milestones, loss of previously obtained abilities, behavioral problems, and poor regulation of emotions. It is quite possible that the child or adolescent is not currently being exposed to such dangers. However, given their pervasive effects, the clinician must be aware of the classic symptoms associated with these environmental threats.

Standardized measures of developmental age are available which provide an age equivalent for each major area of development based on skills mastered. The age equivalent is referred to as "developmental age." Developmental age differs from chronological age in that it takes into account the skills mastered by the individual child regardless of the child's age in years. Several developmental age assessments include the Developmental Profile 3 (DP-3; Alpern, 2007), Battelle Developmental Inventory, Second Edition (BDI-II; Newborg, 2005), Child Developmental Inventory (CDI; Ireton, 1992), and Vineland Adaptive Behavior Scales, Second Edition (Vineland-II; Sparrow et al., 2005). These are norm-based measures which will determine if developmental delays exist. They may be used as an adjunct to the child clinical interview. However, administration times range from approximately 30 min (e.g., DP-3) to 1 h or more (e.g., BDI-II). Because of the time-consuming nature of standardized assessment, clinicians who work with children should be familiar with typical development in order to quickly estimate the child's level of functioning from the interview. From this, clinicians may determine if a more formal assessment of development is warranted.

The ability to contextualize child behavior is also essential to interviewing competence because some referrals may be the result of inappropriate parental expectations for their children. Parent education may be particularly useful for parents who have had little exposure to other children. These parents may lack a frame of reference by which to judge the behavior of their child. Clinicians may need to simply alleviate parent anxieties when expectations of the child are beyond what would be developmentally appropriate. On the other hand, some parents may be unaware that their child exhibits developmental delays. These parents may benefit from a discussion of typical development and the importance of early intervention to address delays.

There are a range of ways in which a clinician may become more familiar with developmental norms. While the *Diagnostic and Statistic Manual of Mental Disorders, Fourth Edition, Text Revision* (DSM-IV-TR; American Psychiatric Association, 2000) is an excellent tool for determining abnormal development, it does not provide a comprehensive outline of typical development (Jayne, Bethay, & Gross, 2007). Competencies associated with chronological age, or the child's age in years, may be obtained from various developmental norm charts. Clinicians may use a chart as a starting point from which to approximate competencies typical of a child the same age as the client. Charts can vary somewhat, however, and clinicians should use those that are empirically validated and reliable.

While developmental norm charts are excellent tools for clinicians they are no match for observing and interacting with many "typical" children. To this end, it is advantageous for clinicians to observe groups of same-age children (Boggs et al., 2003). Indeed, obtaining an "average" picture of age-appropriate behavior is invaluable. After observing many children, clinicians may better determine what behaviors are within the realm of normal development and what behaviors warrant further investigation. Clinicians could, for instance, become more familiar with 5-year-old children by informal observation of a kindergarten class. Subsequently, the clinician may synthesize a composite, or prototype, of average 5-year-old behavior in a structured social environment.

In sum, knowledge of childhood development is an essential clinical skill. With this knowledge, the clinician has the foundation to appraise the child's acquired skills and those yet to be mastered (Boggs et al., 2003; Monaco et al., 1997). Resultantly, the clinician is better able to distinguish needed information, decrease the likelihood of misdiagnosis, and effectively answer the referral.

8.2.2 Diagnosis of Developmental Disorders and Child Psychopathology

The diagnosis of children is quite different from that of adults. Since children are moving targets who perpetually develop and change, clinicians must consider the child's developmental level to assess if functioning is abnormal. Further, symptoms frequently overlap diagnostic classifications, and disorders found in both adults and children may vary in symptom presentation (Jayne et al., 2007; Morrison & Anders, 1999). Research indicates that an interviewer is most efficient when he or she prepares for the interview, on a case-by-case basis, by reviewing and becoming familiar with information related to the referral question (Monaco et al., 1997). This preparation should include review from several different sources.

A review of symptomology and diagnostic criteria associated with the referral question is often the first step. It is important that the clinician recognize that frequently symptoms are not specific to one disorder (Morrison & Anders, 1999). As such, the clinician should more broadly review disorders associated with the symptoms described in the referral. For example, symptoms associated with Oppositional Defiant Disorder (ODD) and Attention-Deficit/ Hyperactivity Disorder (ADHD) are quite similar (Waldman & Lilienfeld, 1991), yet the clinician must be able to differentiate the two disorders. Further, diagnostic criteria found in the DSM-IV-TR (APA, 2000) reflect the most current description of symptoms associated with a particular disorder. Criteria change and are refined across editions. As such, the clinician must be versed in the most current diagnostic criteria (Morrison & Anders).

The clinician should also review disorders that are most frequently diagnosed within the age range of the child. The most common diagnoses of a child under age 3 are much different from those typically made in later childhood or adolescence (Morrison & Anders, 1999). Through review of disorders common to the child's age, the clinician can better identify areas to cover in the interview and obtain information necessary to differentiate between diagnoses.

Knowledge of cognitive and behavioral symptoms associated with genetic and medical disorders is essential. Genetic anomalies and medical illness or injury can have profound effects on a child's development. For example, mental retardation (MR) is a frequently encountered developmental disability, yet over 1,000 genetic causes have been identified (Walker & Johnson, 2006). Similarly, traumatic brain injury in a child may be associated with symptoms of inattention, poor impulse control, and personality changes (Hooper et al., 2004). The clinician should acquire a medical history in conjunction with the evaluation to aid in understanding the etiology and progression of symptomology. However, the competent clinician may also at times identify constellations of symptoms congruent with a genetic disorder or medical condition not previously identified.

Gender represents another important consideration in understanding disorders of childhood and adolescence. Significant sex differences in the prevalence of psychopathology have been identified. Most often, males demonstrate externalizing problems rather than internalizing problems when they experience maladjustment. That is, males exhibit behaviors consistent with ADHD, ODD, and conduct disorder. Females, in contrast, are more likely to experience internalizing problems such as anxiety, depression, or eating disorders when maladjustment occurs (Crick & Zahn-Waxler, 2003; Hayward & Sanborn, 2002). It is reported that these sex differences emerge around adolescence and remain consistent throughout the life span. However, in children younger than 4 years of age, males and females tend to display similar rates of physical aggression, level of activity, and difficult temperament (Crick & Zahn-Waxler).

The clinician will benefit from considering gender throughout the interview process from preparation (e.g., selection of interview format, questions) through interpretation of data collected.

In sum, a primary goal of clinical interviewing is the provision of an accurate and discriminating diagnosis. In order to provide this, the clinician must be knowledgeable in disorders that develop in childhood and adolescence (Monaco et al., 1997). The clinician must not focus exclusively on problem behaviors and related symptoms, but also on aspects of etiology and pathogenesis. When making diagnostic determinations, it is imperative that the clinician consider onset, severity, and pervasiveness of symptoms (Lord, Cook, Leventhal, & Amaral, 2000). The clinician must be also aware of how disorders may present with differing constellations of symptoms depending on the age, gender, and developmental level of the child (Monaco et al.). Lastly, the clinician must recognize the limitations of diagnostic criteria and classifications when interpreting each child's unique constellation of symptoms.

8.2.3 Cultural Considerations

An understanding of the influence of culture is essential to understanding a client's symptom presentation, interpersonal interactions, and psychosocial environment. More importantly, successful interviewing depends on the clinician's ability to apply this knowledge to minimize cultural barriers and facilitate informative dialogue. Despite the recognition of the importance of an individual's ethnic culture, clinicians are often inadequately trained in how to understand, account for, and integrate cultural factors into the assessment/treatment process (Turner, Hersen, & Heiser, 2003). In addition to ethnicity, cultural identity may also be defined within gender, age, and socioeconomic status (Aklin & Turner, 2006; Garb, 1997).

In response to the need for more culturally competent practice, the American Psychological Association (APA, 2003) developed guidelines for multicultural training, research, and practice. The DSM-IV-TR (APA, 2000) provided an outline for the integration of culture in case conceptualization and diagnosis. In general, culturally competent interviewing should include gaining an appreciation of the client's cultural background, acculturation, and language barriers; and an awareness of personal biases or prejudices held by the clinician. Competent interviewing requires careful consideration of these issues as they will influence the manner in which the interview is structured and the interviewing measures chosen. These considerations are also important for accurate interpretation of symptom presentation within the framework of the child's culture (Aklin & Turner, 2006; Fuertes, Mislowack, & Mintz, 2005; Johnson & Tucker, 2008; Paniagua, 2001).

8.2.3.1 Cultural Influences on the Interview Process

Prior to the clinical interview, clinicians should evaluate whether any personal beliefs or biases specific to the client's culture may affect their ability to provide competent services. Possession of biases and stereotypes does not negate the clinician's ability to provide efficacious services, but clinicians should be aware of these and evaluate whether they may impede their ability to provide appropriate and adequate services (APA, 2003; Fuertes et al., 2005; Johnson & Tucker, 2008).

The clinician should consider the cultural context of the child when considering how to structure the interview process. Many cultures are collectivist (i.e., individuals consider themselves relative to the larger systems of family, community, society, and the world) and the family

will expect to be intimately involved in the entire therapeutic process (Johnson & Tucker, 2008; Tseng, 2003). Further, many cultures have strong attitudes regarding the use of mental health services and may be reluctant to discuss problems outside the family (Grieger & Ponterotto, 1995; Johnson & Tucker). To best prepare the child and family, the clinician should explain the interview process and offer to answer any questions (Johnson & Tucker). In particular, the clinician should explain that the interview may include personal or intimate questions, and the purpose of such questions is not to insult or embarrass the family but to help the clinician develop an understanding of the child's difficulties and their environment (Johnson & Tucker).

In addition to the aforementioned considerations, interviewing competence requires clinicians to identify any language barriers prior to the interview. The need for an interpreter presents the clinician with an array of new hurdles. Not only does an appropriate interpreter need to be found, but clinicians must also be cognizant of the potential for significant interview content translation problems. For example, accurate information and meaning, as well as clinically relevant context, may be lost in the translation process (Tseng, 2003). Clients may also bring a family member to serve as interpreter in the interview, which may result in the family member offering interpretations of the client's dialogue rather than offering an objective translation. Additionally, attention must be paid to addressing the potential for the family member not respecting confidentiality and the crossing boundaries within the family system (APA, 2003; Tseng). When possible it is best to contract a professional interpreter with mental health training to minimize these issues (APA; Johnson & Tucker, 2008; Tseng).

In addition to consideration of verbal dialogue, clinicians must consider cultural differences in nonverbal behavior and communication style. These may include direct versus indirect communication, the degree of context that must be inferred from what is stated, and whether it is culturally appropriate to talk about the family or family members. Consideration of these more subtle communication differences can have significant influence on both the clinician's ability to cultivate rapport and to accurately interpret what is being said by the client and his or her family (Aklin & Turner, 2006; Johnson & Tucker, 2008).

The constellation of symptoms with which a client presents is influenced by his or her environment both within the family and in the larger culture. Input from the family is an important component of the clinical interview with any child, but especially with children who are members of a cultural minority. Family members can provide information about cultural values and beliefs and whether behaviors and psychological symptoms are acceptable and normative within the culture (Johnson & Tucker, 2008; Tseng, 2003). However, involvement of family members may come at a price. Specifically, children may be hesitant to disclose information to the clinician because of perceived cultural disapproval regarding discussion of the family and its members (Johnson & Tucker; Tseng). When interviewing a child from a cultural minority, it is the task of the clinician to discriminate psychological distress from culturally specific behaviors that may be common or adaptive. Then the clinician can better identify the role of culture on the presenting problems (Roysircar, 2005).

8.2.3.2 Acculturation

During the interview the clinician needs also to assess the client's level of acculturation. Acculturation describes the transitional process by which individuals experience challenges and changes in their values, beliefs, and behaviors through exposure to, and involvement with,

a culture other than their own (Casas & Pytluk, 1995; Johnson & Tucker, 2008). Acculturation is commonly conceptualized along a continuum (Johnson & Tucker; Phinney, 1990). That is, an individual may feel rejection toward his or her new or old culture on one end of the spectrum, or may have successfully cultivated the ability to function effectively in either culture on the other end. Alternatively, some clinicians conceptualize acculturation as multidimensional or orthogonal in which the individual's identification with each culture is independent of the other (Costigan & Su, 2004; Phinney).

The acculturation process is not unique to immigrant and refugee groups but is also experienced by individuals who transition between cultures, usually from a majority group to a minority group. The acculturation process is influenced by the values, beliefs, customs, and behaviors that differ between cultures as well as a number of additional variables. These include: strength of identification with culture of origin, language barriers, and level and nature of contact with the other culture (Casas & Pytluk, 1995; Johnson & Tucker, 2008). As a result of this transition process, many individuals and families experience acculturative stress. This stress is often manifested as both psychological distress (e.g., symptoms of depression, anxiety, somatization and anger) and behavioral difficulties (e.g., school and work problems, substance abuse, interpersonal conflict). Complicating this transition for the child is that family members often move through the acculturation process at different rates depending on age, language proficiency, and level of contact with the new culture. As such, assessment of the client's level of acculturation may provide valuable insight into the influence of culture on the child's psychosocial functioning, as well as its potential influence on familial interactions (Johnson & Tucker).

8.2.3.3 Cultural Formulation and Diagnosis

There is significant evidence that minorities are frequently misdiagnosed, overdiagnosed, and underdiagnosed depending on group membership (Aklin & Turner, 2006). Consideration of the aforementioned factors (e.g., clinician's self-appraisal of cultural beliefs and biases, communication styles, language barriers, and interviewing methodology) may serve to minimize these errors (Aklin & Turner; Fuertes et al., 2005; Johnson & Tucker, 2008; Tseng, 2003). Clinicians may also integrate the cultural formulation methodology provided in the DSM-IV-TR for more accurate diagnostic assessment (APA, 2000). The methodology uses information obtained in the interview, observation, and review of records to describe the following five domains: *cultural identity of the individual, cultural explanations of the individual's illness, cultural factors related to psychosocial environment and levels of functioning, cultural elements of the relationship between the individual and clinician, and overall cultural assessment for diagnosis and care* (APA, 2000). Integration of a culturally competent interview with the use of cultural formulation methodology should ensure that the clinician develops a well-informed case conceptualization, diagnostic impression, and foundation for treatment planning.

8.2.4 Language Considerations

The interviewing process and social climate of the clinician's interactions with the child are dictated by an array of factors that are both within and outside the clinician's influence. While

it is beneficial to gain background information regarding the child's presenting problems, interpersonal skills, and attitude toward the appointment with the clinician (Monaco et al., 1997), the use of developmentally appropriate language and the format of question presentation are valuable techniques that the clinician must consider and employ in order to facilitate dialogue with the child, and improve the quality and accuracy of the information provided by the child (Monaco et al.).

8.2.4.1 Developmentally Appropriate Language

The manner in which the clinician talks with the child should depend largely on the child's age and developmental level (Monaco et al., 1997). Knowledge or assessment of the child's language abilities will influence the complexity of questions and the manner in which they are presented. Age and developmental level should not be assumed to be equivalent and it is imperative that the clinician consider the child's cognitive and emotional level of functioning to be of greater importance than raw age (Monaco et al.; Salmon, Roncolato, & Gleitzman, 2003). For example, younger children are likely to be concrete in their interpretation of questions and provision of response. As such, the clinician would want to be conscious to use language that effectively conveys to the child what information is sought. Children referred with specific diagnoses may also influence the clinician's language. Interviewing a child with MR is an example of a disorder in which the clinician must be mindful to ask questions that are within the child's ability to answer, but not too basic so as to offend the child or parent (Morrison & Anders, 1999).

Language development has a prominent effect on the quantity of information reported (Salmon et al., 2003). To address potential language limitations associated with younger children, several researchers have found that activities that require active participation from the child (e.g., drawing, re-enactment) may improve the quality of interview question responses (Parkinson, 2001; Salmon et al.). Adolescent's cognitive and emotional development provides improved abstract reasoning and identification of feelings, motives, and behaviors (Monaco et al., 1997). Resultantly, older children and adolescents can be expected to provide greater depth and accuracy in their responses (Hayes & Delemothe, 1997).

In addition to limitations related to development, the clinician will also encounter children with varying speech and language disorders (e.g., speech impediments, auditory processing disorder, Tourette's disorder, selective mutism). Such language disturbances may limit the quality of the responses and the child's ability to understand what is being asked. Further, many children who are aware of their communication difficulties may be hesitant to talk with the clinician. The clinician should consider that the child's hesitancy to disclose may serve as a defense and may be attributable to the past negative reactions of others, discomfort talking with the clinician (e.g., new person), and/or the novel setting (Ford, Sladeczek, Carlson, Kratochwill, 1998; Morrison & Anders, 1999). The clinician should carefully observe these displayed communication difficulties as these likely provide important information in understanding the child's psychosocial profile. As important as these observations are, the clinician should still attempt to engage the child in the interview process. Use of different settings, having the parent in the room, and using play (e.g., games, drawing) may lessen the child's anxiety and aid in the initiation of dialogue (Ford et al., 1998; Morrison & Anders).

8.2.4.2 Question Format

The format in which questions are presented to the child powerfully influences the accuracy and quality of information that is obtained. Interviewing format used with children is a common area of research and debate in the forensic setting as the child is often primarily responsible for testimony related to trauma or abuse (Hayes & Delemothe, 1997; Peterson & Biggs, 1997). Both open-ended and close-ended questions will be employed in most interviews, but the degree that each is used depends on factors such as age, language development, social skills, and amount of information that the clinician has prior to the interview (Morrison & Anders, 1999; Peterson & Biggs, 1997; Powell & Lancaster, 2003).

Open-ended questions are preferable since they offer less suggestion of what may be perceived as the desired response, are indicative of what information the child feels is important, provide insight into the child's linguistic and intellectual abilities, and allow for observation of the child's behavior during responding. However, children, particularly younger children, often provide brief and less descriptive information in response to an open-ended question (Hayes & Delemothe, 1997; Monaco et al., 1997; Peterson & Biggs, 1997; Powell & Lancaster, 2003).

Close-ended questions, questions with specific response options (e.g., yes–no; who, what, where questions), or questions constructed to cue recall, may be misleading, are more vulnerable to inaccuracies or confabulation, and suggest that the clinician is the one who knows what information is important (Hayes & Delemothe, 1997; Peterson & Biggs, 1997; Powell & Lancaster, 2003). Further, when presented close-ended questions in a yes–no format, children are more likely to provide an answer even if they do not know the answer as compared to adults who are likely to report not knowing the answer (Waterman, Blades, & Spencer, 2001). "Why" questions are not often useful since they may be viewed as accusatory, children may feel pressure to rationalize their behaviors, and they may have little insight into "why" they behaved in a particular way (Monaco et al., 1997). Despite these limitations, close-ended questions are often needed to obtain information with the necessary depth and breadth, particularly when interviewing younger children and those with limited language abilities.

8.2.5 Interviewing Parents and Teachers

In addition to interviewing the child as part of the child clinical interview, clinicians may call upon parents, teachers, and others (e.g., bus drivers, religious leaders, physicians) to serve as informants. The use of multiple respondents can result in a more complete picture of the child and corroborate information provided from a single source (Hurwitz, Gaebler, & Kratochwill, 2007; Palmer et al., 2007). Parents are excellent informants about the child's development and duration, frequency, and intensity of symptoms, as well as behavioral and cognitive strengths. Additionally, parents may help the clinician specify target behaviors for treatment (Jayne et al., 2007). However, the clinician should be mindful that parents may exaggerate symptoms or, alternatively, minimize problems in an effort to manage their own image or the image of the family (Nock, Holmberg, Photos, & Michel, 2007). Teachers also serve as important informants due to their ability to observe the child function in academic and social situations. This perspective is unique from the parents', as teachers are able to easily reference the child's behavior relative to the functioning of his or her peers (Wise et al., 2007). Teachers may also be more objective informants of the child's functioning (Monaco et al., 1997).

Dawson (2005) suggested several interviewing steps useful for successful completion of parent or teacher interviews. Similar to the child interview, clinicians are advised to establish rapport with informants and use open-ended questions in the interview. Parents and teachers may also be anxious about talking with the clinician and hesitant to report problems for fear of being blamed for the child's behavior or mood difficulties. Thus, clinicians should display empathy and warmth towards these informants in an effort to diminish these reservations (Hurwitz et al., 2007). Clinicians should also provide guidance for parents and teachers to help them identify primary concerns in objective behavioral terms. Equipped with a clearly defined behavioral definition of behaviors targeted for change, clinicians can work to hypothesize environmental factors that may bring about and maintain problematic behavior patterns (Dawson).

Clinicians should gather information from parents regarding the child's birth (e.g., complications, length of hospital stay), mastery of developmental milestones, family and social environment, and approximate cognitive functioning (Boggs et al., 2003). When appropriate, information can be gathered on questionnaires. Parent packets may include the developmental questionnaire, as well as relevant behavioral rating scales (e.g., Child Behavior Checklist, Achenbach, 1991a; Gilliam Autism Rating Scale – Second Edition, Gilliam, 2006; Conners' Rating Scales – Revised, Conners, 1997). Additionally, many of these rating scales have versions that were developed for teachers (e.g., Teacher Report Form, Achenbach, 1991b; Conners' Rating Scales – Revised, Conners).

Behavior rating scales are excellent tools with which to gather information. They typically include age norms which help determine symptom severity and degree of atypicality of the behavior of concern. Obtaining information on rating scales and questionnaires aids in gathering objective information that will be used to conceptualize the case, aid in diagnostic decisions, and inform recommendations (Merrell, 2000; Villa & Reitman, 2007). However, clinicians should be aware that not all parents are able to complete handwritten forms at home. It is also important to be mindful of the limited time that teachers will be able to provide when selecting the interview and rating scales (Hurwitz et al., 2007). Professional judgment should be used to determine the best manner in which to obtain information. When it is possible to have questionnaires and measures in hand prior to an interview, the clinician may review the measure with the parent or the teacher in the initial meeting, directing the parent or the teacher to elaborate when necessary. Clinicians should note, however, that self-report measures are used as adjunct to the interview and should not be used as a substitute for a verbal clinical interview.

8.2.6 Components of the Interview

While a thorough knowledge of human development, child psychopathology, and cultural variability is a prerequisite for effective interviewing, competent interviewing relies on the clinician's ability to select and administer the interview in a manner that obtains all necessary information. Similar to the previously examined language and environmental considerations, rapport building with both the child and the parents is vital to making the client comfortable and cultivating open communication. Boundaries and expectations of confidentiality must also be addressed at the outset of the interview. Finally, the interview format and content selected by the clinician can either make answering the referral question and diagnosis straightforward or leave the clinician missing information and unable to make discriminating conclusions.

8.2.6.1 Rapport Building

The interview process is predominantly unidirectional in nature; that is, the clinician asks specific questions of the client. Thus, the formality and structure of the interview can lack the warmth that the client may expect (Craig, 1989). Competent clinicians must be able to cultivate rapport with both the parents and the child. Further, establishing rapport is vital as it influences the quality of the disclosures during the interview and may affect the duration, outcome, and ultimate success of treatment (Monaco et al., 1997; Villa & Reitman, 2007).

Meeting with the parents prior to interviewing the child enables the clinician to inquire about the child's attitude toward the interview, what the child's interests are, and if the child will be able to be interviewed individually. Child clients are usually interviewed because of a referral by another person (e.g., parent, teacher, physician, judge). Typically it is this person, not the child, who deemed it necessary that the child undergo assessment or treatment. The referral may have been made due to any number of behavior problems and the child may have little insight into the impetus for the visit (i.e., referral reason). Thus, the child may feel punished, confused, excited, or anxious when in this situation (Villa & Reitman, 2007). The clinician should also inquire about what the child enjoys or does for recreation as this may provide topics for initiating dialogue or helping to maintain momentum during the interview (Powell & Lancaster, 2003; Villa & Reitman). Finally, the clinician must determine whether rapport would be best cultivated with the parents in the room for any portion of the interview. This decision is based primarily upon the child's age and developmental level (Boggs et al., 2003; Monaco et al., 1997).

The physical environment where the interview will occur is another potent factor in cultivating a warm and comfortable social climate. In particular, the setting may present the clinician with unique challenges since location can vary considerably. Interviews may occur in schools, hospitals, and physician offices, as well as in the clinician's office. Further, the location and reason for the referral may be in response to a crisis. If the interview is to occur in a location in which confidentiality is a concern (e.g., hospital, school), every effort should be made to create a private environment and discuss these limitations with the child and their parent or guardian (Villa & Reitman, 2007). The clinician should determine whether the interview will occur with the parents or the guardian present in the room for the entire interview, a portion of the interview, or whether the parents and the child should be interviewed separately (Boggs et al., 2003; Monaco et al., 1997). Rapport and warm social climate may also be facilitated by allowing younger children to explore the room prior to the interview, sitting on the floor or at tables appropriate for children, and providing age-appropriate toys or drawing materials (Monaco et al.; Villa & Reitman). Conversely, older children and adolescents may view the presence of toys and games unfavorably and will likely prefer to be interviewed in a more mature environment (Villa & Reitman). Regardless of age, the clinician should seek to limit potential distractors, both external and internal, and sit at an angle to the child so as to not suggest to the child that the interview is a test or an interrogation (Villa & Reitman).

Establishing rapport in a clinical interview with a child is quite different than with an adult. It may be necessary to allow the child client more latitude in the interviewing process than is typically provided to an adult client. For example, the clinician may allow the child to move around during the interview. Irwin and Johnson (2005) suggest that the child's preferences be identified before the interview to allow for the clinician to set up the environment in such a way

that facilitates the child's comfort level in the interview. These preferences may include drawing, playing a game, etc. The authors indicate that clinicians should not rely on the same rapport building strategy with each child; rather, clinicians should individualize the interaction based upon the child's preferences. However, it may be accomplished, it is crucial to develop a positive relationship (i.e., build rapport) with the child as soon as possible in order to provide a positive initial experience for the child and to build a foundation upon which treatment can easily follow (Monaco et al., 1997; Sharp et al., 2006).

Responsiveness by the clinician can be displayed both in the way that the clinician allows the child to behave within the interview and the manner in which the clinician responds to disclosures. The type of reinforcement provided by the clinician will likely vary in conjunction with developmental level and age. Younger children may find both primary reinforcers, such as a toy or candy, and verbal praise rewarding, while older kids and adolescents are likely to be responsive to secondary reinforcers, such as verbal praise or social reinforcement (Merrell, 2002; Monaco et al., 1997).

Verbal and nonverbal responsiveness by the clinician are potent factors in the cultivation of rapport and the harvesting of useful information. Verbal responses may be in the form of praising the child's behavior or appearance, and are likely to be more effective when the specific behavior is labeled for the child (Monaco et al., 1997). The clinician may also benefit from the use of nods, "uh-huh," "mmmm," silence, and other forms of active listening to impart to the child that the clinician is interested in what is being said (Monaco et al.; Powell & Lancaster, 2003). Nonverbal cues (i.e., nodding, eye contact) can effectively communicate to the child that the clinician is "attentive and interested" while not interfering or disrupting the child's dialogue (Monaco et al., p. 163). Generally, verbal reinforcement is more effective with the younger child, as the child may not be cognizant of nonverbal cues, while verbal and nonverbal reinforcement is suitable for older children and adolescents (Monaco et al.).

Clinicians new to child clinical interviewing may become more skilled in this regard through review and practice of empirically based strategies provided by published literature. Research indicates clinicians should express respect for the child's opinions, respond in a nonjudgmental manner, avoid giving advice, seat the child at a 90-degree angle to the clinician, and practice active listening (Oetzel & Scherer, 2003; Weersing, Weisz, & Donenberg, 2002). Additional techniques found to contribute to success in rapport building with children across the age range include: use of open-ended questions that are easy for the child to answer (Monaco et al., 1997; Turner et al., 2003), meeting individually with the child (Villa & Reitman, 2007), and identifying and incorporating child-preferred activities into the interview process (Irwin and Johnson, 2005; Powell & Lancaster, 2003).

With younger children in particular, clinicians may find it useful to sit on the floor with the child during the interview. However, it is also indicated that clinicians should behave in a manner consistent with the child's expectations to maximize rapport building. In other words, playing toys with the child may be less effective in cultivating a positive therapeutic relationship than merely talking with the child in a manner that affirms the value of beliefs and experiences (Gurland & Grolnick, 2008). Therapist qualities preferred by adolescents (12–17 years of age) include respect, time shared, and openness as most important in the cultivation of a positive therapeutic alliance (Martin, Romas, Medford, Leffert, & Hatcher, 2006).

Finally, while it is advantageous for the clinician to reinforce appropriate behavior, minor problematic behavior should be ignored. The child client may use behaviors in the interview session that have "worked" with other adults with whom they interact. That is, the child's

behavior may gain him or her access to a desired item, allow him or her to escape or avoid the interview, or may bring about attention from adults. Failure to ignore minor problematic behavior could result in a negative interaction with the child, which could undermine the establishment of rapport.

8.2.6.2 Confidentiality

Confidentiality is often a primary concern of the child client. Children are dependent upon adults, which increases the complexity of clinical interviews with children. Due to the nature of adult–child relationships, children are even more vulnerable than adult clients to the power differential often present between therapist and client.

When conducting a clinical interview with a child, it is imperative that the clinician discusses the potential boundaries of confidentiality and determines what is agreeable to the child and parent (Monaco et al., 1997; Villa & Reitman, 2007). A potential consequence of this discussion could be that the child then withholds information; however, informed consent is the foundation of a trusting relationship. Clinicians must present all information up front to avoid later ruptures to the therapeutic alliance. It is suggested that the clinician discuss confidentiality with the child and parents independently, followed by a discussion with all parties to determine expectations and address and clarify concerns (Villa & Reitman).

Clinicians should also discuss, with both child and parents, what information may be released. Various institutions may request information (e.g., schools, hospitals, insurance companies, courts), but the clinician should consider the referral reason and release only relevant information (Monaco et al., 1997). For example, insurance companies should be provided with necessary minimal information to provide services. Regarding information discussed between the child and the clinician, it is recommended that the therapist, child, and parents discuss the extent to which information will be shared with the parents. The parent or guardian is entitled to the content of the interview. However, caregivers are often willing to provide the child some level of privacy and appreciate that this privacy may aid in the development of rapport between clinician and child. In any event, the clinician must inform the child that disclosures related to plans to harm self or others, engage in potentially dangerous behaviors, and allegations of sexual or physical abuse are grounds for notifying the parent or guardian. Further, after an explanation of such limits of confidentiality, the clinician should inform the child client he or she will be notified in most instances if the clinician deems it necessary to make such a disclosure to parents (Monaco et al.; Villa & Reitman, 2007). If the clinician encounters any ethical or legal dilemmas regarding confidentiality, consultation with a supervisor or colleague (Villa & Reitman), and the APA's ethics code (2002) should be considered.

8.2.6.3 Interview Format

Regarding the structure of the interview, various approaches are loosely grouped into three broad styles: structured, semi-structured, and unstructured. The structured interview describes a formal set of questions, which include optional probes, and areas of inquiry that the clinician will cover with each client. Further, the interview format and order of topics are standardized

and provide the clinician a formal method for rating client responses (Rogers, 1995, 2001). The structured interview also limits the influence of potential interviewer bias (Villa & Retiman, 2007). All structured interviews are designed to enable clinicians to differentiate and diagnose Axis 1 disorders (Nock et al., 2007). The purpose of this systematic interview process is to "maximize the reliability and validity of … the assessment process," but the formality of this process serves as a limitation to the variability that is seen across client presentation (Rogers, 2001, p. 24). Additional limitations of the structured interview are that administration often entails measure-specific training, and interview questions target diagnostic criteria rather than obtaining broad information about the child's functioning. Resultantly, information useful for treatment planning may not be obtained (Villa & Reitman).

The semi-structured interview is quite similar to the structured interview in that there is a standardized set of questions with discretionary probes, but the semi-structured interview also allows the clinician to employ unscripted questions to probe for clarification or additional information (Rogers, 2001). This latitude in the interview process and the clinician's ability to adapt the interview is vital, given the varying constellation of symptoms or histories that are encountered across clients (Aklin & Turner, 2006; Villa & Reitman, 2007). Limitations of the semi-structured interview are questionable reliability and validity (Villa & Reitman).

Specific structured and semi-structured interviews vary in ages and disorders assessed, administration time, as well as the training needed for competent administration (Nock et al., 2007). While examination of each available measure is beyond the scope of the current chapter, an example of the more comprehensive structured and semi-structured interviews will be briefly reviewed. Other frequently utilized structured and semi-structured interviews not reviewed in the current chapter include the Children's Interview for Psychiatric Symptoms (ChIPS; Teare, Fristad, Weller, Weller, & Salmon, 1998), the Composite International Diagnostic Interview – Adolescent Version (CIDI-A; Kessler & Üstün, 2004), the Diagnostic Interview for Children and Adolescents (DICA; Reich, 2000), and the Schedule for Affective Disorders and Schizophrenia for School-Age Children – Present and Lifetime Version (K-SADS-PL; Kaufman et al., 1997).

The National Institute of Mental Health Diagnostic Interview Schedule for Children Version IV (NIMH DISC-IV; Shaffer, Fisher, Lucas, Dulcan, & Schwab-Stone, 2000) is a structured interview designed to assess approximately 30 disorders in children and adolescents between 6 and 17 years of age. The NIMH DISC-IV utilizes the diagnostic criteria of both the DSM-IV (American Psychiatric Association, 1994) and the ICD-10 (World Health Organization, 1993). There are two versions of the NIMH DISC-IV. The DISC-P is a parent interview for children between 6 and 17 years of age, while the DISC-Y is a self-report interview for youth between 9 and 17 years of age. Three different time frames (i.e., past 4 weeks, past 12 months, lifetime) are assessed in the interview. Generally, symptoms are first evaluated as occurring in the last year. If a symptom is endorsed as occurring in the last year, the symptom is then evaluated in reference to the past 4 weeks (Shaffer et al., 2000). The NIMH DISC-IV contains nearly 3,000 questions, but many of these will not be asked if symptoms are not endorsed or if the lifetime symptoms module is not administered. The NIMH DISC-IV is available in both computer-assisted and paper formats. Additionally, English and Spanish versions are available. Given the structured format and limited response options of the NIMH DISC-IV, this instrument is able to be administered by nonclinicians. Shaffer et al. indicate that the necessary training may be obtained in 2–3 days for the computer-assisted version, with another 2–3 days needed to be adequately trained in the administration of the paper version.

The Child and Adolescent Psychiatric Assessment (CAPA; Angold, Prendergrast, Cox, Harrington, Simonoff, & Rutter, 1995) is a semi-structured interview designed to be administered to children and adolescents between 9 and 17 years of age. The CAPA allows the clinician to select specific modules to administer if the whole interview is not needed. Additionally, the CAPA provides the clinician three levels of probes in order to allow the presence of symptoms to be confidently established or dismissed (Angold & Costello, 2000). The CAPA utilizes the diagnostic criteria of the DSM-IV (APA, 1994), DSM-III-R (American Psychiatric Association, 1987), and the ICD-10 (World Health Organization, 1993) to assess a broad range of disorders. Broad categories of disorders assessed by the CAPA include disruptive behavior disorders (e.g., ADHD, conduct disorder), mood disorders, anxiety disorders, eating disorders, sleep disorders, elimination disorders (e.g., enuresis, encopresis), substance abuse, tic disorders (e.g., Tourette's disorder), and other disorders (e.g., schizophrenia, posttraumatic stress disorder, trichotillomania). Symptoms are evaluated along the dimensions of onset, duration, frequency, and intensity. In addition to diagnostics, the CAPA assesses the child's family, peer, and adult relationships, significant life events, and psychosocial functioning. The CAPA evaluates the presence of symptoms over the preceding 3 months. Parent-report and self-report versions are available, and these versions differ only in that the self-report version does not include questions related to ADHD. Administration time is approximately 1 hr for both the parent-report and self-report versions. With regard to training demands, it is recommended that administrators have at least a bachelor's degree, but no prior clinical training or practice is required. Also, the administrator must obtain certification from a CAPA instructor, which consists of 2–4 weeks of training composed of didactics and practice. Similar to the NIMH DISC-IV, English and Spanish versions are available (Angold & Costello).

The unstructured or open interview is an unscripted process of questioning and inquiry that is specific to each client. This interview has no standardized areas for the clinician to cover and results in informal recording of client responses (Aklin & Turner, 2006; Rogers, 2001). The strength of this process is that it allows the clinician to individualize interviews specific to each client. However, it is not without limitation. Specifically, unstructured interviews may miss vital information, are subject to clinician and theoretical bias, are more vulnerable to measurement errors, have suspect reliability and validity, and can more frequently lead to misdiagnosis compared to other interviewing methods (Aklin & Turner; Rogers; Villa & Reitman, 2007).

Given the uniqueness of each client and his or her specific environment contingencies, it is reasonable to infer that either the structured or unstructured interview used alone will fall short of adequately capturing the necessary information for case conceptualization, diagnosis, and treatment planning. As such, the competent clinician should employ an array of assessment tools drawn from both structured and unstructured interviewing. Further, the semi-structured interview allows the clinician to cover essential content while providing the flexibility to adapt the process to the client's unique cultural presentation (Aklin & Turner, 2006). As such, it is suggested that clinicians employ a structured format to ensure that the requisite data is obtained, but this structure should lack rigidity and be adapted to each client's unique case.

8.2.6.4 Content of the Interview

The content of the clinical interview is guided by several factors. Competent interviewing should result in an accurate picture of the child's psychological strengths and limitations, as

well as considerable insight into environmental contingencies maintaining these behaviors (Logan, 2005). In addition to seeking information related to the referral problem, a number of environmental and functional domains should be reviewed. These areas include: home environment and family relationships; friendships and peer relationships; school and homework; activities and interests; and self awareness and feelings. While specific content covered in each area will depend upon the child's age and developmental level, each area may provide invaluable information (Monaco et al., 1997). Additionally, the order in which these areas are covered will be determined by who is in the room at different stages of the interview process, as well as by the interviewing format (unstructured, semi-structured, unstructured) chosen by the clinician.

The clinician should consider whether the referral has identified a broad problem behavior or functional difficulty (e.g., inattention, impulsivity, aggression, interpersonal difficulties) or a specific behavioral problem (e.g., not finishing assignments, pushing or hitting peers, yelling at parent/teacher). The clinician should seek to gain as much specificity about what behaviors are problematic and collect ratings of their intensity, frequency, and duration (McConaughy, 2000; O'Brien & Tabaczynski, 2007). Further, the therapist should seek to identify contextual influences that include the environmental antecedents to the occurrence of the behavior and the environmental contingencies (e.g., reinforcers, punishers) that follow performance of the behavior (McConaughy; O'Brien & Tabaczynski). The clinician should also ask the child to provide information about these contingencies, since the child is the greatest authority of what is salient in his or her environment. When interviewing adolescents, clinicians should be prepared to inquire about drug use and sexual activity. It is recommended that the clinician inquire about these activities in a straightforward manner while being mindful to address concerns of confidentiality (Monaco et al., 1997). Information provided by the child should be treated as any other source of data. That is, clinicians may become more confident in the accuracy of information when it is similar across informants (i.e., teacher report, parent report, behavioral observation) (Palmer et al., 2007).

Obtaining a clear understanding of the child's relationships with each family member of importance and the broad social climate in the home is vital yet often elusive. Family members may be hesitant to disclose information that they may perceive as presenting the family as conflictual or dysfunctional (Nock et al., 2007). Further, the family may have experienced divorce, remarriage, guardianship issues, and other changes that may influence the tone and accuracy of the information depending on the source. As such, it is vital that the clinician discusses with the child the features and perceived importance of each relationship (Monaco et al., 1997). Further, the clinician should be mindful that the importance of familial relationships often lessens in comparison to peer relationships as a child matures (Jayne et al., 2007; Monaco et al.). As previously described, clinicians must consider the family's culture when making judgments about familial relationships and dynamics. Many cultures place greater importance on honoring the family and working for the whole (sociocentric) in contrast to Western individualism (Johnson & Tucker, 2007).

Peer relationships can provide keen insight into discriminating problem behaviors and psychopathology (Jayne et al., 2007; Monaco et al., 1997). Children cultivate increasingly sophisticated interpersonal skills as they develop. As such, it is vital that the clinician have knowledge of interpersonal skill development in order to effectively examine and assess a child's social skills (Jayne et al.). Several areas to discuss with the child are his or her perceptions of friendships, and how he or she gets along with peers during school, specific

extracurricular activities, and in more casual settings (Monaco et al.). In particular, the clinician should assess whether the child experiences peer rejection, bullying, or social anxiety as these can limit the child's social development and persist over time. Further, behaviors such as aggression and social withdrawal or avoidance should be assessed as these behaviors also limit the child's ability to cultivate interpersonal skills (Jayne et al.).

School and related programs are a potent influence in any child's life and often the setting in which problematic behaviors occur. Classroom behavior, homework, interest in classes, extracurricular activities, and peer and teacher relationships are prominent factors in the child functioning effectively in the school environment (McConaughy, 2000; Monaco et al., 1997). It is important to directly assess each of these areas and inquire about changes across school years. Discussing activities and interests with the child may provide insight into his or her level of engagement in the environment. As previously described, discussion of interests is also an effective method for cultivating rapport (Monaco et al.; Powell & Lancaster, 2003).

Beyond learning how the child views his or her interactions with the world, clinicians should also discuss self-perceptions with the child (Logan, 2005; Palmer et al., 2007). Self-perceptions may include the child's sense of dependence, autonomy, and self-efficacy (Logan). As such, these perceptions influence the child's interactions with family, peers, school, and other aspects of the environment (Palmer et al.; Salmivalli & Isaacs, 2005). Negative self-perceptions have been found to be associated with depression, hopelessness, victimization, and negative attitudes toward peers (Salmivalli & Isaacs). An effective method for inquiring about these perceptions is to ask for the child's perspective on his or her life and the problems that brought him or her to the interview. By employing more pragmatic language with the child, the clinician can often obtain the needed information without using abstract concepts that many children may either not understand or be put off by.

Collectively, the described content areas represent the core domains that should be incorporated into each clinical interview. Additional areas of inquiry should be integrated based upon the presenting problems and referral needs. Similar to the semi-structured interview, the content should cover areas of functioning that are universally relevant to children, but be elaborated upon as each case demands.

8.3 Expert Competencies

The basic skills needed to be competent in the interviewing of a child or adolescent are extensive and lay the foundation for the clinician to effectively handle more difficult cases. Expert competencies are those additional skills required to effectively interview children when in crisis or danger, when they object to participating in the interview, or when the demands of diagnostic investigation extend beyond what is covered in the typical interview. The goals of accurate case conceptualization, diagnosis, and answering the referral do not change. Rather, the clinician must be prepared to adapt and meet the demands presented by more difficult cases. This section on expert competencies will describe how to handle children who are feeling suicidal or who are victims of physical and/or sexual abuse. This will be followed by a description of how to engage the difficult or oppositional child in the interview. Last, the "Expert Competencies" section will examine forensic interviewing and the unique challenges associated with obtaining accurate information.

8.3.1 Suicide Risk Assessment

Occasionally, clinicians must conduct risk assessments on children. Research indicates that the mean worldwide rate of suicide is approximately 4.5 per 100,000 children and adolescents between 10 and 19 years of age, with males having more than three times the risk of females (Centers for Disease Control and Prevention, 2005). Children also may engage in suicidal gestures or self-injurious behaviors. While these acts may not result in death, they are psychically harmful or threatening (Nock & Kessler, 2006). Asarnow et al. (2008) conceptualized suicide attempt risk along a continuum of increasing risk which ranges from suicidal ideation to one attempt and then up to multiple attempts. All clinicians must have a plan in place for dealing with children in crisis.

Children may be reticent to bring up this topic with clinicians; thus, it is important for clinicians to be aware of potential warning signs or risks. Researchers have identified depression, externalizing behavior problems, posttraumatic stress, substance abuse, environmental stress, and a history of suicide attempts or gestures as associated with increased risk (Asarnow et al., 2008; Nock & Kessler, 2006). Dervic, Brent, and Oquendo (2008) also cited family history of suicide, childhood affective disorders and externalizing disorders, and having a parent with a mood disorder or who displays impulsive aggression may make children more vulnerable for a suicide attempt.

When a client presents with suicidal ideation, clinicians must identify the severity of the threat and make the appropriate referrals. If the child endorses self-injurious behavior or suicidal ideation, the clinician should evaluate what is the intent of the behavior or threat, does the child have a plan, is the plan realistic, does the child have a history of prior attempts, and any additional information that allows the clinician to be confident that he or she can effectively address the threat that the child poses to himself or herself. The clinician should communicate this threat to the child's parents or caregiver, but this must be handled delicately so as to not destroy trust and rapport with the child. The clinician should have covered the bounds of confidentiality at the outset of the interview, so the child should not be surprised that his or her parents need to be notified. An excellent way to communicate this threat to the parents while preserving the therapeutic relationship is to allow the child to communicate the threat or plan to his or her parents. The clinician, however, should not assume that the child will do this at home and this notification should occur within the context of the interview visit. Alternatively, the clinician must communicate this risk, even if the child objects. If the threat is judged to be legitimate and imminent, then the clinician should most often refer the child for inpatient treatment. While the most restrictive environment, inpatient treatment is often best able to manage opportunities for self-injurious behavior.

8.3.2 Difficult Children in the Interview

The clinician should be prepared that often the child will be unwilling to actively participate in the interview for an array of reasons. Reasons may include reticence to discuss their problems or their families, cognitive and emotional limitations in development, and outright opposition to being in the interview (House, 2002; Villa & Reitman, 2007). While each child presents a unique constellation of behaviors, the clinicians should have a number of strategies that can be used in an attempt to put the child at ease, foster trust in the interviewer, and engage the child

in the interviewing process. As with other aspects of the interview, age and maturity will substantially influence the type of opposition and unwillingness to participate in the interview.

The clinician can often anticipate when an interview will be particularly difficult by asking a few questions when the referral is made. Questions may include: "Does the child know that he or she is coming for an interview? Does the child know why the interview is being conducted? and How does the child behave when he or she meets someone new?" The clinician should also consider the context for why the interview is being conducted and who is the referral source. Children being referred for mental health services by their parents may present very differently than children referred by the schools or the courts. It would be quite rare that a child would seek out services on his or her own.

The clinician will often talk with the parents and the child together. The clinician should be attentive to how the parents discuss the problem with the child present. This can provide the clinician great insight into how the problem is perceived and discussed within the family. The clinician should also consider that parents and referral sources often view the problem behavior with greater concern than the child (Handwerk, 2007). This discrepancy may influence the child's reservation to talk openly with the clinician since they may not view that there is a problem, or that by discussing it they are legitimizing their parents' concerns.

When children are resistant to the interview or do not perceive their behaviors as a problem, they are often terse in there responses (e.g., "fine," "good," "ok," etc.). The clinician can best challenge this by citing specific events that the parents or referral sources have reported, but the clinician must be wary that this could polarize the child's perception that the clinician is aligned with the parents. To address this, the clinician will benefit from telling the youth that his or her parents report this as a concern, but the clinician wants to hear the point of view from the child also. The clinician may elaborate that he or she does not uniformly assume that parent or school reports are accurate, and it is important that the child present his or her knowledge and impressions of events and questions being asked in the interview. This open acknowledgment of the importance of the youth's perspective is often very useful in the cultivation of rapport and trust (Handwerk, 2007).

8.3.3 Maltreatment and Abuse

Physical abuse, sexual abuse, and other forms of child maltreatment are unfortunate but important environmental influences of which the clinician must be aware. Due to the sensitivity of discussing abuse, the possibility that the perpetrator of abuse is a parent or a caregiver who has transported the child to the interview, and the susceptibility of children to suggestion, the clinician must be very mindful of the format and phrasing of questions when probing for abuse or details related to abuse. Substantial amounts of research have been conducted in the field of forensic psychology indicating that open-ended, free-recall, and cued-recall questions are more accurate and offer less suggestibility than questions presented in a forced choice format (e.g., yes–no), option format, and suggestive questions (Perona, Bottoms, & Sorenson, 2006; Thoreson, Lønnum, Melinder, Stridbeck, & Magnussen, 2006). The suggestiveness of all questions should be conceptualized as a lying on a continuum. In the context of probing for abuse or maltreatment, the clinician should err on using less suggestive and open-ended questions, but this form of questioning may leave out necessary details. As such, more specific questions may be appropriate later in the interview as a picture of events is developed (Perona et al., 2006;

Thoreson et al., 2006). The clinician must also consider the situational context as it may drastically influence the child's recall and willingness to disclose. This may include being brought to the interview by the perpetrator of the abuse (i.e., parent), or being told misinformation by a family member in an effort to confuse the child or alter the child's recall of events (Palmer et al., 2007; Perona et al.).

Allegations of abuse should be reported to the appropriate agency within each state. This reporting is both required by law and the APA ethics code (Palmer et al., 2007). Clinicians should accurately and specifically document all allegations of abuse in written records as well as videotapes or audiotapes when available. Parents and children should be informed of the bounds of confidentiality and documentation practices at the outset of the interview when conducting informed consent (Wise et al., 2007). It is also suggested that the clinician should inform the child and the parents when an allegation has been made that warrants reporting. While disclosures of abuse and related reporting are oftentimes upsetting and volatile situations, the clinician may preserve or strengthen the therapeutic relationship by using direct and open communication.

8.3.4   Forensic Interviewing

The forensic interview differs from the typical clinical interview since it is conducted for the purpose of legal proceedings. As a result, the clinician should approach the interview with the knowledge that the client's (i.e., child) participation is not voluntary (Meloy, 1989). Forensic interviews are most often requested to make decisions regarding child custody and protection, and to determine competency and appropriate charges for criminals, as well as appropriate clinical interventions. As such, the primary goal of the forensic interview is the same as the traditional clinical interview: answer the referral request. However, the clinician must be vigilant to obtain the information necessary to avoid false allegations and identify abuse in children (Perona et al., 2006; Peterson & Biggs, 1997). It is also possible that a clinician could be requested to conduct a forensic interview with an adolescent who is the accused. For the purpose of the current discussion, this chapter will focus on conducting a forensic interview with a child as the victim.

The clinician must consider a number of factors prior to beginning the clinical interview. First, the clinician should consider the developmental level of the child. Using an open-ended format with younger children may be inadequate for obtaining information with the neces-sary depth and breadth (Perona et al., 2006; Peterson & Biggs, 1997). Conversely, the clinician should be mindful that older children and adolescents are much more cognizant of social consequences that may occur as a result of disclosure. The clinician must also be mindful of the previously examined cultural considerations (Perona et al.). Last, the clinician must also consider that the child may have been deliberately told false or suggestive information prior to the interview. Many accusations are later recanted in the context of the forensic interview. The clinician must not automatically assume that the recant is false, but the clinician should also consider that the child has been pressured either directly by an individual or by the social costs and stigmatization associated with being a victim of a crime such as physical or sexual abuse (Perona et al.).

When conducting the interview, research indicates that information provided by the child is most effectively obtained by utilizing open-ended questions that allow greater latitude of responses. Clinicians should also be mindful to present questions in a manner that limits the clinicians influence on what information is chosen to be reported (Perona et al., 2006).

An example is "Tell me about why you have been asked to talk with me." The clinician will undoubtedly need to use more specific or concise questions at times, but every effort should be made to allow the child to provide an unguided description of events. In particular, the clinician should be wary of employing yes–no questions, using language that the child does not understand, incorporating information into the question that the child has not reported in the context of the interview, asking the same question repeatedly, and inquiring about tangential details rather than core elements of the alleged event (Perona et al.; Peterson & Biggs, 1997). The use of aids (e.g., dolls, drawing) in the context of the forensic interview must be approached with caution. It is suggested that these only be employed after initial details have been provided, that the clinician has the child provide a concurrent verbal description of events, and that the clinician is careful not to present these items as a play activity that may involve imaginative play. Last, the clinician should not make inferences regarding the occurrence of an event based upon observed play or drawing content (Perona et al.).

The general format of the forensic interview does not dramatically differ from that used in the typical clinical interview, but there is evidence that choosing a validated structured interview may obtain more accurate information and minimize the risk of suggestion from the interviewer. Just as each clinical interview conducted for the purpose of diagnosis may be unique to the presenting problems and symptomology, each forensic interview is unique to the alleged crime and population (Perona et al., 2006). While many clinicians may not have interest in forensic interviewing, many clinicians will encounter allegations of abuse, neglect, and other crimes involving their clients. As such, it is essential that clinicians be aware and mindful of forensic interviewing strategies in order to obtain the most accurate information and best serve the client's needs.

8.3.4.1 Trajectory for Obtaining Competency

The importance and utility of the clinical interview is undeniable and reflected in its use by nearly every type of mental health practitioner and its broad application across a myriad of symptom presentations and referral reasons. Competent administration of the clinical interview is an essential skill that is often inadequately cultivated in training programs (Turner et al., 2003). Every practitioner should obtain the core training requirements for competent interviewing, but additional training needs may be necessary depending on the specific interview being utilized, the types of children being interviewed, and the referral questions to be answered. As such, competent interviewing is a two-stage process composed of didactic and applied training experiences. These training experiences do not have to occur in a linear order but may occur concurrently.

Didactic training should include an extensive knowledge of the developmental process, cultural variability, psychopathology, and diagnostic criteria (Sommers-Flanagan & Sommers-Flanagan, 2002; Turner et al., 2003; Villa & Reitman, 2007). While most of this knowledge should be available through graduate-level coursework, the practitioner has the responsibility to supplement areas of need with additional readings and training opportunities. Clinicians should cultivate a strong knowledge of the developmental process. This knowledge should include awareness of developmental milestones, gender differences, and developmental disorders. As such, the clinician should be able to discriminate normal from abnormal developmental trajectories (Villa & Reitman). The clinician must also seek training experiences in culturally sensitive practice as defined by the APA (2003). While extensive knowledge of each culture potentially encountered is not possible, the clinician should be knowledgeable in the cultural limitations of the DSM-IV-TR and structured interviews, as well as communication barriers

(e.g., language, stylistic). Most training programs have coursework available in multicultural psychology; however, practitioners may also consult the DSM-IV-TR (APA, 2000) and the APA's *Guidelines on Multicultural Education, Training, Research, Practice, and Organizational Change for Psychologists* (2003) for additional direction.

Since symptom presentation of psychopathology often differs between children and adults, clinicians who interview children should be aware of these differences and be able to differentiate disorders (Jayne et al., 2007; Villa & Reitman, 2007). In conjunction with this training, clinicians should be familiar with both DSM-IV-TR (APA, 2000) and ICD-10 (World Health Organization, 1993) criteria. Though psychology more often utilizes the DSM-IV-TR criteria, familiarity with ICD-10 disorders and criteria can increase the effectiveness of communication with the medical field, which rely more heavily on the ICD-10. As previously mentioned, much of this core knowledge will be obtained during graduate training; however, clinicians should keep abreast of new research, new and updated interview formats, and future revisions of diagnostic criteria through continuing education (CE) courses and relevant articles found in peer-reviewed journals. Collective integration of these didactic training experiences should provide the clinician the base knowledge necessary to effectively understand symptom presentation and provide discriminating diagnoses.

In addition to didactic training, the clinician should seek diverse and extensive applied training experiences. These may be obtained through in-house and external practica during predoctoral training at one's university, internship, postdoctoral fellowship, and beyond. These applied experiences should include both extensive observation and conducting interviews under the supervision of a more experienced clinician. First, the clinician should be exposed to conducting interviews in a variety of settings (Sommers-Flanagan & Sommers-Flanagan, 2002). In the case of interviewing children, the clinician should seek opportunities to observe and conduct interviews in schools, hospitals, treatment centers, and private practice settings. The clinician should also seek to be exposed to both directive and nondirective interviewing styles. In practice, the clinician will have to utilize both styles depending on the child's attitude toward the interview and their ability and willingness to offer information. The clinician should also seek opportunities to observe and conduct interviews under the supervision of an experienced interviewer. Supervision allows the clinician to receive feedback regarding cultivation of the therapeutic relationship, effective communication with the client, and implementation of the interview. The clinician should also seek opportunities to visit schools and day cares in order to cultivate a model of how normal functioning children behave and interact. These observations serve as a powerful supplement to readings on the developmental process. Finally, additional training is often required for clinicians choosing to use specific structured or semi-structured interviews. These additional training demands vary considerably, but are essential for competent administration of selected measures.

8.4   Summary

The clinical interview is an essential skill for every clinician, whether practicing in an acute care hospital setting, school, or private practice. As such, it is the duty of clinicians to be well prepared to negotiate the distinct challenges encountered in each case for effective practice of the clinical interview. The purpose of this chapter was to detail the skills and competencies necessary in interviewing children and adolescents. Basic competencies specified that the clinician should possess an extensive knowledge of child development, diagnosis, and multicultural psychology. Variability in developmental trajectories and cultural influences makes it clear that clinicians

cannot assume a one-size-fits-all interviewing format. Rather, each case presents an array of factors that necessitate the clinician to balance the uniqueness of each case and the appropriate interviewing style to answer the referral question or accurately differentiate symptoms and diagnoses. Clinicians must also be prepared to effectively and appropriately utilize other sources (e.g., parents, school) in the interviewing process. While the level of outside involvement in the interview may be prominently guided by the age or developmental level of the child, it is undeniable that parents, teachers, and others serve as essential contributors of information regardless of the child's age.

Basic competencies also examined the process of selecting the most effective interview format (i.e., structured, semi-structured, unstructured) to capture necessary and relevant information. While an unstructured format may have merit in select situations, there is substantial evidence that structured and semi-structured interviewing are generally most appropriate and effective in obtaining the necessary information. Related to interview structure, question format represent another potent influence on the accuracy and quality of information provided. Last, the "Basic Competencies" section described effective administration of the core components of the interview (i.e., rapport building, confidentiality, and content).

Expert competencies are those that allow the clinician to effectively address more complex clinical cases. Difficult interviews may occur due to the child's behavior, the nature of the interview content, or some combination of these and other factors. Effectively addressing these factors in the context of the interview and obtaining an accurate appraisal of potential personal and external threats is a vital responsibility of the clinician. As such, the clinician must also be adept in their interactions with outside institutions. In some cases, this may be in the context of the forensic interview. More likely, the clinician will be presented with the need to interact with schools, police, hospitals, and state agencies. Regardless of the scenario, the clinician must be prepared to effectively meet the needs of the client.

Finally, a trajectory for obtaining the requisite interviewing competencies was described. Clinicians cannot assume that competent interviewing can be conducted by merely looking over the structured interview in advance or asking questions specific to the referral reason. Clinicians must seek both didactic and applied training experiences in order to cultivate the requisite skills. While these training demands may appear overly demanding, these experiences will enable the clinician to more accurately diagnose and effectively answer the referral.

9 Cognitive Assessment with Adults

Gerald Goldstein

Abstract: This chapter reviews competencies involved in performing cognitive assessments of adults, making a distinction between cognitive assessment and clinical neuropsychological assessment, each of which require different doctoral level education, different areas of expertise, and different professional practicum training. Cognitive assessment plays its traditional role in clinical psychology maintaining the organizational structure, scientific and professional status, and clinical services that have existed in the past. The APA can now accredit educational programs in clinical neuropsychology at the predoctoral or postdoctoral level, and there are numerous neuropsychology journals and several societies. Clinically, many healthcare facilities now have designated clinical neuropsychologists on their staffs. This chapter reviews the basic competencies required for both cognitive and neuropsychological assessment of adults, including considerations of training models, accreditation at varying levels of expertise, and substantive clinical competencies.

9.1   Overview

In keeping with what has clearly become the pattern of contemporary clinical practice, this chapter will make a distinction, within the field of adult assessment of cognitive function, between cognitive assessment and clinical neuropsychological assessment. While both forms of assessment are involved with the evaluation of cognitive abilities and both represent, in part, what was once a single competency area, they are currently quite different from each other and require different doctoral-level education, different areas of expertise, and different professional practicum training. The distinction between the two areas has been established in numerous ways. Organizationally, the American Psychological Association (APA) now has a Division of Clinical Neuropsychology (40) and has designated clinical neuropsychology as a specialty area. That means that the APA can accredit educational programs in clinical neuropsychology at the predoctoral or postdoctoral level. Scientifically and professionally, there are numerous neuropsychology journals, such as *The Journal of Clinical and Experimental Neuropsychology*, and several neuropsychology societies, such as the National Academy of Neuropsychology. Clinically, many health-care facilities now have designated clinical neuropsychologists on their staffs. Cognitive assessment maintains its traditional role in clinical psychology maintaining the organizational structure, scientific and professional status, and clinical services that have existed in the past. The process involved here may be characterized as one of branching out of clinical neuropsychology as an independent discipline.

9.1.1   Cognitive Assessment

Cognitive assessment is typically associated with evaluation of intelligence, aptitude, academic achievement, and specific cognitive skills such as memory, language and related communicative abilities, and perceptual and motor skills. These aspects of behavior are generally evaluated with published tests, and there is a large number of intelligence, aptitude, psychoeducational, and specialized cognitive tests available to the professional public. Members of professions other than psychology are often qualified to use these tests, mainly teachers, vocational counselors, and individuals involved in selection, notably for student admission to educational programs and military service. While a psychologist is generally involved in the construction and choice of tests to be used in particular applications, the tests themselves may be administered and scored by others, and decisions based upon the tests need not be made by psychologists. Thus, a school psychologist may choose some particular academic aptitude or achievement test, but after that selection is made the implementation of the assessment may be conducted by teachers or managers. It is desirable for the individual choosing the tests and providing oversight to the program in which they are used to be a qualified school, educational, industrial, counseling, or clinical psychologist. Test publishers typically do not sell tests to individuals without credentials in these or related areas, and maintain established qualification procedures.

Clinical psychologists share with educational psychologists the application of these tests to evaluate aptitude and achievement, most notably when these areas become problematic. There is a widely accepted manual for test construction standards that combines psychological and educational tests (AERA, APA, & NCME, 1999). Thus, psychologists may use cognitive tests to aid in diagnosing mental retardation, learning disability, or conditions that frequently impact on learning, notably attention-deficit hyperactivity disorder (ADHD). While this activity mainly involves children, recent literature has strongly documented the presence of persisting learning disability and ADHD in adults (Katz, Goldstein, & Beers, 2001), and cognitive tests are now commonly used in the assessment of these disorders in college, vocational, and clinical settings. Thus, it is not uncommon for a client of a counseling service who is experiencing vocational difficulties to receive intelligence and psychoeducational tests.

Within the specialty of clinical psychology, cognitive assessment is used for a number of purposes related to health-care considerations, mainly involving application of cognitive testing to psychiatric patients. In this case, tests are most typically used as a component of the evaluation of psychopathology, most often as part of a battery given with other kinds of tests. Cognitive tests, in these cases, might be given in association with personality tests, structured psychiatric interviews, projective techniques, and related methods of evaluating mental disorders. An extensive literature has emerged over many years on the use of cognitive tests for individuals with schizophrenia, mood disorders, anxiety disorders, alcoholism and other substance use disorders, and dementia of various types. Intelligence tests continue to be used in their traditional role of diagnosing mental retardation.

An important point to emphasize is that cognitive tests are used for evaluation of normal and abnormal phenomena. In many countries, all children are given intelligence tests beginning in early life which may be repeated, usually in connection with vocational assessment or determining eligibility for military service. There are mandated "IQ" requirements for certain jobs, and cognitive function may be a selection factor for acceptance or appointments of

various types. That being the case, cognitive assessment cannot really be construed as strictly a "clinical" activity, and is clearly not a competency area involving only clinical psychology or some other clinical specialty within psychology, such as geropsychology. Cognitive testing may be performed by teachers, employers, agencies that select people for employment such as the Department of Defense or the Office of Personnel Management and other decision-making entities concerned with classification or selection. However, there is a general acceptance of the view that one should not permit individuals without required competencies to perform such activities as giving an individual intelligence test to a patient or client and describing that person as "mentally retarded" or should unqualified individuals use psycho-educational tests to classify a person as "learning disabled." That is, using cognitive tests in clinical decision-making without possessing the necessary competencies should be viewed as unethical.

Several approaches have been developed to help assure that cognitive assessments are conducted only by appropriately competent individuals. One group of policies has to do with the tests themselves. As indicated, some cognitive tests may also be described as educational tests, although the ambiguous term "psychoeducational" is sometimes used, possibly creating complications. It would appear that teachers with appropriate education and experience should be able to administer, score, and interpret educational tests. One could imagine that tests of other abilities, for example motor dexterity, could be used by a potential employer to determine whether a prospective employee has a sufficient skill level to perform the work required, even though there are designated psychological tests of motor dexterity.

Making this distinction is linked in the case of publishers of psychological tests to restriction policies regarding the sale of the tests. It is not uncommon for publishers to require customers to register, providing their qualifications. In some cases, a license to practice psychology is required. Sometimes tests are graded such that tests may only be sold to qualified psychologists while others are made more generally available. Some test publishers have rated tests at varying qualification levels. In one system, individuals with training in measurement or guidance can purchase some tests; individuals with a Bachelor's degree can purchase some additional tests and other tests may be bought only by individuals with a Master's or doctoral degree. Some tests are only available to individuals with a doctoral degree, and in most cases, a license. For example, a survey of interests can be purchased by someone with a Bachelor's degree while a license is required to purchase an extensive test of personality and psychopathology. Within the area of cognitive assessment, tests of educational achievement, such as reading comprehension tests, are generally available to individuals with Bachelor's degrees, while purchase of comprehensive intelligence tests requires a doctoral degree and/or license. This kind of decision-making is admittedly controversial and there have been disputes regarding which specialties should be permitted to purchase particular tests. It is therefore probably a good idea to establish an adjudication body that can resolve matters of this type. The licensing laws themselves and the APA's code of ethics also provide some safeguards. Considerations of going beyond the scope of practice or the loss of license may be relevant. For example, if a license is lost by an individual in practice because of failure to meet continuing education requirements, such an individual is by definition not competent to perform psychological assessments of patients.

The actual competencies needed to perform cognitive assessments vary with the considerations offered above. In order to do the most basic evaluations, it is desirable to have some training at least at the undergraduate level in tests and measurements. Courses in introductory

psychology and psychometrics or psychological testing are necessary, and additional courses making up a psychology major such as abnormal or educational psychology would be helpful. Such training would allow the individual to purchase lower-qualification-level tests, and provide the information needed to administer and score tests of that type. These individuals should be able to administer tests using manual instructions, do the quantitative scoring, and understand the meaning of the scores: for example, know the distinctions among a raw, standard, and percentile score. Individuals with a Master's degree in clinical or educational psychology should have the qualifications needed to administer, score, and interpret most cognitive tests including the individual, comprehensive intelligence tests such as the Wechsler scales or the Stanford–Binet. As part of their education, they typically take appropriate course work and have practicum experience with numerous cognitive and psychoeducational tests. Many of these individuals are employed as school psychologists and perform these assessment services in their schools.

It is now common practice to have technicians administer and score tests, particularly in programs in which mainly the same tests are given to all clients. Use of technicians by psychologists is allowable in most states, with a small number of exceptions. There are established competency standards for technicians involving education and training. Typically, a technician should have a Bachelor's degree with a psychology major. Upon employment, the technician should undergo a period of instruction involving general procedures for test administration and the specifics of the tests used. There should be monitoring of testing and often an informal examination is given in which testing is observed by the psychologist's supervisor who then provides a critique and makes an evaluation of the ability to work with clients independently. Depending upon the tests used, it is sometimes important to establish reliability of scoring through comparing the scores made by the trainee to those of an established expert. Technicians do not have clinical responsibility and anything they write must be countersigned by the supervising psychologist.

Cognitive assessment conducted by doctoral-level clinical psychologists is probably most often done in clinical settings as part of the evaluations of psychopathology. Typically, the cognitive tests are administered along with a battery including personality tests and diagnostic interviews. In contemporary practice, only individuals with licenses and doctoral degrees have these procedures within their scopes of practice. Such individuals have the qualifications to administer and score tests with sometimes complex procedures, and provide diagnostic evaluations concerning such matters as cognitive profiles and interactions between cognitive function and psychopathology. Sometimes the interpretations made are based in some theoretical framework such as psychoanalytic theory, and cognitive tests are integrated with personality tests and interviews to form inferences about personality dynamics, thinking disorders, or symptomatic anxiety or mood states. Interpretation at this level requires training in the theory upon which these inferences are based and development of the skill to blend together information coming from various test material. Within a psychoanalytic framework, some time ago David Rapaport viewed the Wechsler intelligence scales as a measure of ego functions that could provide important information about adaptive and defense mechanisms. For example, in a discussion of diagnosis of neurosis he said: "In this range, indications of extreme anxiety or utter inability to express anxiety – seen either on the Rorschach Test or the Bellevue [Wechsler] Scale, or in the clash of their indications – are usually accurate in pointing to the presence of a maladjustment justifiably labeled neurotic" (1946, p. 463). Here a clinical diagnosis is inferred from an intelligence test independently or in combination with another test. In current practice, clinical psychologists continue to use test batteries including cognitive tests to make inferences about personality characteristics, psychopathology, disordered thinking, and emotional state, such as anxiety level.

In summary, cognitive assessment is used in a variety of applications with the differing applications requiring different competencies. The tests themselves range from uncomplicated procedures that can sometimes be self-administered or given with simple instructions and objectively, quantitatively scored to highly complex instruments that present challenges that require particular expertise to administer properly and score. Some tests only allow for direct, usually quantitative interpretation, while others provide for very elaborate interpretation that can generally only be provided by appropriately trained psychologists. The applications themselves include the traditional ones of identifying mental retardation and educational difficulties, selection and classification in educational, military, and vocational settings, and their use, generally in full batteries, for clinical evaluations of personality and psychopathology. Efforts have been made by test publishers, licensing Boards, and professional societies to regulate application of tests, such that it is conducted in an ethical manner by individuals with appropriate competencies.

9.1.2 Origins of Clinical Neuropsychological Assessment

Establishment of clinical neuropsychology as an independent scientific and clinical discipline has significantly changed the practice of cognitive testing by psychologists. Previously cognitive testing for clinical purposes was conducted by clinical or educational psychologists, who receive as part of their education instruction in the use of intelligence tests, educational tests and various other cognitive tests of specific functions such as memory, language, or perceptual–motor coordination. In the case of intelligence testing, introduction of the Wechsler scales permitted the assessment of intelligence in adults with procedures that were initially meant for children, such as the Stanford–Binet scales. As part of their general practices many clinical psychologists were asked to assess not only patients with the traditional psychiatric disorders, but also patients with physical disorders that produced cognitive impairment as a result of damage to the brain, such as traumatic brain injury or stroke. Elderly patients, who were suspected of having a dementing disorder such as Alzheimer's disease, were also commonly referred. As this pattern of referral emerged, a great deal of research concerning the use of these tests in the assessment of brain-damaged patients appeared. This research was incorporated into clinical psychology training programs, and it became established that clinical psychologists should have a competency in the assessment of brain-damaged patients. Typically, these assessments were conducted using the tests that the clinician used in general practice. They commonly included the Rorschach Test, the Minnesota Multiphasic Personality Inventory (MMPI), the Wechsler Scales, Human Figure Drawings, and a clinical interview. Correspondingly, the prevailing research literature involved studies that used such procedures as the Wechsler scales or the Rorschach Test in assessment of brain damage.

In another area of health-care practice, other clinicians, mainly physician neurologists, were assessing brain-damaged patients for cognitive dysfunction, but with substantially different strategies and instruments. The history and clinical neurological examination were their major instruments, and they were largely concerned with cognitive abilities that could provide evidence of localized brain damage. Thus, often in association with speech-language pathologists, they had a great interest in aphasia which is generally associated with damage resulting from stroke involving particular areas in the left (dominant) hemisphere of the brain. Some physicians, now known as behavioral neurologists, have particular expertise in cognitive disorders that could be associated with specific brain regions. These clinicians had the expertise

needed to examine for aphasia and also for disturbances of perception and skilled movement. Such disturbances, known as agnosias and apraxias, are organized into numerous clinical syndromes and often have well-defined brain pathways. These behavioral neurologists, sometimes characterized as "diagram makers," identified a large number of these syndromes incorporating the behavioral pattern and the brain correlates. For example, there is a syndrome called "alexia without agraphia" in which the patient has lost the ability to read but can write, as demonstrated by the failure to read what the patient has just written.

A group of psychologists developed an interest in these kinds of patients and, generally in collaboration with neurologists, began to study them. This practice represented a departure from the traditional association between clinical psychology and psychiatry, and promoted an alliance with neurology and neurosurgery. Thus, psychologists began to work in neurology and neurosurgery wards in hospitals and collaborated with neurologists and neurosurgeons in research and clinical practice. Because of the nature of their work, these psychologists needed to develop expertise in neuroscience, clinical neurology, and the behavioral neurology of various disorders. Some of them developed particular expertise in particular disorders such as stroke, multiple sclerosis, brain tumors, dementing disorders of the elderly, etc. These individuals did not actually become neurologists but learned much of the knowledge base needed to work clinically or do research with neurological patients. As this process took place, the need became apparent for new testing procedures because the assessment issues associated with these patients were apparently radically different from those that existed for psychiatric patients. The traditional clinical psychological tests might identify depression in a patient who had a stroke, but they could not characterize the behavioral consequences of the stroke itself.

This new application of psychology resulted in the development of what we now call neuropsychological tests. Perhaps the best definition of a neuropsychological test was made anecdotally by Ralph Reitan, who said that it is a test that is sensitive to the condition of the brain. These tests were derived from four major sources; existing cognitive tests of various abilities such as the Wechsler Memory Scale, tests originally in use in research but not extensively in clinical practice such as the Continuous Performance Test, modifications of the behavioral neurological examination introducing standard administrative and quantitative scoring systems, and tests developed initially for use in clinical neuropsychological testing such as the California Verbal Learning Test. Some of these tests were organized into batteries, and we now have a number of standardized neuropsychological test batteries. Others are the same as those regularly used by clinical psychologists, such as the Wechsler intelligence scales, but it has been suggested that when these tests are used as part of a neuropsychological assessment in the context of other tests they are used for different purposes. It was said some years ago by the neuropsychologist John McFie: "It is perhaps a matter of luck that many of the Wechsler subtests are neurologically relevant" (1975, p. 14). In Reitan's terminology that remark could be translated into saying that some of these tests have been shown in appropriate research with brain-damaged patients to be sensitive to the condition of the brain.

When a referral is made for neuropsychological testing, the concern is for documenting and characterizing known or suspected brain dysfunction. The neuropsychologist, aside from describing the patient's cognitive abilities, is expected to make inferences about the relation between the test results and their correlates in brain function. Typically, the questions asked involve presence or absence of brain injury or disease, location, and extent of the brain lesion if present, associations between the test performance and the nature and site of the brain lesion, and predicted course and outcome. These assessments are generally viewed as part of the full

evaluation which might involve a physical examination, taking of a history, and use of various laboratory and neuroimaging procedures. Ideally, the neuropsychologist, neurologist, and psychiatrist should share a common language and body of knowledge in the interests of communication and integrating all of the assessment data obtained.

Cognitive assessment by psychologists has changed in recent years one reason being the emergence of clinical neuropsychology as a specialty requiring a separate set of skills and competencies from what is required for clinical psychology in general. We, therefore, proposed a distinction in the discussion of competencies between cognitive and neuropsychological assessment. The main difference appears to be the emergence of clinical neuropsychology where there is a major concern with the relationship between behavior and associated brain function. It is based on an extensive scientific literature concerning human brain function and to some extent the animal literature as well. However, in order to be competent in any form of psychological assessment the practitioner needs to have a core of knowledge and expertise. The major category of this background is psychometrics. All psychologists who give tests should have a background in test construction, concepts of validity and reliability, standardization and use of norms, associated statistical procedures such as factor analysis, and the importance of standard administration and scoring. Furthermore, clinical psychologists should not be totally ignorant of brain dysfunction, and should be capable of identifying possible neurological disorders during their assessment. Correspondingly, neuropsychologists should not be insensitive to the influence of factors such as depression, anxiety, and malingering on cognitive test performance. There are therefore basic competencies that all psychologists doing assessment work should have as well as specialized knowledge and skills.

9.2   Basic Competencies of the Clinician

As indicated, there are areas of overlap and divergence between competency in cognitive assessment and clinical neuropsychology. However, there is a common core that applies to both groups. One important component is a background in psychological testing, with particular emphasis on the assessment of cognitive function. Development of basic competencies in cognitive assessment may begin at the undergraduate level in courses in psychological testing. A course of this type is generally considered to be important for students with psychology majors. Psychological testing courses generally cover its history, content areas, matters related to test construction, standardization, and psychometrics involving concepts of validity and reliability, and the statistical methods used to establish them. Content areas typically covered include intelligence, aptitude, interest, academic achievement, and personality. If some basic knowledge of statistics is assumed, such as familiarity with correlation and t-tests, more advanced methods may be covered such as factor analysis and scaling methods. There is generally a consideration of theoretical material particularly with regard to the varying theories of intelligence. Whether intelligence is a general ability (g) or a number of special separate abilities remains an important theoretical issue, as does the factor structure of intelligence. Whether accomplished at the graduate level or later on, knowledge of test construction and its scientific basis are perhaps the most important basic competencies psychologists should have to do clinical work with tests.

Competencies at the Master's degree level typically concern actual administration, scoring, and basic interpretation of tests. The psychologist working professionally with a Master's

degree, such as many school psychologists, is expected to be able to competently administer, score, and interpret cognitive tests. During their education, they are generally required to gain substantial supervised practicum experience. In some states, individuals with Master's degrees may be eligible for licensure, although that practice is diminishing. In clinical settings, individuals with Master's degrees and technicians are supervised by licensed psychologists but can still administer and score cognitive tests. The matter of interpretation is more equivocal, but in any event, written reports are typically countersigned by licensed psychologists.

Training in cognitive assessment at the doctoral level varies with the background of the student and the philosophy of the program. Some students already have Master's degrees when they enter their doctoral program and may already be familiar with intelligence and psychoeducational tests. Some students may want to go on to be clinical neuropsychologists and require in some ways substantially different training from those who want to be general clinical psychologists. Different programs have varying views of the importance of assessment with tests in clinical practice, and so formal cognitive testing may not be highly emphasized. There may be some degree of subtle interplay between the controversies that surround intelligence testing in both the public and professional sectors, and that may influence what one learns in graduate school.

In at least the more traditional doctoral programs in clinical psychology, students are expected to achieve a number of specific goals regarding cognitive assessment as follows: (1) They must become capable of administering, scoring, and interpreting individual intelligence tests. The current version of the Wechsler intelligence scales (now the WAIS-IV) (Wechsler, 2008) is the most commonly used instrument, and it is probably fair to require that the student know the WAIS even when there is a preference for other tests, such as the Binet Scales. Basic concepts such as the deviation IQ, the meaning of intertest scatter, the rationale for distinguishing between verbal and performance IQ, the factor structure of subtests and factor analysis-based indices, and sociodemographic adjustment of scores are perhaps the major areas about which students should learn. Development of test norms accounting for relationships between age and education and test performance should be understood. (2) Depending upon the setting in which they work, they should be familiar with some psychoeducational tests. Because of the large variety of such tests, it is not possible to specify which ones, but there should be some capability of assessing reading, writing, mathematics, and more general attentional abilities. Working with adults in nonacademic settings, it is probably most useful to be familiar with a psychoeducational battery that has been well standardized for adults. The Wide Range Achievement Test is probably the most commonly used one (Jastak & Wilkinson, 1984). More specialized tests may be used with adults when there is a current academic or neuropsychological issue. (3) Whether the training program is oriented toward the Boulder "Scientist-Practitioner" or Vail "Practitioner-Scholar" model, some amount of science and research training is maintained, although it may vary in extent from program to program. However, if results of cognitive tests are to be interpreted at a professional level, the psychologist would appear to need some background in cognition. Courses and readings in cognitive psychology are a crucial part of the curriculum, giving the practicing psychologist some basic knowledge of attention, memory, executive abilities, language, and spatial ability domains of cognition. For those seeking a career working with seriously mentally ill individuals, such as patients with schizophrenia, it is also important to have some background in the form of abnormal thinking found among such patients. Basically, a clinical psychologist using cognitive tests should be

able to make some statements about the individual's information processing, and identify areas of intactness and abnormality. In people without mental illness, it is generally possible to identify areas of strength and weakness that may be academically or vocationally relevant, while in seriously mentally ill patients it is usually important to characterize the nature of the thinking disorder.

(4) In addition to intelligence and psychoeducational tests, there should be some knowledge of tests of more specific cognitive abilities. Psychologists in practice commonly use such instruments as continuous performance tests for assessment of attention, tests of memory, notably the Wechsler Memory Scale, and tests of perceptual–motor coordination, such as the Bender–Gestalt Test. There should also be familiarity with ways of assessing functioning with procedures other than formal cognitive tests. A good example is the "Thought Disorder Index," obtained from the Rorschach Test which is a procedure for identifying schizophrenic-type thinking disturbance from interpretation of ink blot patterns (Hunt, Holzman, & Davis, 1983). In general, competence should be developed in the detection of abnormal thinking in conversation and other behavior aside from formal tests. (5) The clinician should be aware of the ecological validity of the tests used. This information is typically derived from comparisons between test scores and functional assessments of everyday living. Commonly asked questions involve the extent to which cognitive tests are predictive of academic or vocational outcomes. In the case of seriously ill psychiatric patients, intelligence tests may be predictive, perhaps to varying extents, of rehabilitation outcome particularly with regard to adjustment to community living.

These basic competencies should be present regardless of whether the psychologist is a clinical psychologist or a clinical neuropsychologist. Basic knowledge of test development, psychometrics, the psychology of cognition, theories of intelligence and related cognitive functions, the psychopathology of cognition, and knowledge of the predictive validity of tests used would appear to form a basic core of competencies for all psychologists doing cognitive assessment work. Differences in competency requirements depend upon specialty differences, most clearly defined in the differences between clinical psychologists and clinical neuropsychologists. However, there are several subspecialties within clinical psychology. Psychologists who work mainly with elderly individuals have to deal with several cognitive assessment issues. There is first of all the nature of the testing materials themselves. Elderly individuals often have visual and hearing difficulties, and may have experienced some deterioration of motor function. Therefore, if the available tests pose problems for elderly individuals with regard to perceiving or manipulating the materials, modifications may be needed to obtain a valid assessment of cognition. Larger letters for reading tasks may be needed, sound level may have to be amplified, or test materials should produce reduced requirements for fine motor manipulation. Similar matters arise in the case of physically handicapped patients, notably individuals who are blind or deaf. Indeed, psychological testing of the blind and deaf has become a specialty area with an extensive literature (e.g., Dye, Baril, & Bavelier, 2007). Regarding cognitive function itself, some tests do not have adequate norms particularly for very old patients, and it often becomes necessary for the tester to make a judgment regarding whether it is appropriate to use a standard adult test or one of the tests that have been specifically designed for use with the elderly. In the case of elderly individuals with substantial dementia, it is often only possible to use a mental status examination, such as the Folstein Mini Mental State Examination (Folstein, Folstein, & McHugh, 1975) or the Mattis Dementia Rating Scale (Mattis, 1988), rather than the Wechsler Scales or other adult intelligence tests.

Psychologists working mainly in academic or industrial settings require certain specialized competencies. If the main purpose of the assessment relates to academic or vocational placement, classification, or counseling, there needs to be specialized knowledge in aptitude, interest, and psychoeducational testing. Severe psychopathology is usually not the major issue with clients in these settings, although the psychologist should be sensitive to its presence when it does occur. However, it is not unusual to find in the population of people who are referred for cognitive assessment in work or school settings people with learning disabilities or adult ADHD. It is now well established that these conditions, previously thought to occur only in children, may persist into adulthood and continue to produce significant disability (Katz et al., 2001).

Cognitive assessment of patients with psychosis is yet another specialty area. While this activity has blended substantially with clinical neuropsychology, thinking disorder in schizophrenia in particular remains a defined area of knowledge and research. Psychologists, who might not get involved in neuroimaging or related neurobiological procedures relating cognitive abnormalities to brain function, often have good reason to evaluate the cognitive ability of patients with schizophrenia. While the standard intelligence and psychoeducational tests are somewhat helpful in such assessments, it is generally more enlightening to utilize one or more of the many tests that have been specifically designed to evaluate thinking disorder in schizophrenia, or that have been extensively researched for that purpose. Probably the most commonly used group of tests of that type is sorting tests, notably the Wisconsin Card Sorting Test (Heaton, 1981). Other sorting tests sometimes used are the Goldstein–Scheerer Tests and the Hanfman–Kasanin Concept Formation Test (1942). Patients with schizophrenia characteristically have a difficulty with abstract reasoning, failing to either form or identify concepts or conceptual rules based on experience. Sorting tests evaluate the ability to classify objects on the basis of development of a rule (e.g., the objects can be divided on the basis of shape or color). Recently, a new battery of tests called MATRICS has been published that constitutes a battery of cognitive tests found by extensive research to be highly sensitive to thinking disorder in schizophrenia (Green & Nuechterlein, 2004). The clinician who works with patients with schizophrenia should be competent to interpret these specialized tests in addition to the standard tests of intelligence and achievement.

Another consideration regarding competence aside from personal experience, knowledge, and education is standards for designating individuals as describing themselves as clinical psychologists or clinical neuropsychologists. This matter is generally dealt with through the establishment of definitions and adoption of those definitions by appropriate administrative bodies. In our case, we consider the definitions of clinical psychologist and clinical neuropsychologist, and their endorsement by the APA. In essence, the process is one of answering the questions "What is a clinical psychologist?" and "What is a clinical neuropsychologist?" This matter of definition has become one of increasing importance since forensic qualification of expert witnesses and granting of clinical privileges in institutional settings are becoming increasingly involved with documentation that the clinician is what she or he says she or he is.

There are two definitions of clinical psychologist, one more administrative and the other more involved with the actual content of the field. The administrative definition is that a clinical psychologist must have a doctoral degree (Ph.D. or Psy.D.) in clinical psychology from an APA-approved or regionally accredited program, and an internship in clinical psychology equivalent to one full-time year in duration. The more descriptive definition for assessment is that clinical psychologists determine the nature, causes, and potential effects of

personal distress, personal dysfunctions, and the psychological factors associated with physical, behavioral, emotional, nervous, and mental disorders. Examples of assessment procedures include interviews, behavioral assessment, and tests of intelligence, aptitudes, and personal characteristics.

The definition of clinical neuropsychologist is somewhat more complicated because of the absence of a consensus in the field, with different constituencies advocating somewhat different definitions. The most succinct definition of those offered is as follows:

▶ A clinical neuropsychologist is a professional psychologist trained in the science of brain behavior relationships. The clinical neuropsychologist specializes in the application of assessment and intervention principles based on the scientific study of human behavior across the lifespan as it relates to normal and abnormal functioning of the central nervous system. (Barth et al., 2003, p. 161)

This definition is obviously quite different from that of a clinical psychologist, and would appear to be more akin to the original Boulder "scientist-practitioner" model than the Vail "practitioner-scholar" model. More elaborate definitions have been published containing more detail about educational requirements, licensure, postdoctoral experience, and the role of Board certification. Recent deliberations involving the neuropsychology societies and the APA Commission on Accreditation have developed the consensus that specialized training in clinical neuropsychology should be at the postdoctoral level following completion of a Ph.D. or Psy.D. in psychology. In the large majority if not all cases, individuals admitted to postdoctoral programs received their doctoral degrees from APA-accredited programs in clinical psychology. In the future it appears that designation as a clinical neuropsychologist will require completion of a 2-year accredited postdoctoral program.

9.3   Expert Competencies of the Clinician

9.3.1   General Considerations

The definition of expertise is a controversial matter, particularly in clinical psychology and neuropsychology. From the standpoint of personal qualifications, the extreme view is that individuals judged to have expert competencies should be Board-certified Diplomates in clinical psychology or clinical neuropsychology. Since only a small percentage of psychologists in these specialties are Diplomates, this view is often challenged and expertise is evaluated with a number of other criteria. Complicating the Diplomate issue further, there is more than one Board, both in clinical psychology and clinical neuropsychology. While only Boards associated with the American Board of Professional Psychology (ABPP) are listed in the Membership Directory of the APA, there are many advocates of other Boards that believe that their credentialing is as rigorous and meaningful as that of ABPP. In clinical neuropsychology, there is an ABPP-sponsored Board (the American Board of Clinical Neuropsychology [ABPP/ABCN]) and an independent Board, the American Board of Professional Neuropsychology (ABPN). The National Register of Health-Care Providers in Psychology lists both Boards while the APA only lists ABPP/ABCN in its Membership Directory.

Expertise in assessment is often defined in terms of referral. Expert clinicians are those recognized as having particular competence in some area, and who have advanced capabilities in working with particularly difficult cases. Thus, when a diagnosis is unclear or the case is

made particularly complex because of a large number of complicating factors, an expert is sought for consultation. The process is somewhat analogous to a general practitioner physician making a referral to a Board-certified specialist. Sometimes there is a hierarchy in which particular specialists have a reputation for being outstanding in their areas. Within psychology, consumers may seek the services of a Diplomate to help assure that they will receive an expert-level evaluation. In forensic matters, there is often a process of "qualifying" expert witnesses, and Board certification is often used to support a witness's credentials.

Expertise is sometimes evaluated by whether or not the psychologist is a Fellow of the APA. APA policy is that Fellowship is an honor given to the members who have made unusual and outstanding contributions to psychology that have a national impact on the field. This policy is observed in both clinical psychology and clinical neuropsychology, although the specific criteria differ. Drawing a correspondence between Fellowship and expert clinical competence is more difficult than is the case for Board certification because Fellowship may be granted for research productivity or outstanding services to the profession. Memberships in honorary societies such as the American Psychopathological Association or the Society for Research in Psychopathology are also indicators of advanced expertise.

Aside from general personal qualifications, expertise may be evaluated on the basis of competence in specialized areas of assessment. These competencies may be divided into methodological, test, and clinical areas.

9.3.2   Methodological Competencies

We can divide this area into two components, one being test construction and development and the other psychometric analysis of tests. The writing of a new test requires a combination of creativity and technical expertise. Writing the test including making up the items requires particular expertise in its content area. Test items may be words, numbers, photographs, geometric forms, or more unique materials such as faces with differing emotional expressions, film clips of interpersonal behavior, odors, or pictures of doors. The creativity of Rorschach was expressed in his test that used ink blots as the content. A part of the Wechsler scales uses cartoons and line drawings. Cognitive tests generally involve words, numbers, geometric forms, and sometimes graphic material such as line drawings. Thus, the test constructor usually has to organize a team of media people who may be commercial artists, photographers, printers, and, more recently, computer specialists. Once a draft test has been designed, there follows the complex task of developing it for use through devising a scoring system and obtaining preliminary data for such purposes as ranking items by difficulty, modifying unsatisfactory items, and performing a large number of psychometric tasks such as scaling, determination of validity and reliability, and standardization in the target population. In current practice, this process can rarely be accomplished by an individual and typically the work is done by a test publisher or individuals under contract to test publishers. The competencies needed to be a test constructor go substantially beyond those needed for a test user, including aspects of creativity, scientific expertise associated with the content of the test, organizational skills, and the technical skills required to do the standardization and numerous psychometric tasks required. Indeed, it seems that a subprofession has been established of test developers who mainly work for publishing corporations whose major job is creating new tests or revisions of established tests.

9.3.3 Psychometric Analysis

There is an established group of psychologists who did not develop new tests themselves, but who are well-known for the analyses they did of established tests. The most prominent component of this group is the factor analysts who used various forms of factor analysis, largely with normal populations, to determine the structure of sets of tests. This group has made a major contribution to theories of intelligence, and the factor structure of multiple subtest intelligence tests remains an important area of inquiry. The major question at one time regarded whether intelligence was a general, global ability (G) or a number of special abilities (s). The belief that it is one or the other has been abandoned, and it is now widely accepted that intelligence is multifactorial, based to a great extent on factor analytic studies of the Wechsler scales done by Jacob Cohen (1952). Intelligence is conceptualized as having a three-factor structure including verbal reasoning, perceptual organization, and attention, sometimes called "freedom from distractibility." More recent formulations have proposed four factors, separating attention into working memory and processing speed. Other theoretical considerations have led to the view that there is "crystallized" and "fluid" intelligence, the former involving preserved information and the latter adaptive problem solving. There are numerous other theories of intelligence, but it would probably be fair to say that most contemporary clinical psychologists use the three-factor model, explicitly or implicitly, most readily evaluated through use of the Wechsler intelligence scales.

Of particular interest to clinicians are the numerous factor analytic studies of different diagnostic groups. The aim here is usually to determine whether the factor structure of the group under study is the same as that found in the normal population. For example, do individuals with schizophrenia have the same organization of abilities as normal individuals? In recent years this work has been supported by application of confirmatory factor analysis that permits testing of specific hypotheses about factor structure (Allen et al., 1998).

Individuals doing this kind of work typically have substantial competencies in cognitive psychology, mathematics, and advanced statistics. The clinician, who may never do a factor analysis, should nevertheless possess knowledge of the work done with it in the study of cognitive tests. Such work helps provide an understanding of what the tests measure, which would necessarily be pertinent to clinical evaluation.

9.3.4 Test Competencies

Some psychologists have particular expertise for some particular test or test battery. At the most advanced stage either they invented the procedure themselves or published extensively about it, often in the form of books. In personality assessment, we know of many books concerning the Rorschach or Thematic Apperception Test, or the MMPI. In cognitive testing there is similar material including books written about the Bender–Gestalt Test, the tests developed by Arthur Benton and the Goldstein–Scheerer tests (Goldstein & Scheerer, 1941). In clinical neuropsychology there is a voluminous literature concerning the Halstead–Reitan Battery. It has that double name because Ward Halstead originally developed the battery and his student Ralph Reitan supplemented it and did major research demonstrating its clinical application. Thus, while Reitan published studies of patients with numerous disorders, it is probably fair to say that his major reputation lies in his work with the Halstead–Reitan Battery. The same point

can be made for David Wechsler who while doing other work remains most recognized for his intelligence scales.

In clinical practice, referrals are sometimes made to clinicians because they are known to have expertise in some particular test or battery. That is, the consumer specifically wants her or his patient to get the Halstead–Reitan Battery or some specific battery of psychoeducational tests. In clinical neuropsychology, there are in fact clinicians who use the Halstead–Reitan Battery only. Expert status in a particular test or battery has become problematic with regard to competency because of training issues that have been raised. It is assumed that when training and the period of supervised experience have been completed, the psychologist can independently use the standard assessment procedures in everyday practice, without the necessity of further supervision or training. However, when expertise is claimed in some particular procedure, especially when that procedure was not taught in graduate school or postdoctoral training, a question may be raised about competence and qualifications. Should a clinician set up an office or laboratory for some procedure in which expertise is claimed without specific training in that procedure? In neuropsychology, should a clinician use the Halstead–Reitan Battery, the Luria–Nebraska Battery, or the Boston Diagnostic Aphasia Examination without specialized training in these procedures? A proposed solution to the problem has been use of continuing education methods, notably workshops in which these procedures are taught by established authorities. For example, workshops have been available in the Halstead–Reitan Battery for many years. There now seems to be a consensus that these specialized procedures should not be offered by otherwise well-qualified psychologists who have not, at least, received such education. Other critics have stated that workshops are not sufficient, and that procedures like the Halstead–Reitan Battery or comprehensive aphasia examinations should not be used by individuals who do not have the basic neuroscience background to understand the conditions being diagnosed. As a recommendation, it could be suggested that clinicians claiming expertise in specialized procedures should assure themselves that they are working within their scope of practice, and that they have appropriate experience and training for using those procedures. However, what is appropriate appears to remain a controversial matter.

9.3.5 Clinical Competencies

Some clinicians have particular expertise with certain kinds of patients. Some are highly competent in assessing patients with schizophrenia, some with posttraumatic stress disorder (PTSD) patients, and some with patients with physical disabilities or other diagnostic or conditional characteristics. In this case, the referring consumer sends the patient to the clinician not so much to receive particular tests but because the clinician is particularly knowledgeable about, or sensitive to, the disorder the patient has and can work effectively with the patient. Some clinicians, mainly those who work in specialty clinics, only see patients with the same disorder or who are being evaluated for the same disorder. In these cases, knowledge about the disorder is an obvious area of competency, and the clinician should have extensive experience with patients with the disorder. In the area of cognitive assessment of psychiatric patients, there would be particular concern about serious mental illnesses, particularly schizophrenia, in which disorders of thinking are cardinal symptoms. Individuals with autism also have a unique cognitive profile that the clinician should be able to detect. Clinicians who have worked with children and adults with autism should recognize this characteristic profile, while clinicians

who have not been around people with autism much might miss it, or might identify it but not associate it with the autism.

Competency in assessment of some particular group relies heavily on experience. While efforts have been made to generate prototype cognitive profiles for different diagnostic groups they have been mainly unsuccessful. Taking schizophrenia as an example, adult individuals with schizophrenia may have IQs that essentially span the entire range of intelligence, and there does not seem to be any characteristic subtest profile. However, even with average or above intelligence, they may show clearly identifiable abnormalities on tests of conceptual ability, such as the Wisconsin Card Sorting Test. Results of this test also span a considerable range, and there is a small group of individuals with schizophrenia who produce a normal performance on this test, although that performance may be reduced relatively to a previously higher level. In essence, schizophrenia is a cognitively heterogeneous condition (Palmer et al., 1997), and cognitive tests really cannot be used to determine if one is schizophrenic or not. They are used differently by experienced clinicians in regard to such matters as prediction of functional outcome, level of competency, and rehabilitation planning.

Some clinical neuropsychologists may only evaluate patients with known or suspected brain damage. They may use different tests or batteries, but the purpose of the evaluation is the same. In some cases, the practice is quite specialized, as in the case of clinicians who work on a stroke or neurosurgical service, or more general as with clinicians who have an office practice. The competencies between these two situations are somewhat different with the more specialized clinicians having to know a great deal about the patients they are serving. For example, working on a stroke unit requires that one knows about aphasia, specific constructional disorders, and movement disorders. The clinician in office practice must have knowledge of a variety of disorders, but perhaps with more of an emphasis on head injury, developmental disorders, and disorders of the elderly. Competencies therefore need to be "fine-tuned" to the pattern of referrals the clinician receives. Characteristics of supervised experience would appear to be important here. Training on a surgery ward in an acute care hospital would seem to be poor preparatory training for working in an office practice in the community, and the reverse would also be true.

9.4 Substantive Competencies for Cognitive Assessment of Adults

9.4.1 Clinical Cognitive Assessment

Here, we will consider some of the specific competencies typically needed for practice by clinical psychologists,

9.4.2 Intellectual Assessment

Probably the most common form of cognitive assessment done by clinicians is intelligence testing. Doctoral-level training should include course and practicum experience in intelligence testing, and intelligence testing should be done with patients during the internship. Course work should consider theories of intelligence, psychometrics, and descriptions of the individual

and group intelligence tests available. Clinical training involves knowledge of intelligence of various diagnostic groups including the traditional area of mental retardation and extending to learning disabilities, other developmental disorders, and psychiatric disorders. The role of socioethnic and gender considerations should be covered. While several individual test batteries are available, the common use of the Wechsler scales would appear to make it fair to require all clinical psychology graduate students to be familiar with it. The clinician may choose not to do intelligence testing but if she or he does, there should be some knowledge of the Wechsler scales even in the rare cases in which it is not used in practice. Even if it is not used, there is the matter of communicating with colleagues who are likely to use it. As indicated, high levels of competency in intelligence testing are associated with psychometric expertise, an unusually good understanding of particular disorders, or a high skill level in the kinds of diagnostic assessments that are associated with clinical neuropsychology. The skilled clinician should also be able to productively integrate intelligence test results with results of personality, interest, and achievement tests.

9.4.3 Psychoeducational Tests

In the past, competencies in the use of educational achievement tests was only thought to be pertinent for psychologists working with children, but several considerations now encourage such competencies in working with adults. First, it is now well established that learning disability may persist into adulthood, and it is often of value to assess adults for that condition. Second, academic achievement level has been shown to be a reasonably good predictor of premorbid level in individuals who become mentally ill or cognitively impaired because of structural brain damage. In schizophrenia research, there has been extensive use of achievement tests as predictors of premorbid level, in combination with other cognitive tests. It is also useful to establish literacy level for adults for counseling purposes. The difficulty in the past is that there were not psychoeducational tests normed for adults, but that is no longer the case. There are now "wide-range" tests available, the most popular one being the Wide Range Achievement Test (WRAT) (Jastak & Wilkinson, 1984) which assesses reading, spelling, and arithmetic and is usable across the adult age range. There is also the Wide Range Assessment of Memory and Learning (WRAML) (Sheslow & Adams, 1990) which may be used up to age 17. Clinical psychologists should have such tests in their repertoire.

9.4.4 Cognitive Tests

There is a large number of tests of specific cognitive functions, but a relatively small number of them are used by clinicians for assessment of patients. Probably the most commonly tested areas are abstract reasoning or executive ability, attention, and memory. These tests have some overlap with intelligence tests but differ in that they focus on some specific ability in detail. The most commonly used of the abstract reasoning procedures is the Wisconsin Card Sorting Test. It involves conceptualizing a principle based on exposure to a series of stimuli, in this case colored geometric forms that can be sorted by size, color, or number. A crucial part of the test assesses the person's ability to shift concepts when the contingencies change (e.g., color becomes relevant replacing shape that was previously relevant). Verbal abstract reasoning may be tested

with proverbs or analogy tests. Tests of abstract reasoning are mainly used in detecting structural impairment of brain function and thinking disorder in schizophrenia. Its assessment is a key component of any cognitive assessment of patients being evaluated for brain damage or schizophrenia.

Tests of attention are of particular value in assessment of individuals with significant problems involving distractibility, inability to concentrate, and impulsivity. While it can be evaluated with the arithmetic and digit span subtests of the Wechsler scales, when a more detailed analysis of attention is needed, as in the evaluation of a client for ADHD, it is desirable to use a continuous performance test (CPT) or related procedure. The CPT involves measuring reaction time usually to stimuli viewed on a screen under varying conditions. For example, the client may be asked to push a button only when the letter A appears or when an A is followed by an X. There are several published tests of this type (e.g., Conners, 2000), and psychologists who see ADHD patients in particular should be competent to use them.

9.4.5 Formal Testing of Memory

Assessment of memory is important for several areas of assessment including identification of neurologically based amnesic disorders, evaluation of mental deterioration, detection of memory difficulties associated with mood or anxiety disorders, and claims of memory failure that require documentation, sometimes in association with litigation. The most widely used adult memory tests are the Wechsler Memory Scale and the California Verbal Learning Test. The Wechsler Memory Scale contains both verbal and visual memory sections, and has recently been expanded, now constituting what may be described as a memory battery. Clinical psychologists should have the capability of interpreting memory tests on the basis of knowledge of the psychology of memory. That is, concepts such as immediate, short-, and long-term memory, working memory, encoding, storage and retrieval, differences between verbal and visual or spatial memory, and retroactive and proactive interference should be understood by the psychologist and used in interpretation of memory tests. Clinically, in combination with an intelligence test, there should be the capability of evaluating memory problems of the elderly and patients who suffered from traumatic brain injury. Patterns of recovery and deterioration should be assessed as appropriate.

9.5 Substantive Competencies in Clinical Neuropsychology

We have taken the position that cognitive assessment and clinical neuropsychology are two different specialties, although they may both use some of the same procedures. In making the distinction, we have the benefit of the Houston Conference, which like the Boulder and Vail conferences before it for clinical psychology presented a description of what ideally should make up the training of clinical neuropsychologists. As indicated, clinical neuropsychology was designated as a specialty in 1996 and there is an APA Division of Clinical Neuropsychology with almost 4,400 members. According to Houston Conference standards education at the doctoral level to become a clinical neuropsychologist includes: (1) a generic psychology core including statistics, methodology, learning, cognition, perception, social psychology, biological basis of behavior, life span development, history, and cultural and individual differences

and diversity; (2) a generic clinical core including psychopathology, psychometric theory, interviewing and assessment techniques, intervention techniques, and professional ethics; (3) foundations for the study of brain–behavior relationships including the neurosciences of basic human and animal neuropsychology, functional neuroanatomy, neurological and related disorders (clinical neurology) including etiology, pathology, course, and treatment, and non-neurological conditions affecting central nervous system (CNS) function; (4) neuroimaging and other neurodiagnostic techniques, neurochemistry of behavior including psychopharmacology and neuropsychology of behavior; (5) practice of clinical neuropsychology including specialized neuropsychological assessment and intervention techniques, research design, and analysis in neuropsychology, professional ethics and issues in neuropsychology and practical implications of neuropsychological conditions.

It is now the general consensus that the formal educational and experiential requirements for practice require the addition of 2 years of postdoctoral training following completion of a Ph.D. or Psy.D. doctoral program. While not specifically stated, most students going on to this residency period have doctoral degrees in clinical psychology from APA-accredited programs. An organization has been formed that coordinates the activities of the postdoctoral programs called the Association for Postdoctoral Programs in Neuropsychology (APPN). The Houston Conference standards contain elements that would be important for both clinical psychology and clinical neuropsychology, which are included mainly in the generic core items. The major difference appears to be the neuroscience items. Clinical neuropsychologists are expected to have high levels of expertise in brain function and pathology. Current training standards recommend that this expertise should be gained with formal instruction as well as on-the-job experience. Student clinical neuropsychologists are expected to take courses in neuroscience, which may include functional neuroanatomy, neuropathology, pharmacology, and various aspects of neurobiology which might include neurochemistry, neurophysics, and neurophysiology. In recent years the study of genetics has become increasingly important. Course work or supervised experience should provide a background in neuroimaging, such that the student learns about magnetic resonance imaging (MRI), computed tomography (CT) scanning, and other neuroimaging procedures. Individuals without this background generally do not have the competencies to relate behavioral data to their associations with brain function and pathology. In earlier generations, clinical psychologists were usually limited to inferences concerning presence or absence of "brain damage" or to distinguishing between neurological and functional disorders. It is noted that during those previous generations there was the commonly held belief that such disorders as schizophrenia and autism were functional conditions and distinguishable for that reason from the "organic brain syndromes" based upon brain disease or injury. That view is no longer viable, and the current common wisdom has changed to the view that disorders such as schizophrenia and autism are neurobiological disorders with possible genetic components. Therefore, clinical neuropsychologists, while still concerned with the matter of presence or absence of brain pathology, are largely involved in determining relationships between behavioral, neuropsychological assessment findings and status of the brain including location of damage, type of damage, and system that might be involved.

Another major difference between clinical psychologists and clinical neuropsychologists has to do with practice patterns. While some neuropsychologists practice in psychiatric settings, large numbers of them practice in general medical facilities, particularly in neurology, neurosurgery, and geriatric departments. The assessment component of these practices generally involves the use of specialized neuropsychological tests or test batteries. Tests used generally

include some procedures that are not neuropsychological tests with regard to detection of status of brain function. These relatively neuropsychologically insensitive tests are used to help establish baseline functioning or premorbid status, providing an assessment of how the patient functioned before onset of the brain disorder. Thus, for example, it is often desirable to administer the entire Wechsler intelligence scale because while some of the subtests are quite sensitive to brain dysfunction some are not, thereby providing baseline information.

The clinical neuropsychologist is expected to be competent at neuropsychological test or test battery interpretation, although there are a great many such tests in the literature and the choice of tests depends upon the training and orientation of the neuropsychologist. As a general consideration some use a "fixed battery" in which the same tests are given in the same way to all patients, while some use a "flexible" battery in which individual tests are selected on the basis of information in the clinical history or the referral question. Often the method learned during doctoral training or the internship is what the clinician carries into practice. However, all clinical neuropsychologists are expected to be competent in some systematic method of performing a neuropsychological assessment. Within that framework, any degree of claim of competence at some particular method of assessment should be supported by the appropriate training. If one uses the Halstead–Reitan Neuropsychological Battery, its use in practice should be supported by training and ideally supervised experience in its use. If one does assessment online during neuroimaging, appropriate training to do so should have taken place. This training may take place in graduate school or during the internship or residency, but practicing clinicians often develop new competencies through continuing education courses or workshops, or through working with a competent colleague for a period of time.

The considerations raised here are not mandatory, and we know of no specific licensure or other legal requirements that limit the use of the term clinical neuropsychologist to those who have the training and qualifications described above. The Houston Conference standards have been described as aspirational and not a set of policies that would be immediately implemented. However, it has become increasingly difficult to meet eligibility standards for Diplomate status without postdoctoral training, and many institutions recruiting neuropsychologists state in their advertisements that they will only consider individuals who meet Houston Conference standards.

This matter is associated with the controversial issues of the distinction between a proficiency and a specialty. A proficiency is a specific skill in an area within a specialty. For example, a clinical psychologist may have a proficiency in the MMPI obtained through education in combination with clinical experience. Individuals who attend workshops that qualify for APA-approved continuing credit and apply what they have learned in practice may claim to have proficiency in the area covered by the workshop. A specialty is a broad area of competence that defines the entire scope of one's professional practice. One can have numerous proficiencies within a specialty (e.g., a clinical psychologist can have a proficiency in the MMPI). It has been argued by some that clinical neuropsychology is a proficiency within clinical psychology. An established clinical psychologist can become proficient in clinical neuropsychology through continuing education, usually involving workshop attendance, reading, and supervised experience. Within clinical neuropsychology before its establishment by APA as a specialty, it was the only means available, but during the debate concerning whether it should become a specialty, the argument was made that it should remain within clinical psychology as a proficiency. Ultimately the view that it should be a specialty prevailed, but problems remained.

There were apparently some clinical psychologists who became proficient in an area, for example, administration and interpretation of the Luria–Nebraska Neuropsychological Battery, through attendance at a workshop and associated reading and experience. Other psychologists criticized this practice, indicating that many of these individuals did not have the background in neuroscience and neuropathology described above to competently do neuropsychological assessment. Furthermore, there were more traditional clinicians who expressed the view that any practicing clinical psychologist should have the skills to perform a competent assessment of brain-damaged patients. This dilemma persists, with no mandatory requirements for designation as a clinical neuropsychologist and insufficient time to allow for graduation of individuals with doctoral degrees from APA-accredited programs in clinical neuropsychology. Establishment of certifying Boards, the Houston Conference, and current efforts to produce written standards of practice are now under way, but they remain works in progress (AACN, 2007). At a local level, granting of clinical privileges and defining scope of practice also may contribute to the process of developing more, well-defined competencies.

9.5.1   Transition from Basic Competencies to Expert

Several forces appear to be acting to produce rapid changes in how competency is evaluated in psychology. There are general matters, such as the movement toward evidence-based practice, the growth of clinical psychology through the establishment of the still new professional schools, and the increased presence of psychology in forensic work. The growing movements toward obtaining informed consent from clients, requirements concerning licensure, clinical privileges, and scope of practice have also played roles. Within the field of cognitive assessment, we have tried to show how Draconian changes in the field have accompanied the rapid growth of clinical neuropsychology. Change seems inevitable as graduates of professional schools and specialized programs in clinical neuropsychology account for increasing proportions of psychologists in clinical practice. The APA and the examining Boards are becoming increasingly concerned with the matter of standards of practice, and are active producing documents in that area stating policy and goals.

In general, there appears to be a trajectory in the direction of increased emphasis on evidence-based practice in both the treatment and assessment areas. Cognitive assessment has always had a tradition of quantitative evaluation, but now there is an increasing concern with ecological as well as psychometric validity regarding the capacity of tests to predict adaptive behavior in the environment. Cognitive tests are now commonly used in forensic applications and clinical trials, thereby creating a need for clinicians to develop competencies in these areas (Larrabee, 2007). Particularly in the forensic field, there is a growing concern with malingering, and evaluating how to determine whether the client is exerting her or his best effort, and special tests and procedures have been developed for this problem. Clinicians are now expected to make reasonable judgments about whether their clients were feigning illness or not doing their best on tests. New tests and procedures derived from existing tests have been developed to deal with that matter, and it is assumed that especially in forensic applications psychologists are competent to use these methods. Extensive research on malingering has been published in recent years.

Use of cognitive testing in clinical trials of medications and other treatments has become more common, leaving the field with the now widely recognized practice-effect problem.

Many cognitive tests are not repeatable because after taking the test once and learning the right answers, subsequent testing may be spoiled. A body of literature has emerged identifying these effects and devising methods to reduce them. Clinical trials have always been required for new medications, but the emphasis on evidence-based treatment has generalized its use to other treatments. Repeated testing has become an important part of treatment monitoring. Two approaches have been taken to the problem, one involving statistical correction and the other identification or development of tests that are resistant to practice effects. An example of the latter approach is the development of MATRICS, a cognitive assessment procedure specifically designed for clinical trials with patients with schizophrenia (Green & Nuechterlein, 2004). The subtests of MATRICS were chosen not only because of their sensitivity to thinking disorder in schizophrenia, but also because they were resistant to practice effects. For those reasons, MATRICS will hopefully be a good procedure for clinical trials with schizophrenia patients. Future psychologists involved in the monitoring and evaluation of treatment will need to develop competencies in the management of practice effects.

There appears to be a trend in intelligence and other cognitive testing to associate test materials with appropriate aspects of cognitive theory. Thus, on the Wechsler scales we have gone from the distinction between verbal and performance intelligence to the most recent edition of the scale (Wechsler, 2008) in which there is now consideration of those constructs as well as attention, working memory, and processing speed. Specific subtests are now frequently interpreted in terms of specific cognitive processes. For example, on Block Design the distinction may be made between synthetic errors in which there is difficulty maintaining the contour of the block pattern and analytic errors in which the total pattern cannot be divided conceptually into separate blocks. Another example is the California Verbal Learning Test from which scores that are based upon constructs from the psychology of memory may be derived. For example, the effects of retroactive interference can be evaluated or characteristics of the learning curve can be described. It is probably fair to say that psychologists doing cognitive assessment will have to gain increasing competence in relating test results to pertinent cognitive theory.

At the time of this writing clinical neuropsychology is a new specialty, and it is not now possible to point to an established structure of training programs and patterns of practice that exist for clinical psychology. One might say that the game plan is there, but it is far from implementation.

Goals already achieved include establishment of several membership societies, creation of an extensive research literature contained in part in a number of neuropsychology journals and numerous books, recognition by the APA of clinical neuropsychology as a specialty area, drafting of educational standards based on the Houston Conference, establishment of Diplomate Boards, and establishment of over 50 postdoctoral training programs at various hospitals and medical schools throughout the country. The proceedings of the Houston Conference, in particular, provided at least a working statement of the competency requirements for describing oneself as a clinical neuropsychologist. The postdoctoral programs have been graduating people for some time who have begun practice.

A key remaining problem is the absence of APA accreditation of the postdoctoral programs. While it is possible to obtain it, several obstacles appear to have prevented its occurrence except in a very small number of programs. Currently, clinical neuropsychologists are often hired by institutions that only employ APA-accredited graduates as clinical psychologists;

most of the graduates of the postdoctoral programs have an APA-accredited Ph.D. or Psy.D. degree in clinical psychology. While the APPCN, the organization of postdoctoral programs, has rigorous standards for admission to programs and their content, it does not have the status of an official accrediting body. Thus, competency standards are not yet mandatory, but strenuous efforts have been made to promulgate appropriate standards through various channels. Another problem involves sheer number since it will be a long time before the journeyman clinical neuropsychologist in the field will always have formal postdoctoral training in clinical neuropsychology. Most clinical neuropsychologists in practice at present gained their competence between a combination of predoctoral education and postdoctoral continuing education, generally involving course, workshops, reading, consultation with colleagues, and practical experience.

The matter of evaluating competency on the basis of achieving Diplomate status is problematic, particularly in recent years when there has been a proliferation of Boards, several of which accredit psychologists who do assessment work. The Boards have their advocates and critics, and there appears to be a continuing rivalry among them. Within assessment, there are the two neuropsychology Boards (ABCN/ABBB and ABPN), the ABPP clinical psychology Board and the American Board of Assessment. Membership in Boards appears to be increasing, but it is a matter of conjecture if large numbers of practitioners will become Board-certified in the future. Some Boards have been characterized as "Vanity Boards," having minimal admission requirements, and the public may be confused about which Boards actually represent exceptionally high levels of competence. The Board issue remains problematic for the field, and it is probably not wise to view Board certification as a sole criterion for competence or for expert status (Goldstein, 2006).

9.6   Summary

In summary, the psychologist of the future involved in cognitive assessment will be a psychologist trained in the scientist-practitioner model with a Ph.D. degree, the practitioner-scholar model with a Psy.D., or a clinical neuropsychologist with postdoctoral training and expertise in brain function. Competencies vary among the three, but there appears to be a common core of increased concern with evidence-based practice, maintenance of ethical and professional standards that define scope of practice, and, in our opinion at least, an increased concern with the scientific basis of one's practice. Areas of increased concern in recent years have been the ecological validity of cognitive tests, malingering and reduced effort, and the use of repeated cognitive testing in clinical trials. Future psychologists doing assessment work should be trained in these areas and are likely to be expected to have competencies in them.

10 Cognitive Assessment with Children

Jennifer R. Bailey · Alan M. Gross

Abstract: The aim of this chapter was to provide a comprehensive overview of the process of child cognitive in children. Following a brief overview of the area, basic clinician competencies were discussed. The four core areas of clinician competency outlined by the APA task force were delineated. These areas include having a basic understanding of psychometric theory; knowledge of ethnic, racial, cultural, gender, age, and linguistic variables; knowledge of how to test individuals with disabilities; and supervised experience. Following this brief discussion, an example of a basic psychoeducational test battery was explored. Test administration guidelines, test selection, and test interpretations were discussed. Additionally, suggestions were provided for enhancing rapport with the child and increasing the readability of the written assessment report. An overview of a typical assessment report was also provided. This example offered a broad picture of the assessment process, beginning with identifying the referral question, the child's background (general, educational, family history, medical background, and psychological factors), behavioral observations, and presenting the test results. A discussion on clinician competency in ethnic and cultural issues, gender and age, and linguistic variables was also offered. Another section of the chapter highlighted factors associated with the development of expert assessment competencies. Clinician competency was explored in the context of the examination of test batteries for several of the most common types of child assessments. The section on expert competency ended with a trajectory for obtaining the necessary skills to proficiently work with children. Finally, suggestions concerning how best to provide the training clinicians need to achieve competency were explored.

10.1 Overview

Cognitive assessment is an important component of diagnosing learning and behavior problems in children. Intellectual deficits and learning disabilities (LDs) may have an adverse effect on a child's ability to comprehend and retain information (Krishnamurthy et al., 2004). In addition to diagnosing learning and behavior problems, cognitive assessments also play an important role in academic placement decisions (e.g., special education, gifted programs, etc.) (Krishnamurthy et al., 2004; Sattler, 2008). Assessment is a method that allows teachers, parents, and clinicians to gain an understanding about a particular child's capabilities in order to facilitate informed (academic and training) decisions (Sattler, 2008). Most frequently, assessments are used for evaluating the progress of children's academic/cognitive development. Teachers and parents may request testing to identify if a child has a specific cognitive or learning deficit (such as a reading or LD). Intellectual and achievement tests provide a context through which a child's strengths and weaknesses can be ascertained and are used frequently with school-aged children in order to determine if they meet the requirements for additional special school services or placement into gifted programs.

The need for clinicians with clinical competency in cognitive assessment of children is great due to the number of school-aged children in USA receiving Individualized Education Programs (IEPs). According to the National Center for Educational Statistics (2007), approximately 13.5% of children in USA between the ages of 3 and 21 were provided with special education services through the Individuals with Disabilities Education Act (IDEA) for various LDs and other health-related problems. Thus, approximately 6,686,000 children during the 2006–2007 school year participated in some form of psychoeducational testing.

According to the American Psychological Association (APA, 2000, p. 7), psychological assessment can be defined as a "conceptual, problem-solving process of gathering dependable, relevant information about an individual, group or institution to make informed decisions." In 2000, an APA task force outlined basic assessment competency guidelines. The guidelines suggested core skills necessary for ethical use of testing materials and qualifications for specific areas of testing. The basic skills are the fundamental abilities thought to be relevant and necessary for the administration and interpretation of all types of assessment tools. The Task Force on Test User Qualifications (TFTUQ) emphasized that these guidelines are of particular importance for clinicians using standardized assessment instruments for evaluating ability, achievement, and intellectual functioning of a specific population (APA, 2000). A standardized assessment tool is any form of measurement in which the intellectual, behavioral, and psychological characteristics of an examinee are obtained using a standardized method (APA, 2000).

The goal of this chapter is to provide an overview of clinician competency in the area of cognitive assessment of children. The APA task force delineated four areas of core knowledge and skills necessary for basic test-user competency. These skills include having a basic understanding of psychometric theory; knowledge of ethic, racial, cultural, gender, age, and linguistic variables; knowledge of how to test individuals with disabilities; and supervised experience. In addition to examining expert competencies, suggestions concerning how to best provide the training that clinicians need to achieve competency will be explored.

10.2 Basic Competencies

10.2.1 Psychometric Theory and Measurement

Psychometric theory and measurement provide the foundation from which psychological tools are developed. The psychometric properties of an instrument outline the basic structure of the instrument and provide a key for understanding the psychological constructs being measured (Cohen & Swerdlik, 2005). A benefit of having a basic foundation in test theory is that the knowledge of psychometric theory allows clinicians to have a comprehensive understanding of the measurement tools they use (e.g., item construction, item discrimination, etc.). It is important for clinicians to have a basic understanding of how the test items on the measure were derived as well as an awareness of item parameters. Item parameters include knowledge of item difficulty, item discrimination, and examinee guessing on items (APA, 2000).

It is important for clinicians to understand the nature of test development and what abilities the instrument is designed to assess. According to the APA task force, clinician competency in this core area includes knowledge of (1) descriptive statistics, (2) reliability and measurement

error, (3) validity and meaning of test scores, (4) normative interpretation of test scores, (5) selection of appropriate test(s), and (6) test administration procedures.

10.2.1.1 Descriptive Statistics

Competency in test administration and interpretation requires an understanding of descriptive statistics. Basic concepts such as means and standard deviations play an important role when comparing a child's scores to their normative peer group. Statistics such as correlations are often used to explain the relationship between intelligence test subtest scores. Additionally, knowledge of frequency distributions, characteristics of the normal curve, statistical concepts such as mean, median, mode, variance, standard deviation, and scale score transformations are important pieces of statistical knowledge vital for clinical success in the area of cognitive assessment of children (APA, 2000). The protocols used to score the various measures of intelligence are based on the above-mentioned statistical concepts. Standard deviations are used to determine the area under the normal curve where the child's performance fits (such as above-average or below-average intellectual abilities). Knowledge of scaled scores also allows for the child's percentile rank to be determined. For instance, on the Wechsler tests, the scaled scores are associated with a particular percentile rank which then allows for a suggested qualitative description for each of the scaled scores to be provided.

10.2.1.2 Reliability and Measurement Error

A benefit of understanding reliability and measurement error is that it allows clinicians to have a more comprehensive understanding of the instrument that they are using. Reliability provides an estimate of how accurate the test is at measuring a child's abilities from one testing time to another (Cohen & Swerdlik, 2005). Knowledge of instrument reliability is of particular importance in academic settings where children may need to have their academic skills assessed over a number of years. Similarly, measurement error provides clinicians with a framework from which they can understand the meaning of a given set of scores. The measurement error sets the upper and lower boundaries for a set of scores, allowing the clinician to provide the best estimate of the child's intellectual and/or academic abilities (APA, 2000).

10.2.1.3 Validity and Meaning of Test Scores

The validity of a particular assessment tool begins with the test makers during the construction of the instrument (APA, 2000). Construct validity reflects the evidence supporting the use of a given measurement tool for a particular psychological construct (Cohen & Swerdlik, 2005). That is, validity provides evidence supporting the notion that an instrument measures what it intends to measure. Competent clinicians must be able to evaluate whether assessment data accurately reflect a child's skills. Based on the skills outlined by the APA task force, competent clinicians must be able to understand the various sources

associated with a given test's validity and how the different sources of evidence influence the meaning of a particular test's set of scores.

10.2.1.4 Normative Interpretation of Test Scores

All standardized tests are normed by age group. Test norms provide a description of a set of scores within a particular population. As an example, the Wechsler Intelligence Scale for Children (WISC) was standardized on 2,200 children who were selected to be representative of children in the USA (Sattler, 2008). Standardization of intelligence and achievement tests by age groups allows for the consideration of developmental abilities. Performance expectations for each of the different tests (subtests) are based on what is developmentally appropriate. For example, children between the ages of 3 and 7 would not be expected to complete the same subtest items as a 13-year old.

Knowledge of how each child's individual test scores differ from those of the normative group form the basis on which clinicians identify intellectual strengths and weaknesses. Each time a set of test scores is to be interpreted or a particular assessment instrument is selected for use, clinicians must consider the descriptive characteristics of the normative group (i.e., age, gender, ethnicity, and region).

10.2.1.5 Selection of Appropriate Test(s)

As mentioned by the APA task force, competent clinicians must be able to select appropriate instruments. Clinicians must have knowledge in how to select the most appropriate version of a test or the most appropriate test for a specific purpose. The clinician's knowledge of basic test theory should form the basis of selecting the most appropriate test form.

The basic starting point in the assessment process is the referral question. Serving as the foundation on which the clinician bases the selection of testing materials, it provides information on the end goal of the assessment (Sattler, 2008). When reviewing the referral question, it is the responsibility of clinicians to make certain that they have a comprehensive understanding as to what is hoped to be gained from the assessment. A great way to determine the end goal is to ask the referring source (Sattler, 2008). For example, in a basic LD assessment, the most widely used test would include an intelligence quotient (IQ) and achievement test, along with parent and child interviews. However, if there is also a question concerning reading ability or reading difficulties, the administrating of a supplementary test of reading (e.g., Nelsen Denny) can help to specify the nature of the problem.

As just noted, the referral question along with the child's age, verbal abilities, developmental level, and psychometric considerations influence the instrument selection process. Provided below are examples of assessment instrument choices for a common referral question associated with the cognitive assessment of children.

Basic Psychoeducational Test Batteries

Basic psychoeducational assessments are designed to establish estimates of a child's intellectual and academic abilities. Typically in this type of assessment an intelligence test (e.g., the Wechsler scales: Wechsler Preschool and Primary Scale of Intelligence-Revised (WPPSI), Wechsler

Intelligence Scale for Children-Fourth Edition (WISC-IV), and Wechsler Adult Intelligence Scale-Third Edition (WAIS); Woodcock Johnson Test of Cognitive Skills-Third Edition (WJIII COG)), an achievement test (e.g., Wechsler Individual Achievement Test-Second Edition (WIAT-II), Woodcock Johnson Test of Achievement (WJ-III ACH)) as well as a clinical interview, behavioral rating scales, and other tests selected based on the child's presenting problem are administered. Additional tests of memory (Wechsler Memory Scale (WMS)), concentration (such as the Learning and Study Strategies Inventory (LASSI; Conner's Continuous Performance Test (CPT-II); Barkley Attention-Deficit Hyperactivity Disorder (ADHD) scales parent and teacher forms), or various other self- report measures (Beck Depression Inventory-II (BDI-II); Minnesota Multiphasic Personality Inventory-Adolescents (MMPI-A); Behavior Assessment System for Children-Second Edition (BASC-2)) may be administered in order to provide an accurate picture of the child's strengths and weaknesses in regards to the referral question.

10.2.1.6 Test Administration Procedures

In order to avoid compromising the integrity of assessment instruments, clinicians must be able to follow the standardized procedures outlined in the test's administration manual. In addition to being familiar with the administration procedures (e.g., following reversal and stopping procedures on a given subtest when a specific number of items have been missed; not divulging information about the actual answers, methods for scoring each item), procedural requirements also include maintaining the confidentiality of test information (i.e., test security).

The APA considers competency in basic test administration procedures an essential element of clinician competency. Proficiency in test administration must be more broadly defined than simply following standardization procedures during the administration of selected tests. As emphasized in this chapter, the assessment process begins with the referral, and clearly the referral question will be a variable in test selection. However, the initial decision the clinician must make is whether or not to accept the referral (Sattler, 2008). It is the responsibility of the clinician to determine if a comprehensive assessment is necessary for a given child. Consideration of the nature of the problem, learning environment, maturation level, and parental expectations should provide the content for determining if the youngster is experiencing serious difficulties or whether the target behavior represents a transient response pattern, or deviation within developmentally normal limits (Mash & Wolfe, 2005). Clinicians must also recognize the limits of their competency, and referrals requiring skills that fall outside a clinician's training should be referred to a more appropriate provider.

Cognitive assessment is multifaceted and, as such, requires a comprehensive understanding of the child. Prior to meeting with the child, it is useful to gather information from several sources in order to obtain a complete understanding of the presenting problem (Allen & Gross, 1994). Interviews with the child, parents, teachers, or significant others often provide valuable insight into factors associated with the problem. These factors may include various environmental variables such as recent changes in family environment, recent death in the family, divorce, birth of a sibling, recent move, or significant family illness (Allen & Gross, 1994). Children are particularly vulnerable to changes that occur within their environment, and as such, it is important to determine the impact of the environmental context on the child's presenting problem.

During the parental interview, the clinician should ask parents to address the specific behaviors that they are interested in the child being able to perform. Asking parents about their assessment expectations will aid the clinician in determining what assessment tools to use, as well as provide guidance when writing the recommendation section of the written report. Furthermore, it is important for clinicians to ask questions about the frequency, duration, and intensity of the presenting issue. The initial parental interview also allows clinicians to evaluate other contextual pieces that may be important for answering and understanding the referral question (Boggs, Griffin, & Gross, 2003). During the parental interview, clinicians obtain a comprehensive developmental and family history. This would include information on the child and family's medical history, family history of psychiatric illness, difficulties during pregnancy and child's achievement of the various developmental milestones (Boggs et al., 2003).

Interviewing other individuals in the child's life may also be beneficial allowing a broader picture of the child's presenting problem. Teachers often provide the best additional source of information. The teacher will be able to provide a description of the problem or the problem responses seen in the classroom setting and methods that have been used in attempts to address the problem (Schwean & Saklofske, 2005). Specific questions as to the child's performance in class, on homework, during free-play activities help provide a complete picture of the child (e.g., does the child complete her homework regularly and in a timely fashion? Does the child have trouble staying on task during structured and/or unstructured classroom activities?) (Schwean & Saklofske, 2005). If the child is being referred for testing by his or her school, the clinician should determine if any corrective or instructional methods (e.g., tutoring, extra resources) are in place (Sattler, 2008).

Once the initial interviews with the child's parents and teachers have been conducted, it is important for the clinician to observe the child in natural settings prior to beginning the administration of the assessment material (Kaufman & Reynolds, 1984). Observations of the referred child in play and classroom settings are an important aspect of creating a complete understanding of the child's performance during the testing session. Classroom or playground behaviors provide important contextual clues concerning child functioning. Similarly, noting the child's behavior in the waiting room may also yield useful information. Most importantly, understanding the child's performance will require "close insightful observation and recording of behavior during the testing period" (Kaufman & Reynolds, 1984, p. 201).

The next step in the test administration process is to establish a working relationship with the child. Establishing rapport with the child will influence a child's testing performance. A child who feels at ease with the examiner will be more relaxed and better able to concentrate on the tasks at hand. The process of establishing rapport with a child often begins with the parents' understanding of the assessment (Sattler, 2008). Parents are frequently the first persons to convey to their children that they will be meeting with a psychologist. For children between the ages of 3 and 6, the concept of a psychologist may be beyond the grasp of their cognitive abilities (Sattler, 2008). Clinicians may want to spend some time prior to the first meeting with the child explaining the assessment process to parents. Meeting with the parents prior to the assessment provides an opportunity to explain the purpose of the assessment, and allows the clinician to suggest how to explain the visit to the child (Sattler, 2008). Psychologists should discourage parents from telling their children that they will be playing games. Oftentimes, the child will enter the session and be disappointed upon learning that not all of the tasks will involve game playing (Sattler, 2008). Besides informing the parent that most children enjoy the

assessment activities, this meeting will give clinicians an opportunity to possibly alleviate parental anxiety concerning the assessment.

When the child enters the assessment room, clinicians should introduce themselves to the parent and then the child using their first name (Sattler, 2008). Sattler indicates that with younger children, psychologists may want to refrain from introducing themselves as a doctor as it may lead to an increased level of anxiety. If the child is very young, the psychologist may want to provide the child with a toy or allow him or her to bring a favorite animal or object into the testing area (Sattler, 2008). For children of all ages, it is important to make the tasks as pleasant as possible and encourage effort without rewarding certain responses. With older children, it is important for the clinician to be honest and adapt their language to an age-appropriate level. Sattler suggests saying something like the following: "Your parents are concerned that you're not doing as well as you're capable of doing, and I'm here to find out how we can help you." (p. 191).

Establishing rapport with children requires the clinician to be patient and maintain a general flexibility throughout the initial meeting and interview. Expressions of warmth and understanding may also enhance the rapport-building experience (Barker, 1990). Children are often anxious or fearful of being away from their parents, so it may be helpful to allow the child's parents to stay in the room until the child feels comfortable in the presence of the assessor (Sattler, 2008). Knowledge of the dynamic aspects of interpersonal relationships and an individual's personality are the basic components for beginning to understand the basic principles that will allow behavior change to occur (Leon, 1989). In the initial meeting with the child, how clinicians introduce themselves, their posture, and other small gestures often set the tone for rapport building (Leon, 1989). Additionally, small gestures such as leaning forward and tiny nods of the head indicate a genuine interest in the client, and will aid in assuaging the patient's initial anxiety (Leon, 1989).

Older children may have developed misconceptions about testing based on information from other children. To eliminate any uncertainty, the clinician can provide an opportunity for the youngsters to share their views as to why they are being tested (Sattler, 2008). Always share with the child the steps that will occur during the evaluation procedures, and if it is feasible indicate that you will be meeting with them at a later date to discuss test results. If the assessment will be conducted at the child's school, building rapport with the child's teacher(s) will be an important step in establishing a working relationship with the child. It is important for psychologists to introduce themselves to teachers several days before the evaluation is to take place (Sattler, 2008). Eliciting cooperation from teachers will provide a more pleasant experience for the child, and rapport will be easier to establish and maintain.

Once a working relationship has been established, the clinician may begin with the actual administration of the assessment materials. As previously noted, it is important for clinicians to administer the tests based on the standardized procedures outlined in the testing manuals. Unfortunately, the most common errors associated with the administration of standardized tests occur in test administration and scoring. McQueen, Meschino, Pike, and Poelstra (1994) stated that improving competency in these areas can be accomplished through both lecture and laboratory interventions designed to improve graduate student testing performance. Interventions that consisted of weekly lecture and laboratory exercises and alerting students to the most common errors associated with a particular instrument prior to the administering of the test reduced the number of errors associated with the administration of standardized tests. Other administration errors were addressed with a variety of interventions including: practicing

determining chronological age, using a ruler when reading test tables, reviewing all derived scores, using electronic calculators, reviewing rules and procedures, having a reviewing study partner, and adhering to standardization procedures.

Sattler (2008) provides an administrative checklist for the WISC-IV and WAIS-III designed for training beginning clinicians. The checklist identifies a number of things that the assessor must do in order to facilitate standardized test administration. Attending to the above-described issues will facilitate an accurate pretest understanding of the child, an awareness of contextual variables of importance, reliable and valid assessment data, as well as promote the child's ability to perform at his or her best during the assessment.

Interpretation of Assessment Material and Results

In the interpretation of test results, multiple sources of data (knowledge of child development, test theory, developmental psychopathology, personality theory, and psychopathology) must be considered (Kaufman & Reynolds, 1984). Integration of assessment data must result in an accurate representation of the child's abilities. Clinicians must never rely solely on test scores when making a diagnostic determination (Sattler, 2008).

Interpretation of assessment data requires an understanding of all the factors that may be influencing the performance of the child (APA, 2000). In addition to simply assessing cognitive abilities, it is imperative to attend to other variables that may potentially influence the learning and testing environments. These variables may include environmental change (e.g., divorce, recent move, etc.), as well as cognitive, emotional, and political factors that may potentially influence the child at home or at school (Boggs et al., 2003). During the assessment, clinicians should keep in mind the child's behavior, attentiveness, reaction to the testing material, posture, gestures, language, and affect. Making note of the nonverbal behavior of the child may play a key role in understanding the results of the various measures (Kaufman & Reynolds, 1984).

Prior to the actual interpretation of the assessment data, the clinician should determine whether the test data are reliable and valid. Outside factors such as loud distracting noises, interruptions, or the temperature in the room may influence the reliability of the child's test performance (Sattler, 2008). Additional factors to consider would be how the child is feeling during the day of the testing. For instance, if the child is not feeling well, or is overly distracted, or is extremely sleepy, test results may not be valid or reliable. A competent clinician should be observant of these issues when interpreting and proceeding through the testing process. A statement about the validity and reliability of the testing results should be included in the beginning portion of the assessment report.

The child's strengths and weaknesses should be determined in relation to the skills of their related age peers. A comparison to the child's peers will allow the clinician to make an informed decision as to whether the child's strengths and weaknesses fall outside the normal developmental ranges (Sattler, 2008). Test interpretation also should involve the examination of any discrepancies observed between background information and the child's test performance (Sattler, 2008).

The Reporting Results

The APA task force emphasizes that clinician competency includes the ability to explain test results and the limitations of the testing to a diverse audience, along with the ability to provide written and verbal communication regarding the results of the assessment. The communication of assessment results begins with the written report. Thorough report writing includes

sections devoted to "interpreting the referral question, test selection, case conceptualization, theoretical orientation, process involved in the interview, interpretation of test scores, integrating various sources of information, prioritizing what is the most important information to include, and the selection of the best means of presenting the information" (Groth-Marnat & Horvath, 2006, p. 73).

The main purpose of the report is to communicate to the readers the results of the assessment in a manner that allows them to understand the main features of the treatment/intervention plan, as well as how the child's strengths will be used to enhance his/her weaknesses. The assessment process is fruitless if the end product cannot be understood (Groth-Marnat & Horvath, 2006). The goals of report writing are to describe the client in a manner that provides readers with a clear picture of the child. Treatment/intervention goals should be presented in a manner that is readily understood and can be easily placed into action. Finally, reports should lead to the suggestion that if they are followed they have a high potential for increasing the quality of the client's life. The need for clarity and concisely written psychological reports is great, and according to Harvey (2006) is one of the most important skills for a competent clinician to possess. Reports often include unnecessary psychological jargon making them hard to comprehend. All psychological reports should be written at a reading level appropriate for the intended audience, client-focused, clear and concise, and recommendations should be easily understood and doable. In this regard, it is important for clinicians to define terms in everyday language (Groth-Marnat, 2003; Harvey, 2006; Sattler, 2008). Report readability can be enhanced by using short sentences minimizing difficult words, reducing the use of jargon and acronyms, omitting passive verbs, increasing the use of subheadings, using everyday descriptions of client behavior, using time-efficient strategies, and collaborating with the client (Harvey, 2006).

In training the beginning student to write a clear and concise report, several suggestions have been made. Example reports should be provided to students as models of appropriate language and reading levels. The reading level of the report should be checked by one of the recommended computer formulas and all reports should be written in a concrete manner that provides examples that are relevant to the client's daily life. It has additionally been suggested that the information provided in the report provide a balance between the strengths and weaknesses of the client (Snyder, Ritschel, Rand, & Berg, 2006).

Typically an assessment report begins with identifying client data. These data include the client's date of birth, chronological age, gender, ethnicity, year of education, date of examination, date of report, and name of the examiner/supervisor. This section is followed by a description of the referral question. Once the referral issue is summarized, a description of the client's background information is provided. In the background section, many reports will include a summary of information gathered from the child's family and teachers. Additional information would include: (1) general information on the child, (2) educational information, (3) family history, (4) medical background, and (5) psychological factors (such as a history of mental illness or previous experience with psychological testing or therapy). A section on behavioral observations typically follows the child's background information. This section provides a description of the client's overall appearance and various behaviors observed throughout the testing sessions such as the child's interest in the testing, level of motivation, and their overall interactions with the examiner. The behavioral observation section typically ends with a statement of the validity of the assessment such as "the examiner believes that these tests should be a valid measure of client x's current level of intellectual functioning based on his/her effort throughout the assessment." The section on test results not only includes a listing of subtest

scores, but also a brief discussion regarding strengths and weaknesses (e.g., verbal IQ subtests reflect strength in verbal comprehension, verbal concept formation, language development, and a capacity for associative thinking). In some settings, it is beneficial to provide a technical protocol page along with the report. Including a technical protocol page allows the clinician to easily provide third parities with the necessary information about the client without having to divulge confidential information in the actual written report.

The final section of the report focuses on recommendations. The recommendation section of an assessment provides possible options for treatment and interventions that would be most beneficial to the child. The suggestions made by the clinician should be specific and provide examples as to how the child can use his or her strongest areas to help build skills (Geffken, Keeley, Kellison, Storch, & Rodrigue, 2006; Sattler, 2008). Recommendations need to specifically address the referral question. According to Turner, DeMers, Fox, and Reed (2001, p. 1106), all psychologists who use "psychological tests in social institutions like schools should be particularly skilled at communicating the results of testing to many different audiences, including educational decision makers, teachers, students, parents, and the public." In an educational environment, the clinician may be asked to determine if the child will require special education services or classroom accommodations (Sattler, 2008). When making the recommendations, clinicians should be sensitive to the ability and motivation of the youngster's teacher.

In addition to the written report, clinicians must be skilled at communicating feedback directly to parents (and or guardians). The feedback session provides the examiner and interested parties with an opportunity to discuss the assessment results. The clinician must present the information to the parents in a manner that facilitates their understanding of the child's strengths, and how these skills will be used to build new skills. The extant literature indicates that providing verbal feedback along with the written report can enhance rapport and allow for all the client's questions to be answered (Allen, Montgomery, Tubman, Frazier, & Escovar, 2003). Clearly, it is helpful to present the results to the parents and teachers in a discussion-based format.

10.2.2 Maintaining the Highest Level of Ethical Standards

10.2.2.1 Ethnic, Cultural, and Linguistic Issues

Knowledge of ethnic, racial, cultural, gender, age, and linguistic variables reflect clinical skills for understanding how contextual variables may impact the entire testing process (APA, 2000). The number of culturally and ethnically diverse individuals living in the USA is increasing. According to the projections made by the US Bureau of the Census, by 2050, approximately 25% of the population will be formed by Hispanic Americans, and approximately 9% of the population will be formed by Asian Americans United States Bureau of the Census (1996, February). It is important for clinicians to be mindful of how cultural variables may influence the assessment process. Cultural characteristics, including the youngster's degree of acculturation, English as a second language abilities, may influence the child's motivation toward and understanding of the assessment process (Sattler, 2008).

APA (2002) suggests that multicultural competency involves recognition of the importance of cultural competence and an awareness of any personal biases the clinician may have that would have an unwanted influence on the assessment outcome. The clinician must also stay

abreast of multicultural affairs and take part in multicultural educational opportunities. When providing services to an individual from a minority group, the clinician must consider the child's/family's ethnic identity, level of acculturation, psychological mindedness, and willingness to access mental health services (Li, Jenkins, & Sundsmo, 2007). Acculturation may be defined as the various stages of change that occur within an individual as he or she adjusts to a new culture (Sattler, 2008). The degree to which individuals accept and adopt the new culture's social norms and rules refers to the degree to which they have acculturated into the society.

Clinicians who provide assessment services to ethnically diverse children must be able to apply their skills and bring their awareness of cultural diversity to the entire assessment process (Ecklund & Johnson, 2007). According to Ecklund and Johnson, the most important skill for clinicians is an ability to establish a working relationship with the child. Second, clinicians must be able to bring sensitivity to any question concerning the child's ethnic background. Third, clinicians must be able to discuss the assessment in a manner that is understood by both the parent and the child. Finally, clinicians must be able to integrate the child's ethnic background into the written report and recommendations. It has been suggested that clinicians address all culturally relevant issues during the interview.

There is limited availability of culturally relevant norms for many of the most commonly employed standardized cognitive tests (Sattler, 2008). Most of the assessment devices were normed using Caucasian samples and relatively few data exist for children of various cultural backgrounds. For this reason, some clinicians suggest that standardized tests should not be used with bilingual populations (Sattler, 2008). They suggest that in the absence of relevant nationwide norms, these instruments hold the potential for harm to culturally diverse populations. Despite these arguments, cognitive assessment is often the primary pathway available for identifying at-risk children and accessing appropriate services. It is suggested that learning about the child's culture enhances the level of understanding and cooperation between the child, the child's family, and the clinician improving the quality of information the assessment provides.

Individuals from minority populations have often experienced segregation, poverty, and discrimination (Sattler, 2008). Being raised in a fiscally impoverished environment is associated with elevated levels of health and stress problems, which are also associated with increased risk for poor social functioning, delayed rate of learning, and decreased level of achievement both in and outside of school (Sattler, 2008). Additionally, beliefs of the family may have a profound impact on the results of the assessment (Sattler, 2008). It should be noted that ethnic and cultural constructs can influence the expression of the individual's intellectual and achievement difficulties, as well as the validity of the assessment instruments for use with an ethnically diverse youngster (Li et al., 2007). To avoid a cultural misunderstanding, it may be helpful for the clinician to seek guidance from a trusted colleague who is knowledgeable in the area of multicultural issues in general, and multicultural assessment in particular. Similarly, the clinician may chose to ask the child's parents about their feelings about seeking help from health professionals (Sattler, 2008). Asking parents questions about their values and beliefs regarding health-related aspects of their cultural values will help facilitate a mutual understanding between the client, the child's parents, and hopefully the child.

An additional concern when assessing culturally diverse children is whether English is their native language. Many children from multicultural families are bilingual raising the question of which language would be best for conducting the assessment (Sattler, 2008). One method for overcoming language and/or value differences is to have a trusted family translator

present when meeting with the parents and child. It may also be helpful to spend sometime directly observing the child in daily interactions with his or her parents, siblings, teachers, and friends. Such observations will offer insight into the child's language of preference and other cultural variables. There are a few measures available for testing language preferences. These tests include the Bilingual Verbal Ability Tests (BVAT; Munoz-Sandoval, Cummins, Alvardo, & Roef, 1998 as cited in Sattler, 2008, p. 157) and the Language Assessment Scales-Oral (LAS-O; Duncan & DeAvila, 1990 as cited in Sattler, 2008, p. 158). Additionally, test translations are available for a few of the standardized measures. However, it is important for clinicians to be aware of the differences in the normative data. A measure must have normative information for the translated version of the test (Sattler, 2008). Based on the guidelines set forth by the APA (2003, p. 389), clinicians are "encouraged not to use instruments that have not been adopted for the target population." It would be unwise for a clinician to translate a test into a different language and use the measures of original normative information to score the protocol.

Clinicians should also be aware of additional language barriers that may impact the outcome of the assessment. For instance, some cultural groups may have words or phrases that are specific to their ethnic background. Clinicians can overcome these language barriers by becoming familiar with the various ethnic groups' particular dialect (Sattler, 2008). Additional factors that may impact the outcome of the assessment are cultural differences in nonverbal behaviors such as eye contact, hand gestures, and sensitivity to spatial distances (Sattler, 2008). In some cultures making direct eye contact for long periods of time is considered to be a sign of disrespect. Similarly, some children may want to sit or stand directly in front of or next to the clinician. Clinicians who make a step backwards may be viewed as rude or as having a lack of cultural understanding. Again, clinicians can avoid these cultural misunderstandings by becoming familiar with each ethnic group's nonverbal behaviors prior to beginning the assessment.

10.2.2.2 Developmental Considerations

Standardized tests employed in cognitive assessments are developmentally normed. However, clinician competency also requires an understanding of the normative developmental process (Boggs et al., 2003). Recognizing that a child's behavior differs significantly from those of peers requires awareness of children's developmental functions and abilities across ages (Mash & Wolfe, 2005). Knowing what milestones are accomplished by most children of a given age, a clinician might more easily recognize deviations from typical variation in childhood growth and development (Boggs et al., 2003). That is, clinicians must recognize the relationship between the areas of concern (i.e., in the referral question) and normal developmental pathways. Using the child's peers as a normative reference provides a "convenient summary of a child's developmental standing in several areas" (Edelbrock, 1984, p. 22).

Sattler (2008) provides examples of common trends in cognitive development, language acquisition, self-concept, person perception, moral judgment, temporal concepts, and recognition of emotion. Knowledge of these developmental trends is important as the assessment, assessment materials, and initial interview are all tailored to meet the developmental level of the various age groups. Boggs et al. (2003) suggest that clinicians can become familiar with activities associated with each developmental level by observing the child in the classroom and

in other daily activities. The observations of daily functioning are suggested to provide a framework from which observations within the assessment setting can be integrated into completing an accurate description of the child. Thus, the child's developmental level can provide a prognostic framework that has implications for a diagnosis as well as treatment considerations (Allen & Gross, 1994).

10.2.3 Testing Individuals with Disabilities

Knowledge of testing individuals with disabilities is the third core knowledge area necessary for clinician competency. Competency requires the ability to administer tests to children with a wide array of physical and mental abilities. That is, clinicians must be skilled in the area of making appropriate accommodations during testing of children with disabilities. Much of the above discussion concerning test selection and test administration procedures applies to working with individuals with identified disabilities.

The first step in providing assistance to a child with a disability is to determine if testing accommodations are appropriate. Clinicians must pay attention to the testing environment as well as other environmental characteristics that may influence the outcome of the testing session. At times, obtaining accurate assessment data may require adapting the method by which the youngster responds to test items, changing the manner in which the material is presented to the child, changing the actual testing environment, adapting the time of the test, or substituting or selecting out portions of the testing material (American Educational Research Association, APA, & National Council on Measurement in Education, 1999). Test substitution or using only selected portions of the testing material is a common practice when testing children with physical or sensory deficits (American Educational Research Association, APA, & National Council on Measurement in Education, 1999). For example, if a portion of the test requires an oral presentation of material, the oral section of the test may be eliminated. In instances were a child has a severe disability, it may be necessary for the child's aid to be in the testing room. Clinicians should indicate to the aid that the testing materials require the use of standardized procedures in which helping and questioning would not be appropriate (Sattler, 2008).

It should also be noted that not every child with the same disability will require the same accommodation. In some instances, simple changes such as providing access to a wheel chair, enhanced lighting, and allowing for extended breaks may be appropriate testing accommodations (American Educational Research Association, APA, & National Council on Measurement in Education, 1999). Clinicians must use their judgment to consider what accommodations would best fit the current child's needs (American Educational Research Association, APA, & National Council on Measurement in Education, 1999). For example, if a child has a visual impairment presenting the testing materials in Braille may be suitable. However, if the child has a physical disability in addition to the visual impairment, it may be more appropriate to present the testing material through some type of audio device.

A main issue for clinicians when assessing children with auditory deficits is to differentiate between deficits associated with intellect versus deficits associated with lack of experiential abilities (Braden, 2005). As a result of being raised in an environment in which spoken language is the norm, children who are hard of hearing or deaf may experience developmental delays (Braden, 2005). Additionally, children with auditory deficits are often provided limited

access to culture and language creating additional delays in obtaining basic developmental milestones (Braden, 2005). When testing children with auditory impairments clinicians must determine the child's primary language and provide this language throughout the testing session (e.g., sign language, access to a trusted sign language interpreter, etc.). The child may be assisted through the use of written test instructions. If a child displays severe disabilities, such as profound blindness or illnesses like cerebral palsy, collaboration with the child's teachers or aids may provide excellent information for choosing an appropriate test for the child. Finally, it may be helpful to ask the child's teacher, parents, or aids when the best time of the day for testing would be (Sattler, 2008).

According to the American Educational Research Association, APA, & National Council on Measurement in Education (1999), when deviations from the standardized testing procedures have occurred, clinicians should make note of the modifications in the assessment report. In the report, a statement as to the reliability and validity of the testing scores should be made. In some instances, a special notation such as an asterisk must be placed next to any scores in which alternate forms of the testing procedure were used. Clinicians should also provide readers with a rationale for why modified testing procedures were chosen, and documentation outlining the testing procedures followed. It should also be noted that the APA recommends that when necessary clinicians should seek legal advice prior to making alterations, and when possible clinicians should pilot test administration and scoring alterations before administering the materials to an actual client.

In addition to documenting procedural differences, clinicians should also pay particular attention when interpreting test results. Competent clinicians who provide testing to children with disabilities must be familiar with norms for regular and special populations (APA, 2000). In some instances, the use of regular norms is "appropriate when the purpose involves the test taker's functioning relative to the general population" (American Educational Research Association, APA, & National Council on Measurement in Education, 1999, p. 107). However, even when normative data are not available for deviations in standardized procedures, valuable information can still be obtained and reported. As an example, seeing a child correctly complete a difficult task on a subtest in which additional time was allotted would provide the examiner with clinically relevant information on the child's abilities to see a task through to completion. It is also important to remember that clinicians, regardless as to the population being tested, should always interpret test scores in context with information obtained from other forms of assessment (e.g., parent or teacher interviews, behavioral observations).

10.3 Expert Competencies

In addition to acquiring competency in the four core areas of knowledge and skill, clinicians who chose to specialize in testing children need to demonstrate an ability to assess youngsters with a wide variety of needs. At the expert level, clinicians must demonstrate an ability to administer specialized test batteries necessary for making differential diagnoses as well as important academic decisions. As noted in the previous section, clinicians who display expert competency must be able to select the most appropriate test batteries based on the referral question and the abilities of the child being evaluated. Thus, clinicians who specialize in the assessment of children need additional expertise in context-relevant areas.

10.3.1 Tests for Children Who Present with Learning Disabilities

When children are referred for a LD evaluation the goal is to determine why the child is struggling academically. LDs are determined by examining an individual's achievement test (e.g., WIAT-II) and IQ scores (WISC-IV). The IQ discrepancy model is the most popular model used for identifying a LD. A LD is diagnosed when a child's achievement test scores are substantially below his or her intellectual abilities. It requires that the child's achievement score be at least 2 SD below that of the IQ score (Dombrowski, Kamphaus, & Reynolds, 2004; Proctor & Prevatt, 2003). That is, a LD is diagnosed when a child's achievement test scores are substantially below his or her intellectual abilities.

10.3.2 Tests for Children Who Present with Reading Difficulties

LD assessment and general psychoeducational assessments share much in common. General tests of intelligence and achievement are employed in both types of assessments. A major difference between these assessments generally involves use of the additional specialized measures in the LD assessment. Clinician competency not only involves the selection of relevant measures, but also the ability to interpret and integrate LD instrument test results against the backdrop of more general measures on intellectual and academic functioning. For example, in the case of the child suspected of suffering from dyslexia, the first step in the diagnostic procedure would be to rule out other sources of difficulty that may result in the child's low reading achievement while taking into consideration the child's developmental, medical, educational, and family history (Berninger & O'Donnell, 2005). The assessment battery might include a test such as the WISC-IV Verbal Comprehension Index to assess the range of the child's verbal reasoning ability. Additional measures of accuracy and rate of "oral real world reading, phonological decoding, and morphological decoding, text reading, and measures of accuracy and written spelling would likely also be administered to evaluate whether reading and spelling skills are low" (Berninger & O'Donnell, 2005, p. 208). Next, an achievement measure such as the WIAT II or WJ III would be selected. The clinician would then determine whether the inclusionary criteria for dyslexia are present. The competent clinician would also determine if the child has additional problems with arithmetic, attention-deficit disorder or other disorders due to chronic academic difficulties (Berninger & O'Donnell, 2005). If any of additional problems were present at the time of testing, the clinician must address these issues in the recommendations and intervention sections of the assessment report.

10.3.3 Assessment of Children Who Present with Attention Difficulties

ADHD assessments are a common referral question. Although not created to specifically address problems associated with ADHD, intelligence tests such as the WISC-IV play a crucial role in making a differential diagnosis (Schwean & Saklofske, 2005). To make a differential diagnosis of ADHD, the four most important scales in the WISC-IV are "the Verbal Comprehension (VC) index, the Perceptual Reasoning (PR) index, the Working Memory (WM) index, and the Processing Speed (PS) index" (Schwean & Saklofske, 2005, p. 244). These are important because according to theories of ADHD, children who present with symptoms

consistent with ADHD generally have difficulties with comprehension, organization, concentration, and tasks that measure selective attention (Schwean & Saklofske, 2005). In the above-mentioned sections of the WISC-IV, the VC index provides a marker of the child's verbal comprehension, verbal abilities, ability to think with words, as well as an ability to apply verbal skills and information to find solutions to novel situations. The PR index provides an indication of a child's perceptual reasoning and organizational abilities. The WM index yields information on attention, concentration, and working memory (Schwean & Saklofske, 2005), while the PS index reflects mental processing speed. Additionally, knowledge and awareness of the child's overall cognitive functioning is important for planning the behavioral and educational programming.

A differential diagnosis of ADHD requires parceling out other developmental conditions such as other forms of LDs, or several of the internalizing (anxiety and depressive disorders) and externalizing disorders diagnosed in childhood (such as conduct disorder or oppositional defiant disorder). Most ADHD assessment batteries include an IQ test (such as the WISC-IV), an achievement test (such as the WIAT-II), interviews with both the parent and child, the CPT-II, the Barkley ADHD (parent and teacher forms) or the Conner's ADHD scales, and some measure of personality (e.g., The Minnesota Multiphasic Personality Inventory-Adolescent (MMPI-A) or BASC-2). If the child is in high school, the LASSI-HS would be administered to determine problems related to study skill and school issues. Furthermore, if reading problems are evident, a supplementary administration of a test such as the Nelson Denny may help to specify the exact nature of the problem.

10.3.4 Testing Gifted Children

Children who fall within the gifted category are generally assessed through IQ testing. According to Sparrow, Pfeiffer, and Newman (2005), in USA, the Wechsler scales are the most widely used instruments for assessing gifted abilities. School districts typically view gifted as being defined by IQ score, academic performance, or both. As with other forms of assessment, it is recommended that multiple assessment measures be used when identifying children who fall within the gifted category. Along with an intelligence test, such as the WISC-IV or WPSSI-III, a test such as the Gifted Rating Scales (GRS) should be administered, along with an achievement test such as the WIAT (Sparrow, Pfeiffer, & Newman, 2005). These instruments provide an additional indication of the child's achievement and motivation in school. In particular, the GRS scale includes a teacher form (GRS-S), which allows for additional information on the child's in-class performance to be obtained.

10.3.5 Tests for Children Who Present with Language Disabilities

When testing children who are presenting with a language disability, use of a multifaceted assessment approach is important (Sattler, 2008). A multifaceted approach would include ruling out any underlying medical conditions that may be contributing to the language impairment, by obtaining behavioral reports from teachers and parents, direct observation of the child, the administration of an IQ test, and some type of language test. Frequently, instruments such as the WISC-IV or WJ-COG to evaluate IQ and the Clinical Evaluation of Language

Fundamentals (CELF) to evaluate language are employed (Wiig, 2005). In particular, subscales on the WISC-IV that tap into Verbal Comprehension and Working Memory index are most relevant for evaluating language impairments (Wiig, 2005). The Verbal Comprehension index taps into the child's verbal abilities, ability to think with words, as well as an ability to apply verbal skills and information to find solutions to novel situations. Scores obtained on these subtests can provide a marker for identifying the child's verbal strengths and weaknesses (Wiig, 2005). As an example, the similarities subtest taps into the child's ability to form verbal concepts, abstract and concrete reasoning ability, and ability to separate essential from nonessential details. Often, children with language disabilities such as Expressive or Mixed Receptive disorders will provide random responses that are impulsive in nature. Such "responses may indicate a focus on differences in meaning rather than on similarities" (Wiig, 2005, p. 338). The Working Memory index taps into the child's ability to sustain attention, short-term memory, and numerical/encoding abilities and provides additional support for language difficulties. Children who struggle with the subtests that form the Working Memory index often have difficulties with letters and other tasks that require sustained attention, encoding, and shifting focus on various types of symbolic information.

Clinicians who administer assessments to children with language abilities must make certain that the tasks required for each subtest are understood. To determine if comprehension has occurred, it may be helpful for the clinician to question the child about task expectations (Wiig, 2005).

Clinicians should also record all responses made by the child during the assessment. Impulsive responses provide useful tools for diagnosing a language disorder. In particular, responses that include the use of "similar sounding words (e.g., television for telephone)" are indicative of a child with language difficulties (Wiig, 2005, p. 340). It has also been suggested that if cognitive deficits that are found to be linked to language and communication disabilities are observed, the clinician should interpret the results with a speech pathologist (Wiig, 2005).

10.3.6 Additional Ethical Considerations

Since children are most frequently referred for cognitive assessment in order to identify developmental and/or learning delays, the assessment process may result in labeling or diagnostic classification. There are a number of consequences associated with diagnostic labels. Benefits may include legal protection, increased awareness of the disorder, access to relevant services, development of school-based intervention programs, and increased research on the etiology of the problem (Sattler, 2008). However, many argue that there are a number of undesirable consequences associated with the use of diagnostic labels with children. The most prominent concern associated with labeling/classification is the concept of self-fulfilling prophecy. Individuals who believe that labels lead to a self-fulfilling prophecy claim that categorization leads to a decreased level of performance expectations in both children who carry the label, as well as from those working with the youngsters (e.g., parents, teachers, friends; Sattler, 2008).

Although it is not always possible to avoid use of the diagnostic labels, this issue may be mitigated by focusing on descriptions of the child's behavior (e.g., reporting descriptions of the child's behavior or skills instead of diagnostic labels) when presenting and interpreting assessment data. By describing the behaviors instead of labeling the child based on cutoff scores, the clinician will assist in creating a well-rounded understanding of the child. It will also enhance

the reader's understanding of how the recommendations in the report can be facilitated. Thus, competent clinicians must be aware of the problems associated with the use of classification and labeling systems, and not allow them to unfairly influence consumers of their evaluations of the child's abilities.

10.3.7 Trajectory for Obtaining Competency

APA accreditation guidelines for doctoral programs in clinical psychology require a curriculum plan that exposes students to the breath of scientific psychology, its history, and research methods. Training must include coursework covering the scientific, methodological, and theoretical foundations of practice and issues of cultural and individual diversity. Students also receive exposure to coursework related to diagnosing and defining problems through measurement and assessment, as well as courses focusing on treatment formulation. Lastly, students are expected to receive supervised practicum experiences (APA, 2007). While it is clear that the conceptual and applied fundamentals of assessment are being provided during pre-doctoral training, it may be that clinical assessment competency requires an increased training focus. Survey data indicate that internship directors are frequently disappointed with the assessment skills displayed by interns (Clay, 2006).

Internship directors would like their psychological interns to be competent with the most commonly used intellectual tests (Krishnamurthy et al., 2004). However, Clemence and Handler (2001) found that over half of the internship sites that they surveyed reported that it was necessary to reteach interns basic introductory-level assessment skills. While some skills are retaught at the internship, the opportunities for assessment during the internship year may not be enough to facilitate the development of assessment competency. In order to improve assessment skill training, it may be necessary to incorporate additional assessment-related coursework into the curriculum, along with providing cross-training experiences during all semesters of both departmental clinic and external clinic practicum training.

In addition to general training in cognitive assessment, students interested in the assessment of children must also receive additional specialized training in order to become competent clinicians. For example, clinicians who test children within the context of an educational setting must have the "skills and knowledge to evaluate the relative contribution of teacher competence and motivation, school and classroom climate, peer group influence, class size, and other factors that play a critical role in determining a student's future performance" (Turner et al., 2001, p. 106). Success in this setting also requires training that will facilitate familiarity with the general requirements (e.g., eligibility rulings) schools utilize when making decisions concerning placing children into specialized programs (Turner et al., 2001). Clinicians can accomplish this requirement by keeping current with the research literature in the area of psychoeducational assessment, and remaining up to date on changes regarding special education services through the IDEA.

Roberts et al. (1998) suggested that graduate training should offer students an opportunity to work with an array of children of both gender and from various ethnicities. These experiences should also include the training and use of numerous assessment instruments. Practicum experiences should consist of exposure to settings including inpatient and outpatient facilities, schools, facilities that serve children with disabilities, and private practices. Additional courses in mental retardation/developmental disabilities, assessment techniques

specialized for children, and specific legal and ethical issues associated with working with children, adolescents, and their families should be accessible to students throughout their training (Roberts, Erickson, & Tuma, 1985).

Psychologists who work with children from diverse populations need to have a knowledge base of cultural variations in beliefs as well as an understanding of assessment tools that have been shown to be reliable and valid for certain groups (APA, 2003). In order to obtain these skills, clinicians must be provided with training in multicultural approaches as well as cultural-centered training. The APA recommends that an emphasis on multicultural diversity begins at the graduate training level. Finally, in recent years, many of the most frequently used assessment tools have been adapted for computer administration. Computer-adapted testing tools allow for consistency in administration, scoring assessment protocols, and generating assessment reports. Clinicians must be familiar with the computerized testing material (Sattler, 2008).

10.3.7.1 Additional Training

Clinicians who wish to enhance their competency should select a postdoctoral position that allows them to complete specialized training. According to the APA's (2001) accreditation guidelines, postdoctoral sites for specializing in work with children should provide training and educational experiences that will allow the clinician to provide services at an advanced level of proficiency. The educational experiences at the postdoctoral level should require a residency of at least 1 year as well as provide exposure to psychological services for infants, children, and adolescents in various settings. Specialized training at the postdoctoral level will allow the clinician to gain a depth of information crucial for gaining expert competency.

Clinician competency in assessment is reflected in the clinician's ability to display sensitivity to a variety of factors that extend beyond the basic administration and interpretation of the assessment results. This knowledge and skill allow for a complete picture of a child to result from the assessment process. Cognitive assessment with children is best viewed as an ongoing dynamic process for evaluating the child's abilities. The process does not end with the assignment of a diagnostic label. Assessment serves as a starting point for gathering meaningful information that will aid in the development of an effective treatment plan for the child, which will ultimately aid in the improvement in the quality of the child's life.

10.4   Summary

The aim of this chapter was to provide a comprehensive overview of the child's cognitive assessment process. Following a brief overview of the area, basic clinician competencies were discussed. In this section, the four core areas of clinician competency outlined by the APA task force were delineated. These areas include having a basic understanding of psychometric theory; knowledge of ethnic, racial, cultural, gender, age, and linguistic variables; knowledge of how to test individuals with disabilities; and supervised experience. Following this brief discussion, an example of a basic psychoeducational test battery was explored. Next, guidelines for test administration, test selection, and test interpretations were presented. In these subsections, suggestions were provided for enhancing rapport with the child and increasing the readability

of the written report. An overview of a typical assessment report was also provided. This example offered a broad picture of the assessment process, beginning with identifying the referral question, the child's background (general, educational, family history, medical background, and psychological factors), behavioral observations, and presenting the test results. Subsequently, a discussion on clinician competency in ethnic and cultural issues, gender and age, and linguistic variables was presented. In the third section, factors associated with expert competency were discussed. In this section, test batteries for several of the most common assessments were explored with an emphasis on clinician competency. The section on expert competency ended with a trajectory for obtaining the necessary skills to proficiently work with children. Issues associated with graduate and post-doctoral-level training were also discussed. Finally, suggestions concerning how best to provide the training clinicians need to achieve competency were explored.

11 Behavioral Assessment with Adults

William H. O'Brien · Carmen K. Oemig · Jebediah J. Northern

Abstract: Behavioral assessment is an approach to the measurement and understanding of human behavior that requires several conceptual and clinical competencies. Basic conceptual competencies in behavioral assessment include a well-developed knowledge of empiricism, learning theories, idiographic measurement strategies, behavioral change processes, and multivariate causality. Behavioral assessment also requires familiarity with psychometric principles such as norms, reliability, and validity. Basic clinical competencies in behavioral assessment are two-fold. One set of basic clinical competencies subsumes information gathering methods such as interviewing, behavioral observation, self-monitoring, and self-report inventory use. The other centers on the generation of topographical and functional analyses of behavior that can be used to guide treatment design. In addition, the evolution and expansion of the behavioral tradition has created a need for expert-level conceptual and clinical competencies in behavioral assessment. Expert conceptual competencies in behavioral assessment center on familiarity with recent "third wave" advances in the philosophical, theoretical, and empirical foundations of behavioral assessment and behavior therapy. Expert clinical competencies require familiarity with decision-making processes, the fallibilities of clinical judgment, and the quantitative strategies that can be used to aid clinical decision-making and case formulation in behavioral assessment.

11.1 Overview

Behavioral assessment is a well-developed and critically important area of research and practice designed to yield comprehensive evaluations of the form and function of target behaviors (i.e., target behaviors are cognitive, emotional, physiological, and motor responses that are the focus of assessment; target behaviors can be either adaptive or maladaptive) for an individual clients or groups. As a theoretical approach, behavioral assessment requires familiarity with cognitive-behavioral theories and psychometrics. As a clinical approach, behavioral assessment requires familiarity with specific skills designed to acquire and evaluate behavioral data. Thus, behavioral assessment can be divided into conceptual and clinical competencies. Additionally, these competencies can be further divided into basic and advanced levels. In this chapter, we will present a general overview of behavioral assessment and its status as an approach to assessment. We will then present the basic conceptual and clinical competencies associated with behavioral assessment. Following this, the advanced competencies will be described. Finally, areas of future research and development of behavioral assessment will be presented.

11.2 Overview of Behavioral Assessment with Adults

The core characteristics of behavioral assessment are made clearer when they are contrasted against psychodynamic and personality-oriented approaches to assessment. These assessment approaches take the position that target behaviors can be best understood as being *caused* by stable, internal, and dysfunctional psychological processes. Further, in many cases, it is presumed that these dysfunctional psychological processes are largely unconscious or outside of the client's awareness. Some commonly encountered examples of dysfunctional internal psychological processes include: defense mechanisms, impaired object relations, and personality characteristics (cf. Bond, 2004; Laplanche & Pontalis, 1973).

As dysfunctional internal psychological processes are thought to be the primary cause of target behaviors, psychodynamic and personality-oriented assessment procedures emphasize measurement of unobservable or inferred constructs. Additionally, situational factors that may be exerting an important influence on target behaviors are de-emphasized. The Rorschach provides an excellent example of this inferential and nonsituational measurement approach. In a typical Rorschach assessment, the client is presented with the classic ambiguous inkblots and asked to provide a verbal account of what he or she sees. The examiner will prompt for clarification of vague responses but is also cautioned to be as neutral as possible. The client's verbal responses are recorded verbatim. These verbatim accounts are then often coded along a number of dimensions (e.g., perception of certain images; verbalizing the use of form, color, shading, white space; verbalizing perception of the movement; etc.) using a manual developed by Exner (1986, 1991). The coded responses are then summed and aggregated in many ways to derive various indices of the client's internal dynamics.

An assumption underlying the use of the Rorschach is that the manner in which the client structures his or her perceptions of the inkblots reveals critical information about personality, psychological processes, and unconscious conflicts. For example, the color-affect hypothesis, which is derived from psychodynamic theory about emotional regulation, posits that cards containing inkblots with color (e.g., red, blue, green) elicit emotional activation (Exner, 1991). If a client reports that color is used in forming his or her perception of a number of inkblot responses (e.g., "it looks like an undersea landscape with different colors of coral"), it is thought that the client has impaired self-regulation because he or she is not able to suppress the emotional reaction elicited by the colors in the inkblot. This poor self-regulation would be taken as an index of an affective disorder or psychosis. Alternatively, if the client does not report the use of color in many responses, then he or she is thought to have excessive self-regulation consistent with repression.

As is evident in the Rorschach example, the test is designed to identify stable internal psychological processes using verbal responses to test stimuli. The scoring and interpretation system also makes no allowance for interpreting client responses in relation to ongoing and/or recent situational events that may exert significant impact on verbal responding such as recent life stressors. These two characteristics of the Rorschach have been extensively researched in the past decade. Although there is continuing debate about the utility of the Rorschach, it appears to be clear that the test can be scored reliably, but that the validity of most summary scores is poor or undermined (Acklin, McDowell, Verschell, & Chan, 2000; Lilienfeld, Wood, & Garb, 2000). Further, key psychodynamic assumptions (e.g., the color-affect hypothesis) have not been supported (Frank, 1993). Finally, there is ample evidence indicating that life stressors and ongoing contextual factors exert a significant influence on Rorschach responding

(Exner & Sendin, 1997). Taken together, these flaws in the Rorschach system have resulted in a number of researchers recommending a moratorium on its use (e.g., Garb, 1999).

Personality assessment is similar to psychodynamic approaches because it is thought that responses to paper-and-pencil questions represent highly inferential and stable internal psychological processes. Additionally, like psychodynamic approaches, the measurement of contextual factors is de-emphasized. The Minnesota Multiphasic Personality Inventory (MMPI), a commonly used personality measure, illustrates these two characteristics. Items on the MMPI are carefully worded to avoid linking the item to a specific situation or time frame. For example, a client can only respond "yes" or "no" to broadly worded items such as "I feel uncomfortable in public." Thus, there is no possibility of measuring how discomfort in public situations varies across situations (e.g., giving a public presentation, sitting in a classroom, being at a social event, taking public transportation) and time. Additionally, an "yes" response will be interpreted as an indicator of an internal psychological process such as introversion.

Behavioral assessment approaches find fault with psychodynamic and personality-oriented approaches in two important ways. First, because unobservable internal constructs are presumed to be the primary cause of target behavior, circular reasoning is frequently encountered in psychodynamic and personality approaches to assessment. As noted by O'Brien and Haynes (1995), circular reasoning is evident in Fenichel's (1945) description of the reaction formation, which is described as a defense mechanism that occurs when unconscious sexual or aggressive impulses are reorganized by ego into behaviors that appear to have the opposite intent. For example, Fenichel describes that a reaction formation would be evident when "a hysterical mother who unconsciously hates her child may develop an apparently extreme affection for the child" (p. 151). The circular reasoning in this example is clear. The observable action, extreme affection, is interpreted to be an index of inferred unconscious hatred. However, the only evidence used to support the presence of unconscious hatred is affectionate behavior itself. This problem of tautology in psychodynamic and personality approaches to assessment remains a pervasive and pernicious problem for researchers and clinicians alike.

Another example of circular reasoning evident in psychodynamic and personality approaches is oftentimes evident in behavioral consultations which we encounter in medical settings. A common referral concern is that a patient may be using his or her call light excessively and/or calling out for help from nursing staff. Upon arrival to the room, the nursing staff may find that the client is experiencing what is determined to be a minor concern such as need to have his or her bed adjusted or requesting the use of restroom. The nursing staff will then typically apply a personality approach to the problem suggesting that the patient is "attention seeking," "manipulative," or "a whiner." Note that the locus of cause in these accounts lies within the patient rather than the environment. Further, note that the internal causal factor is thought to be a dysfunctional psychological characteristic. This is an example of circular reasoning. The calling-out behavior is presumed to be caused by an internal state (e.g., attention seeking). However, the presence of the internal state is based on the calling-out behavior itself.

Interestingly, the patient will also typically apply personality-based and circular reasoning to the behavior of the nursing staff. So, when asked why he or she is calling out, the patient will often respond that the nursing staff are "uncaring," "ignoring me," or "too busy for me." Again, the locus of cause in these accounts resides within the nursing staff rather than the environment, the internal causal factor is thought to be a dysfunctional psychological characteristic, and the reasoning is circular.

One can uncover circular reasoning by asking three questions: (a) what is the problem behavior, (b) what is the presumed cause, and (c) what evidence is there to support the presence of the cause and its effect on the problem behavior? If the answer to (c) is the same as the answer to (a), then the explanation is circular. Applied to the aforementioned example, we can clarify the problem in logic. Question: what is the target behavior? Answer: calling out for help for minor concerns. Question: what is the cause? Answer: the patient is manipulative. Question: how do you know the patient is manipulative? Answer: the patient calls out for help for minor concerns.

A behavioral assessment approach to this type of referral problem would explore the problem from a very different and noncircular stance. Rather than search exclusively for internal causes of the target behavior such as assessing "manipulativeness," the behavior therapist would explore situational factors such as the functional relationship between the nursing staff behavior and patient behavior. When this approach is taken, the cause of the calling-out behavior becomes evident – calling-out behavior is shaped and maintained by negative reinforcement (i.e., visiting with the patient reduces distress and/or physical discomfort) which is provided by the nursing staff. The process unfolds as follows. Initially, the nursing staff members provide consistent responding to the call light. However, after it is determined that the patient is "manipulative," the nursing staff will begin to withhold or delay responding to the call light. This is essentially withdrawing negative reinforcement for call-light use. The patient then experiences increased distress about being isolated from medical care while he or she is in discomfort and unable to obtain relief independently. Given intensified distress and withdrawal of reinforcement for call-light use, the client will escalate help-seeking behavior by calling out. This is analogous to an extinction burst which occurs for a period of time after reinforcement for a behavior is removed. The nursing staff members respond to the calling out and, thereby, provide negative reinforcement for this new help-seeking behavior. The patient is now more likely to call out for help in the future. Further, as the nursing staff members continue to withhold reinforcement until calling-out behavior occurs, the patient will continue to use it as a means for obtaining help.

It is important to note that this behavioral formulation of calling-out behavior is not based on an unobservable internal psychological characteristic. Instead, the cause of the calling out is based on the nature of observable and measurable interactions between the patient and the nursing staff. Further, the behavioral formulation is noncircular because the causal variable (nursing staff reinforcement) is different from the target behavior (calling out). We can return to the three questions presented earlier to confirm that it is noncircular. Question: what is the target behavior? Answer: calling out for help for minor concerns. Question: what is the cause? Answer: nursing staff members are providing negative reinforcement for calling-out behavior by withholding responding until the client begins yelling. Question: how do you know that the nursing staff members are withholding reinforcement until the client begins yelling? Answer: it has been reported by the client, confirmed by the nurses, and observed by the consultant.

It is also important to note that behavioral formulations such as these readily lead to the development of an intervention – having nursing staff provide consistent reinforcement for call light use and *not* calling out (e.g., nursing staff visit patient when he or she is quiet to check on a consistent basis). This is known as differential reinforcement for incompatible behavior and has been shown to be an effective intervention for a wide variety of problem behaviors.

The second major criticism leveled at psychodynamic and personality assessment approaches to assessment has been the lack of research support for the main assumptions that:

(a) internal psychological characteristics account for meaningful amounts of variance in target behavior occurrence and (b) assessment of these factors leads to effective interventions. This lack of research support is, at least partially, a function of the use of poorly defined internal psychological characteristics in many investigations. Additionally, interventions targeting modification of myriad internal psychological characteristics such as cognitive structures, personality, traits, and the like have yielded inconsistent outcomes relative to behavioral interventions (Hayes, 2004).

In contrast to psychodynamic and personality approaches described above, behavioral assessment emphasizes the evaluation of *behavior in context*. Thus, the onset, maintenance, and termination of any behavior are thought to arise out of an interaction between individual characteristics (his or her learning history and biological characteristics) and the environment (which includes relationships with people or animals as well as the inanimate characteristics of the environment). Focusing on a single component of this complex interaction (i.e., internal personality characteristics) is thought to be excessively simplistic and likely to yield an inadequate account of how and why behavior occurs.

11.3   Current Status and Applications of Behavioral Assessment

One indicator of the utility of an assessment method is the extent to which it is used in research and practice. Previously, we evaluated the behavioral assessment practices among scientist-practitioners who endorsed a cognitive-behavioral perspective in a national survey (O'Brien, McGrath, & Haynes, 2003). The results of the survey indicated that behavioral assessment was reported to be very important in treatment formulation. The more commonly reported assessment methods used by survey respondents are summarized in ▶ Table 11.1. These data can be compared to those obtained by Elliot, Miltenberger, Kaster-Bundgaard, and

■ Table 11.1

Results of surveys investigating assessment methods used by members of the association for the advancement of behavior therapy

Assessment method	Percent of clients assessed with this method	
	O'Brien et al., 2003	**Elliot et al., 1996**
Interview with client	92	93–94
Direct behavioral observation	55	52
Behavior rating scales and questionnaires	49	44–67
Self-monitoring	44	44–48
Interview with significant others	42	42–46
Interview other professionals	37	38–42
Mental status exam	32	27–36
Structured diagnostic interview	31	23–29
Personality inventory	16	15–20
Role play	15	19–25
Intellectual assessment	11	16–20
Analog functional analysis	10	10–16
Projective testing	3	3–5

• **Table 11.2**

Assessment methods reported in the *Journal of Consulting and Clinical Psychology*

Publication year	Treatment outcome studies (N)	Self-report questionnaire (%)	Behavioral observation (%)	Self-monitoring (%)	Psychophysiological assessment (%)	Projective testing (%)
1968	9	33	56	33	0	0
1972	23	48	35	22	0	0
1976	34	50	44	9	18	4
1980	21	62	33	29	14	9
1984	37	51	16	32	16	0
1988	21	81	24	38	10	0
1992	21	81	33	14	9	0
1996	28	86	7	25	25	0
2000	42	98	17	17	33	0
2004	55	100	13	27	20	0
2007	53	100	4	2	9	0

Lumley (1996) who also conducted a survey of academic psychologists and practitioners. Like Elliot et al. (1996), we observed that behavioral interviewing (with the client, a significant other, or another professional) is the most commonly used assessment method. The administration of self-report inventories is the next most commonly used assessment method followed by behavioral observation and self-monitoring.

In addition to the methods reported by behavior therapists, another indicator of the applicability of behavioral assessment is in clinical research. Haynes and O'Brien (2000) evaluated data on the types of assessment methods used in treatment outcome studies published in the *Journal of Clinical and Consulting Psychology* (JCCP) from 1968 through 1996. *JCCP* was selected because it is a high-quality, nonspecialty journal that publishes important clinical research. Articles published in 2000, 2002, 2004, and 2007 were added to these data and the results are summarized in ❯ Table 11.2.

❯ Table 11.2 illustrates several important points about assessment. First, self-report questionnaire administration has become the most commonly used assessment method. Additionally, most of these questionnaires used in these treatment outcome studies assessed specific target behaviors (e.g., depressed mood, anxiety) rather than psychodynamic characteristics or personality constructs. Thus, their use tends to be consistent with a behavioral assessment approach which focuses on specific and observable behaviors. Second, core behavioral assessment methods such as behavioral observation and self-monitoring are frequently used in outcome studies. Finally, projective testing, which is a mainstay of psychodynamic approaches, has become virtually nonexistent in the treatment outcome literature.

In summary, behavioral assessment is an approach that differs from traditional psychodynamic and personality assessment approaches because it emphasizes an understanding of behavior in context. It has become an important assessment approach in clinical practice and research. The increased use of behavioral assessment reflects the utility of this approach for measuring how and why behavior occurs for an individual client. In the following section, we will introduce the basic conceptual and clinical competencies of behavioral assessment.

11.4 Basic Competencies

11.4.1 Conceptual Competencies 1: Basic Assumptions of Behavioral Assessment

Understanding the essential philosophical and theoretical characteristics of behavioral assessment is critical for understanding it as an approach to the measurement and evaluation of behavior. The most important characteristic is functionalism (Hayes, 2004; Haynes & O'Brien, 2000). Functionalism is a philosophical and theoretical approach to behavior which posits that target behaviors occur as a function of complex causal influences that can be partitioned into intrapersonal events (e.g., physiological states, cognitive experiences, learning history, etc.), social environmental events (e.g., interpersonal interactions), and nonsocial environmental events (e.g., settings, time of day, etc.).

From a functional perspective, the essential unit of analysis in behavioral assessment is the *relationship* between target behaviors and the contexts within which they occur (Fletcher & Hayes, 2005). Thus, target behaviors cannot be isolated from the environment and evaluated for form and content. Instead, the focus is on how and why target behaviors occur within specific and well-defined intrapersonal, social environmental, and nonsocial environmental settings.

Empiricism is another key characteristic of behavioral assessment. The endorsement of empiricism provides support for the use of well-developed and minimally inferential operational definitions of target behaviors and contextual variables in any assessment. Further, there is a preference for the use of operational definitions and measures that permit quantification of target behaviors, contextual variables, and the relationships among them. Finally, the empirical assumption supports the use of quantitative methods to evaluate treatment process and outcomes (O'Brien, Kaplar, & McGrath, 2004; Watson & Gross, 1999).

A third characteristic of behavioral approaches is the reliance on learning theories to explain how and why target behaviors are acquired, maintained, and changed. The crucial learning theories required for a basic understanding of behavioral assessment are respondent conditioning, operant conditioning, and social learning theory. It is also becoming apparent that functional contextualism, an extension of functionalism, is emerging as an important element of a behavioral approach to human behavior (Hayes, Luoma, Bond, Masuda, & Lillis, 2006). However, familiarity with functional contextualism requires a very solid understanding of the traditional learning theories as well as psycholinguistics. Therefore, we consider familiarity with that approach to be an advanced conceptual competency in behavioral assessment.

Because it is believed that behavior arises as a function of unique interactions among target behaviors and contexts, it is also believed that optimal understanding results when assessment, case conceptualization, and treatments are designed at the individual level (Haynes & O'Brien, 2000). Thus, behavioral assessment endorses an idiographic approach. In addition, because empirical methods are endorsed, case conceptualizations and treatment evaluation will rely on methodological and statistical procedures that are designed to evaluate data collected from an individual client.

The fourth characteristic of behavioral assessment is "behavioral plasticity" (O'Brien & Haynes, 1993). This assumption supports the belief that virtually any target behavior can be changed through the careful evaluation of its function and the use of learning principles to design an intervention. Therefore, it is believed that *any* behavior can be modified under the correct circumstances.

Finally, behavioral assessment espouses multivariate perspectives in which it is presumed that target behaviors and contexts are comprised of many, if not an infinite, number of elements. Further, there are an infinite number of ways that these behavioral and contextual elements can relate to one another. Some relationships will be correlational and some will be causal. Thus, behavioral assessments will emphasize multimodal and multimethod measurements with an aim of identifying the more important relationships among behavioral and contextual elements (Hayes, 2004).

In summary, behavioral assessment has several characteristics about why target behaviors occur, how behavior should be measured, the preferred level of analysis, the possibility for change, and complexity. These assumptions are evident in the use of specific assessment procedures that are designed to yield data from well-defined and validated measures of target behaviors and contextual variables for an individual client.

11.4.2 Conceptual Competencies 2: Psychometrics

An understanding of psychometrics is necessary for proper evaluation of behavioral assessment data. *Psychometrics* refers to a group of techniques used to measure and understand

cognitive-verbal, affective-physiological, and/or overt-motor responses. Consequently, it is a basic conceptual competency. Some of the more important psychometric concepts in behavioral assessment are: norms, reliability, and validity.

Norms. Assessment data provide the most useful information when an individual's performance can be compared to a reference point. This is the idea behind *norms*. As the name implies, norms are the average performance of a standardization sample on a given instrument. In addition to average performance, norms also provide information about the relative frequency of varying degrees of deviation above and below the mean. Norms serve two major functions: they provide context for a measurement value and they facilitate the interpretation of a measurement value.

During the construction of some behavioral assessment instruments, the instrument is initially administered to a large sample or a standardization sample. Norms are then developed from the resulting data. After normative data have been collected, raw scores on a measure can be converted to derived scores which are a relative measure of performance. Consequently, two types of comparisons can be made, individual to group comparisons and individual to self comparisons. The first is an evaluation of an individual's performance relative to the standardization sample and the second is a comparison of an individual's performance on one subscale to his/her performance on another subscale. Both comparisons provide context to raw scores that allow for more informed clinical decision making such as social significance or diagnosis.

Reliability. Reliability is a psychometric term used to describe the accuracy, consistency, and stability of scores obtained from an assessment instrument across varying contexts. Even the best assessment instruments are susceptible to *error*, or inaccuracies in measurement. A good measure, however, will have measurement error that is small, known, and stable.

A mathematical conceptualization of reliability is the ratio of true score variance to observed score variance and ranges on a scale from 0 to 1 with higher numbers reflecting more reliable measures. A number of different methods have been developed to calculate reliability when error is introduced through various situations.

Of particular relevance to behavioral assessment is *inter-rater reliability*, the degree to which two or more observers agree in their ratings of a target behavior. It is a quantitative appraisal of the variation introduced by the observer. Well-developed behavioral observation instruments typically provide explicit scoring instructions to raters to minimize variance among observers. The statistic used to report inter-rater reliability is dependent on the characteristics of the assessment instrument. Frequently, Pearson's *r* is used for continuous scores, Spearman's *r* is used for categorical scores, and *kappa or weighted kappa* is used for categorical ratings for multiple subjects.

Imagine a situation requiring the repeated measurement of a target behavior over time. Assuming that all extraneous variables are held constant and that the instrument being used is not affected by the passage of time, it could be reasonably assumed that changes in the score reflect actual changes in the target behavior being measured. *Test-retest* reliability is a means to assess the assumption that an assessment instrument is not affected by the passage of time. Test-retest reliability is assessed by using Pearson's *r* as a measure of the correlation between the scores obtained by an individual on a given assessment instrument at different times. Theoretically, reliabilities of this type should be higher for target behaviors that are relatively stable (e.g., metabolic rate) and may not be as useful for target behaviors that are expected to vary (e.g., mood).

At times it is important to know whether different elements of an assessment instrument are measuring similar or dissimilar target behaviors. The similarity or dissimilarity of target behaviors can be assessed with measured of *internal consistency*. A number of methods can be used to assess internal consistency. *Split-half reliability* can be obtained by splitting a test into two equivalent halves and then correlating the scores with one another using Pearson's *r*. Constructing two equivalent forms of a test measuring a particular construct is a technique used to determine *parallel forms reliability*. Another method, *inter-item consistency*, is attained by correlating all individual items of a measure with one another and then determining the mean inter-item correlation. The test statistics used for internal consistency are the Knuder-Richardson statistic (for measures with categorical responses) or Cronbach's alpha (used for continuous variable responses).

Validity. Even though a behavioral assessment instrument may be properly normed and have adequate reliability, it has limited utility unless it exhibits *validity*. An instrument is thought to be valid if it measures the construct that it is intended measure. There are several methods used to evaluate validity. A commonality in all methods is that they evaluate the extent to which the instrument that measures a given target behavior is associated with another instrument that measures that same target behavior or a similar target behavior.

There are a few types of validity most relevant to behavioral assessment. *Content validity* emphasizes the assessment of whether elements on an assessment instrument adequately represent the target behavior. There are two aspects to content validity. Content coverage refers to the notion of whether the items on an assessment instrument contain an adequate sample of the elements of the target behavior. Content relevance refers to whether items are clearly associated with the target behavior. For example, a self-report measure of depression would be lacking in content coverage if items were limited to the measurement of faulty cognitions and failed to examine other aspects of depression (e.g., affect, physical symptoms, etc.). Alternatively the hypothetical depression measure would be low in content relevance if the items intended to measure faulty cognitive processes assessed unrelated experiences (e.g., perceptual disturbances). Statistical tests are not used to measure content validity. Instead, the behavior therapist has to critically evaluate the instrument.

If an instrument correlates well with another criterion target behavior, it is said to have high *criterion validity*. Here it is important to note that the criterion should be a carefully selected, well-established measure or outcome. There are two subtypes of criterion validity, *predictive* and *concurrent validity*. High predictive validity is achieved when an instrument accurately predicts a future outcome that is related to the target behavior. Because chronic pain has an established association with occupational absenteeism (Munce, Stansfeld, Blackmore, & Stewart, 2007), the number of days of work that an individual misses in the next month may serve as an important criterion for a self-report measure of pain. The current relationship between an instrument and the criterion is termed *concurrent validity*. Researchers have documented a relationship between stress and insomnia (Bernert, Merrill, Braithwaite, Van Orden, & Joiner, 2007), so the relationship between daily ratings of stress and the number of hours of sleep at night can serve as a measure of concurrent validity. Pearson's *r* is used as the validity coefficient for criterion validity.

In summary, an understanding of psychometrics is essential for behavioral assessment. Norms are used to interpret an individual's score on an instrument relative to self or others and they are important for establishing social significance or a diagnosis. Reliability and validity provide information about the extent to which a behavioral assessment instrument will yield data that are accurate and clinically useful.

11.4.3 Clinical Competencies 1: Generating Topographical and Functional Analyses

The primary goal of behavioral assessment is to improve clinical decision making by obtaining reliable and valid information about the form and function of target behaviors. This primary goal is achieved when two subordinate goals are met: (a) objective measurement of target behaviors and (b) identification of contextual factors that exert important influences on target behaviors. To achieve the two subordinate goals, a behavior therapist must have competencies in processes used to generate operational definitions of target behaviors and contextual factors. Additionally, strategies for collecting empirical data about relationships among target behaviors and contextual factors must be developed and implemented. Finally, after data collection, effective evaluation procedures must be used to measure the magnitude of relationships between target behaviors and contextual factors. In the following sections, these basic assessment competencies are reviewed.

Generating a Topographical Analysis of Behavior and Context. A primary goal of behavioral assessment is to accurately measure target behaviors. To accomplish this, the behavior therapist must determine which behaviors are important and how they should be measured. Operational definitions are used to capture the specific and observable elements of target behaviors. When developing an operational definition, the behavior therapist should emphasize content validity. And, in line with the multidimensional assumption, it is expected that target behaviors will need to be operationalized in a number of different ways.

In order to simplify the operationalizations, we recommend that target behaviors be divided into three modes of responding: verbal-cognitive, physiological-affective, and overt-motor. The verbal-cognitive mode includes spoken words and myriad cognitive experiences (self-statements, beliefs, attitudes). The physiological-affective mode includes physiological responses, sensations, and emotional states. Finally, the overt-motor mode includes observable motor responses.

Once a target behavior has been operationally defined in terms of modes, the behavior therapist must determine which response parameters are most relevant. The most commonly used measurement parameters of target behaviors are frequency, duration, and intensity. Frequency refers to how often the behavior occurs across a specific time frame (e.g., number per day, per hour, per minute). Duration refers to the amount of time that elapses between target behavior onset and ending. Intensity refers to "force" or salience of the target behavior in relation to other responses emitted by the client.

In addition to determining which parameter of measurement will be used to quantify a target behavior, the behavior therapist will need to measure the relative importance of a target behavior if more than one is described by the client (which is most often the case). Ratings of importance (low, medium, high) can be reliably generated by the client in consultation with the behavior therapist (Haynes & O'Brien, 2000). These importance ratings are helpful in treatment design because the more highly rated target behaviors should be emphasized in the intervention.

For example a client's experience of public-speaking anxiety would include cognitive elements (e.g., catastrophic appraisals, scanning the audience for unhappy faces), affective-physiological elements (e.g., elevated heart rate, dry mouth), and overt-motor elements (e.g., trembling, voice hesitations, eye contact avoidance). Further, each of these elements could be measured in terms of frequency, intensity, and duration. Finally, the client could rate the importance of each set of target behaviors in terms of the degree to which they interfere with public speaking and/or cause social impairment.

Subsequent to generating operational definitions of target behaviors, the behavior therapist needs to generate operational definitions of contextual factors. Contextual factors are environmental events that exert important effects on the target behaviors. Contextual factors can be sorted into two broad categories: social/interpersonal events and nonsocial/environmental events. Social/interpersonal factors include interactions with other living beings – most typically people and groups of people. Nonsocial/environmental factors include interactions with the "nonliving" elements in the environment. Examples of nonsocial/environmental factors include the structure of the built environment, noise levels, temperature, work schedule, work load, and the like. These nonsocial/environmental causal factors tend to be understudied but can exert a significant impact on behavior. Consider, for example, the case of classically conditioned nausea and vomiting among chemotherapy patients. These patients can acquire a number of adverse immunological, emotional, and behavioral responses when they come into contact with smells, images, tastes, or sensations that are associated with the hospital setting where they undergo treatment (Zachariae et al., 2007).

The measurement parameters of contextual factors are similar to those used with target behaviors. Specifically, there is an emphasis on the measurement of frequency, intensity, and/or duration of contextual factor occurrence. Additionally, it is helpful to rate the clinical utility of a contextual factor (Haynes & O'Brien, 2000). The clinical utility rating is an estimate of the extent to which a particular contextual factor can be modified for the purposes of creating a change in target behaviors. For example, some important contextual factors can be unmodifiable (e.g., temperature, season, work characteristics, presence of a partner who is unwilling to participate in therapy, etc.). While these important contextual factors should be noted and understood as having an impact on target behaviors, they are de-emphasized in subsequent case conceptualizations and interventions.

In summary, the initial step in a behavioral assessment is the topographical analysis of target behaviors and contextual factors. The topographical analysis of target behaviors involves generating operational definitions of cognitive, affective, and motor responses. Additionally, importance ratings of the target behaviors are obtained. The topographical analysis of contextual factors involves generating operational definitions of intrapersonal, interpersonal, and environmental events that exert important causal effects on target behaviors. These contextual factors are then rated in terms of modifiability or clinical utility.

Estimating Relationships Among Target Behaviors and Contextual Factors. Once the topographical analyses of target behaviors and contextual factors have been completed, the behavior therapist evaluates interrelationships among target behaviors and contextual factors. In most cases, the emphasis is on identifying and evaluating a subset of all possible relationships – those that have causal properties. Reliable covariation between a target behavior and contextual factor is a critical index of possible causality. However, covariation alone does not imply causality. Causal relationships should meet three criteria: (a) temporal order – the changes in the causal variable should precede effects on the target behavior, (b) a logical explanation for the relationship (based on logic and learning theory), and (c) the exclusion of plausible alternative explanations for the observed relationship (O'Brien, Kaplar, & McGrath, 2004).

Three basic methods can be used to identify causal functional relationships. Each method has strengths and limitations in relation to causal inference and clinical applicability. The marker variable strategy is the most commonly used method of inferring causality. A marker variable is an easily obtained measure that denotes the presence of a causal relationship. Client

interview responses are typically used as marker variables. For example, a client's statement that his or her migraine headaches are almost always "triggered" by stress is taken as an index of a potentially strong causal relationship between stress and headaches in daily life. Marker variables can also be derived from self-report inventories specifically designed to identify functional relationships, structured interviews, and structured therapist–client interactions. The Motivational Assessment Scale (Durand, 1990) and the School Refusal Assessment Scale (Kearney & Silverman, 1990) are two examples of self-report measures that can be used to identify causal relationships.

The major advantage to the marker variable strategy is convenience. A behavior therapist can quickly identify potential causal relationships with a very limited investment of time and effort. The most significant problem with using marker variables is lack of validity. Specifically, the extent to which the most commonly used marker variables such as patient reports, self-report inventory responses, and in-session observation reflect "real life" causal relationships is undetermined. Thus, we recommend that when marker variables are used, the assessor should collect additional assessment data that will permit empirical validation of the hypothesized causal relationship.

A second procedure commonly used to obtain information about causal relationships is systematic observation of naturally occurring target behavior–causal variable interactions. Most commonly, assessors use client self-monitoring to evaluate causal relationships in this way. For example, a client may be instructed to record the daily levels of stress and headache activity to determine whether there is a causal relationship between these two variables. An alternative strategy is to have trained observers record target behavior–causal variable interactions. An example of this approach would be to have observers record the occurrence of a child's off-task behavior and social reinforcement in a class room setting.

Self-monitoring and direct observation methods can provide very good information about causal relationships (see special series on self-monitoring in *Psychological Assessment*, Volume 11, 1999). However, these techniques have two limitations. First, clients or observers must be motivated, well trained, and compliant with the procedures in order to obtain consistent, accurate, and reliable recordings. Second, as the number and complexity of the variables to be observed increases, accuracy and reliability decrease (Hartman & Wood, 1990).

The third method that can be used to identify casual relationships is experimental manipulation. Experimental manipulations involve systematically modifying a causal variable while observing consequent changes in target behavior (see special series on analog behavioral observation in *Psychological Assessment*, Volume, 13, 2001.). These manipulations can be conducted in the natural environment, analog settings (e.g., Iwata, Smith, & Michael, 2000), psychophysiological laboratory settings (e.g., Anthony & O'Brien, 1999; O'Brien & Haynes, 1995), and during assessment/therapy sessions (Tsai et al., 2008).

Data obtained from experimental manipulations permit strong causal inference. Further, experiments conducted in laboratory and analog settings can be arranged with modest investment of time and effort by the behavior therapist. There are, however, some limitations to this approach. First, the psychometric properties of experimental manipulations are not well known. Second, most demonstrations of the treatment utility of experimental manipulations have been limited to a very restricted population of clients (typically mentally retarded clients) who were presenting with a restricted number of target behaviors. Thus, utility of this procedure for identifying the target behavior–causal variable relationships may not generalize to other client populations and settings.

In summary, marker variables, observation of target behavior–causal variable occurrence, and experimental manipulations can be used to gather data on causal relationships. As Haynes (1992) noted, however, the strength of causal inference associated with each method varies inversely with clinical applicability. Experimental manipulations, self-monitoring, and behavioral observation yield high-quality data on causal relationships. However, each method requires significant effort and only a few target behaviors and causal factors can be reasonably evaluated. In contrast, the marker variable strategy provides data about causal relationships that has limited or unknown validity. However, it is easily conducted and can provide information on many target behavior–casual variable relationships.

We recommend using different methods at different points in the assessment. In the early stages of model design, the assessor can rely on marker variables so that many potential causal relationships can be identified. Later, after additional information has been collected on target behavior–casual variable interactions, the assessor can select a subset of important causal relationships and subject them to more intensive scrutiny using self-monitoring, observation, and/ or systematic manipulation.

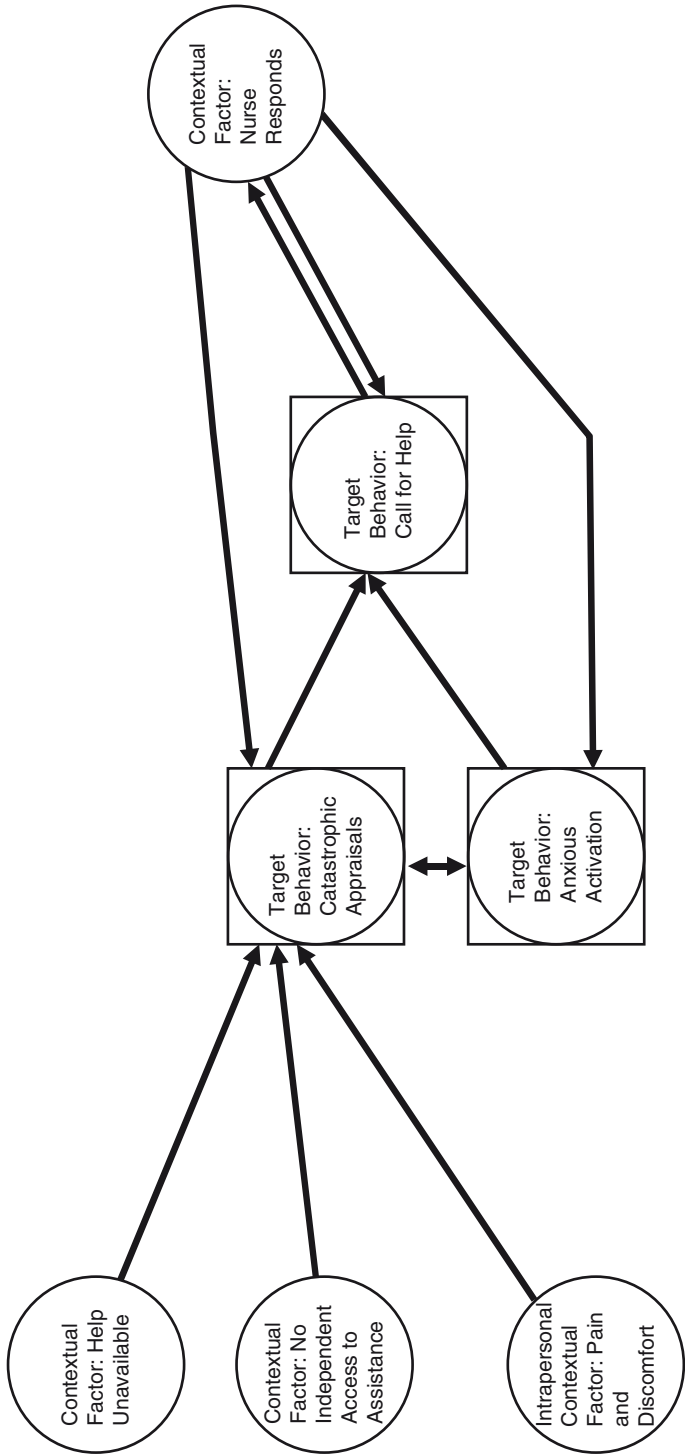
Generating a Functional Analysis. Once target behaviors and contextual factors have been operationalized a working model of interrelationships among these variables needs to be developed. This conceptual model of interrelationships between target behaviors and contextual factors is the functional analysis which has been more formally defined as "the identification of important, controllable, causal functional relationships applicable to a specified set of target behaviors for an individual client" (Haynes & O'Brien, 1990, p. 654).

The functional analysis is a core methodology in behavioral assessment because it creates a conceptual model of behavior–context interactions which addresses the onset, maintenance, and modification of target behavior occurrence. Thus, the functional analysis can aid in treatment design. Failure to generate an accurate or complete functional analysis can reduce the effectiveness of treatments.

We have recommended that behavior therapists generate functional analytic causal models (FACM) to depict functional analyses. FACMs are vector diagrams that graphically depict the interrelationships among target behaviors and contextual factors for an individual client. Consider the patient described earlier in this chapter. As you may recall, the example involved a patient who was reported to be calling out for help inappropriately. The FACM for this patient is presented in ❯ Fig. 11.1.

The FACM identifies four contextual factors and three target behaviors which are interrelated in specific ways. Three contextual factors (help unavailable from others, no independent access to assistance, pain and discomfort) can be thought of as predictors of target behavior occurrence. One contextual factor can be thought of as the consequence of target behavior occurrence (in this case a negative reinforcer delivered by nursing staff in the form of social attention). The three target behaviors were derived from interviewing the client and conducting behavioral observations. The FACM specifies that when the patient encountered increased discomfort, no independent access to assistance, and unavailable help from others, she generated catastrophic appraisals (i.e., "Something serious may be wrong with me," "I may die if I don't get help.") which, in turn, brought about anxious activation. When her anxiety and catastrophic thoughts reached a high level of intensity, she would call out for help. After calling out for help, a nurse would respond to her and, in turn, her anxious activation and catastrophic thinking would be immediately and significantly decreased (negative reinforcement).

■ **Fig. 11.1**

Functional analytic causal model for calling-out behavior in a medical setting


We have found FACMs to be useful in three important ways. First, FACMs systematize the clinical decision-making process and thereby encourage the therapist to consider the complex relationships that exist among target behaviors and contextual factors. Second, FACMs can provide an interpretable and parsimonious summarization of a functional analysis. Third, they provide guidance on treatment design. Using the current example, one examines the interrelationships among variables and notes where most vector lines converge. In this case, it is with nurse responses and also catastrophic appraisals. Consequently, the intervention should target modification of client beliefs about his or her vulnerability to catastrophic medical events and modification of nurse responding to calling-out behavior.

11.4.4 Clinical Competencies 2: Information Gathering Strategies

Thus far, we have described processes involved with generating a topographical and functional analysis of behavior. It is also the case that there are several unique clinical techniques associated with behavioral assessment. These techniques are used *in addition to* the many nonspecific clinical techniques that are used by behavior therapists such as rapport establishment, use of active listening, and providing empathic support.

Behavioral interviewing. Behavioral interviewing differs from other forms of interviewing in terms of structure and focus. Structurally, behavioral interviewing is designed to gather information about the topography and function of target behaviors. Topographical questions direct the client to describe the mode, parameters, and importance of target behaviors and contextual factors. Functional questions direct the client to provide information about causal relationships among target behaviors and contextual factors.

In terms of focus, client verbalizations are interpreted in two ways. When viewed as marker variables, client verbalizations are treated as an *index* of casual relationships between target behaviors and contextual factors. When viewed as target behaviors, client verbalizations are treated as a *direct occurrence* of the target behavior that was emitted during the interview itself. For example, a client may provide a vague response about factors that contribute to increased headache activity. This verbal response may be taken as a marker (i.e., that the causes of the client's headaches are unknown or inconsistent) or as a direct occurrence of a target behavior (i.e., the client has poor capacity for identifying cause–effect relationships).

Despite the fact that the interview is the most commonly used assessment method, few researchers have evaluated its reliability and validity. For example, Hay, Hay, Angle, and Nelson (1979) and Felton and Nelson (1984) presented behavior therapists with video-taped interviews of a confederate who was acting as a client and measured the extent to which the therapist observers agreed on target behavior identification, causal factor identification, and treatment recommendations. Low to moderate levels of agreement were observed on target behavior identification and causal factor identification. However, these studies were limited because the therapists could only evaluate information that was provided on a videotape which used another examiner's questions. Thus, they could not follow-up with clarifying questions or direct the client to provide greater details about various aspects of their target behavior. It is likely that observed agreement rates would be substantially different if interviewers were allowed to use their own questioning strategies. Further research is needed to improve our understanding of the psychometric properties of behavioral interviews.

Behavioral Observation. Observations are conducted by nonparticipant observers and participant observers. Nonparticipant observers are trained technicians who systematically record target behaviors and causal factors. Because nonparticipant observers are essentially hired to conduct observations, they are often able to collect data on complex behaviors, causal factors, and target behavior–casual event sequences. Although nonparticipant observation is a versatile assessment method, it is infrequently used in clinical settings due to cost.

Participant observers are persons who typically have a relationship with the client. In most cases, participant observers are family members, teachers, friends, or caregivers. Because participant observers are persons who are already involved in the client's life, they are able to conduct observations in many settings. However, because participant observers have multiple responsibilities, only a small number of target behaviors and causal factors can be reliably and accurately observed.

Self-monitoring. Self-monitoring is an assessment in which clients systematically record their own behavior. Because clients can access all three modes of responding (cognitive, affective, overt-motor) in multiple naturalistic contexts, self-monitoring has great clinical utility (see special section on self-monitoring in the December 1999 issue of *Psychological Assessment*). Self-monitoring has many advantages. As noted above, clients can observe all modes of behaviors with self-monitoring. Second, it can be used to monitor target behaviors that are private or concealed from others (e.g., drug use, sexual behavior). Third, self-monitoring often promotes improved client awareness of how contextual factors influence target behaviors. Finally, self-monitoring often promotes reductions in undesirable target behaviors and increases in desired target behaviors (Korotitsch & Nelson-Gray, 1999).

The main limitation of self-monitoring is observer bias. Specifically, a client may not accurately record target behaviors because of: expectations of positive or negative consequences, lack of awareness, inconsistent motivation, and use of criteria for target behaviors and contextual factors that is different from the therapist. Finally, noncompliance with self-monitoring is often quite problematic.

11.4.5 Summary of Basic Competencies

The basic competencies associated with behavioral assessment fall into theoretical/conceptual and clinical/technical domains. The theoretical/conceptual competencies include knowledge of the basic assumptions underlying a behavioral approach to understanding human behavior and knowledge of psychometrics. The clinical/technical competencies include knowledge of processes used to generate and summarize the form and function of target behaviors as well as specific skills used to conduct interviews, observations, and the self-monitoring of behavior.

11.5 Expert Competencies

11.5.1 Conceptual Competencies: "Third Wave" Behavioral Approaches

As the field of behavior therapy has developed, the characteristic assumptions, techniques, and goals that organize theory, assessment, and treatment have also shifted. These changes have been sorted into three "waves" of evolution (Hayes, 2004). The first wave is represented by the

development and application of interventions based on respondent conditioning (also called classical conditioning) and operant conditioning. The second wave can be thought of as a phase during which cognitive variables were incorporated into behavioral models as causal variables and target behaviors. The third wave of behavior therapy is exemplified by models that are based on functional contextualism. In the following sections, we will present the basic principles contained in each wave of behavior therapy and how they are relevant to behavioral assessment.

Wave 1: Respondent and Operant Conditioning Applied to Observable Target Behaviors and Contextual Factors. Drawing from the experimental works in respondent conditioning, the first wave behavior therapists conducted basic research that ultimately demonstrated how respondent conditioning principles could account for the acquisition, maintenance, and change in many target behaviors. An excellent example of this type of approach is evident in the work of Joseph Wolpe. Through careful experimentation on animals and humans, Wolpe (1952a, b) demonstrated that the anxiety states characteristic of "neurosis" could be induced using respondent conditioning. He also demonstrated that these same responses could be reduced using principles of experimental extinction and reciprocal inhibition (Wolpe, 1958, 1963, 1997; Wolpe & Lazarus, 1966; Wolpe, Salter, & Reyna, 1964).

Inspired by Wolpe, other researchers investigated how respondent conditioning could account for the acquisition and/or maintenance of many target behaviors in adults and children. Having established the link between respondent conditioning processes and various forms of psychopathology, researchers then set their attention on the use of conditioning principles to modify a wide array of target behaviors associated with anxiety disorders, eating disorders, mood disorders, sexual disorders, and psychophysiological disorders.

The other major learning theory explored during the first wave of behavior therapy was operant conditioning. Here, behavior therapists drew upon the theoretical and empirical work of Watson (1919), Skinner (1938, 1974), Hull (1952), and others to understand the ways that contingencies of reinforcement and punishment, stimulus generalization, stimulus discrimination, stimulus control, and extinction could account for the acquisition, maintenance, and change in target behaviors. Many types of behavioral interventions were subsequently developed using operant conditioning principles as the framework. Further, randomized control outcome trials and single-subject investigations demonstrated that these interventions were consistently effective.

The success of wave 1 interventions laid the foundations for the entire behavior therapy movement. Firmly grounded in experimentation and empiricism, early behavior therapists embraced a singular focus on the observable features of target behaviors and environments. As such, behavioral assessments emphasized measurement of observable target behaviors and contextual factors.

Wave 2: An Expansion into the Measurement and Modification of Cognitive and Emotional Experiences. As noted by Hayes (2004), the second wave of behavior therapy emerged out of a growing recognition that there were important aspects of human experience such as thoughts and felt emotions that were underemphasized in wave 1 formulations. It was not the case that basic conditioning principles could not accommodate these responses, rather it was that the early behavior therapists tended to reject the use of unobservable experiences as target behaviors or contextual variables. Moreover, Skinner argued (cf. Skinner, 1974, 1986, 1990) that thoughts and felt emotions were not necessary for reliable prediction of behavior.

The introduction of cognitive variables into behavior therapy was spearheaded by researchers who drew on the works of social learning theorists and cognitive psychologists. They took the position that cognitive variables functioned as important mediators between observable contextual factors and observable target behaviors. From this perspective, thoughts and emotions should be measured because they could account for unique variance in target behaviors. A prototypical model of this mediated relationship can be found in Beck's cognitive model of depression (cf. Beck, Rush, Shaw, & Emery, 1979). According to Beck and colleagues, depression arises from negative automatic thoughts about the self (incapable, helpless), one's life circumstance (unfair, uncontrollable), and one's future (hopeless). This "cognitive triad" is acquired through negative life experiences and is maintained by dysfunctional cognitive processes (e.g., overgeneralization, selective abstraction, dichotomous thinking) and more general cognitive structures called "schemas." The automatic thoughts, cognitive processes, and schemas are activated by specific contextual factors (e.g., exposure to a stressor) and lead to problematic behavioral and emotional responses such as withdrawal, guilt, sadness, and the like.

As cognitive variables were presumed to act as important causal variables, assessment techniques were developed to measure their occurrence and relationships with other target behaviors. In addition, cognitive therapy techniques were developed. These techniques were aimed at helping the client learn to identify, stop, confront, and/or nullify the problematic cognitive experiences. They also typically involved using logic, corrective experiences, and the rehearsal of alternative adaptive thoughts as a means for changing cognitive experiences. Importantly, wave 2 interventions also typically included components targeting behavior change using the respondent and operant conditioning principles established during wave 1.

The effectiveness of cognitive-behavioral interventions is very well established. For example, meta-analyses of the treatment outcome literature indicate that cognitive-behavioral interventions yield large and robust improvements in client functioning across a number of disorders (e.g., Butler, Chapman, Forman, & Beck, 2006).

Many of the core second wave assumptions are recently coming under scrutiny. Cognitive models presume that controlling or correcting maladaptive cognitive experiences is a necessary element of treatment. However, a large-scale component analysis study of the treatment of depression demonstrated that cognitive therapy techniques did not produce improvements over and above those obtained by techniques targeting behavioral activation alone (Jacobson, Martell & Dimidjian, 2001). Others have argued that it is not possible to effectively control the occurrence and intensity of cognitive experiences because they can arise spontaneously (Hayes et al., 2006).

In summary, wave 2 behavior therapies added cognitive variables into behavioral conceptualizations of disordered behavior. Skills and methodologies used to assess overt target behaviors were modified to include cognitive variables. For obvious reasons, these assessment advances relied heavily on patient self-report. The second wave also expanded on the first to include intervention techniques aimed at helping patients reduce the frequency, intensity, and/or duration of unwanted/target cognitions using principles of respondent and operant conditioning.

Wave 3: Functional Contextualism. The theory and application of models arising from the first and second waves of behavior therapy represented important gains for patients presenting with a wide variety of psychological difficulties. In recent years, however, a growing number of new behavioral interventions have been developed which are quite different from their predecessors.

Examples of these "third wave" interventions include: Acceptance and Commitment Therapy (ACT; Hayes, Strosahl, & Wilson, 1999), Dialectical Behavior Therapy (DBT; Linehan, 1993; Linehan et al., 2006), Functional Analytic Psychotherapy (FAP; Kohlenberg et al., 2004; Tsai et al., 2008) and Mindfulness Based Cognitive Therapy (MBCT; Hayes, Follette, & Linehan, 2004; Segal, Williams, & Teasdale, 2002). While all behavior therapies share the twin goals of prediction and influence of psychological events. The new therapies diverge from wave 1 and 2 therapies in terms of philosophical stance, theoretical formulations, and treatment aims. These differences have important implications for the methods and targets of behavioral assessment.

As noted by Hayes (2004), the third wave of behavior therapy represents a movement away from the positivism and cognitivism that is embedded in the first and second wave approaches and a recommitment to radical behaviorism which is founded on *functional contextualism*. The differences between these two philosophical stances are substantial. From the first and second wave point of view, overt behavior, cognitive events, and other "private experiences" (e.g., emotional experiences) can be broken down into constituent parts and the relationships among these parts can be studied/analyzed separately. It thus is logical to take the position that, for example, a thought such as, "I've been contaminated," might *lead to*, or *cause*, a problematic behavioral response such as excessive hand washing. The thought itself is identified as "dysfunctional" because it causes maladaptive behavior. Therefore, it is critically important to stop, alter, or otherwise control the occurrence of this thought in order to stop excessive hand washing.

In contrast to the positivistic stance just described, functional contextualism takes the position that cognitive, emotional, and motor responses occur in *relation to, and derive meaning from*, historical and ongoing internal and external events (Hayes, 2004). Consider again, the thought "I've been contaminated." From a functional-contextual perspective the thought is neither functional nor dysfunctional. It is simply a cognitive experience. What is important to assess is the relationship between the thought and other responses. Specifically, the focus is on whether the thought *is believed to be literally true and whether it is associated with* adverse or undesired behavioral outcomes. Thus, for example, if the thought is believed to be literally true and it is associated with adverse outcomes, then it would be targeted in an intervention.

Unlike second wave approaches, however, the goal of wave 3 interventions would not be to eliminate or control the occurrence of the thought. Correspondingly, the client would be encouraged to *not* attempt to control the thought but instead accept it as one of many cognitive experiences that occur thousands of times per day. Additionally, the client would be encouraged to use techniques that (a) reduce the extent to which the thought is believed to be literally true (e.g., defusion techniques) and (b) reduce the strength of its relationship with other target behaviors (e.g., mindfulness techniques that involve noting the thought and allowing it to occur without taking action). Finally, the client would be encouraged to acquire other behaviors that allow him or her to more fully pursue valued life goals (Hayes et al., 1999).

The implications of third wave innovations for behavioral assessment are becoming clearer and a great deal of research is needed. First, there is a pressing need to develop reliable and valid measures of key constructs such as acceptance, experiential avoidance, willingness, thought fusion, construction of the "self," values, and mindfulness. Second, there is a need to develop and validate case conceptualizations and/or FACM that depict client difficulties from a functional-contextual perspective. Finally, there is a need for a better understanding of how important principles derived from first and second wave approaches can be integrated with third wave assessments and interventions.

11.5.2 Clinical Competencies: Statistically Evaluating Behavioral Assessment Data

Once a FACM has been developed, the behavior therapist will typically want to measure the magnitude of relationships among variables. There are a number of methods available for accomplishing this task. In the two sections that follow, the more common approaches will be reviewed.

Some researchers have argued that intuitive data evaluation such as visual inspection of a line graph or scatterplot is an appropriate, if not preferred, method for evaluating behavioral assessment data. Arguments in favor of intuitive evaluation are based on convenience (it requires only a modest investment of time and effort) and clinical significance. In the latter case, it has been argued that visual inspection is conservatively biased, and as a result, a judgment that there is a relationships between two variables will only occur when the relationship is of moderate to high magnitude.

For example, we conducted an investigation in which graduate students who had completed coursework in behavioral therapy were provided with a contrived set of self-monitoring data presented on three target behaviors: headache frequency, intensity, and duration. The data set also contained information from three potentially relevant contextual factors: hours of sleep, marital argument frequency, and stress levels. The data were constructed so that only a single causal factor was strongly correlated (i.e., $r > .60$) with a single target behavior (the remaining correlations between causal variables and target behaviors were of very low magnitude).

Students were instructed to evaluate data as they typically would in a clinical setting, estimate the magnitude of correlation between each causal factor and target behavior, and select the most highly associated causal factor for each target behavior. Results indicated that the students predominantly used intuitive evaluation procedures (e.g., "eyeballing") to estimate correlations. The students also consistently and significantly underestimated the magnitude of strong correlations and overestimated the magnitude of weak correlations. In essence, they demonstrated a central tendency bias or guessing that two variables were moderately correlated regardless of whether or not they *were in fact* correlated. Finally, the students were able to correctly identify the most important contextual factor variable for each target behavior less than 50% of the time.

We further evaluated the potential limitations of intuitive data evaluation methods by surveying members of a large organization of behavior therapists (Association for Behavioral and Cognitive Therapies (ABCT)). Similar to the O'Brien (1995) study, we created a data set that contained three target behaviors and three potential contextual factors in a 3 × 3 table. The correlation between a target behavior and three contextual factors was either low ($r = .1$), moderate ($r = .5$), or high ($r = .9$). Participants were instructed to identify which of the three possible contextual variables was most strongly associated with each target behavior. Results indicated that when the true correlation between the target behavior and contextual factor was either low or moderate, the participants were able to correctly identify the correct contextual factor at slightly better than chance levels. When the true correlation was high, the participants' performance rose to only 72%.

Taken together, these results suggest that intuitive evaluation of behavioral assessment data is not well-suited for estimation of covariation which, as noted earlier, is critical for causal inference. As many decision-making researchers have argued, intuitive analysis of data similar to those described above, oftentimes results in inaccurate interpretations of clinical data

(Garb, 1996, 2005). One reason for this phenomenon is that confirmatory information or "hits" (i.e., instances in which the causal variable and hypothesized effect co-occur) are overemphasized in intuitive decision making relative to disconfirming information such as false positive misses.

A number of other biases and limitations in human judgement have been identified (cf., Chapman & Chapman, 1969; Einhorn, 1988; Garb, 2005; Kleinmuntz, 1990). A particularly troubling finding, however, is that a clinician's confidence in his or her judgments of covariation increases with experience, while accuracy remains relatively unchanged (Arkes, 1981).

In summary, intuitive data evaluation approaches can be convenient. Fundamental problems emerge, however, when clinicians attempt to intuitively estimate the magnitude of covariation between target behaviors and contextual factors. This problem is compounded when one considers the fact that multiple behaviors, multiple causes, and multiple interactions are encountered in a typical behavioral assessment. It is thus recommended that statistical evaluations be conducted, whenever possible, to evaluate the strength of hypothesized causal functional relationships. In the following sections, two statistical approaches are described.

Conditional Probability Analyses. Conditional probability analyses assume that functional relationships can be mathematically described as elevated conditional probabilities (James, Mulaik, & Brett, 1982; Schlundt, 1985). An elevated conditional probability indicates that the likelihood of observing a change in a target behavior, given that some hypothesized contextual factor has occurred (i.e., its conditional probability), is greater than the probability of observing a change in a target behavior without considering the occurrence of the hypothesized contextual factor (i.e., its base rate or unconditional probability).

To illustrate, let A = migraine headache occurrence, B = stress level (coded as high or low), and P = probability. A functional relationship between migraine and stress level would be inferred if the probability of experiencing a migraine headache given the presence of high stress ($P[A|B]$) is greater than the base rate probability of experiencing a migraine ($P[A]$).

Conditional probability analyses have important strengths. First, a small number of data points can yield reliable estimates of association (Schlundt, 1985). Second, the statistical concepts underlying the methodology are easily understood. Third, many statistical programs can be used to conduct conditional probability analyses or, if none are available, the computations can be easily done by hand. A limitation of conditional probability analysis, however, is that it can evaluate the interactions among only a small number of variables. Further, because it is a nonparametric technique, it can be used most easily when the target behavior and contextual factors are measured using nominal or ordinal scales.

Time Series Analysis. Time series analyses involve taking repeated measures of particular topographical dimensions of the hypothesized controlling variables and target behaviors across time. The magnitude of causal functional relationships then can be estimated by calculating a measure of association between controlling variables and target behaviors after partitioning out the variance accounted for by autocorrelation (Wei, 1990).

When the assessment data is quantified using nominal or ordinal scales Markov modeling and lag sequential analysis can be used to evaluate the magnitude of functional relationships (Gottman & Roy, 1990). With interval and ratio data, other time series methodologies such as Arithmetic Integrated Moving Averages modeling (ARIMA), hierarchical linear modeling, and spectral analysis can be used (Cook & Campbell, 1979; Hox, 2002; Wei, 1990).

Time series methodologies provide excellent information about the strength and reliability of functional relationships. They also can be used to examine the effects of contextual factors on target behaviors across different time lags. However, they require a minimum of approximately 50 points of measurement for reliable estimation of relationships (Gottman & Roy, 1990; Matyas & Greenwood, 1990) and can evaluate the interactions among only a few variables. Finally, the statistical theory and procedures are quite complex.

11.6 Summary

Behavioral assessment has been in existence as a research and clinical approach for several decades. It is continuing to exert an important influence on research and clinical practice. Behavioral assessment is based on learning theories and embraces functional contextualism, empiricism, idiographic measurement, and multivariate measurement. Further, relative to psychodynamic and personality-based approaches, behavioral case formulations are less susceptible to tautological reasoning. The advanced competencies in behavioral assessment are related to understanding the newly developed theories of behavioral problems and their associated interventions. Additionally, there is a clear need for researchers and practitioners to be familiar with the statistical tools needed to evaluate complex data that comprises a FACM. The evolution of behavior therapy has brought with it the need for behavioral assessment to expand the range and types of variables that are typically evaluated in clinical settings. In particular, there is a need for better measures of the key constructs associated with the third wave therapies.

12 Behavioral Assessment with Children

Kathryn L. Humphreys · Brian A. Feinstein · Brian P. Marx

Abstract: Behavioral assessment, as opposed to traditional assessment, emphasizes the ante-cedents and consequences of behavior. The primary goal of behavioral assessment is to opera-tionalize behavioral excesses and deficits, such that the situations or events that precipitate the event and the responses to the event are reframed as causes and reinforcers of problem behav-iors. The information obtained via behavioral assessment can be used to create interventions that aim to alter those problem behaviors through the use of the environment. Although be-havioral assessment was initially concerned with strictly observable behaviors, the domain has expanded to include beliefs, attitudes, and emotional states. Interest in behavioral assess-ment with children specifically has increased dramatically since Ollendick and Hersen (1984) published the first text devoted to this topic. The use of behavioral assessment with children poses new challenges to clinicians who are accustomed to working with adult clients. This chapter intends to explain and provide specific examples of various behavioral assessment techniques that can be implemented with children, while emphasizing the unique challenges that present when working with such clients. The first half of this chapter is devoted to basic behavioral assessment competencies (e.g., behavioral interviewing, direct observation) that all clinicians who work with children should be familiar with and comfortable using. The second half of this chapter focuses on advanced behavioral assessment techniques (e.g., peer sociometry, psychophysiological assessment) that are likely to require additional, specialized training. It is our hope that this chapter will help clinicians who encounter child populations in their practice by refreshing their knowledge of basic behavioral assessment competencies and introducing more advanced behavioral assessment techniques that can be implemented with children.

12.1 Overview

Since the first text devoted to child behavior assessment was published in 1984 (Ollendick & Hersen, 1984), interest in behavioral assessment targeting children and adolescents has markedly increased. Much of the growth in the focus on child-specific assessment and treat-ment is due to the budding field of developmental psychopathology (Sroufe & Rutter, 1984). The focus on development and maturity is inseparable from the expression of symptoms in children and adolescents (Cicchetti & Rogosch, 2002). Cicchetti and Rogosch have also argued that adolescence is a time when the boundaries between normal and abnormal are less set, in part because mood swings and increased risk taking are common to the adolescent experience.

Child assessment differs from adult assessment in several ways. According to Boggs, Griffin, and Gross (2003), child assessment differs from adult assessment in that: (1) adults (not the children themselves) are typically the ones seeking services; (2) development and

developmentally appropriate behaviors are a focus; and (3) there is a greater use of informant information in child assessment. As the child is typically not the individual who is seeking assessment or treatment, it is helpful to involve multiple informants, such as parents, teachers, peers, other caregivers, previous therapists, physicians, as well as the child, to obtain information for the behavioral assessment. Clinicians should be open and honest about confidentiality issues with the child and parents, as they have a responsibility to both parties.

This chapter focuses on behavioral assessment with children and adolescents. Behavioral assessment differs from traditional assessment because of the behavioral theoretical framework (e.g., emphasis on antecedents and consequences of behavior) in which behavioral assessment is based. The behavioral framework aims to define and operationalize the problem behavior, and attempts to determine the best intervention strategy and evaluate the treatment (Reitman, 1998). The behavioral lens differs from traditional theory, as behaviorists assume that behaviors may not be consistent across all situations and that behaviors are not simply outward expressions of stable traits. The focus is on what the child *does*, rather than what the child *has*.

When using the behavioral framework, clinicians should use little inference and instead rely on the methods described within this chapter. Child behavioral assessment was at one point completely concerned with observable behaviors or potentially observable constructs (e.g., heart rate, skin conductance), but has broadened to include beliefs, attitudes, and emotional states (Cone, 1998; Hayes, Follette, & Follette, 1995), as long as the constructs are evaluated relative to appropriate standards (Barrios & Hartmann, 1986; Cone, 1998). There has been a shift from the traditional operant and classical conditioning perspective to include cognitive and affective components as well (Mash & Terdal, 1988).

The goal of behavioral assessment is to seek information to determine the purpose, cause, or function of behavior in order to create a functional analysis of the child's problem behaviors. A functional analysis identifies the causes or reinforcers of the problem behavior, and within the behavioral framework, the causes are usually social or environmental settings or events. The functional analysis should aid in the clinician's ability to identify the mutable environmental events so that appropriate interventions can be determined to change the current environmental dynamic. In addition, clinicians may want to use the assessment to confer diagnoses and evaluate treatment progress and outcome.

Parents are usually the first choice for information gathering regarding their child's problems. It is important that clinicians attempt to form a relationship with the parents. They need to be able to ask about how the parents respond to their child, what types of responses tend to elicit a particular response from the child, and which situations or responses tend to result in the most problematic behavior. Clinicians may also consider collecting information about the parents, as there are reciprocal behavioral relationships between children and caregivers. For example, parental psychopathology has been associated with inconsistent discipline and other negative parenting behavior (Johnson, Cohen, Kasen, Ehrensaft, & Crawford, 2006). Additionally, a reciprocal relationship has been found between maternal depression and childhood externalizing problems (Gross, Shaw, & Moilanen, 2008), so gathering information about the parents themselves can be extremely useful in better understanding the child's behavior.

The dynamic nature of interpersonal relationships should emphasize that children should not be simply passive recipients of what the environment gives to them. Traditional assessment

perspectives have viewed the subjects (in this case, children) to be passively responding to the environmental changes around them, thereby focusing on changing the environment. However, it is important for clinicians to keep in mind that the child can become engaged with self-directed decision making and can be an actor in the development of self-regulation skills.

Sometimes parents bring their child in for treatment or assessment with regard to behaviors that are developmentally appropriate or typical. It is important for clinicians to be prepared for parents to have unrealistic expectations and provide materials that enumerate developmentally appropriate behaviors. For example, parents may be concerned that their child is not demonstrating appropriate self-care skills in a timely manner. It would be useful to provide parents with information about when to expect the appearance of self-care skills, such as using the bathroom, feeding, and walking on their own. Clinicians should emphasize that there is a wide variability in the development of certain skills, and that it is important to maintain patience with children. A national study collected information about what adults know about child development and found that nearly half of the parents with young children think it will spoil a 3-month-old child if the child is picked up every time he or she cries (CIVITAS Initiative, Zero to Three, & BRIO Corporation, 2000). Additionally, 61% of parents with young children think that spanking is an appropriate form of punishment. Clarifying these myths and misconceptions may be one of the first steps of the assessment process as it will help provide a better parenting environment for the child as well as provide the parents with more realistic expectations of their children's behavior. In line with this, clinicians should be well-versed in the normative ranges for physical size, motor skills, language, cognition, and emotion across the age span, as all of these domains are important components in understanding the child and assessing the current state of functioning. Furthermore, sensitive normative comparisons are the foundation of diagnosis for disorders in the childhood years (American Psychiatric Association, 1994; Kamphaus & Frick, 1996).

This chapter is primarily concerned with early and middle childhood behavioral assessment, but many of the techniques described may be useful for a broader age range with tools specific to infancy as well as the late teenage years. In working with young children, clinicians must be mindful of the development of "theory of mind," which will affect whether children can attribute thoughts, desires, and knowledge to themselves and others. Having a theory of mind enables the ability to understand that mental states cause behavior, as well as predict the behavior in others (Premack & Woodruff, 1978).

This chapter intends to explain and give examples of the various behavioral assessment techniques that can be implemented in the assessment of children. The first group of assessment tools described in this chapter is the most basic and all clinicians who work with children should be familiar with the existence, purpose, and use of those tools. The second group of assessment tools described in this chapter is concerned with more advanced techniques that will require additional, specific training. For clinicians working with a child population, this chapter can help refresh the techniques that are available and provide suggestions as to which specific tools to use in particular situations. We recommend that interested readers seek additional information on the techniques explained in this chapter before incorporating them into their child behavioral assessment practices. Continuing education courses on the specific topics discussed below and further reading are typically the best option for clinicians who are interested in expanding their basic competencies.

12.2 Behavioral Interviewing

The behavioral interview is the first step in the assessment process. It sets the foundation for future interactions with the client throughout assessment and treatment. As such, being a competent behavioral interviewer is essential for any clinician. The behavioral interview is usually the first opportunity for the clinician to interact with the client and it helps to set the tone of the relationship. The behavioral interview is a comprehensive assessment, but should identify areas for future in-depth exploration. The use of a behavioral interview is common in clinical practice and, compared with other assessment tools, is relatively unstructured. Clinicians should use the interview to collect information on general and cognitive functioning, as well as specific problem areas and their environmental concomitants. In terms of identifying the targets for intervention, the behavioral interview is generally better able to do so than structured interviews, as the flexibility of an unstructured interview allows more pertinent topics to be focused upon and less relevant areas to be skimmed over or omitted altogether.

It should be noted that there is no standard for the behavioral interview. However, there is a general consensus among practitioners and theorists that the interview must have a beginning, middle, and end. Clinicians should begin with open-ended questions and continue to ask more specific questions later in the interview. The lack of a clearly defined structure for the behavioral interview may make the process somewhat difficult for those trained and comfortable with manualized interviews. The guiding concept, as with behaviorism in general, is to emphasize the current environment's antecedents, behaviors, and consequences (Sheridan, Dee, Morgan, McCormick, & Walker, 1996), as opposed to traditional psychological interviews that focus on more remote causes of behaviors (Gresham & Davis, 1988). In regard to behavioral assessment with children, behavioral interviews typically include several informants, such as parents, teachers, other caregivers, and the child. Depending on the age of the child, the use of multiple interviewers may be necessary to ascertain behavior in various social contexts, as different caregivers may have different experiences with the child and some behaviors may only occur at school or at home. For younger children, parents will be the primary interviewees in the assessment. However, for older children, clinicians may consider seeing the parents and child separately and spending equal time with both.

At the beginning of the initial session, clinicians should spend some time talking with clients about what will take place during that session. This includes introducing oneself and one's role in the assessment process and how involved you may be in treatment following the assessment. You should then restate what you already know about the client and explain that this session is mostly about gathering information, thus it will involve asking a lot of questions. One should also explain the types of topics that will be broached with the parents and the child, as well as the expectations both should have for future sessions. Behavioral interviews should take place in a private and quiet office or room. Clinicians should try to make the clients feel comfortable, use empathic, warm language, and maintain eye contact throughout the session. Bringing one's child in for a behavioral assessment can be intimidating and clinicians should acknowledge the difficulty the parents might have faced in making such a decision.

The goal of the behavioral interview is to gather information to help conceptualize the problem behaviors and contexts around those behaviors, rather than simply focusing on making a diagnosis. Clinicians should use the behavioral interview to objectively identify problem areas and form treatment plans, which are related processes (Hayes & Follette, 1992). It is likely that parents will bring their child in seeking help for a particular problem. However, the

behavioral interview allows for the exploration of other possible problem areas that could prove to be more pressing. Oftentimes problems do not present singularly, so a broad base of information should be obtained during the interview process.

The behavioral interview is the best time to gain insight into the family's financial situation, education level, ethnic background, and religious background. All of these factors may affect parental expectations for the child and perception of the presenting problem. Clinicians should also use the interview to ask about any pertinent medical conditions experienced by the child and/or parents, as serious illness in the family may be related to the expression of depressive or other problematic behavior. Specific topics to consider talking about during the interview are parent–child relationships, sibling relationships, peer relationships, school environment, and possible family changes, such as divorce. Regarding the necessary skills for performing a behavioral interview, Sharp, Reeves, and Gross (2006) suggested that clinicians should be able to create and maintain a positive rapport with the client, listen attentively to the client, and effectively communicate with the client using clear language.

Prior to the behavioral interview, the clinician should try to obtain as much information about the child as possible from the person who referred the patient to assessment. This allows the clinician to start making hypotheses about the specific problem areas to explore in depth during the behavioral interview. An interviewer should use operant conditioning concepts as well as a social learning perspective to create a functional analysis. Instead of deep inquiry into the immutable past, clinicians should focus mostly on the "now," as that is what can be modified.

Clinicians will need to go beyond simply identifying the problem. They must try to best operationalize behavioral excesses and deficits by clearly defining their frequency, severity, and duration. Although the parents may report that the child or the family is having problems in several areas, start by asking what is the most troublesome problem that they are facing right now. The aim should be to obtain a thorough account of the problem behavior – when it started, how often it occurs, and whether there have been any changes in the frequency or intensity. Some questions the clinician may want to keep in mind when conducting the behavioral interview include: Do the behavioral excesses or deficits only bother the child or do they affect others? What are the current negative consequences when the behavior is exhibited? Does the child seem to have control over the behavior? What may be reinforcing the behavior? What elicits it? As behaviorism's driving principles are set in conditioning and learning, the behavioral interview should attempt to understand the patient's problems as a maladaptive response that is sustained and altered by social surroundings (Beaver & Busse, 2000).

It may be challenging for the client to think systematically about the problem behaviors, so try to ease parents and children into thinking and talking in this manner. Clinicians should be flexible with the interview, as some parents will need more time to adjust to operationalizing the behavior and the social environment. The behavioral lens used to examine a child's problems may be difficult for some patients or parents. Oftentimes individuals may have already researched the problem issue and think that biological or other causes are to blame. Taking some time to explain how environmental causes and effects could reinforce behavior may be enlightening to those who are resistant to the behavioral perspective.

With this in mind, clinicians should try to avoid the use of inference and rather look for concrete information. Efforts should be made to obtain information on overt behavioral responses (e.g., increased food consumption) as well as covert responses (e.g., thoughts, feelings). Parents may be somewhat vague and/or nonspecific about problems with their child and

not attuned to specific antecedents. One should explain the purpose of the functional analysis and emphasize the importance of paying close attention to the antecedents and consequences of behavior. It may be useful to use language emphasizing the timing of events to model the use for patients. For example, with a child who experienced a trauma, it may be important to clearly define whether the child seems to be tense or fearful most of the time or if these behaviors appear suddenly following a reminder of the traumatic event. This can be accomplished by asking for examples and quantifying the length of time the behavior exists, the strength of the behavior, cases in which the behavior is stronger or weaker than usual, and whether the patient engages in any avoidant behaviors when they anticipate an event or setting that may trigger the emotional response.

When talking about potential antecedent's to the child's behavior, it is important for the clinician to keep in mind, and remind the parent, that antecedents are not merely unidirectional. The dynamic nature of a social environment means that the target behavior itself can elicit an antecedent to another behavior that is problematic (see O'Brien & Haynes, 1993). In this way, children could be perpetuating negating situations and conflicts. Difficulties or problem behaviors are often governed by learning principles, especially with children. They may have learned inappropriate responses or failed to learn more appropriate responses to certain situations. Although the situations can often be the source of problem behaviors being perpetuated, be careful not to assign blame to parents. Oftentimes, problematic responses are inadvertently reinforced, such as when a parent gives into a child's demand for a treat at the grocery store, only after the child repeatedly screams for the treat. Parents may be especially defensive of their parenting and reluctant to talk about any connection to their child's problem behaviors, causing them to potentially hide some important information. Be aware of this possibility and try to comfort the parents by acknowledging that you are not there to judge their parenting, but to assess the situation and look for ways in which it may be possible to intervene.

Although the behavioral interview is not a direct observation method of assessment, it provides an opportunity for the clinician to make behavioral observations and collect information about interpersonal behavior. Valuable information can be gained by simply observing the child's responses during a meeting. During the interview, the clinician should also keep in mind avenues for intervention. Obtaining information about the child's strengths and interests will be useful in planning future rewards for reinforcing positive behavior change. At the end of the session, close the interview with a positive note, encouraging the child and parents that treatment does help and acknowledge that they took a positive first step by seeking assessment and treatment.

12.3　Structured and Semi-structured Interviews

The use of structured and semi-structured interviews is an important component of child behavioral assessment and should be considered a basic competency that all clinicians should be trained in. The main goals of conducting a structured or semi-structured interview are to identify and quantify behaviors and symptoms, as well as to help in the diagnostic decision-making process. In behavioral assessment, it is recommended that the clinician begins the assessment with a behavioral interview to gain a preliminary understanding of the child's presenting problem behaviors and symptoms. Then, it can be useful to proceed with a structured

or semi-structured interview. There is a wide variety of structured and semi-structured interviews that can be used with children and adolescents. These interviews are commonly categorized by their structure (i.e., structured versus semi-structured) and by their orientation (i.e., symptom-oriented versus syndrome-oriented).

A structured interview is one that is intended to be read verbatim. This gives the interviewer no discretion on what to ask or how to ask it. Although it may feel restrictive not to be able to modify the wording of the questions, the use of a structured interview permits instrument standardization and the comparison with normative response data. For example, a clinician could administer the Diagnostic Interview Schedule for Children (Shaffer, Fisher, Lucas, Dulcan, & Schwab-Stone, 2000), a structured interview that assesses various forms of psychopathology (e.g., depression, anxiety). By following the scoring guidelines provided by the interview's creators, the clinician could determine whether the child meets diagnostic criteria for each disorder. This information could be used to gain a complete understanding of the child's presenting problem(s), which is imperative for adequate assessment and treatment planning. Conversely, a semi-structured interview provides the interviewer with flexibility on how to word questions and how to interpret responses. It is important to emphasize that the administration of semi-structured interviews requires more training than a structured interview, because the interviewer needs to be able to use some clinical judgment as to how to ask the questions and how to respond to the child's answers. One example of a semi-structured interview is the Anxiety Disorders Interview Schedule for Children (Silverman & Nelles, 1988), which could be used if the child has been described as exhibiting anxious behavior. This interview may be used to determine whether or not a child meets diagnostic criteria for an anxiety disorder as well as other related disorders, which will also help guide the rest of the assessment and treatment process.

The main difference between symptom-oriented and syndrome-oriented interviews concerns the arrangement of questions. Symptom-oriented interviews group all related items together, which is intended to make the interview less repetitive and more easily understood. On the other hand, syndrome-oriented interviews group questions according to disorder, such that questions about the same symptoms may be asked in relation to one disorder and then asked again, perhaps slightly differently, in relation to a different disorder. This structure is intended to adhere more closely to making a specific diagnosis. For example, a symptom-oriented interview would ask all questions related to sleep behavior in one section, whereas a syndrome-oriented interview would ask some questions about sleep behavior in relation to depression and then slightly different questions about sleep behavior in relation to mania (Orvaschel, 1995).

⊙ Table 12.1 provides information about several structured and semi-structured interviews that can be used in child behavioral assessment. All of the interviews listed have parallel forms that can be given to the child and an adult informant (e.g., parent, caretaker) and take between 60 and 90 minutes, per informant, to administer. Additionally, all of the interviews listed were developed for use with children and adolescents, thus they typically do not require extensive verbal expressive skills and are geared toward the language capabilities of younger children (La Greca & Stone, 1992). It is common for interviews to provide recommended age ranges, but some interviews provide additional questions or sections to administer to older children with content that does not apply to younger children. It is important that clinicians keep the age and developmental level of the child in mind, particularly when conducting a semi-structured interview. The less rigid structure of a semi-structured interview allows for the wording to be

■ **Table 12.1**

Structured and semi-structured interviews for child behavior assessment

Interview	Structure	Orientation	Description
Anxiety Disorders Interview Schedule for Children (Silverman & Nelles, 1988)	Semi-structured	Syndrome	Assesses primarily anxiety disorders; assesses other disorders for differential diagnosis
Child and Adolescent Psychiatric Assessment (Angold & Costello, 2000)	Between semi-structured and structured	Symptom	Assesses psychiatric symptoms; requires extensive training; has a version for young adults (18+), preschoolers (3–6), a shortened version, and a Spanish translation
Child Assessment Schedule (Hodges et al., 1982)	Semi-structured	Symptom	Assesses behavioral/emotional problems related to school, family, friends, and activities; typically administered to child and parent
Children's Interview for Psychiatric Syndromes (Weller et al., 2000)	Structured	Syndrome	Assesses Axis 1 disorders and psychosocial stressors; requires IQ of 70+; revised version extends into adolescence (6–18); provides opportunities to skip sections
Diagnostic Interview for Children and Adolescents (Herjanic & Reich, 1982)	Between semi-structured and structured	Syndrome	Assesses behavioral/emotional functioning; separate interviews for children and adolescents; particularly useful for younger children; requires highly trained interviewers; has computerized version
Diagnostic Interview Schedule for Children – Version IV (Shaffer et al., 2000)	Structured	Symptom	Assesses psychopathology; for ages 6–17; most widely used structured interview; has the most parallel versions and translations; has computerized version
Interview Schedule for Children (Kovacs, 1985)	Semi-structured	Symptom	Assesses psychopathology symptoms; easy language for children; particularly useful for depression
Interview Schedule for Children and Adolescents (Sherrill & Kovacs, 2000)	Semi-structured	Symptom	Assesses psychopathology symptoms; for ages 8–17; requires the most extensive training; time-consuming administration
Schedule for Affective Disorders and Schizophrenia in School-Aged Children – Epidemiological Version 5 (Orvaschel, 1995)	Semi-structured	Syndrome	Assesses current and lifetime Axis I symptoms; can adjust language for age appropriateness; most widely used semi-structured interview

modified in order to accommodate the developmental level of the child. Finally, when clinicians use both the child and parent(s) to obtain information, they should expect that responses will not always match. Research has demonstrated that children older than preschool age can self-report reliably on behaviors, cognitions, and experiences (Hodges, 1993), but preschool-aged children may be less reliable in their responses. It is recommended that clinicians integrate information gained from child and parent reports to obtain the most comprehensive and accurate understanding of the presenting problem.

When it comes to integrating interviews into behavioral assessment, it is important that clinicians pay attention to the age appropriateness of the interview, whether the child seems able to accurately and reliably self-report on behaviors, cognitions, and experiences, and the potential differences between a child's and an adult informant's responses to the same questions. Overall, interviews are a useful tool for collecting information about children's presenting problem(s), but should be used subsequent to, and in conjunction with, other assessment methods.

12.4 Rating Scales

In addition to structured and semi-structured interviews, clinicians can also use self-, parent-, and teacher-rating scales. The ability to use rating scales should be considered a basic competency for all clinicians who conduct child behavioral assessments. Traditionally, behavioral assessment did not involve the use of self-rating scales, because they do not assess observable behaviors. However, Kratochwill, Sheridan, Carlson, and Lasecki (1999) argued that self-rating scales are particularly important in child behavioral assessment because they provide information on the child's internal, subjective experiences, which are difficult to assess using other means. Currently, self-rating scales, as well as parent- and teacher-rating scales, are commonly used instruments in child behavioral assessment (Ollendick & Greene, 1998).

Rating scales should be used in addition and subsequent to other assessment techniques. A clinician could conduct a behavioral interview and follow up by administering a rating scale to objectively and quantitatively measure the identified symptoms and problem behaviors. There are several advantages to using rating scales, including their ease of use, low cost of administration, validity for assessing targeted behavior problems, objective scoring procedures that minimize the role of clinical inference and interpretation, and usefulness for a wide range of populations and problems (Ollendick & Greene, 1998). For example, if it is found out during a behavioral interview that the child is exhibiting aggressive behavior, it may be useful for the clinician to administer a rating scale such as the Children's Inventory of Anger (Nelson & Finch, 2000). This could provide the clinician with a quantifiable index of the child's level of anger and serve as a useful assessment tool to re-administer throughout the course of treatment. Similarly, instruments such as the Connors Parent Rating Scale (Connors, 1990) and the Teacher Report Scale (Achenbach, 1991b) could be given to the child's parents and teachers, respectively, to obtain information from adults in the child's life who see the child in various environments. The information obtained from these rating scales could be useful in assessing the environmental factors that may influence the problematic behavior as well as the frequency or severity of such behavior.

It is important for clinicians who plan to use rating scales to keep in mind that such measures do have limitations, many of which are similar to those inherent to structured and

semi-structured interviews, such as children's ability to report on their internal states and children reacting to demand characteristics. Research has demonstrated that children's reports of internalizing behaviors are internally consistent and relatively stable as early as first grade and children's reports are both concurrently and predictively associated with their ability on developmentally appropriate tasks (Ialongo, Edelsohn, Werthamer-Larsson, Crockett, & Kellam, 1994; Kellam, Rebok, Ialongo, & Mayer, 1994). Another potential limitation of self-report measures is that some children may react to demand characteristics by responding in socially desirable ways. For example, when asked to fill out a rating scale, a child might not endorse exhibiting certain behaviors that the child knows are inappropriate and cause for punishment. This can be addressed by using carefully worded instructions (e.g., "There are no right or wrong answers") or by using other measures that assess potential response biases (e.g., the Children's Social Desirability Scale; Crandall, Crandall, & Katkovsky, 1965) to assess the child's tendency to respond in a socially desirable way. Despite their potential limitations, rating scales are an efficient tool for objectively quantifying a child's problem behaviors and symptoms and can be effectively integrated into a child behavioral assessment protocol. ❯ Table 12.2 provides descriptions of several commonly used self-, parent-, and teacher-rating scales.

12.5   Assessment of Cognitive Constructs

Behavioral assessment was originally only concerned with behavior that could be directly observed. As the cognitive movement grew, clinicians began integrating reports of covert behavior (e.g., thoughts, feelings) into behavioral assessment. This has been controversial, as cognitive constructs, compared with traditional behavioral constructs, are more dependent upon the client's self report. Still, numerous cognitive-behavioral theories propose that cognitions (e.g., automatic thoughts, Beck, 1976; irrational beliefs, Ellis, 1994; attributional styles, Seligman, 1975) are the mechanisms through which behavioral and emotional problems operate. In addition to conceptualizing cognitions as antecedents to behavioral problems, cognitive constructs can also be conceptualized as consequences. For example, if a child is being teased at school by other children for being overweight, this could cause the child to experience negative automatic thoughts such as "I am worthless because I am overweight." In this case, the cognition is a consequence of the situation, rather than an antecedent to a behavioral problem.

As a result of cognitive constructs serving as potential antecedents to, and consequences of, behavioral problems, the assessment of cognitive constructs has the ability to improve behavioral assessment, diagnostic decision making, and treatment planning. This can be considered a basic competency and clinicians should be knowledgeable in techniques to assess cognitive constructs.

The fact that numerous cognitive constructs have been implicated in the development and maintenance of behavioral and emotional problems poses a challenge for clinicians. For example, Beck (1976) proposed that automatic thoughts (i.e., repetitive, automatic self-statements) are involved in behavioral and emotional problems, whereas Ellis (1994) implicated irrational beliefs (i.e., beliefs that are illogical or based on false assumptions) in the development and maintenance of emotional and behavioral problems. Thus, there are various cognitive constructs that may be at the core of each child's problems and it may be unclear to the clinician which construct(s) should be assessed. Ideally, clinicians would use multiple techniques on a

◘ Table 12.2
Self-, parent-, and teacher-rating scales for child behavior assessment

Scale	Rater	Description
Child Behavior Checklist (Achenbach, 1991a)	Parent/teacher	Assesses behavioral problems associated with internalizing and externalizing disorders; includes items about positive behaviors; has a social competence scale and a behavior problems scale; can be completed quickly (15 min); norms available for children (2–18)
Children's Action Tendency Scale (Deluty, 1979)	Self	Assesses externalizing behaviors (e.g., aggressiveness, assertiveness, submission) in children (6–12)
Children's Assertive Behavior Scale (Michelson & Woods, 1982)	Self	Assesses assertive behaviors in children (fourth–sixth grade)
Children's Inventory of Anger (Nelson & Finch, 2000)	Self	Assesses anger control problems in children (third–eighth grade); identifies situations that anger control problems occur in; uses pictorial responses; quick and inexpensive to administer
Children's Self-Report Rating Scale (Beitchman et al., 1985)	Self	Assesses the following factors: conduct problems, lie-immaturity, positive self-peer, worry, negative peer, antisocial-permissive, sensitive-emotional, and positive family, in children (6–13)
Connors' Rating Scales (Connors, 1990)	Parent/teacher	Assesses hyperactivity; the most common version (48-item) assesses the following types of problems: conduct, learning, psychosomatic, impulsive-hyperactive, and anxiety; also has Hyperkinesis Index that consists of the items most sensitive to pharmacological treatment
Eyberg Child Behavior Inventory (Eyberg & Ross, 1978)	Parent/teacher	Assesses conduct disorder within a behavioral framework; norms available for children (2–12)
Matson Evaluation of Social Skills (Matson et al., 1983)	Parent/teacher	Assesses deficiencies in social functioning; has an assertiveness/impulsiveness scale and an appropriate social functioning scale; can be completed by teachers or parents, but norms available for teachers only
Revised Behavior Problem Checklist (Quay, 1983)	Parent/teacher	Assesses psychopathology associated with conduct disorder, personality disorder, inad-equacy/immaturity, and socialized/delinquent personality; revision also assesses psychotic behavior; most commonly used rating scale; can be completed quickly (15 min); norms available for parents and teachers
Teacher Report Form (Achenbach, 1991b)	Parent/teacher	Assesses academic performance, adaptive functioning, and behavioral/emotional problems in children (6–18)
Youth Self-Report Form (Achenbach, 1991c)	Self	Assesses behavioral problems with the following scales: activities, social, total competence, total problems, internalizing and externalizing problems, and nine syndrome scales, in children (11–18); requires fifth grade reading level or can be administered orally

repeated basis to assess as many cognitive constructs as possible, but this is unlikely and impractical. Instead, clinicians should use the information gained from previous assessment techniques (e.g., behavioral interviewing) to guide the assessment of cognitive constructs. For example, if a clinician was to conduct a behavioral interview and learn that a child is displaying obsessive-compulsive behavior (e.g., hand-washing), it would be useful to follow up with an assessment of the child's automatic thoughts or irrational beliefs that occur before, during, and after the display of the hand-washing behavior. This could help the clinician to better understand what the child is experiencing that causes the child to engage in this particular behavior.

There are numerous techniques for assessing cognitive constructs, including the recognition method, recall method, and expressive method (for a more thorough description of each technique, see Linscott & DiGiuseppe, 1998). The recognition method, a technique that is commonly used in clinical practice, involves using a self-report instrument that asks the child to endorse thought items based on either their frequency or strength of belief. For example, if a clinician conducts a behavioral interview and learns that the child has been exhibiting depressed behavior, the clinician could administer the Dysfunctional Attitudes Scale for Children (D'Alessandro & Burton, 2006), which assesses the dysfunctional attitudes that are often associated with depressive symptomatology. This instrument could help the clinician confirm or disconfirm that the child is, in fact, suffering from depression as well as aid in determining whether or not maladaptive cognitions (i.e., dysfunctional attitudes) are a possible mechanism through which the emotional disturbance is operating. Additional instruments that can be used to assess cognitive constructs other than dysfunctional beliefs when using the recognition method include the Children's Automatic Thoughts Scale (Schniering & Rapee, 2002), the Hopelessness Scale for Children (Kazdin, Rodgers, & Colbus, 1986), the Children's Cognitive Assessment Questionnaire (Zatz & Chassin, 1983), and the Cognitive Triad Inventory for Children (Kaslow, Stark, Printz, Livingston, & Ling Tsai, 1992).

These instruments can be extremely useful in clinical practice, because they are easy to administer and interpret following the guidelines provided by the instruments' creators. Still, clinicians should be aware that a child who does not endorse the examples of the cognitive construct that the instrument assesses may still have thoughts that are related to that construct, but that are not specific examples used in the instrument. On a related note, these instruments may identify problematic cognitions that are not related to the presenting problem. For example, if a clinician was to administer a battery of cognitive construct assessment instruments, the clinician may learn that a child endorses having thoughts related to hopelessness. However, the child may be displaying anxious behaviors that are a more pressing problem to address. Further, the hopeless thoughts may be in response to the anxiety problems that the child is experiencing, thus it may be more useful to assess and target the anxious behavior than the hopeless thoughts. As a result, it is extremely important to choose cognitive construct assessment techniques that are based on the information gained from the use of previous assessment methods (e.g., behavioral interviewing).

Another regularly used technique for assessing cognitive constructs is the recall method, which requires the child to list the thoughts that occur before, during, and after a particular behavior or event. For example, a clinician may conduct a behavioral interview and learn that a child is exhibiting withdrawn and shy behavior at school. The clinician can use the recall method to have the child list the thoughts that are being experienced when the child is behaving in this manner as well as preceding and following this behavior. This information could be useful in gaining a better understanding of why the child is behaving in a particular way and how to proceed with assessment and treatment planning. Specific instruments have been developed for

assessing cognitive constructs using the recall method such as the Daily Record of Dysfunction Thoughts (Beck, Rush, Shaw, & Emery, 1979), but this method can also be used in a less formal way as demonstrated in the aforementioned example. Although it is common practice to have adult clients perform the recall method by listing their thoughts in writing, it may be useful to have children do so orally, depending on the level of their writing ability. A modified version of the recall method is the prompted recall method, which involves presenting the child with an audiotape or videotape of a conflict scenario and asking the child to provide the thoughts and feelings of the person in the scenario. A clinician may choose to use a prompted recall method with children who are particularly resistant to expressing their thoughts and feelings, because it is likely going to be easier for such children to talk about the thoughts and feelings that someone else may be experiencing than their own. When interpreting a child's response to the prompted recall method, it is important to keep in mind that it cannot be guaranteed that the child's responses reflect what their own thoughts and feelings would be in the same situation. It is also important that clinicians remain aware that children may modify their responses (in the recognition and recall methods alike) in order to present a more socially desirable view.

Finally, the expressive method requires children to speak their thoughts while simultaneously performing a task. This has been described as the best technique for assessing cognitive constructs (Merluzzi, 1993), but Kendall and Hollon (1981) pointed out that the act of thinking aloud may distort the content of the cognition. This technique may be particularly challenging for younger children, because they may find it difficult to think aloud while performing a task. The Articulated Thoughts in Simulated Situations paradigm (for a review, see Davison, Navarre, & Vogel, 1995) appears to be a promising expressive method. It requires the clinician to create simulated situations, based on the information obtained from a previous assessment technique (e.g., behavioral interviewing), and have the child report the thoughts and feelings that are experienced when the scenario is replayed. For example, if a clinician learned that a child is exhibiting aggressive behavior in response to receiving directions from parents and teachers, the clinician could create a videotape of a simulated situation in which a child is being given directions from an authority figure. The clinician could then ask the child to describe the thoughts and feelings that the child in the video may be experiencing while being directed to do something. This could help the clinician understand how the child views the experience of authority figures giving direction, in turn, helping to determine the next step in the assessment process.

It is important for clinicians to choose cognitive construct assessment methods that are based on information gained from the use of previous assessment techniques, thus being appropriate for the individual child's presenting symptoms and developmental level.

12.6 Direct Observation

Direct observation is the "hallmark of behavioral assessment with children" (Franz & Gross, 1998, p. 362). Observing children in the settings in which they naturally interact is the best method to clearly understand how the environment reinforces and interacts with the behavior. While the process of direct observation has a number of difficulties in practice, it is a very useful tool that clinicians should consider using in their practice when applicable, particularly when other assessment tools fail to provide accurate representations of behavioral antecedents and consequences. Although the skills involved in direct observation are a basic competency for all clinicians who interact with children, some techniques involved in the coding systems used in direct observation are more advanced and may require specific training.

Perhaps the greatest benefit to direct assessment is that you no longer have to depend on self- or adult informant-report, which may provide biased representations of the problem behaviors, especially because of recall bias. The direct observation of behavior by an unbiased observer allows for an objective account – a real-time tally of the frequency and duration of target events. Overt behavior (e.g., hitting) as well as verbal behavior (e.g., number of words spoken) can be quantified. Behavioral assessment does not aim to understand or define underlying traits, but instead identify current behavior under current environmental circumstances (Barrios, 1988). The primary goal is to quantify the behavior. In this way, it is similar to the atheoretical approach of the Diagnostic and Statistical Manual of Mental Disorders – Fourth Edition (DSM-IV; American Psychiatric Association, 1994). The DSM-IV confers diagnosis based on behaviors to define the presence of symptoms. The behavioral observation goes beyond simply documenting symptoms for the purpose of making a diagnosis, as behavioral observation seeks to identify the potential environmental predecessors of specific behaviors.

Direct observations that take place in a natural setting are most likely to elicit the genuine pattern of behavior. However, natural observations are often so cumbersome that they are unlikely to be used in clinical practice. It can be time-consuming to travel to the natural setting (e.g., home, school) as well as difficult and/or expensive to find impartial raters. Further, the mere addition of new people into the setting may be considered intrusive. An alterative to direct observation within a natural setting is using an analog direct observation in a location more convenient to the clinician and agreeable to all parties involved.

One should prepare for a direct observation by defining exactly what target behaviors will be noted. For either natural or analog settings, it is important to have a clear coding system on which observers are properly trained. For example, if parents report that their child repeatedly bites them, then the biting is identified as the target behavior. If the biting primarily takes place at home, then the observation should ideally take place at the child's home. Observers should pay particular attention to the events that occur directly before the biting and the reactions that take place immediately after the biting. Beyond this, each behavioral excess or deficit should be clearly defined for each observer using a written training manual. The manual should include exemplars for the target behavior as well as borderline examples and how decisions in each case should be made for coding purposes. The best possible choice for observers would be trained independent observers. However, this option is not always feasible, particularly for use in clinical practice. Other options for observers are adults involved in the child's life, including parents and teachers (Loeber, Dishion, & Patterson, 1984).

When finding a coding system for the observers to use during the direct observation, one can create definitions of behavior based on clinical experience or use definitions created by others who have studied the particular problem behavior. It is important to use more than one independent observer when coding information from direct behavioral observation, as this allows interrater reliability, or the degree of agreement between raters, to be assessed. This is an important construct to assess, because poor interrater reliability may suggest that the coding system is flawed or the raters need additional training to ensure that they are coding in the same manner. If you decide to create your own system, be sure to define specific acts and not the emotions inferred behind them. For example, foot tapping should be coded as opposed to "nervousness" and laughter should be coded instead of "joy." Prior to the observation, various possible antecedents or consequences should be identified and appropriate coding should be assigned to those acts. ❯Table 12.3 provides basic information on several coding systems that can be used in direct behavioral observation.

■ **Table 12.3**

Coding systems for direct behavioral observation with children

System	Naturalistic/ analog	Age	Description
Classroom Observation Code (Abikoff, Rachel, & Donald, 1977)	Naturalistic	6–12 years	Measures children's classroom hyperactivity levels while in and out of their seats; observation categories: interference, solicitation, attentiveness, minor motor movement, gross motor movement, noncompliance, time out of chair, physical aggression, threat or verbal aggression, aggression towards teacher, extended verbalization, daydreaming
Compliance Test (Roberts & Powers, 1988)	Analog	2–8 years	Measures children's responses to standardized parental commands; observation categories: compliant and non compliant behavior of child
Family Interaction Coding System (Robinson & Eyberg, 1981)	Naturalistic	4–8 years	Measures quality of parent–child social interaction; observation categories: verbalization (e.g., direct command, labeled praise, neutral talk), vocalization (e.g., positive or negative tone), physical behavior (e.g., positive or negative touch), and response behavior (e.g., compliance to command, no opportunity to comply, answer to question)
OCD Behavioral Avoidance Test (Barrett, Healy, & March, 2003)	Analog	7–16 years	Measures objective information relating to behavioral responses to exposure to feared stimulus; observation categories: fear avoidance (e.g., distance to object), symptomatic distress, ritualizing
Preschool Observation Scale of Anxiety (Glennon & Weiz, 1978)	Naturalistic	2–5 years	Measures children's anxiety levels; observation categories: physical complaint, desire to leave, expression of fear or worry, vocal distress, posture, etc.

The coding systems detailed in ❯Table 12.3 are good examples of coding systems for use with many presenting problems. However, some clients will have unique needs for observation. In these cases, the behavioral interview should provide information about the behavior in question as well as when and where it takes place. When possible, try to schedule the direct observation in the settings in which the child is most likely to exhibit the target behavior. For more general behavior problems, such as social phobia, it may be possible to stage a direct observation at many locations. If a child is particularly fearful of speaking in front of a group, one can find an audience in the child's family or using volunteers from across the hall. The first observation could start with the group the child is more comfortable speaking in front of, with a given task of talking for a few minutes without a break. This observation may help to inform the difference between the behaviors in a more comfortable setting when compared with the same task but in front of strangers. During the task, observers could note the duration of speech, amount of eye contact, "ums" and "uhs," and fidgeting behavior.

Instruments like recording devices or computers can be implemented to ease in the data collection and analysis. This may be particularly useful given the potentially high costs for hiring personnel to observe, code, and analyze the results. If real-time coding for multiple coders is difficult or intrusive (e.g., several adult strangers in the home may be hard to ignore for both the parents and child), the use of a video recorder could be a helpful alternative. Another tip for coding is to use time stamping to determine the duration of a behavior. Instead of determining duration using a stop-watch, the observer can simply record the time in which the target behavior began and a second note at the time the behavior stopped. These two times will provide an easy way to calculate the length that the behavior occurred. The time of day should be noted during the behavioral observation. To be thorough, a clinician may consider sampling the child's behavior several times a day to determine the frequency during each time period and whether activity level or fatigue affect the behavioral frequency, intensity, or duration as well as any differences in antecedents and consequences.

Although direct observation may be the most accurate method to collect information about behavior, there is still the possibility that observers will be inaccurate. One type of inaccuracy to be aware of is observer bias, which is the tendency for observers to unintentionally distort their observations, and therefore coding, based on internal biases and prejudices. Those using behavioral observation should be aware of the possibility of observer drift, the phenomenon of observers changing in their coding of the same observations over time. Observer drift can be minimized by additional trainings throughout the observations.

Observer reactivity may be one of the greatest limitations to direct observation. Similar to the Hawthorne effect (discussed in Olson, Verley, Santos, & Salas, 2004), individuals being observed may change their behavior due to the presence of the observer. The presence of an observer may lead to observer reactivity, in which children may be less likely to engage in behaviors they know to be negatively viewed and more likely to engage in behaviors they know to be positively viewed. Reactivity reduces over time (Harris & Lahey, 1982), so it may be worthwhile to be in the room for some time before the actual recording of observation. Using a covert observation style (e.g., a one-way mirror) or videotaping may also reduce observer reactivity.

A final note is regarding the interpretation of the codes following the direct observation. In order to make appropriate judgments based on direct observations, one must be familiar with norms for the age group. Developmentally appropriate behaviors should be considered when determining whether the target behavior is truly a "problem." For example, temper tantrums

are common among 2- and 3-year-olds, but the same behavior exhibited at age nine is clinically relevant and should be targeted for intervention.

12.7   Self-monitoring

As an assessment tool, self-monitoring gives the reigns to the patient in order to maintain a record of identified problem behaviors. Self-monitoring is used to determine the actual frequency and severity of the problem, and in line with the goals of behavioral assessment, to identify the antecedents and consequences to and from the behavior. It may be preferable to other types of assessment because self-monitoring allows for continuous monitoring of the problem behaviors and context, and therefore will likely provide a more accurate description of the problem than retrospective reports.

Self-monitoring has many benefits, but it should be noted that this technique may be challenging for children. It requires dedication and significant effort, and the clients must be able to attend to their problems and remember to keep an accurate and up-to-date record. For these reasons, self-monitoring works better with certain clients; in particular, older children are better candidates for this assessment strategy. Research on self-monitoring in children (although not solely as an assessment tool) has shown the technique to be useful and effective with various problems such as internalizing disorders (Beidel, Neal, & Lederer, 1991; Stark, Reynolds, & Kaslow, 1987) and weight loss in obese children (Germann, Kirschenbaum, & Rich, 2007; Kirschenbaum, Gernmann, & Rich, 2005).

One can implement the use of self-monitoring as an assessment strategy for a variety of behavioral problems. For children who have difficulties in controlling their weight, you may ask them to create a record of the items they consumed in the day and at what time. It may be difficult for children to accurately log their caloric intake, but basic information about the type of food and time of day it is consumed is a good start for identifying areas for improvement.

Clinicians should try to tailor the method of self-monitoring for the particular child. Setting a particular time of the day for record keeping may be best for children who are easily distracted or have busy schedules (e.g., extracurricular activities and shared custody). Adapting the self-monitoring task to better suit the abilities of the child and his or her family will increase motivation as well as the likelihood of engaging in the task.

Structured logs can be created and personalized for children given their particular presenting problems. For example, one should adapt the type of log that is required to a client's ability to self-monitor (e.g., a log sheet which requires only that they mark off when he or she is reprimanded for being off-task at school). For whichever system of record keeping is chosen, instructions must be clearly delineated such that the child knows when, where, and how to record responses. If possible, try to encourage motivation for task completion, as a complete record may be an invaluable assessment tool for gauging information about the problem, designing an intervention, and assessing treatment outcome.

In addition to structured logs, diaries are frequently employed in self-monitoring. Diaries are preferable when the target behavior involves more complex thoughts and emotions and when the children are able to identify antecedents to those thoughts and feelings. Researchers have used self-monitoring to obtain records of emotional reactions to situational contexts among depressed adults (Beck et al., 1979; Jarrett & Nelson, 1987). Silverman and Serifini

(1998) have successfully used a "daily diary" with older children. The diary provides a record of the child's daily experiences with their targeted problem. For example, children who experience social phobia can record the number of times they felt afraid to speak to others in the day, the time of day that they experienced fear, the intensity of the fear on a 1–10 scale, and events that immediately preceded the experience as well as what happened afterwards. For those children who are able, it may be useful for them to write down their exact thoughts at the time of the event.

Reactivity to the act of self-monitoring (similar to observer reactivity in direct observation) can occur with this assessment approach. Self-monitoring has also been used as a treatment (Germann et al., 2007; Kirschenbaum et al., 2005), as children are both the observer and the recorder of their behavior, which emphasizes the control one has over their own actions. Because of the possibility of reactivity, children should be instructed not to change their behavior as a result of the monitoring, as reactivity (usually in the desired direction) may impair the ability to obtain an accurate portrayal of the problem behavior prior to treatment. Additionally, having the recording take place post-behavior, rather that before the behavior occurs, can help to reduce reactivity. When considering the use of self-monitoring as a treatment vehicle, reactivity may be encouraged. However, for the initial assessment stages, make sure to remind the children to behave the same as usual while completing the task.

Although self-monitoring may be difficult when the client is a child, it is still possible to effectively use this tool. Perhaps the greatest challenge to effectively implementing this assessment approach is compliance. Compliance may be particularly difficult to obtain in younger and/or oppositional children. Thoroughly explaining how to complete the task, as well as explaining the reasons for the task, may help to improve compliance. Additionally, compliance with self-monitoring has been shown to be higher when the family is involved in the task (Germann et al., 2007; Kirschenbaum et al., 2005). Another option to improve the effectiveness of self-monitoring is the use of a more obtrusive monitoring device. Having the child wear a watch to count the frequency of the behavior is one option. Amato Zech, Hoff, and Doepke (2006) used a MotivAider device that vibrated and beeped to remind students of times to record their behavior.

12.8   Motor, Sensorimotor, Language, and Cognitive Development

Bloom (1956) stated there were three domains of human development – motor, affective, and cognitive. There are several measures designed to assess growth and maturity. While it is possible to think of these domains as independent, it is important to recognize how the three intersect and affect each other. The purpose of this section is to discuss domains of development that should be considered when working with child clients, as well as to give examples of techniques that can be used to assess those domains. Although it is most common for clinicians to be more oriented to the affective areas of impairment, they should also be attuned to motor, sensorimotor, language, and cognitive development. Clinicians need to keep an open mind as to the source of problems, as medical or environmental issues may be the cause of some behavior problems or poor performance on tests. Particularly with very young children, parents may bring their child to a psychologist for problems they perceive as being in the affective domain, whereas the problem may fall outside of the emotional domain. Assessing the various areas of

human development can help to rule out problems or disorders or to further investigate the extent of a hypothesized problem.

When meeting with the child, be aware of the signs of neglect or physical or sexual abuse. Signs of abuse include injuries, bruises, and scars, often accompanied by an unclear or inconsistent explanation of the cause (Blackman, 1997). Signs of neglect one may notice are poor hygiene and delays in development such as stunted height or low body weight. A young child engaging in sex play or use of inappropriate sexual conversation may indicate the possibility of sexual abuse in the child's past.

Pay attention to motor, cognitive, language, and perceptual abilities. You will need to decide whether the child's behavior is developmentally appropriate for the age of the child or whether the behavior is non-normative. In order to do this, all clinicians who see children should be familiar with basic normative motor, speech, and cognitive developmental stages. Has the child reached all of the developmental milestones appropriate for his or her age? If not, this knowledge may help to produce hypotheses into what needs to be assessed further and give insight into the child's own difficulties interacting with the environment.

Progression in skills over time is the general expected developmental trajectory. Although leveling off and small periods of regression may be common in development, the typical child will continue to show great advances in motor, speech, and cognitive skills as they age. A standstill in progression or regression that lasts several months in early infancy may be a red flag for a developmental disability. For example, if you notice a 2-year old refraining from using words or motions to communicate, it may be a sign of autism. Children with autism or other developmental disorders have abnormal social interactions in which they have severe impairments in reciprocal social communication (Blackman, 1997).

All clinicians should have some basic knowledge about the normative development of language. Deficits in speech may indicate a language delay that is related to a learning disorder, mental retardation, or autism. Children between the ages of 18 and 24 months should be able to produce word combinations, understand and respond to names of objects, and follow simple commands (Olswang & Bain, 1988). Between the ages of 2 and 2.5 years, children should be able to ask and answer simple questions. Between the ages of 2.5 and 3, children should be able to display a greater understanding of grammatical rules (e.g., correct verb tenses and use of plural nouns).

Before administering an assessment for language, motor, or cognitive skills, the clinician should take time to calmly and patiently discuss the process with the child and parents. Assessments for these skills may be particularly anxiety provoking given the repercussions of a disability diagnosis. Explain to parents the length of the assessment and specifically what you will be assessing. After the session, make sure to share the test results with the parents. This type of communication is typically conveyed best in person, especially if the assessment results indicate the possibility of a disability. If this is the case, the child's school and teachers should also be informed of the assessment results.

There are a handful of disorders to keep in mind when you see a child with motor, language, or cognitive difficulties. Cerebral palsy, a condition that occurs in one out of every 500 live births, is a non-progressive condition that causes physical disability and is usually detected within the first 12 months of the child's life. The disorder is marked by a history of delayed developmental milestones. Children with cerebral palsy will have delayed motor skills, but normal language and visual-motor abilities. On the other hand, children with mental retardation may have normal monitor skills, but display delays in language and visual-motor abilities.

For very young children who may exhibit difficulties in these areas, one may consider using the Capute Scales. They were originally developed in the 1970s to assess language and visual-motor abilities in children with a cognitive age of 36 months or younger. One method to test motor skills in older children (ages 3–10 years) is the Test of Motor Development (Ulrich, 1985). This assessment takes approximately 15 minutes to administer and assesses 12 motor skills (i.e., run, gallop, hop, skip, horizontal jump, leap, slide, two-hand strike, stationary ball bounce, catch, kick, overhand throw).

For a broader assessment of the child's functioning, The Bayley Scales of Infant and Toddler Development, Third Edition (Bayley, 2006), is norm-referenced and commonly used. It is a quantitative evaluation composed of three scales that the child completes and two scales that the parents complete about the child. The child scales are cognitive, motor, and language, and the parent scales are social, emotional, and adaptive behavior. Each scale can be administered individually or as a complete assessment. The time for a complete assessment is 30–90 minutes. The Bayley Scales-III was designed to be used with children between the ages of 1 and 41 months.

A more comprehensive assessment for an older age group is the Battelle Developmental Inventory-2 (Newborg, 2005), a developmental assessment for early childhood (birth to age 8 years) that can be administered to the child or parent. It consists of a screening test that takes between 10 and 30 minutes to administer, while the full assessment takes between 1 and 2 hours to administer. This norm-referenced inventory assesses five domains – affective, cognitive, communication, motor, and personal-social. A notable benefit to the Battelle Developmental Inventory is that it was standardized on a population that included children with developmental delays.

In order to assess intelligence, the Wechsler Intelligence Scale for Children – Fourth Edition (WISC-IV; Wechsler, 2003) can be used. The WISC-IV assesses verbal comprehension, perceptual reasoning, working memory, and processing speed by creating indices based on the results of ten subtests. The administration time varies depending on the child, as younger children may need more breaks and take more time to complete the untimed portions. For children with possible learning disorders or attention problems, the General Ability Index may provide a more informative assessment of intelligence because it is less influenced by processing speed and working memory.

When interpreting the results of any norm-referenced instrument you should keep in mind that the majority of the assessments provide the normative information for a specific population that may not include your client (often based using an American, nondisabled population). Some ethnic groups tend to have smaller children than other groups, on average, in terms of height and weight. Therefore, a specific child may be classified in a lower percentile using the typical American normative percentiles, but not when compared to other infants from their specific ethnic group. Also, test results for children with physical or mental disabilities may not accurately reflect their abilities for a variety of reasons, particularly if the assessment was not created using other children with disabilities in the sample. Being aware of developmentally appropriate behavior in children should be a basic competency for clinicians who encounter young people in their practice. The developmental plateaus or even regressions are often what parents notice as problems in their child and could be the reason they are seeking assessment and treatment. Every clinician should be familiar with the domains of human development and potential assessment tools to implement given the various types of presenting problems.

12.9 Advanced Competencies

The behavioral assessment techniques that have been described thus far, are basic competencies that all clinicians who work with children should be knowledgeable about and proficient in. The remainder of this chapter will describe more advanced techniques (i.e., peer sociometry, virtual reality assessment, and physiological and biological assessment). These techniques differ from the previously described basic competencies in that they require additional, specific training. As mentioned previously, we recommend that interested readers seek additional information on the techniques, particularly the advanced techniques, before incorporating them into their child behavioral assessment practices.

12.10 Peer Sociometry

Sociometry is a quantitative method of measuring social standing and relationships among individuals in a group. The informants being assessed with sociometric measures are often the client's peers, so the target constructs tend to be traits or qualities (e.g., do you like to play with [client's name]?) instead of objective social skills. This form of measurement is most often used with children in school settings, and although it provides clinically useful information, it is primarily used in social research as an assessment technique. The target variable can vary depending on the area most interesting to the researcher or clinician. Typically, target variables are acceptance, preference, popularity, and visibility (Mpofu, Carney, & Lambert, 2006), which are all proxies of social standing. Most commonly, classmates provide the information on these target variables, although in some cases adult informants (i.e., teachers or caregivers) may provide sociometric data.

Obtaining data on peer relations from individuals other than the client allows the clinician to obtain an independent view of the child's social standing and areas that may be strengths or weaknesses for the child. Self-reported social standing may not be accurate, given the age of the child and the biases the child may have. Mpofu (2003) explored the discrepancy between perceived social status and actual social status, suggesting that perceived social status may be more important than actual social status in determining how individuals interact with their environment. However, data on actual peer social status demonstrated a link between social skills with peer social acceptance (Mpofu & Watkins, 1997). Most research assumes that social status and peer standing are indicators of social skills and social development.

Clinicians may be interested in peer relations in order to better understand the child's social environment, as well as to provide support for a diagnosis. For example, researchers have found that aggressive children are less preferred than nonaggressive children on sociometric measures (Cairns, Cairns, Neckerman, Gest, & Gariépy, 1988). Although it is difficult to pinpoint the causal relationship, children with lower peer acceptance were more likely to drop out of high school than those liked by their peers (Berndt, Hawkins, & Jiao, 1999). Peer relationships and social standing may also affect psychological symptomatology. In an investigation comparing children with and without close friends, Bagwell, Newcomb, and Bukowski (1998) found that not having friends and peer rejection were predictive of psychological symptoms, particularly depression, at a 12-year follow-up.

There are various methods to collect sociometric data, such as peer nomination, rating scales, and ranking. The peer nomination technique consists of tasks in which each child is

asked to nominate peers that most fit a specific target trait. For example, children could be asked to nominate those children who they most like to play with, who share the least, or who are the most helpful. In each case, the children can be instructed to limit the number of possible responses to one child, to list as many children who fit the description, or anything in between. For this task, children may use recall to list the children or draw from a list of names. For younger children, picture prompts may help children keep in mind their choices for the task as well as make the task more tangible. Landau and Milich (1990) used this technique in children as young as preschool age.

With prompts such as "who do you like the most" and "who do you like the least," one can generate a number of interpretive frameworks. The children who received many positive nominations and no or few negative nominations may be considered socially accepted, whereas those with the opposite combination of nominations may be considered socially rejected (Elksnin & Elksnin, 1997). Children who have many of both types of nominations may be highly visible in their classroom, whereas those with no or few nominations may be socially ignored or neglected (Terry, 2000). There are several classification systems (see Asher & Dodge, 1986; Coie et al., 1982; Worthen, Borg, & White, 1993).

Mpofu et al. (2006) pointed out that the classification any individual child receives from the peer nomination technique should be considered as part of, but not the entire, picture. Some children may have more friends outside of school than in their classroom, thus they may be rated as less popular than their social skills would indicate. Additionally, children who are new to the city or classroom may need more time to become familiar with the names or faces of other children when completing this type of task.

The rating scale technique is a task that requires each child to rate every other child in their classroom on the given target trait. The target measure can be similar to those in the peer nomination tasks, but instead of nominating particular children who fit that trait, children are asked to what degree (on a scale) an individual child has those characteristics. For example, each child rates from 0 to 10 how much he or she likes to play with each other child. Again, when younger children are involved, picture cues (e.g., smiling, neutral, and frowning faces) can be used to indicate how much they like each child.

As with peer nomination, a limitation of the rating scale technique is that those children who are new to the class or less well known may be rated lower than if they were more familiar (Bukowski, Sippola, Hoza, & Newcomb, 2000). Therefore, lower scores do not necessarily translate to being disliked.

The rating scale technique may be preferable to the peer nomination technique because it provides more complete data on the entire classroom of children, as every child rates every other child. As such, this tool can be used to obtain social acceptance data on all children within the given group. Researchers also suggest that the combination of rating scales with peer nomination techniques provides a more complete picture of social status than either method independently.

There are a series of ranking techniques, which are similar to peer nomination in that the rater must choose people who fit the given target characteristic. However, in peer rankings, the order in which the individuals are named should begin with the child most like the trait, then second most like the trait, and so on, until the end of the list where the child least like the trait should be placed. Oftentimes, the raters or "rankers" in this task are teachers. A full ranking procedure was described above, in which all children are rated for each target measure. One variation to the full ranking procedure is partial ranking, which is when only those children

who fit the description are to be rank-ordered (Merrell, 2003). Another ranking procedure is paired comparisons, in which each child is compared with each other child on a given trait. This method provides a very thorough account of each child's standing compared with their classmates and can be used to construct an understanding of social standing. Data obtained from sociometric ranking can generate the relative social position of a given individual (e.g., are they more or less popular than most other children in their classroom?) and show social networks at an individual level (e.g., Sally is friends with Paola, but not James), or classroom level.

Researchers have suggested that peer sociometric techniques should be combined with other assessment methods when constructing the social standing and relationships of a particular child (Bierman, 2004; Merrill, 2003). It may be difficult for clinicians to integrate peer sociometry assessment in clinical practice, as there are a number of challenges in obtaining the information. Getting access to the classroom and permission to obtain information about a specific child may be challenging, as well as potentially damaging to the child. Alternative options are garnering information through the parent or teacher as well as siblings and close friends of the child. As noted above, all sources may have some bias, but the information gained using techniques that assess social standing and skills may still be helpful in planning areas for intervention. Merrell (2001) recommended that the first stage of social skills assessment should be composed of direct observation and rating scales, and using peer sociometric techniques following those procedures to obtain more information if needed.

12.11 Virtual Reality Assessment

Virtual Reality (VR) technology has been recently incorporated into behavioral assessment protocols with children and adolescents. This technology has been used to enhance direct observation or role-play assessment. VR has been defined as a "three-dimensional interface that puts the interacting subject in a condition of active exchange with a world re-created via the computer" (Vincelli & Molinari, 1998, p. 67). This technology allows participants to feel fully present in this recreated environment by involving all of the sensorimotor channels and allowing for real-time navigation and interaction with the virtual environment (Riva, 1997; Vincelli & Molinari, 1998).

There are three types of VR systems: immersive VR, which utilizes head-mounted displays (HMDs), partially immersive VR, which involves a wide field-of-view display, such as a projection screen, and desk-top VR, which uses a desk-top monitor (McComas, Pivik, & Laflamme, 1998; Riva, 1998). Interaction occurs via joystick, keyboard, or a data glove, a glove with sensors that transmit spatial and tactile information to a computer, thus allowing users to manipulate and explore VR environments (Ku et al., 2003). Although the full immersion format may lead to an enhanced, all-encompassing experience for the user, this technology is much more expensive than the desktop version. In addition, some research on VR with adults has found that the use of HMDs causes symptoms of motion sickness in some subjects, resulting from a discrepancy between visual and vestibular inputs to the brain (Rose, Attree, & Johnson, 1996).

VR offers advantages over other assessment techniques. First, it allows for increased confidentiality. The assessment procedure can be limited to the therapist's office and devoid of human confederates, while still immersing the subject in a simulated situation that involves others (North, North, and Coble, 1998). In addition, the technology allows the therapist to

generate stimuli of greater perceived magnitude than may not be possible with in vivo or imaginal techniques (North et al., 1998). Furthermore, VR systems can simultaneously monitor diverse responses from the entire body and are sensitive to the properties of these responses, whereas other computer-based assessments can only accept one or two sources of input at one time (Riva, 1997). With respect to assessment, VR programs can alter what is presented auditorally, visually, olfactorially, etc., thus allowing for a flexible and multifaceted form of adaptive testing that is specifically tailored to the individual being tested (Riva, 1997). Finally, when compared with analog assessments that involve contact with a feared stimulus, the VR methodology provides an added measure of safety by limiting contact to a computer-generated simulation within an office or clinic (North et al., 1998). For example, if assessing a child with a dog phobia, the child's contact would be limited to a virtual rather than a real animal that could potentially harm the child. Because of its incipient status, the majority of systematic VR research has applied this technology to the assessment and treatment of adults, although some have commented on the potential application of VR to children (Muscott & Gifford, 1994; Rizzo, Wiederhold, & Buckwalter, 1998). The limited pilot data that have been conducted thus far on use of VR assessments with children have indicated that children find the technology usable and enjoyable (Rizzo et al., 2000).

Analog and VR assessment offer specific advantages over other assessment methods. They provide the therapist with the opportunity to observe behaviors that are difficult to assess via direct observation in natural settings, such as those that are highly situation-specific or occur infrequently (Hintze, Stoner, & Bull, 2000). This may be particularly relevant for children whose behaviors of interest occur at recess or on the school bus, where gaining access is difficult and their behaviors are likely to be influenced by the obvious presence of an adult observer. VR and analog assessment differ from other techniques, such as retrospective self-report or naturalistic observation, in that they provide the therapist with environmental control, which is relevant to successful functional analysis. By manipulating external stimuli, the assessor can test ideographic hypotheses about the behavior of interest. Specific aspects of the behaviors can then be linked to environmental factors that explain their etiology and maintenance, thus clarifying and simplifying case conceptualization. In addition, this information can speak to treatment planning by finding ways to create an environment that fosters healthy behaviors and extinguishes those that are unhealthy (Hintze et al., 2000).

12.12 Psychophysiological and Biological Assessment

While the use of psychophysiological assessment with children has lagged behind its use with adults, there has been substantial progress in the use and understanding of this assessment tool, creating the opportunity for clinicians to integrate psychophysiological assessment into their behavioral assessment practices. Psychophysiological assessment can be considered an expert competency, as it requires training and experience beyond that which is required for a clinician to practice. However, there are certain psychophysiological assessment techniques that may be integrated into behavioral assessment without extensive additional training. A unique advantage to psychophysiological assessment is that it is language-free, which provides an assessment tool that transcends culture, ethnicity, age, and disability. Psychophysiological assessment may be particularly useful with children, because children may be less aware of their emotional or cognitive processes and often lack the necessary language to describe such processes (Wilhelm,

Schneider, & Friedman, 2006). At this time, the impact of psychophysiological assessment in clinical work with children has been minimal, with the exception of its use in the assessment of sleep disturbance and pain (Roth, 1998). The purpose of this section is to provide clinicians with a brief overview of psychophysiological assessment with children (for a more detailed review, see Fox, Schmidt, Henderson, & Marshall, 2007) and how it can be integrated into child behavioral assessment.

If clinicians are interested in using psychophysiological assessment, it should be used in addition and subsequent to other assessment techniques (e.g., behavioral interviewing). It is likely that clinicians who are interested in integrating psychophysiological assessment into behavioral assessment will primarily choose to measure heart rate (HR), as it is easier than other psychophysiological indices to measure. There are HR monitors available that resemble wrist watches (e.g., Polar heart rate monitors) and are relatively easy to use. If a clinician were to conduct a behavioral interview and learn that the child is exhibiting fearful and anxious behavior, the clinician may want to measure HR, which has been suggested as the preferred cardiovascular index in the assessment of fearful and anxious behavior (Nietzel, Bernstein, and Russell, 1988). The clinician would use the behavioral interview to gain specific information about the child's anxious behavior, such as what the specific behaviors are, what precedes them, and how long they last. If the child's anxious behavior is in response to a specific stressor (e.g., spiders), it would be useful to assess the child's HR before, during, and after presenting the child with variations of the feared stimuli (e.g., a picture of a spider, a video of a spider, a live spider). The clinician could compare the child's reactivity to each of these stimuli in order to gauge the severity of the child's anxious behavior. The clinician may choose to proceed differently in the course of assessment and treatment planning if the child is exhibiting anxious behavior in response to live spiders only versus both live spiders and pictures of spiders, as the latter situation is likely to be more impairing. Research has demonstrated that HR is associated with anxious behaviors in childhood (e.g., Beidel, 1991; Ryan, 2004), thus a clinician could use HR measurement to help confirm or disconfirm a diagnosis of an anxiety disorder and to gain a more complete understanding of the presenting problem. It is important to acknowledge that there are other methods for measuring HR (e.g., electrocardiogram), but clinicians will likely prefer the ease of measuring HR using a wrist monitor.

There are other psychophysiological indices that could be clinically useful to assess, but they require more advanced equipment, training, and resources that may not be available to clinicians. Skin conductance is an electrodermal measure that has been implicated in autonomic nervous system activity and response to stress in children (El-Sheikh, 2007). A clinician could use skin conductance measurement in a similar manner as HR measurement, assessing a child's reactivity in response to specific stressors that were identified in the behavioral interview. Additionally, the hypothalamic-pituitary-adrenocortical (HPA) axis, an important part of the neuroendocrine system, has also been implicated in children's reaction to stress (Granger, Stansbury, & Henker, 1994; Kagan, Reznick, & Snidman, 1987) and has been associated with both internalizing and externalizing problems (El-Sheikh, Erath, Buckhalt, Granger, & Mize, 2008) as well as specific disorders such as Conduct Disorder (McBurnett et al., 1991) and Obsessive-Compulsive Disorder (Gustafsson, Gustafsson, Ivarsson, & Nelson, 2008) in children. HPA axis functioning can be reliably assessed by measuring cortisol level (Wilhelm et al., 2006). Although cortisol level can be measured by collecting a saliva or urine sample, which should not be particularly difficult to do in a clinical setting, it is unlikely that clinicians will be quick to integrate this into behavioral assessment, as it requires clinicians to find a local laboratory to

have the sample analyzed at, which entails additional time and financial resources. Furthermore, tools such as Positron Emission Tomography and functional Magnetic Resonance Imaging are available and can be used, for example, in the event that a clinician suspects a possible brain abnormality. However, it is unlikely that clinicians will routinely use these with children as they add additional time and resources and they might be seen as frightening to children.

There are various general concerns that must be kept in mind when considering psychophysiological assessment. First, baseline measurements taken in a clinical setting may not accurately reflect those taken outside of the laboratory. Second, the use of medication may have an effect on psychophysiology. If a child is taking a prescribed medication (e.g., Ritalin), it is useful to speak with the child's prescribing doctor to see if it is possible to discontinue the use of the medication on the day of the assessment. Finally, and perhaps most importantly, there is little normative psychophysiological data for children, making it challenging to use psychophysiological assessment to make meaningful diagnoses at this time (Wilhelm et al., 2006).

Psychophysiological research with children is progressing at a slower pace than with adults, in part, because the methods are more difficult to use with children. Additionally, more ethical justification is required to conduct this type of research with children. It is unlikely that clinicians will use psychophysiological assessment methods in practice if they are able to obtain sufficient assessment information using less complicated and invasive methods, but psychophysiological assessment has the potential to improve behavioral assessment by providing a more objective measure of the child's response to specific stressors. Overall, the use of psychophysiological assessment as a component in child behavioral assessment has conceptual promise, but it seems to have limited practical use at this time. Nonetheless, the substantial progress that has been made in psychophysiological assessment in recent years is making it easier for clinicians to use these technologies in clinical practice.

The growing number of studies on the biological assessment of mental disorders gives promise to the use of biological tools as another way to detect risk, predict the course, monitor, and treat disorders. As yet, many clinicians cannot make use of these new technologies. However, clinicians should be aware of the possibility of using biological testing to confirm or rule out disorders in children exhibiting certain problem behaviors. Currently, the most promising biological assessment research has occurred with disorders that are genetically based (e.g., Down syndrome) or caused by environmental events (e.g., brain damage). Genetic disorders can be associated with a variety of behavior problems, and in cases in which clinicians might think a genetic disorder may be the source of the presenting problem they should refer the child and family to the appropriate institutions. For example, Fragile X syndrome, a genetic disorder found on the X chromosome, has been linked to autistic and compulsive behaviors (Hall, Lightbody, & Reiss, 2008). Currently, genetic testing is used to rule out genetic conditions with autism-like symptoms (Volker & Lopata, 2008). Biological factors other than genes have also been implicated in autism, as Mulder et al. (2004) found elevated levels of blood platelet serotonin levels in individuals with this disorder. Conversely, decreased serotonergic activity has been found to be associated with impulsivity, aggression, and suicidal behavior (Brown & van Praag, 1991).

The brain is another frontier in studying the biological roles in mental disorders. Strakowski, Delbello, and Adler (2005) implicated prefrontal limbic structures as well as a trend of overactive amygdala response in both pediatric and adult bipolar disorder. Similarly, the same brain abnormalities associated with adults with schizophrenia have also been found in those with child-onset schizophrenia (Frazier, Giedd, Hamburger, & Albus, 1996). Although these assessment tools are not readily available to clinicians, all those who work closely with children should be aware of the possible biological causes of presenting problems and, when applicable,

create opportunities for the children with potentially biological-based problems to be explored more fully by geneticists and physicians.

12.13 Summary

Interest in child behavioral assessment has increased dramatically since Ollendick and Hersen (1984) published the first text devoted to this topic. This growth can be attributed to the burgeoning field of developmental psychopathology (Sroufe & Rutter, 1984), which emphasizes the importance of development in the expression of psychopathology in children and adolescents (Cicchetti & Rogosch, 2002). Child behavioral assessment was initially concerned with observable behaviors or potentially observable constructs, but has broadened to include beliefs, attitudes, and emotional states. The primary goal of behavioral assessment is to obtain information in order to determine the purpose, cause, or function of behavior. This allows for the creation of a functional analysis of the child's problem behaviors, which identifies the causes or reinforcers of the problem behaviors.

This chapter described and provided examples of the various behavioral assessment techniques that can be implemented in the behavioral assessment of children. The first group of assessment tools that were described (i.e., behavioral interviewing, structured and semi-structured interviewing, rating scales, assessment of cognitive constructs, direct observation, and motor, sensorimotor, language, and cognitive development) are basic competencies and all clinicians who work with children should be proficient in their use. The second group of assessment tools that were described (i.e., peer sociometry, virtual reality assessment, and psychophysiological and biological assessment) are more advanced techniques and require additional, specific training. For clinicians who conduct behavioral assessments with children, it is our hope that this chapter will help refresh what techniques are available for child behavioral assessment and what tools can be used in specific situations. We strongly recommend that interested readers seek additional information on the techniques explained in this chapter before incorporating them into their child behavioral assessment practices.

Research

13 Psychometrics

Paul G. Michael · Susan T. Li

Abstract: Clinical psychologists must develop a specific set of competencies in the area of psychometrics and measurement theory in order to be successful professionals. The competency models put forth by professional organizations within psychology have provided the framework for identifying the broader foundational and functional competencies that pertain to the field of psychometrics, specifically assessment, and research and evaluation. As producers and consumers of research, clinical psychologists must have a firm understanding of measurement development and the ability to interpret and summarize information obtained from various types of assessment tools. Thus, the main focus of this chapter is to describe the application of psychometric concepts in clinical endeavors. Central to this discussion are psychometric concepts such as, scales of measurement, reliability and validity of psychological instruments, and approaches to test theory. Both basic and expert competencies in psychometrics are reviewed and discussed in the context of training professional psychologists at different levels of readiness (e.g., practicum, internship, licensure, etc.). However, it is noted that there are certainly areas in which there may be a difference of opinion as to what constitutes the core body of knowledge in psychometrics. Further, there is less consensus and literature on the definition of expert or master as compared to the articulation of basic competencies. Nonetheless, what is evident is the need to increase efforts to integrate psychology and new innovations occurring in the field of psychometrics. Additionally, as we prepare and train the next generation consideration should be given to developing ways to increase the number of psychologists entering the field of quantitative psychology.

13.1 Overview

What are the competencies, consistent with evidence-based practice, essential for professionals who refer to themselves as clinical psychologists? Specifically, what are the basic and expert competencies in the area of psychometrics that the clinical psychologists must develop over the course of their training and career that will make them successful?

In order to address the questions mentioned above, we will first provide a brief synopsis of the competency movement (and competency modeling) within the field of psychology. Next, we provide an overview of the field of psychometrics as well as a discussion of the core concepts found in this discipline. Then, we turn our attention to the identification of foundational competencies in the realm of psychometrics and measurement theory. Finally, the remainder of the chapter illustrates those competencies in the field of psychometrics that are required to be a successful clinical psychologist. This chapter speaks both the basic and expert competencies that would be fostered across the developmental lifespan of a competent clinical psychologist (i.e., doctoral training, internship training, postdoctoral education, licensure, and practice).

13.2 Competency Models

If one is competent, it is implied that he/she is qualified and capable of understanding and doing certain things in an appropriate manner. In professional psychology, the term competency further suggests that behaviors are carried out in a manner consistent with the ethical principles and standards of the profession, especially those that serve to protect and benefit the public (Rodolfa, Bent, Eisman, Nelson, Rehm, & Ritchie, 2005). Definitions of competence are abundant, and while it may seem trite to present a definition of competence in a handbook of clinical competencies, we do so only to serve as a basis for the discussion that follows. Mentkowski (as cited in Rubin et al., 2007) defined competencies as "complex interactive clusters of integrated knowledge of concepts and procedures; skills and abilities; behaviors and strategies; attitudes, beliefs, and values; dispositions and personal characteristics; self-perceptions; and motivations" (p. 453). This definition is comprehensive, and it also speaks about the key aspect of competencies; they are not simple stand-alone entities. Thus, while there may be general consensus on what constitutes the foundational and functional competencies within professional psychology, it is not a simple task to speak about only one competency domain without addressing its overlap with other areas. Further, when we identify the clusters of knowledge, skills, and abilities within the field of psychometrics, we must consider several of the competency domains within clinical psychology.

Over the past 20 years, the field of professional psychology has been making headway in the movement toward competency-based models (Peterson, Peterson, Abrams, & Stricker, 1997; Peterson, 2004; Rodolfa et al., 2005; Rubin et al., 2007). The American Psychological Association's (APA's) Task Force on Assessment of Competence in Professional Psychology and the National Council of Schools and Programs of Professional Psychology (NCSPP), with the aid of experts in the field, have focused their efforts on competency-based education, training, and credentialing (Kaslow, 2004; Kaslow et al., 2004). The APA's Ethical Principles and Code of Conduct (American Psychological Association, 2002), in conjunction with insights from authors and researchers, provide us with the critical domains of competency. The following framework reflects the latest work in the development of competency models within professional psychology. Both the cube model for competency development (Rodolfa et al.) and the NCSPP Competency Model of Education and Training (Peterson et al., 1997) contain functional competencies that consist of knowledge, skills, and attitudes essential to the practice of psychology. Additionally, the domains are not mutually exclusive, are interrelated, and occur at every stage of professional development (Rodolfa et al.). The six functional competencies from the cube model are assessment, diagnosis, and conceptualization; intervention; consultation; research and evaluation; supervision and teaching; and management and supervision (Rodolfa et al.). The seven competencies from the NCSPP model are relationship, assessment, intervention, diversity, research and evaluation, management and supervision, and consultation and education (Peterson et al.). As expected, there is a great deal of overlap between these two models. While many of the competencies are addressed throughout this text, for the purpose of this chapter, we will concentrate on only two functional competencies: assessment and research. Further, it is appropriate to draw attention to the scientific knowledge-methods foundational competency found in the cube model.

13.2.1 Assessment and Research Competencies

The scientific knowledge-methods foundational competency domain is critical to laying the groundwork for psychologists to subsequently acquire functional competency in assessment and research. Without a foundation in the scientific method, it would be impossible to develop the functional capacity to successfully conduct assessments and research. The foundational competency of scientific knowledge-methods is defined as "the ability to understand research, research methodology and a respect for scientifically derived knowledge, techniques of data collection and analysis, biological bases of behavior, cognitive-affective bases of behavior, and lifespan development" (Council of Credentialing Organizations in Professional Psychology, CCOPP, 2004, p. 11). The role of clinical psychologists as professionals not only includes the application of knowledge derived from scientific research, but rather is a form of science and research (Peterson et al., 1997). As such, professional psychologists must be able to design and critique approaches to systematic inquiry using qualitative and quantitative methods.

Clinical psychologists must be adept at the assessment and diagnosis of problems and issues associated with individuals, groups, and organizations (CCOPP, p. 11). According to the NCSPP educational model, assessment is defined as "an ongoing, interactive, and inclusive process that serves to describe, conceptualize, characterize, and predict relevant aspects of a client" (Peterson et al., p. 380). The definition further states that, "the assessment process uses a multimethod and multitheory approach…" (Peterson et al., p. 380). Training in psychological assessment requires more than simply learning to administer and score psychological tests; it must comprehensively include psychological measurement theory.

The research-evaluation functional competency domain has been defined as "the generation of research that contributes to the professional knowledge base and evaluates the effectiveness of various professional activities" (CCOPP, 2004, p. 11). This definition easily encompasses such research endeavors as developing measurement instruments and conducting validity studies. While many graduate students completing scholarly projects may find such research efforts to be daunting, it is within reason that practicing psychologists would attempt these types of studies.

Given the above descriptions of the assessment and research competency domains, the overlap with the field of psychometrics should be obvious. However, we will elaborate by first identifying the typical tasks performed by a psychometrician and then address specific knowledge areas as well as skills that contribute to becoming a competent assessor and researcher.

13.3 Psychometrics as a Discipline

To put it simply, psychometrics is the field of study concerned with the development and refinement of theoretical approaches to measurement and the construction of instruments and procedures for measurement. With regard to psychological measurement this may include, but is by no means limited to, the measurement of knowledge, abilities, attitudes, and personality traits.

Broadly speaking, the following represent the core subject matter one would need to scrutinize to further their understanding of this discipline: psychometric theory (e.g., classical test theory), measurement development, scaling procedures, measurement error, and the reliability and validity of measurement tools. It is important to note that there are a variety of statistical procedures one might utilize, and thus need to become proficient in, to assess the psychometric properties of measurement tools, including correlational analysis, regression analysis, structural equation modeling, item response theory (IRT) modeling, factor analysis, discriminant analysis, and analysis of categorical data. Statistical analyses pertinent to clinical competencies will be discussed elsewhere in this text; however, at times, it is difficult to separate the competencies one would develop in both disciplines, that is, statistics and psychometrics.

Coursework at the graduate level typically includes an introduction to the foundations of psychological measurement that covers the history of testing and assessment along with the exploration of the basic issues in psychological measurement, including reliability, validity, fairness, item analysis, and score reporting and interpretation. Emphasis is often placed on the interpretation, use, and evaluation of achievement, ability, attitude and personality measures. A critical analysis of the impact of testing on culture should also be a component of the program of study. Further, in many doctoral programs, students are expected to engage in the evaluation of existing and construction of new measurement instruments (e.g., attitude scales, performance measures, etc.). A course of this nature would focus on the planning, construction, administration, analysis, and validation of a test. Special emphasis would be placed on domain sampling, item writing, development of scoring protocols, differential item functioning, and reliability and validity studies. Many graduate programs also offer additional coursework on advanced topics in psychometrics. For example, the offerings may include a range of specialty topics designed to enhance the knowledge, skills, and abilities of students related to the technical developments in classical test theory, IRT and Rasch models, generalizability theory, models of selection bias, and test score estimation methods.

During internship training, clinical psychologists continue to apply their knowledge of theories underlying psychological tests and testing methods. Clinicians at this developmental level must be knowledgeable of the strengths and weaknesses of standard intellectual and personality measures (National Council of Schools and Programs of Professional Psychology, NCSPP, 2007). As they continue to hone their skills to administer and score measures, they begin the process of integrated interpretation under supervision. Further, these novice professionals must be aware of the methods of norming tests and implications for test usage with diverse populations. At the onset of postdoctoral training, professionals should have advanced knowledge of the strengths, weaknesses, and appropriateness of a broad range of psychological tests across a wide variety of individuals and populations (NCSPP). Over the course of their postdoctoral training, professional psychologists become increasingly autonomous as they demonstrate the capacity to choose, administer, score, and interpret tests, appropriate to the referral question (NCSPP).

In the United States, licensure in the field of psychology requires one to achieve a passing score on the Examination for Professional Practice in Psychology (EPPP). The EPPP assesses knowledge in a variety of areas that are required for the various responsibilities psychologists are expected to assume in professional practice. One area of the exam pertinent to our

discussion is assessment and diagnosis. Test takers are assessed on their knowledge of psychometric theory (e.g., classical test theory, IRT, etc.), generalizability theory, test construction and standardization procedures, reliability and validity of measures, examination of test fairness and bias, test and item characteristics, curve analysis, and the application of test standards (The Association of State and Provincial Psychology Boards, 2008). This exam serves as the final hurdle where one must demonstrate a certain level of competency before becoming a practicing professional.

Psychometricians, and similarly clinical psychologists, engage in the development of measurement theory and apply statistical theory and methods to collect, organize, interpret, and summarize numerical data to provide usable information with regard to measurement tools. The following embody the typical tasks of both novice and expert psychometricians. It is often the case that one must process large amounts of data for statistical modeling using computer software. Additionally, one will report results of statistical analyses, including information in the form of graphs, charts, and tables. Those engaging in research are tasked with identifying relationships and trends in data, as well as any factors that could affect the results. It is a common practice to analyze and interpret statistical data to identify significant differences in relationships among sources of information (e.g., the multi-trait multi-method matrix). Psychometricians must further evaluate the statistical methods and procedures used to obtain data to ensure validity, applicability, and accuracy. Additionally, they evaluate sources of information to determine any limitations in terms of reliability or usability. In order to complete the aforementioned tasks successfully, one must acquire a broad knowledge base as well as develop a plethora of basic and advanced skills. While this chapter is not intended to be a psychometrics text, in an effort to help guide the discussion of psychometric competencies, we will provide a review of the central topics in the field of psychometrics as they relate to core competencies of professional psychologists. Later, we will review these concepts in an illustrative capacity to suggest what should be learned and exhibited at different stages of training and practice.

13.3.1 Psychometric Concepts and Related Competencies

Those who engage in measurement development or simply use measurement devices must be knowledgeable about the science of measurement. Measurement consists of rules for assigning symbols to objects so as to represent quantities of attributes numerically or to define whether objects fall in the same or different categories with respect to a given attribute (Nunnally & Bernstein, 1994). Requisite measurement concepts include levels of measurement and standardization. At the undergraduate level, psychology students learn and become familiar with the four standard levels of measurement: nominal, ordinal, interval, and ratio. Graduate students are further trained on the use of measurement scales and learn that the number of permissible statistics one may utilize to analyze data is dependent upon the level of measurement. For example, one may be restricted to nonparametric tests when constructs are measured using only nominal scales. When clinical psychologists use measurement tools they must be able to interpret diagnostic information, taking into account the scale of measurement employed. It is important to be mindful of how the level of measurement might restrict the information collected and subsequently impact interpretation.

Standardization allows us to apply specific rules (usually involving norms from a population of interest) to measure attributes. When a measure is standardized, scientists are provided with a more efficient way to communicate and compare results. Additionally, standardized measures provide a certain level of objectivity and quantification. Numerical results provided by standardized measures permit the use of more powerful methods of statistical analysis (e.g., parametric tests). For example, basic to any standardized test is the ability to apply descriptive statistics, including those characterizing the normal curve (e.g., skewness and kurtosis), measures of central tendency (e.g., mean, median, and mode), and measures of variation (e.g., variance and standard deviation). Psychologists in training and practicing professionals alike must be knowledgeable of standard scores (e.g., z-scores, t scores, stanine scores, etc.) so that they are able to apply these concepts when interpreting an individual's score and make comparisons to the normative data typically found in test manuals.

Another central topic in psychometrics, and in particular test construction, is scaling. Scaling is the assignment of objects to numbers according to a rule (Stevens, 1946), and in many instances, the objects are text statements – usually statements of attitudes or beliefs. Scaling is often used to test a hypothesis and is conducted as part of exploratory research. For example, we might want to know whether the construct or concept is one-dimensional or multi-dimensional and we are interested in what dimensions underlie a set of ratings. The most common reason for employing scaling procedures is for scoring purposes. When a participant gives their responses to a set of items, we often would like to assign a single number that represents that person's overall attitude or belief. It is advantageous for both graduate students and practicing professionals to be familiar with and understand various scaling methods that may be used to select items.

Among scaling procedures, there is a collection referred to as stimulus-centered, with the classical method for development being the Thurstone approach. Other types include the Q-sort method and rank-order methods (e.g., paired comparison method). A second set of scaling methods, somewhat more popular in clinical psychology research, is the subject-centered scaling technique. The typical procedure for developing these scales is the Likert method, and an alternative is the semantic differential. Recently, there have been developments in scale construction methods that assign scale scores to both subjects and stimuli (e.g., IRT and the Rasch model). It must be stated that test development is not only a time consuming and laborious research endeavor, but also one that requires, in order to produce tools of high quality, a great deal of expertise in a number of areas related to psychometrics. Therefore, test development should only be taken on by someone with an expert level of competency in the above-mentioned areas as well as in the areas discussed below.

There will likely be some error involved in measurement no matter what the scaling method, level of measurement, or psychological construct being assessed. There are several classical theories of measurement error, some of which assume that the objects of measurement (e.g., people) have true scores on the attribute being measured (Nunnally & Bernstein, 1994). Students of psychometrics need to have a firm grasp on the concept of measurement error, and specifically the standard error of measurement.

Classical test theory is a body of related psychometric theory based on the breaking down of a person's observed score that is obtained on a test into a true score component, that is free from error, and an error component. Measurement error, in this sense, may come from internal (e.g., the person) and external (e.g., testing conditions) factors that are extraneous to the construct being measured and affect the observed score. Generally speaking, the aim of classical

test theory is to understand and improve the reliability of psychological tests. Classical test theory is a special case of generalizability theory in that classical test theory only takes one source of error into account at a time, whereas generalizability theory can take many concurrent sources into account. Developments in analysis of variance approaches to classical test theory, like the intraclass correlation, have allowed psychometricians to look at more than one source of variance simultaneously. The term "classical" is typically linked to those measures that are scored using the linear combinations of responses to individual items and is in contrast to the more recent psychometric theories, generally referred to collectively as IRT, where scoring tests are based upon the pattern of item responses (Nunnally & Bernstein, 1994). Knowledge of the fundamentals of IRT must be acquired in order to be considered an expert in psychometrics.

In psychometrics, IRT involves the application of mathematical models to data from questionnaires and tests as a basis for measuring abilities, attitudes, or other variables. Typically, IRT research involves abilities, and the attribute central to the research effort is some form of skill. While complex mathematics are employed, at its most basic level, IRT is based on the idea that the probability of getting an item correct is a function of a latent trait or ability (Nunnally & Bernstein, 1994). Hence, it is often referred to as latent trait theory. IRT assumes that there is a correlation between the score obtained by a person for one item and their overall ability on the latent trait which underlies test performance. The simplest IRT model is the one-parameter (Rasch) model in which items are assumed to vary only with respect to their difficulty. IRT can be used to create a unique plot for each test item (e.g., Item Characteristic Curve, ICC). The ICC is a plot of probability that the item will be answered correctly against ability, keeping in mind that the questions cannot be answered correctly by guessing. No matter which theoretical model of measurement error is being utilized, test developers and researchers must demonstrate that measurement instruments are reliable. Without reliability of measurement, research results are not replicable (which is fundamental to the scientific method).

Reliability refers to the consistency of a measure's items or the dependability of a measure over time. Since identifying a person's "true" score on a measure is conceptually theoretical, reliability must be estimated. As mentioned above, observed scores for a person on a given measure consist of both that person's true score as well as the error inherent in the measurement of a psychological construct. Thus, the larger the amount of measurement error present, the weaker the reliability estimates will be. It is important to understand that measurement error can be a mixture of both systematic and random processes; however, according to classical test theory, the error component of one's observed score is attributed to random error. Systematic error should be dealt with by researchers when considering the research design and methodology (e.g., random assignment). In other words, investigators should pay special attention to ways in which they might limit the opportunity for systematic measurement error to occur.

There are four ways in which reliability estimates are determined: (i) Internal consistency reliability produces a reliability estimate based on the correlation (interrelationships) among the test items comprising a set (e.g., Cronbach's alpha). (ii) Split-half reliability estimates reliability based on the correlation of two equivalent forms of the scale. It should be noted, however, there are specific criteria that must be met in order to have "equivalency" among forms (e.g., identical means and standard deviations). (iii) Test–retest reliability produces an estimate based on the correlation between two (or more) administrations of the same instrument at different points in time. (iv) Inter-rater reliability consists of estimation based on the correlation of scores between or among two or more raters who rate the same item, scale, or instrument.

These four reliability estimation methods are not necessarily mutually exclusive. All reliability coefficients are forms of correlation coefficients, but there are multiple types representing different meanings of reliability, and more than one might be used in single research setting. In order to be truly competent, it is vital that psychologists at all levels of training are comfortable computing as well as interpreting reliability estimates.

Many authors have provided guidelines for interpreting reliability estimates. For example, Nunnally and Bernstein (1994) suggest that for basic research purposes 0.70 is a sufficient reliability estimate, and it may not be worth the time and resources to attempt to increase the number of items and reduce error in other ways such that the estimate would exceed 0.80. That being said, a satisfactory level of reliability is truly dependent upon how a measure is being used. Some authors have suggested an estimate of 0.85 or higher when scores are used to make clinical decisions (Rosenthal & Rosnow, 1991; Weiner & Stewart, 1984). It seems reasonable to conclude that when clinical psychologists use assessment tools, important decisions will be made with respect to a client's score, thus "…a reliability of .90 is the bare minimum, and a reliability of .95 should be considered the desirable standard" (Nunnally & Bernstein, p. 265). It is important to note that these "guidelines" that psychologists may employ to interpret internal consistency reliability estimates have been met with some criticism. In particular, Streiner (2003) believes that Nunnally and Bernstein may have set high a criterion for alpha when assessing the internal consistency reliability of clinical scales. Streiner's comment stems from the fact that many clinical scales are intended to tap into a unidimensional construct; however, the construct may be conceptualized as having many different aspects (i.e., components or subscales). Thus, if alpha is too high (i.e., over 0.90), this may represent redundancy across items rather than homogeneity.

It is often stated, and truthfully so, that reliability is a necessary but not sufficient condition for validity. In other words, measures may be reliable without being valid; however, they cannot be valid without being reliable. Technically speaking, it is not the measurement tool itself that is valid, but rather it is the inferences (or interpretations) that we make from that tool that require evidence of validity. Validity refers to "truthfulness," and a measurement instrument is said to be valid if it measures what it purports to measure. The classic approach to validity consists of addressing a measures content, criterion, and construct validity. At a very basic level, a measure may be said to have good "face" validity if the instrument appears to be a credible and plausible measure of the construct. Professionals in training often confuse this concept with content validity. Face validity is the least important kind of validity since, unlike content validity, it is retrospective rather than prospective and some measures (e.g., The Minnesota Multiphasic Personality Inventory) have low face validity but good criterion validity. Content validity addresses whether a measure adequately samples the content in the domain of interest. Content validity is usually assessed by the inspection of the content of the items for relevance to the construct of interest by subject matter experts. Additionally, one may ensure a tool has adequate content validity when a specific theory is used for scale development or a systematic planning tool is utilized to outline the content of a test. Criterion-related validity speaks of establishing a statistical relationship between a measure and some relevant behavioral outcome that is external to the measuring instrument. There are two common types of criterion-related validity studies, concurrent and predictive. The difference between these two strategies simply boils down to when data on the criterion variable are collected. Construct validity is a bit more difficult to define, as there tends to be a certain level of disagreement among scholars. Cronbach and Meehl (1955), who wrote the seminal article on the topic, state that "construct validation

is involved whenever a test is to be interpreted as a measure of some attribute or quality which is not operationally defined" (p. 284). There is consensus, however, on the steps involved in construct validation. First, the theoretical relationships among the concepts involved must be identified. Then, the hypothesized observed relationships among the measures and concepts are specified. Finally, the empirical results are interpreted to determine the consistency of the findings with the hypothesized relations in the first two steps. Construct validity is demonstrated by investigating convergent and discriminant validity of scales. Convergent validity refers to whether the scale correlates with other scales that it should be related to, while discriminant validity refers to whether the scale does not correlate with other scales that it should not be related to. Traditionally, the multi-trait–multi-method matrix was utilized to assess these relationships (see Campbell & Fiske, 1959). More recently, these validation procedures are conducted by using exploratory and more specifically confirmatory factor analyses.

Factor analysis is both a theoretical and data reduction tool. Theoretically, it helps us to understand the latent constructs underlying observed measures. It also provides a method by which we can reduce large amounts of data to smaller sets that still capture most of the same information. In this fashion, it is commonly employed in the process of test development. Further, it can be used as a validation tool to the extent that one has clear theoretical hypotheses and a measure that purports to match those hypotheses. This is especially true when confirmatory factor analysis is used. At a basic level of competence, one must demonstrate an understanding of the basic concepts related to factor analysis and be able to evaluate research utilizing this statistical technique. To exhibit a more expert level of competence, clinical psychologists would be expected to perform and interpret the results from these procedures. In order to be proficient in factor analysis, professionals must first learn how to assess the appropriateness of the data, specifically the correlation matrix. For example, there are a series of tests that may be conducted to determine if the items of a measurement tool are related (e.g., Bartlett's test of sphericity, Kaiser–Meyer–Olkin measure of sampling adequacy, etc.). Without a suitable correlation matrix, it would be difficult to determine if there is a latent construct underlying the items. Furthermore, if one expects to be an expert with regard to factor analysis, concepts such as a "Heywood" case, eigenvalue, and communality must be well understood. When conducting a factor analysis, one is presented with many options with regard to factor extraction techniques (e.g., principal components, principal factor, maximum likelihood, etc.). A qualified individual would be well versed in each of these methods and their intended impact on the estimates of communality (i.e., part of a variable's variance that is common to the factors extracted). One must also make a decision with regard to rotation (i.e., orthogonal vs. oblique rotation), and thus must be cognizant of how each would treat the factor scores. A clinical psychologist who is proficient in factor analysis would also be well aware of the problems that may arise when trying to determine the number of factors that are extracted in a given analysis. The professional has many tools at their disposal to properly identify the number of factors, including the eigenvalue-greater-than-one rule, the scree test, significance tests, the minimum average partial (MAP), and parallel analysis. An authority on factor analysis would be able to aptly utilize these methods so as not to under- or over-extract the estimated number of factors. It should also be pointed out that there are a number of other statistical procedures related to factor analysis that clinical psychologists should be knowledgeable about including, cluster analysis, profile analysis, and multidimensional scaling.

Psychologists at all levels of training and those practicing professionals should be able to demonstrate some level of competence with regard to the psychometric concepts discussed

above. In the following section, we will further illustrate how these psychometric concepts and competencies are connected to the practice of clinical assessment.

13.4 Psychometric Concepts and Clinical Endeavors

In the practice of clinical psychology, the most basic level of competency involves an ability to understand and apply learned concepts. In this section, we link concepts defined and described in earlier sections to application of psychometric concepts in clinical endeavors.

After learning about probability, reliability, and the normal curve in entry-level statistics and psychometrics classes, most students have little recognition of how these fundamental concepts will ever be applicable to clinical work. Coursework in assessment begins to change those perceptions, and clinical practica often make the most impact in generating an "A-HA" experience for the novice clinician.

Clinical application is best illustrated by examples and vignettes. Therefore, we offer the following scenario as starting place to aid in the illustration of psychometric competency.

Michelle is a 16½-year-old biracial (Caucasian and Native American) female who was diagnosed with phenylketonuria (PKU) at birth. Michelle's primary care and psychological services are coordinated through an inter-professional clinic in the Pacific Northwest. This month, Michelle will be evaluated by a practicum student, Donna, who is just beginning her first external training experience (outside the university training clinic) at St. Paul's Hospital. Is Donna competent to evaluate Michelle? Does she have the basic level of knowledge, skills, and abilities to perform effectively with supervision? What does Donna need to know to demonstrate basic competency in the area of psychometrics at a novice level?

13.4.1 Probability and the Normal Curve

Donna is a diligent student and although this is her first case with PKU, she does her homework and learns that PKU occurs in 1 in 15,000 births with varying estimates across ethnic groups (National Institutes of Health [NIH] Consensus Development Panel, 2001; Sullivan & Chang, 1999) – probability revisited! An understanding of probability theory is critical for determining the "likelihood" of a particular event. Diagnosis and assessment are predicated on the assumption that individuals with disorders deviate from the norm, and thus, atypically is an essential defining feature. Atypicality is often determined using odds ratios and/or standardized measures. In this case, PKU is not a common event and unless Donna continues to work in specialty clinics, her chance of encountering clients with this disorder in a typical outpatient setting is low.

We noted previously that basic competency in regards to the normal distribution involved understanding the nature of the distribution and assumptions of normality. What does this mean in clinical practice? In combination with probability theory, the normal distribution challenges users of psychological instruments to think critically as to what they truly mean by 'unlikely to have occurred by chance' and how confident they are that their client's findings deviate from the normal range. Specifically, what defines aberration from the norm? If Michelle's test scores fall within the middle range (±1 standard deviation), will Donna be concerned? At what point on the continuum from one to three standard deviations below the mean does

functional impairment in a specific skill appear? Obviously, there is not a one-to-one correspondence between behavior and test scores; however, all too often, an incomplete under-standing of the continuous nature of the normal distribution leads to a knee-jerk response of over or under-interpretation and subsequent inappropriate diagnosis.

Furthermore, normality is assumed for particular psychological constructs in assessment, but not for others. We assume that general cognitive intelligence is normally distributed with many individuals clustering around the average and few individuals scoring at the extremes. This means that Michelle would be most likely to have average intellectual functioning; however, her diagnosis of PKU is expected to result in a lowered cognitive score. Conversely, characteristics such as polysubstance abuse or suicidality are expected to be relatively uncom-mon in the general population, and thus, to be positively skewed rather than normally distrib-uted. Most individuals will not endorse these characteristics while a few individuals will endorse high levels of these risky behaviors. In contrast to both of these traits, the expected underlying distribution for gross motor skills is less apparent. This might be an example of a truncated distribution in which little meaningful variability is found at the upper end of the distribution. The inability to walk at age 3 is clinically significant and indicates gross motor skills that fall well below the mean (or the lower tail of the distribution). However, what inter-pretation is made for the upper tail of the distribution? Is there much clinical utility in making interpretations of superior walking performance? In practice, most individuals learn to walk, and little inference is made beyond typical skills.

13.4.2 Scaling and Measurement

Students are particularly boggled by score transformations and comparing scores across vari-ous scaling metrics. It is difficult for the novice examiner to keep in mind that a score of 100 (IQ or standard score), 50th (percentile), 10 (scaled score), and a 0 (z-score), all indicate aver-age performance. However, it is extremely important that professionals are sufficiently grounded in score transformation, scaling, and various distributions to be able to translate scores into a single system for view by others, and to be able to explain scores in language that lay individuals can understand. In Michelle's case, Donna needs to be able to explain to her and her caregivers the meaning of her scores relative to the general population and to her own areas of strength and weakness.

13.4.3 Central Tendency, Variability and the Standard Error

All scores vary within an individual, across individuals, and over time. Furthermore, scores will tend to cluster together around a central common value. The extent of variability is deter-mined by many factors including characteristics of the given construct. It is valuable for novice examiners to understand distinctions between measures of central tendency such as the mean, median, and mode. The median and mode are rarely used in assessment practice, whereas, the mean is the most heavily relied upon measure of central tendency. At a basic level, users must keep in mind that the mean is affected by extreme scores. Questions involving the mean may take several forms. Is the full scale IQ a good indicator of the individual's general intelligence? If extreme scores are present among the indexes, is the overall aggregate score misleading? Is it

reasonable to make idiographic interpretations of single subtest scores, or is it more appropriate to base conclusions on an aggregate score that synthesizes information from a variety of smaller samples of behavior? The answers to these questions continue to be debated (see the special issue of *Applied Neuropsychology*, Reynolds, 2007). However, it is still necessary to understand the underlying psychometric concepts in order to arrive at a justifiable conclusion. Related to this issue is interpretation of profile strengths and weaknesses. Which mean should be used for determining strengths and weaknesses (i.e., a global mean based on ten subtests or a specific index mean of three subtests)? How is the determination of the amount of clinically meaningful intersubtest scatter influenced by the number of subtests being aggregated? The interpretation of intersubtest scatter is linked both to the concepts of central tendency and variability. How much should ten subtests vary from one another particularly when the subtests tap different underlying constructs? What about the variability of three subtests? The degree of variability is directly related to the number of inputs being compared and the homogeneity of the constructs the inputs reflect.

Finally, we address the importance of the standard error in assessment. As noted previously, the standard error is the standard deviation of the sampling distribution of the mean. The notion of a standard error, coupled with the central limit theorem, is a difficult concept for most students to fully integrate. Most novice students internalize and memorize a mantra that goes something like, "big standard error is bad." While this is often true, students place less attention on understanding the factors that affect the size of the standard error and what information it conveys. The application of the understanding of the standard error is most directly seen in the formation/calculation of a confidence interval around a score for reporting purposes. Does the student truly understand the purpose and interpretation of the confidence interval? Does he or she recognize that the standard error provided in the manual is derived from the normative sample and if that sample was not sufficiently large then the standard error will likely be inaccurate? Does the student notice that the standard errors for some subtests are much larger indicating greater variability for some subtests than others? Observation of this information should influence the degree to which a finding on a subtest is interpreted idiographically rather than ignored in favor of interpreting only aggregate findings. It is noteworthy that Koocher (1993) identifies failure to understand the standard error of measurement as a common ethical issue that arises in the practice of psychological assessment further underscoring the need for competence related to this psychometric concept.

13.4.4 Regression to the Mean, Reliability, Floor and Ceiling Effects

Re-evaluation of an individual for a variety of purposes is a common recommendation by psychological professionals. This practice must be conducted on a foundation of psychometric competency or errors in interpretation will result. Several concepts are relevant, including regression to the mean, test–retest reliability, and the standard error. Regression to the mean is a statistical concept that must be well understood when a test is repeated. In our example client's case, Michelle is being re-evaluated to determine whether or not cognitive decline has occurred since the last evaluation. When individuals with PKU are compliant with dietary restrictions and eliminate phenylalanine from their food intake, they are able to reduce the likelihood of neurocognitive impairment associated with elevated levels of phenylalanine

(hyperphenylalanine) in the bloodstream. However, dietary compliance is a major issue for adolescents with PKU (Gleason, Michals, Matalon, Langenberg, & Kamath, 1992; Ievers-Landis, Hoff, Brez, Cancilliere, McConnell, & Kerr, 2005). In this clinical scenario, re-evaluation entails examining previous scores on an intelligence test such as The Wechsler Intelligence Test for Children – Fourth Edition (WISC-IV; Wechsler, 2003) relative to current scores. The Wechsler tests have been and continue to be some of the most widely taught and used cognitive tests (Piotrowski & Keller, 1992) in psychology. If Michelle's full scale IQ score on the WISC-IV drops from 107 to 99, is this evidence of decline? Extreme scores for the person will regress to their mean with repeated administration. Depending on the standard error, a drop of eight points may be within the confidence interval and does not represent true change. Furthermore, a score on an unreliable scale that has low test–retest reliability would be expected to change from time 1 to time 2 even if there is no true change in the underlying trait. With multiple administrations of the intelligence measure or with many tests being administered, there is a possibility of detecting a change in scores solely by chance. Alpha inflation as a construct is rarely considered during the process of assessment; however, a type I error (i.e., we say there is a significant effect when in fact there is not) is increased with multiple tests. For example, comparing all WISC-IV indexes in a pairwise fashion (e.g., perceptual organization [POI] vs. processing speed [PSI]) as is recommended on the WISC-IV protocol without any correction for type I error is likely to result in a significant difference purely by chance. For this reason, the use of a more conservative p-value/significance level such as 0.01 as opposed to 0.05 may be preferred.

Another psychometric concept to consider in Michelle's evaluation is floor and ceiling effects. The WISC-IV is normed for children and adolescents ages 6 years 0 months to 16 years 11 months. The age range of this test is unlikely to be a problem for Michelle even though she is at the upper end of the test norms, because cognitive impairment is a common symptom of PKU when diet is not well managed (Fishler, Azen, Henderson, Friedman, & Koch, 1987; Gassio et al., 2005; Griffiths, Paterson, & Harvie, 1995; NIH, 2000). Taking into account floor and ceiling effects, it is more important that there is greater variability at the lower end of the test in this client's particular case than variability at the upper range. Were the referral question to be related to giftedness, this test might present a different concern.

13.4.5 Validity

Construct validity in assessment is an ever-evolving question when tests are constantly being revised and redesigned. The rate at which tests are re-normed and re-published has quickened as evidenced by a period of 26 years from the introduction of the Wechsler Adult Intelligence Scale (WAIS) in 1955 (Wechsler, 1955) to its revision as the WAIS-R (WAIS-R, Wechsler, 1981), 16 years from the WAIS-R to the WAIS-III (Wechsler, 1997) as compared to 11 years between the WAIS-III and the WAIS-IV (Wechsler, 2008). The WISC has followed a similar trajectory (1949 WISC; 1974 WISC-R; 1991, WISC-III; 2003, WISC-IV). Each time a test is re-introduced, the validity of any revised subtests must be established. For example, there is evidence that matrix reasoning, a relatively newer subtest on the Wechsler tests, is verbally mediated although it is designed to be a measure of nonverbal fluid reasoning (Dugbartey, Sanchez, Rosenbaum, Mahurin, Mark Davis, & Townes, 1999). Thus, research is needed to establish the construct validity of newly developed scales as well as slight modifications to existing scales that are

made in the revision process. For example, in the 2008 revision of the WAIS-IV, the similarities, comprehension, information, and vocabulary subtests all have items which have been replaced as well as revised scoring rules. Another influence to consider is the Flynn effect (Kanaya, Scullin, & Ceci, 2003) which is a phenomenon in which intelligence scores tend to increase over time after a test is released. Once a test is re-normed, scores are reset to the standard mean of 100.

Let us assume for our discussion that 2 years have passed and our client, Michelle, has turned 18 and is being moved from the child and adolescent clinic to the adult clinic for continued follow-up. Although it was routine practice in the child clinic to evaluate patients with the WISC-IV, the D-KEFS (Delis-Kaplan Executive Functioning System, Delis, Kaplan, & Kramer, 2001), and the WIAT-II (Wechsler Individual Achievement Test – Second edition, Wechsler, 2001), the adult clinic has adopted a battery that includes the WAIS-IV, the DKEFS, and the WJ-III NU (Woodcock–Johnson Tests of Achievement – Third Edition, Norm Update [WJ-III NU], Woodcock, McGrew, & Mather, 2006). What is the expected relationship between Michelle's scores on the WISC-IV and the WAIS-IV, two measures of cognitive ability normed on different aged populations? There are many factors which will affect Michelle's WAIS-IV scores including new subtests on the newly released WAIS-IV with yet to be established validity (e.g., visual puzzles), statistical artifacts such as regression to the mean, and the Flynn effect which will likely result in a decreased score on the WAIS-IV relative to a prior version of the WAIS (i.e., the WAIS-III) or the WISC-IV.

13.4.6 Multi-trait Multi-method – Convergent and Discriminant Validity

We return to our clinical example, to extend its complexity to aid us in illustrating yet more psychometric concepts important to the assessment endeavor. We have discussed some of the issues related to Michelle's cognitive/intellectual functioning. However, although Michelle has exhibited longstanding problems with attention and concentration, she was never formally diagnosed with Attention-Deficit Hyperactivity Disorder (ADHD) in addition to her PKU diagnosis. Attentional problems are often present in individuals with PKU as a result of exposure to high levels of phenylalanine (Antshel & Waisbren, 2003; Channon, German, Cassina, & Lee, 2004). Recently, Michelle has self-reported problems that she believes are impacting her performance at work. Further investigation and evaluation is needed to determine if Michelle meets criteria for an additional diagnosis, and if she is eligible for work place accommodations. Because there is no single measure that includes a set of tasks specifically designed to address attention and concentration, the competent assessor is looking for convergent findings on a variety of subscales and individual tests that tap this domain. We are reminded of the need to understand validity. What information from various administered tests should be expected to hang together and what information should not be related?

We can utilize the psychometric concept of the multi-trait multi-method matrix as a foundation for how to view data obtained across measures. We are expecting Michelle's scores on various attention and concentration tasks to be similar. However, we need to recognize that when two tests measure attention in the same way, the scores will be more similar than when two tests measure attention in different ways. Thus, an example of a mono-trait mono-method relationship would be Michelle's performance on two cancellation tasks, in which the same skill is being tapped in the same way by two tests. In contrast, mono-trait hetero-method

would apply to her performance on a cancellation task and a continuous performance task in which one is a paper–pencil measure and the other is computer administered. Multi-method must also be distinguished from multi-source data in which we are looking for information from various sources or reporters. Attention problems as reported by Michelle and her employer on a questionnaire measure with similar items worded differently depending on the person completing the measure would be an example of multi-source data. If we find evidence of convergence across measures of the same trait using different methods, we can be more confident that we have arrived at an accurate diagnosis. This is a more stringent requirement than if only one test must meet significance or if we only use tests that evaluate the trait in the exact way. Conversely, there is a greater burden placed on the examiner to truly understand how to make sense of results that are not in agreement. The literature is replete with examples of low agreement between raters of a given trait (e.g., see a classic article by Achenbach, McConaughy, & Howell, 1987). It is incumbent upon the examiner to evaluate the evidence, taking into account psychometric theory, to arrive at an accurate conclusion rather than assuming that an individual does not meet criteria for a disorder because not all scores or raters are in agreement.

13.5 Basic Competencies in Psychometrics

13.5.1 Assessment Competency – Readiness for Practicum

Basic psychometric competency involves the ability to read and understand psychometric data as presented in test manuals, computer generated reports, and the research literature. Understanding scaled scores, base rates, and intersubtest scatter; calculating discrepancies and interpreting scores; and evaluating reliability and validity of standardized measures are all general assessment skills required for competency. As noted, a key skill of the educated clinician is the ability to read psychometric information and decipher it. New tests are always being developed. Foundational core knowledge should be sufficient such that when new tests are released, the individual is able to pick up a new test manual and decipher it.

　　There is widespread agreement that an understanding of basic psychometrics is required for competency in assessment. Krishnamurthy et al. (2004) identified eight core competencies for psychological assessment with the first one being a background in psychometric theory. These authors were part of a working group charged with identifying the core components of psychological assessment competency. The American Psychological Association's *Guidelines for Test User Qualifications* (Turner, DeMers, Fox, & Reed, 2001) recommends core knowledge in psychometrics and measurement. Within this domain, required topics include descriptive statistics, reliability and measurement error, validity and the meaning of test scores, normative interpretation of test scores, and selection of appropriate tests (pp. 1100–1101). The recent *Standards for Education and Training in Psychological Assessment* by the Board of Trustees of the Society for Personality Assessment (Society for Personality Assessment, 2006) recommends as minimal requirements for competence in assessment, didactic instruction and practical experience in "psychometric theory, including issues of reliability, validity, reference group norms, limits of generalizability, and test construction" (p. 356). In a survey conducted by Ryan and Sackett (1992) regarding competency for individual assessors, 69.1% of those surveyed endorsed psychometrics as a necessary area of training.

Exactly how much psychometric proficiency is needed for competency, the particular topics that should be taught, and the best way to teach psychometric concepts is an issue for debate. Childs and Eyde (2002) surveyed accredited clinical psychology doctoral programs to determine what programs teach and how various topics are taught within each program. Of the programs surveyed, 73% had at least one course that covered the topic of psychometrics and 24% had at least one course that focused on the topic of psychometrics (a focus was defined as devoting at least half of a course to the topic). In terms of required content, 65% of programs required a course in which psychometrics was covered as a topic and 17.9% required a class which focused on psychometrics. The psychometric topics being taught, including the percentages of programs stating that the topic was covered, were: validity 63%, reliability 60%, test development 43%, norming 20%, test/item bias 15%, classical test theory 15%, IRT 5%, and standard setting 5%. These percentages illustrate the relatively greater importance placed on understanding validity and reliability relative to topics such as IRT.

Psychometric concepts currently being taught in graduate programs and topics in psychometrics considered to be important for competency are both similar and different. In 1999, an APA division 12 task force, titled Assessment for the 21st Century (APA Presidential Task Force, 1999), was formed and charged with creating a curriculum model for graduate programs for teaching psychological assessment. The task force convened a group of psychologists considered to be, "eminent in various assessment fields" (p. 10), and this working group generated a list of recommended topics. Of the topics that emerged as being foundational for assessment, construct validity had the highest rating. Other areas of psychometrics and statistics considered to be important for competency included reliability, standard error of measurement, Bayes theorem, clinical versus statistical prediction, and an understanding of base rates.

Topics associated with assessment and psychometrics are often taught in conjunction with psychometrics when relevant. According to Childs and Eyde (2002), psychological assessment "requires an understanding of psychometric concepts, such as reliability and validity, and of other issues, such as professional ethics, legal issues, and assessment of diverse populations" (p. 131). The ethical standards pertaining to assessment and addressing psychometrics are mostly found in standards 9.01 to 9.11 of the American Psychological Association's Ethical Principals for Psychologists (APA, 2002). Quality and fairness in assessment of diverse populations is addressed in the Educational Testing Service's Standards (ETS, 2002) which is based upon the Standards for Educational and Psychological Testing developed by the American Educational Research Association (AERA), the American Psychological Association (APA), and the National Council on Measurement in Education (NCME) (AERA, APA, & NCME, 1999).

Many experts agree that exposure to psychometric content should appear early in graduate training. In 1978, Russ noted the value of an introductory seminar in psychometrics as the best way to "teach the skills necessary to evaluate tests critically in areas of reliability, validity, and appropriate use of the test" (p. 454). Psychometrics is usually introduced during didactic courses in a doctoral program prior to a clinical practicum. According to Stout (1992), "it appears that a core exposure to theory, instrument construction and development, administration, scoring, and interpretation is best done in the training program" (p. 16). In contrast to perspectives that emphasize early acquisition of psychometric concepts in a didactic format, writers who focus on the applied aspects of assessment can seem to downplay the importance of basic psychometric knowledge as a training need that is separate from beginning assessment training (Piotrowski & Keller, 1992).

Whether training should occur in reference to a particular intellectual or personality tests is open for debate. Early writers such as Levy (1974) suggest that "it is more important that students know what is entailed in the development and standardization of tests, how to evaluate the research bearing upon them, and the principles of good clinical test administration, than it is that they become proficient in the administration of any particular set of diagnostic tests" (p. 16).

In contrast, Piotrowski and Keller (1992) emphasize the importance of specific assessment instruments. They reviewed the most commonly used tests in applied settings and in their implications for training, they stated the following: "we agree with others that there is a critical difference between teaching *how* the clinician approaches 'psychological assessment,' analyzes the psychometric properties of tests, and integrates test data versus mastering certain specific tests …. However, we firmly believe that these fundamental aspects of assessment are *learned* on specific tests" (p. 75). In their section on implications for training, Piotrowski and Keller recommend that students "review the clinical and research literature on the select tests" (p. 78) but do not mention the need for basic psychometric courses or detailed knowledge in order to understand this information.

13.5.2 The Training and Psychometric Competencies of the Advanced Beginner – Readiness for Internship

As students move from readiness for practicum to readiness for internship, the nature of competency in psychometrics changes and should increase. According to Hatcher and Lassiter (2007), students should begin internship with a baseline competency of knowledge from graduate classroom experience and practicum training that includes skills in assessment. However, exactly what students should know in psychometrics and assessment, and the skills they should possess when they begin internship has been continually debated. As Levy expressed in 1974, "the quality of training of students when they arrive at their internships serves as a focus of controversy between university and internship-based psychologists concerning their respective conceptions of the practice of clinical psychology" (p. 17). This being said, there is a general consensus among internship directors that psychometric knowledge should be a prerequisite for internship. Clemence and Handler (2001) surveyed internship training directors to ascertain what students are expected to know before internship. Of the sites surveyed, 79% indicated that knowledge of psychometrics and/or test construction was an important area of competency. Unfortunately, not all students are prepared in the basic areas of assessment competency as indicated by the fact that 56% of internships provide instruction in introductory assessment skills (Clemence & Handler). If doctoral programs follow the Practicum Competencies Outline, psychological assessment is one of the skills that should be developed during practicum before internship commences (Hatcher & Lassiter).

Assuming basic competencies are met before internship, students should move from advanced beginner status to competent status through internship training experiences. Almost all internships (i.e., 99%) provide assessment training with emphasis on report writing and advanced assessment skills for proficient independent practice. During the internship year, assessment competencies may continue to develop; however, core psychometric skills may not. Very few internship programs provide training in assessment research which is one way that

core psychometric skills could be advanced. Only 21% of the internships surveyed by Clemence and Handler (2001) provided any training in research in assessment during the course of internship (p. 21). Thus, preparation for assessment research or advanced psychometric skills is not often a focus of internship training.

13.5.3 Different Schools of Thought

At this juncture, it is necessary for us to take a slight detour in our consideration of aspects of psychometric knowledge that are foundational for competency in clinical assessment and clinical research to address various issues related to this content area. Up to this point, the majority of the discussion and literature cited has been generated by professionals whose main professional identification is psychology. As we move from a consideration of basic competency to our eventual discussion of expert competency, it is important to address areas in which there may be a difference of opinion as to what constitutes the core body of knowledge in psychometrics.

There are those who view psychometrics as a means to an end for the purpose of clinical research or clinical practice and there are those who are engaged in advancing the field of psychometrics. This distinction gives rise to a debate of what psychometricians might like to see as the competencies of an advanced beginner upon graduation from a doctoral program. Boorsboom (2006) is a notable voice in this discussion. Boorsboom in his article, "The Attack of the Psychometricians," describes a "lack of integration between psychometrics and psychology" (p. 426) that has led to a disconnect between psychometric theory and psychological research. In Boorsboom's opinion, "psychometrics, as a discipline, has not succeeded in penetrating mainstream psychological testing to an appreciable degree" (p. 425), such that outdated concepts such are being taught in psychology training rather than new innovations from the field of psychometrics. Some of the reasons cited for this lack of integration include insufficient mathematical training in calculus and matrix algebra by psychology students, and an over-reliance on the *Statistical Package for the Social Sciences* (and the defaults embedded within) as a statistical program relative to other statistical software.

It is clear from Boorsboom's (2006) writings that at present, psychologists are failing to achieve basic competency particularly in the area of psychometric modeling and are relying on outdated models of psychometric concepts. Boorsboom asserts that psychometric modeling should be part of the skill set of the average researcher in psychology and gives recommendations for revising material taught in textbooks with regard to classical test theory, construct validity, and operationalist thinking. This represents a significant departure from most sources including the APA's Guidelines for Test User Qualifications which state that it is important for users to understand classical test theory, but an understanding of IRT is only required if IRT is deemed "appropriate or necessary" (p. 1100).

13.5.4 Achieving Proficiency – Readiness for Practice

Going back to our early training example of Donna, let us assume that it is several years later and Donna has returned to St. Paul's Hospital to begin postdoctoral training, semi-independent

or independent practice. She has completed her predoctoral training requirements including her predoctoral internship. Although she is still under supervision, she is in the final phases of her training before becoming an independent clinical psychologist. At this stage in her career, what should Donna exhibit in regards to her level of competency in psychometrics? Should she be able to teach a class in the topic, supervise practicum students in assessment, determine the standard or fixed battery to be used in the child assessment clinic at the hospital?

As we review Donna's level of competency at this level, we expect her to have a certain level of proficiency in psychometrics. According to Marlowe, Wetzler, and Gibbings (1992), Donna should be "thoroughly familiar with methods of test construction, as well as indices of reliability, validity, generalizability, so as to be [a] competent and effective consumer[s] of tests, test manuals, and related professional literature" (p. 15).

There are a number of perspectives which underlay the determination of competency and training in psychometrics. Training models differ for those who are being trained as consumers versus creators of psychometric knowledge. This is sometimes considered to be indicative of a scientist versus practitioner model of graduate training. However, both scientist and practitioner skills are essential for competent assessment. This dialectic between science/research and practice is best summarized by Marlowe et al. (1992) who discuss psychometric and assessment competency from the following standpoint: in the area of assessment, it is "insufficient for … curriculum to focus solely on the "interpretive aspects" or 'how to do it' of testing … without simultaneously attending to general psychometric principles and test-specific attributes" (p. 13). Although these authors assert that "one cannot be clinically competent without research knowledge" (p. 11), they describe competency in terms of effective consumption of assessment manuals and research literature. However, the extent to which practicing psychologists should be directly engaged in psychometric and assessment research and generative activities is left open for debate. In reality, very little training in assessment research or advanced psychometric skills is received after initial coursework and practica are complete. Advanced training in psychometrics is usually acquired by those who seek out specialized programs and opportunities. Postdoctoral training in psychometrics is generally obtained through fellowships at institutes and universities. For example, the Institute for Education Sciences provides funding for universities to establish postdoctoral training programs in education measurement with the specific goal of producing "a cadre of education researchers capable of and willing to conduct a new generation of methodologically rigorous and educationally relevant scientific research that will provide solutions to pressing problems and challenges facing American education" (Interdisciplinary Research Training Programs in the Education Sciences, 2007). Readiness for independent practice would thus entail having the skills to contribute to the field as a psychometrician who can "conduct rigorous evaluation studies, develop and evaluate new products and approaches that are grounded in a science of learning, and design and validate tests and measures" (Institute of Education Sciences, 2008). Differences in training lead to variations in professional outcomes. The next step following proficiency is expert competency. Expert competency in assessment is distinct from expert competency in psychometrics. In the following section, we address both of these areas with greater attention to expert competency in psychometrics. A detailed discussion of expert assessment competency is provided in the cognitive and behavioral assessment chapters of this text.

13.6   Expert Competencies in Psychometrics

What are the expert competencies with regard to psychometrics? And, who are the professionals that have achieved expert or master competency? There is less consensus and literature on the definition of expert or master as compared to the articulation of basic competencies. The APA Task Force on the Assessment of Competence in Professional Psychology (Final Report, October 2007) defines experts as those who excel in particular competency domains, and masters as individuals who are creators and innovators. In this model, individuals who excel in psychometric competency domains would be considered experts, and creators and innovators of psychometrics would be viewed as masters. In comparison, the APA division 12 taskforce on assessment training for the twenty-first century was composed of individuals that many would consider experts in the field of assessment (APA Presidential Task Force, 1999). Experts were defined as those who were "eminent in assessment, especially if they had produced research in more than one area of assessment" (p. 10). This definition emphasizes the reputation of those in the field as well as their contributions to research. On the APA division 12 task force, Gwynneth Boodoo was chosen to represent the area of psychometrics and at the time was working for the Educational Testing Service. Individuals who advance the field of assessment and psychometrics through their work at institutions that shape the test instruments that psychologist rely upon would also be considered experts.

13.6.1 Experts in Assessment and Psychometrics

An expert in assessment should have fluency or command of the assessment literature in their area of expertise, their interpretation skills should be based on the latest scientific findings, and their experience and knowledge are integrated in their conceptualizations of psychometric test data. Their breadth and depth of knowledge in assessment and psychometrics should enable them to fluidly respond to challenges and aberrations from typical or modal findings.

How does one gain expertise in assessment and psychometrics? Earlier, we discussed readiness for practicum, internship, and independent practice. The expert has moved through these levels of competency and has furthered his or her skills often by engaging in roles or activities that require continual skill refinement and knowledge acquisition. These individuals may teach, mentor, and supervise in their area of expertise. They may participate in continuing education for themselves and provide opportunities for continuing education to advance the skills of others. And, they are distinguished from those with less proficiency by their role as consultants when challenging situations arise.

What are the activities experts are engaged in? The following list illustrates some of the activities in which experts in assessment and psychometrics are engaged. Experts may write reviews for the *Mental Measurements Yearbook*, review and critique newly developed tests, author textbooks on the intricacies of various assessment instruments or psychometric theory, revise outdated assessment instruments, conduct large scale reliability studies, write technical manuals to accompany administration manuals, and may develop computerized scoring and interpretation programs. Psychometric experts may be members or officers of The Psychometric Society which is a professional organization devoted to the advancement of quantitative measurement (Psychometric Society, 2008) or Division 5 (Evaluation, Measurement and Statistics) of the American Psychological Association. Experts in assessment may be more likely to be

expert consumers of psychometric research and knowledge, and experts in psychometrics may be more likely to be expert producers of such knowledge.

13.7 Summary

Within the field, there is concern that training is inadequate to produce experts and masters in psychometrics and assessment. This is best illustrated by a comment from Weiner (2007) on education and training in personality assessment in which he bemoans the fate of experts in assessment. "From whence will come future generations of psychologists sufficiently well educated and trained in personality assessment to provide quality services, conduct good research, and function effectively as teachers and supervisors" (p. 1). Weiner does not believe competence in personality assessment should be a specialized skill, but rather believes that training has not been sufficient to ensure proficiency in assessment for most individuals. Assessment experts who are senior in the field have wondered how their ranks will be refilled (Weiner), and have reflected concerns regarding declines in the education and training of juniors (Merenda, 2007). Merenda discusses the decline of psychometricians, quantitative psychologists, and personality assessment psychologists. He cites problems with measurement education and training in personality assessment as reasons for the decline in individuals proficient in these areas. Overall, graduate training in measurement appears to be declining (Aiken, West, Sechrest, & Reno, 1990). Some individuals identified as experts have also retired or died leaving unfilled openings for assessment and psychometric experts. For example, Paul Meehl was noted for his contributions to prediction models and clinical versus statistical prediction died in 2003. Mark Appelbaum, another well-regarded quantitative psychologist, noted that that many psychometricians are becoming more senior and retiring (Clay, 2005). Furthermore, large assessment companies have been criticized for a lack of sufficient psychometricians on staff due to the shortage of adequately trained professionals. In order to address the pressing need for greater numbers of quantitative psychologists, the American Psychological Association created a task force in 2006, the task force for increasing the number of quantitative psychologists, which is charged with developing ways to increase the number of psychologists entering the field of quantitative psychology (APA, 2008).

Experts in psychometrics are greatly needed given the ever-changing landscape of quantitative methodology and significant advancements in the complexity of tests and measures. We hope that the articulation of psychometric competency in this chapter may highlight the importance of this set of knowledge and skills, and further serve to attract individuals to pursue psychometrics by bringing greater attention to this underrepresented and possibly ignored area of psychology and education.

14 Design and Analysis

Joseph R. Scotti · Vanessa M. Jacoby · Stanley Cohen · Julie Hicks Patrick

Abstract: A critical aspect of moving psychology into the realm of paradigmatic science, and of ensuring the development and meaningful dissemination of empirically supported interventions, is competency in research design and statistical analysis. We present evidence that psychology graduate programs are not performing as well as they might in this area of training. An expanded version of the *Competency Cube Model* is used to present the specific skills that are central to seven areas of research design and data analysis by levels of training (bachelors, master's, doctoral) and career path (clinical, research). The seven areas include: problem conceptualization, measurement and scaling, research methodology, core statistics, specialized statistical procedures, data analysis and management, and communication of findings. In keeping with the Competency Cube Model, we discuss both foundational (broad professional skills) and functional (area-specific skills) competencies in the seven areas, and introduce three overlapping stages of competency, from *familiarity to knowledge*, *knowledge to use*, and *use to contribution*. An extended listing of skills by content area, level of training, and stage of competency is presented to expand the discussion on both the curricula that should be offered for various academic degrees, and the manner in which the knowledge and skills learned should be documented or demonstrated. We recognize the multiple variations and mixtures along a continuum from practicing clinical psychologist to basic research psychologist, and the resulting differences in competencies in research design and statistical analysis. As the field experiences a shortage of quantitative psychologists, researchers need to better document their competence in this area beyond the traditional means (e.g., peer-reviewed publications), as well as seek lifelong learning opportunities to expand their knowledge and skills. Clinical psychologists, on the other hand, must remain sufficiently conversant with this content area so as to evaluate published intervention research and competently evaluate their own practice.

14.1 Overview

Psychology is striving to be a science, although the field appears to be a long way from having a unified paradigm or even agreeing that there should be a single unifying paradigm (Kuhn, 1996; Popper, 2002a, b; Staats, 1990, 1995). Regardless of the status of this quest, to reach the goals of understanding human behavior, be it of individuals or groups, and effectively improving people's lives in a positive manner, it is critical that we use the scientific methods in basic and applied research and, we would argue, within clinical practice. Given clinical psychology's research and applied branches, one may find clinical psychologists calling themselves scientist-practitioners, clinician-researchers, basic or applied researchers, or clinicians, among other titles. These descriptors, be they of individuals or training programs (e.g., doctoral program, internship site), place greater or lesser emphasis on research, application, and empiricism. Clearly, clinical researchers must be conversant with research design and data analysis techniques at the level necessary to competently investigate their area of interest and publish

their findings. However, most clinical psychologists would likely identify themselves as practitioners (American Psychological Association [APA], Center for Workforce Studies, (n.d.); Bechtoldt, Norcross, Wyckoff, Pokrywa, & Campbell, 2001), and may view research design and data analysis only as necessary – and aversive – graduate school hurdles to be gotten over and then left behind. Nonetheless, even practitioners should be sufficiently familiar with research design and data analysis in order to consume the research literature and make sound, informed judgments as to whether or not to include specific assessments and interventions in their practice.

Given the above and the goals of these volumes on clinical psychology competencies, in this chapter we focus on the stages of competency in research design and data analysis necessary in relation to the levels of training and career paths. We utilize three stages of competency, ranging from being familiar with designs and techniques to being able to effectively use and teach these designs and techniques, and, finally, to being contributors to the development of new designs and techniques. Level of training is reflected in our coverage of what should – in our opinion – be known at the basic level of undergraduate training up to the expert knowledge and use at the level of professional researchers and practitioners. We stress that, even at the highest degree of expertise, continuing education and lifelong learning are imperative for keeping abreast of new developments in research design and data analysis, just as in any active field. Finally, we discuss differential competencies according to career paths as divergent as solely providing clinical services to those focused on basic laboratory research, and various combinations in between.

We begin with a discussion of the construct of *competency*, and then provide a listing of research designs and data analysis techniques. We suggest stages of competency needed in these designs and techniques for various training levels and career paths, using research and applied examples to support our decisions. We present this information for its heuristic value in making decisions about curriculum design and postgraduate training. This step is necessary as discussion of competency in multiple areas of clinical psychology remains at the level of defining the basic construct rather than elucidating the specific behaviors and skills required for varying stages of competency. For example, the conference titled *Competencies Conference, 2002: Future Directions in Education and Credentialing in Professional Psychology* (Kaslow et al., 2004) focused on the domains of competency, but did not provide a listing or catalog of skills and knowledge. The outline provided here is a starting point for further discussion, with the eventual goal of determining skill-based competencies that can be taught and evaluated. We emphasize the importance of lifelong learning in the development of increasing degrees of expertise and note the multiple ways in which skills can be evaluated.

14.1.1 Defining Competency

One online dictionary (Dictionary.com, n.d.) defines *competence* as "the quality of being competent; adequacy; possession of required skill, knowledge, qualification, or capacity." Although a seemingly adequate definition, it focuses on *possession* rather than *demonstration* of skills and knowledge and does not take into account how one might measure or evaluate the demonstration of skills and knowledge. Rodolfa et al. (2005) provide a particularly cogent discussion of the concept of competency. The most basic characterization of competency should

reflect knowledge, performance, and outcome (Reilly, Barclay, & Culbertson, 1977). Rodolfa et al. provide a three-dimensional model, the *Competency Cube*, to elucidate the development of competency across multiple *functional* domains in psychology, including (a) assessment, diagnosis, and case conceptualization; (b) intervention; (c) consultation; (d) supervision and teaching; (e) management and administration; and, the focus of this chapter, (f) research and evaluation. These functional domains represent the knowledge, skills, and practices of the professional psychologist. However, there are other competencies that form the foundation upon which these functional competencies stand. The *foundational* competencies described by Rodolfa et al. include: (a) reflective practice and self-assessment; (b) scientific knowledge and methods; (c) relationships; (d) ethical and legal standards, and policy; (e) individual and cultural diversity; and (f) interdisciplinary systems. An essential element of this model is the interaction between foundational and functional competency domains. The focus of this chapter is on the functional competency of research and evaluation, specifically the component of research design and statistical analysis, and its intersection with each of the six foundational competencies.

The functional competency of research and evaluation, as described by Rodolfa et al. (2005), involves "the generation of research that contributes to the professional knowledge base and/or evaluates the effectiveness of various professional activities" (p. 351). This description most closely fits what one might consider to be the "expert" stage of competence, and focuses on the *contribution* stage of competency. We would add two subordinate stages of competency, that of *knowledge* and familiarity, and *use* and consumption. This allows us to expand this definition to fit different levels of training and career paths. For instance, the undergraduate psychology major should be knowledgeable about basic analysis procedures, such as correlation, *t*-tests, and analysis of variance (ANOVA), and might use these procedures to generate an honors thesis that will not necessarily contribute to the professional knowledge base, but will contribute to the student's training. At this level of training, competence would be evident as the ability to describe procedures and use them within the context of a course examination or project. This is a critical building block for the next level of training, such as graduate school, in which one further develops competence.

14.1.2 Foundational Competency

The Competency Cube model (Rodolfa et al., 2005) calls for multiple foundational competencies within each domain of functional competency. That is, one must be competent in each *foundational* domain in order to be fully competent in any one *functional* domain. As noted in the prior section, Rodolfa et al. outline six foundational competencies. Clearly, within the functional competency of research and evaluation, one must have the foundational competency of scientific knowledge and methods; that is, a respect for the scientific method and empirically derived knowledge; the ability to conceptualize problems; and the knowledge of basic statistical procedures, methods of data collection and analysis, and research designs at various levels of sophistication. The other five foundational competencies may appear less relevant, but are of equal importance. For instance, reflective practice and self-assessment requires one to know the limits of her or his skills in designing research studies, analyzing data bases, and having a commitment to continuing education to develop and enhance one's skills. Not recognizing one's limits could result in inappropriate use of statistical procedures and a misrepresentation of findings. The

foundational competency of legal and ethical standards has clear implications for research and evaluation with regard to the requirements for the protection of human research participants, privacy of research and clinical information (Health Information Protection and Portability Act [HIPPA]), and the need to document the effectiveness of interventions. If one fails to competently adhere to these standards it could lead to physical or psychological harm of clients or research participants.

The foundational competency of individual and cultural diversity requires one to be continuously aware and sensitive to the diversity of the populations with which he or she may interact, including issues of culture, race, ethnicity, sexual orientation, gender, age, and mental and physical disability. The issue of diversity most immediately comes to mind with regard to clinical practice. The possible cultural biases in assessment devices have long been a topic of discussion within psychology (Cleary, 1968; Sattler, 1988); this is now also a prominent issue in the tailoring of interventions for specific groups (Bernal & Scharró-del-Río, 2001; Rosselló, Bernal, & Rivera-Medina, 2008; see the APA journal: *Cultural Diversity and Ethnic Minority Psychology*). Diversity is also of critical importance in research. Clinically relevant research has moved far beyond the captive population of white college students to a focus on specific groups or populations in the community (unless, of course, the focus is meant to be college students). Knowledge about, understanding of, and sensitivity to, diversity is vital to even formulating meaningful and relevant empirical questions. Further, ensuring diversity within a research sample adds to the ability to generalize findings to the population at large. Less obvious when conducting research with culturally and ethnically diverse groups are issues such as: (a) accurate translation and back-translation of assessment measures, (b) willingness to participate in research that crosses the cultural boundaries of self-disclosure, and, (c) culturally specific gender roles that impact the ability to be alone with a researcher of opposite gender and may prevent adult women from giving their own informed consent. Of course, all research samples need not be heterogeneous and cover the full range of diversity; some questions require homogenous samples in order to control for critical factors and potential confounds.

Lack of competence in this area, in terms of sensitivity to the wide range of human diversity, may well result in wasted effort and unrepresentative findings. The insensitive or unaware researcher may also cause damage to relationships with the community or population with which one is attempting to work, which is the next foundational competency. Viable research is dependent on good working relationships with individuals, groups, agencies, and communities in order that the research can even be accomplished. More and more, larger research projects are planned and implemented with the input of important stakeholders, such as representatives of the population under study, agencies that might assist in the conduct of a project, and policy-makers for whom the findings may hold relevance.

Lastly, the foundational competency of interdisciplinary systems involves the ability to effectively interact and collaborate with other professionals within psychology and across multiple disciplines. Large research grants are more likely to be funded when they are multidisciplinary and multisite, as this adds a diversity of perspectives and research questions and improved sampling of the population of interest. A psychologist may be at the forefront of knowledge in her or his field of interest, such as posttraumatic stress disorder (PTSD), but may benefit from collaboration with colleagues in other disciplines who specialize in rural health, military affairs, or social policy. Such a collaboration would bring to the fore a broader range of empirical questions than the psychologist acting alone (e.g., combat exposure and levels of PTSD versus additional risk factors associated with living in a rural community). Without

interdisciplinary collaboration, research is narrower, and has a lower likelihood of advancing the knowledge base. No individual can be an expert in every area, no matter what level of training is obtained.

14.1.3 Lifelong Learning

The third dimension of the Competency Cube model (Rodolfa et al., 2005) illustrates the levels of professional development over the course of one's career. In the Rodolfa et al. model, the levels begin at doctoral education and end with "continuing competency," that being the gaining, maintaining, and enhancement of competencies throughout one's professional career. These authors suggest that their levels may be depicted in finer detail; we do so here. We would contend that the levels of professional development might better be conceptualized as the contexts within which training occurs. These contexts include formal education at the bachelor's, master's, and doctoral levels. Additional training in internship, residency, or fellowship programs may occur following any level of education. Continuing education in the form of additional coursework, professional conferences, seminars, and workshops may be completed at any point in one's career. These training contexts do not occur in the linear fashion that this axis of the Competency Cube implies. We agree that the development of competencies is a lifelong learning process; however, it is not dependent on final academic degree, but on recognizing one's competencies, and thus one's limits, and seeking to continually develop and master new skills.

14.1.4 Stages of Competency

Harkening back to the earlier definition of competency as "possession of knowledge and skills," competency can be viewed as having three stages: knowledge, use, and contribution. Here, we view knowledge as the basic information learned and demonstrated through class examinations, national licensing exams, and specialty board certification exams. It is, in essence, the verbal or written confirmation of one having learned the essential information about specific types of research design and data analysis needed to then proceed to the stage of competent use. For example, one may be able to describe the rationale and formula for conducting a *t*-test, or the statistical underpinnings of hierarchical linear regression, but be currently unprepared to decide which analyses are used with which research designs and how to construct a data set and run and interpret the analyses independently. We would say that this individual is competent at the stage of requisite *knowledge*, but not yet competent at the stage of independent *use*. Reaching this latter stage of competence requires experience and skill building.

When, then, is one considered competent in *use* of research designs and statistical analysis procedures? Again, we would note the importance of level of training, such that the master's candidate, in developing her or his thesis protocol, will need to demonstrate the ability to select among basic designs (e.g., survey, two-group comparisons, 2×2 factorial) and use them appropriately. Doctoral candidates will likely utilize higher-order designs that require sophistication in regression procedures and the handling of missing data. Similarly, a master-level project might take advantage of a college student population, while dissertation research might involve intervention with a clinical population. Competencies at these levels of education would be assessed via the final thesis or dissertation document and oral defense. At higher levels of

professional independence, such competencies are demonstrated by the acceptance of manuscripts by peer reviewers, ultimately for journal publication. Note, however, that a bachelor-level research assistant might work in a setting that trains her or him in the competent use of higher-order statistical designs, such that the assistant becomes a meaningful contributor to a research publication. As such, the stage of competence is not dependent solely on formal educational degree, but includes multiple training contexts and continuing professional development.

The highest stage of competence is the ability to *contribute*, not only to the knowledge base through publication, but to establish one's expertise in an area of research or practice through the improvement of existing techniques or the development of new procedures and directions. This stage of competence is likely evaluated by one's prestige in a field as noted by frequency of citation of one's works and the acclamation of one's colleagues.

With this framework in mind, the next step in the development of a complete competency model is to have a comprehensive list of knowledge and skills that could be evaluated at the various levels of training and stages of competency discussed above. The stages of competency that we suggest are needed at different levels of training are listed in ❯ Table 14.1. We note that there will be variation in the stages of competence (knowledge, use, contribution) that should be evident, not only by level of training (bachelor's, master's, doctoral), but also according to one's professional focus (research, clinical practice, teaching, or a combination of the three). We illustrate the range of competence that might be seen for each skill at various levels of training and career paths by the ratings of 1 (*family to knowledge*), 2 (*knowledge to use*), and 3 (*use to contribution*) entered into the table. These ratings reflect an overlapping range of competency at each level. Functionally, one must be competent in the work they are doing. This stage of competence may often be beyond the stage of competence required to obtain specific academic degrees. Broadly, in keeping with the design of this volume, *Basic Competency* is reflected in familiarity, knowledge, and movement to independent use (ratings of 1–2) of research designs and statistical analysis procedures. *Expert Competency* is reflected in fully independent use, plus not only using techniques to contribute to the research base in an substantive area, but also being able to contribute to the further development of research designs and statistical analysis procedures. In the next section, it is evident how we view the "basic" and "expert" stages of competency as a continuum along which one can vary according to specific domains, levels of training, and contexts.

14.2   Basic and Expert Competencies

Having discussed the construct of competency, its various stages, and its relation to levels of training, we turn to specific functional competencies within research design and data analysis. ❯ Table 14.1 presents a listing of these subordinate competencies in seven domains, from problem conceptualization (e.g., scientific method, literature review, hypothesis development) through measurement and scaling (e.g., psychometrics), research methodology (e.g., design selection, validity threats, data collection), core statistics (e.g., descriptives, ANOVA, regression), specialized statistical procedures (e.g., survival analysis, bootstrapping), and data analysis and management (e.g., data entry and error checking, security), to communication of findings (e.g., publication, plagiarism). These seven domains are meant to represent the key components in the application of foundational competency of scientific knowledge and methods to the functional competency of research and evaluation. These components range from initial conceptualization to the dissemination of findings. The reader is reminded that this

◼ **Table 14.1**

Suggested stages of competency in seven areas of research design and data analysis by levels of training and career path. Three stages of competency are: (1) familiarity to knowledge, (2) knowledge to use, and (3) use to contribution

Skills within areas of research design and data analysis	Level of training and career path

listing is only a starting point. Any topic in this table arguably can be collapsed or expanded from what is presented here, and other topics can be added. This listing is a work in progress with the eventual goal of determining specific skill-based competencies that can be taught and evaluated according to different levels of training.

A primary source for the construction of this table is the work of Aiken, West, and Millsap (2008; see also Aiken, West, Sechrest, & Reno, 1990). The work of these authors was of critical importance as they had surveyed all Ph.D.-level programs in the USA and Canada, resulting in an extensive listing of topics in research methodology and data analysis in the curricula of those programs, as well as the "judged competence" of graduates of those programs. We extended and modified the listings of Aiken et al. (2008) by reference to the Research Competency Checklist developed by several of the authors and other colleagues at the West Virginia University Department of Psychology, and our own knowledge and experience. In what follows, we provide research examples to illustrate the domains covered in the table, along with the varied expectations associated with different stages of competency and levels of training. We focus on the intersection of the foundational competency of scientific knowledge and methods, and the functional competency of research and evaluation. Additional foundational competency domains are discussed to illustrate necessary competencies beyond that of scientific knowledge and methods.

We utilize, as a basic research example, a study conducted by Scotti et al. (Scotti, Majewski, Heady, & Tunick, 2008) on West Virginia veterans returning from military service in the conflicts in Iraq and Afghanistan. The basic aspects of this study were the conduct of a large sample mail survey ($n = 6,400$) asking recent returnees about their pre- and post-military functioning, combat exposure, psychiatric symptoms, and help-seeking behavior. We use the decisions made throughout the conduct of this study to demonstrate key topics from ▸Table 14.1, providing exemplars of directions we might have taken at each choice point. We do not present actual results from that study; any "data" are purely to demonstrate key points.

14.2.1 Problem Conceptualization

The topics in ▸Table 14.1 outlined under the functional competency of problem conceptualization represent initial steps in the scientific process, including selection of focus area, scientific approach, theoretical models, examination of existing literature, and hypothesis development. In our example, all research team members, regardless of level of training, had basic competency in the scientific method. That is, they understood the need for formal research methods to collect data systematically that would result in reliable, valid, and generalizable conclusions. Relating these steps to our example study, our initial selection of focus area began with a request from the West Virginia Legislative Committee on Veterans' Affairs to evaluate the current health and mental health status of veterans returning from the conflicts overseas and to assess their access to care. This is the kind of research question that might be presented by persons outside of a scientific discipline that needs to be focused, operationally defined, and developed into testable propositions. The resulting multidisciplinary research team consisted of a doctoral-level psychologist with 20 years of experience in the field of combat stress and survey research; and master-level professionals in social work and rural health care with strong backgrounds in survey implementation, knowledge of physical and mental health resources, and the specific needs of rural veterans. This team was able to narrow

the focus to the key question concerning the impact of combat exposure on returning veterans and their likelihood of accessing physical and mental health care. The familiarity of the team with the basic issues and findings from a review of recent literature resulted in their developing multiple testable hypotheses. Foremost among these hypotheses were: (a) veterans reporting higher versus lower levels of combat exposure will report a higher number of symptoms of depression and PTSD, (b) veterans with a higher versus lower number of symptoms of depression and PTSD will be less likely to seek professional care, and, (c) veterans residing in rural versus urban areas of West Virginia will differentially experience more symptoms and have less access to care.

The person at the bachelor-level of training may be familiar with some general issues involved in such a project, but typically would not be able to formulate a hypothesis beyond a simple comparison of symptom levels in two groups of veterans (e.g., a *t*-test comparing number of PTSD symptoms in high versus low combat exposure groups). Such a person would be unlikely to have extensive experience in this area and may not be able to complete an independent literature review resulting in the level of hypotheses developed by the research team. As level of training and stage of competency increased, one would expect a greater ability to identify knowledge bases and prior research that the research questions in the present study could both replicate and extend. Further, the number and types of independent variables (IVs) and dependent variables (DVs) that might be identified and included in the research questions would be more complex, and a greater ability to identify strengths and limitations of the study and prior research would be evident.

For instance, there is little existing research on the mental health and help-seeking of veterans residing in rural areas other than those who are recruited into studies by virtue of their having previously enrolled in services through Veterans' Affairs (VA) hospitals (Heady, 2007). Although there currently are 26 million veterans in the USA, fewer than 6 million participate in VA programs, or about 23%. Despite this rate being somewhat higher for veterans of the conflicts in Iraq and Afghanistan (40–50%; cf. Scotti et al., 2008; Tanielian & Jaycox, 2008), little is actually known about the mental health and help-seeking of the majority of veterans. The bachelor-level research assistant with limited knowledge would be unlikely to identify such a gap in the literature. Being competent at the stage of making applied and research contributions to the field, the research team readily identified the need to survey the general veteran population and to proceed through a recruitment source other than VA service lists.

Additional Foundational Competencies. We stress here, the importance of several additional foundational competencies beyond that of scientific knowledge and methods. First, we note the issue of interdisciplinary collaboration as exemplified by this team of researchers and the sharing of knowledge across specializations. Second, several members of the team were conversant with policy issues related to rural health and conducting research within the VA system. Further, each member of the team knew the boundaries of their competency in developing and conducting research of this nature. For instance, only senior members of the team with a higher level of training and a more advanced stage of competency could identify the conceptual models (e.g., two-factor model of fear conditioning as it relates to PTSD; Keane, Fairbank, Caddell, Zimering, & Bender, 1985), and study approaches (e.g., primarily inductive and data-driven) relevant to the project. Further, the more senior members were also aware of intrinsic limitations of the research (e.g., self-report data collected via mail survey) and the known and potential confounding variables (e.g., pre-military mental health status, state-wide literacy rates, lower return rates from those with more serious mental health problems).

14.2.2 Measurement and Scaling

❯Table 14.1 includes a section on measurement and scaling, the discussion of which is purposefully short because another chapter in this volume focuses solely on competency in psychometrics. However, it is critical to note the strong relation between research design, data analysis, and psychometrics, that being like a three-legged stool (as our coauthor, Stanley Cohen, has oft noted). Being competent at the stages of use and contribution in the area of measurement and scaling necessarily requires skills in psychometrics. Research employing measurements that are not reliable or valid calls into question the internal validity of the study and, consequently, its external validity (see Kazdin, 2003, on the priority of internal over external validity). Thus, without competence in psychometrics, the legs of research design and data analysis cannot provide a fully balanced stool.

With regard to this area, the bachelor-level student, and even the typical master's and doctoral student is very likely only to be familiar with the basic topics of measurement theory, test construction, reliability, and validity; and not be competent in their application (Aiken et al., 2008). Thus, those members of the research team whose competency in psychometrics was at the stage of knowledge and familiarity, might, at best, have attended to the psychometric properties of key measures incorporated in the survey, such as the PTSD Checklist (PCL; Ruggiero, Del Ben, Scotti, & Rabalais, 2003; Weathers, Litz, Herman, Huska, & Keane, 1993) and the Center for Epidemiological Studies: Depression Scale (CESD; Radloff, 1977). The senior researcher, who not only teaches a course in psychometrics, but has published in this area, readily identified issues related to scales that were locally developed to address specific questions of interest. For example, a listing of mental and physical health resources that was developed had face validity, was reviewed by multiple content-area experts, and piloted with veterans to ensure coverage and readability. Subsequent analyses were conducted to support the internal consistency and discriminant validity of the measures.

Additional Foundational Competencies. Examples of important additional competencies in this area include, as in all areas, knowing the limits of one's knowledge and skills. The ethical standards for psychologists (APA, 2002), with regard to assessment and measurement, might less readily come to mind, but are of critical importance. Further, with regard to cultural diversity, the simple translation and back-translation of scales from one language to another may not result in a full appreciation of the inherent differences in world views of various cultures (Dana, 1993). Thus, constructs related to independence and autonomy may not be translatable or even appropriate to cultures with different value systems with regard to community, family, and the individual (e.g., individualistic versus communal or competitive versus cooperative orientations; Dana, 1993). In the present research example, we were sensitive to both veteran and rural cultures in the development of specific sets of questions, and in carefully monitoring the overall reading level of the survey (7th grade).

14.2.3 Research Methodology

The research methodology component of ❯Table 14.1 includes methods, designs, and the issues involved in the selection of a method and design with regard to a particular research question (e.g., internal and external validity). With respect to our research example, all team members were clear that the research question would not be answerable through an experimental group

design (e.g., a laboratory task examining differential rates of help-seeking behavior by level of PTSD symptomatology). However, beyond this, not all personnel had the training or were at the stage of competence to select, develop, and implement the appropriate research design. For instance, the members of the legislative committee that initiated the request for this research had suggested we complete qualitative interviews with 30–60 veterans. The research team, instead, considered three quantitative approaches to the committee's question: (a) program evaluation (e.g., evaluating specific community resources in terms of access by veterans and service outcomes); (b) epidemiology (e.g., random-digit dialing of persons throughout West Virginia to evaluate mental health status and help-seeking among those who were and were not recently returned veterans); and (c) a direct mail survey to identified veterans (having ruled-out phone, Internet, and other survey methodologies), the method was finally selected.

With the selection of survey methodology, those at the basic level of training should be well familiar with the correlational aspects of these data, be able to do the basic correlation analyses, and should recognize that – due to lack of experimental control – the findings describe relations and not causation. Persons with higher levels of training should be additionally knowledgeable about complex issues that arise within the otherwise deceptively simple survey approach. For instance, it should be recognized that these data were not collected cross-sectionally (e.g., groups at ages 24, 30, 36, 42 years; or groups at 2, 4, 6, or 12 months post-deployment), as they were not gathered at a specific point in the lives of groups of participants. Further, although the participants can be divided into groups based on test scores (e.g., high versus low levels of PTSD symptoms or combat exposure), such a division would not truly represent an *a priori* experimental group or quasi-experimental research design. Thus, the more knowledgeable researcher must be able to use statistical procedures appropriate to the assumptions of the research method and design.

The team members at the highest level of training were not only familiar with the issues of internal and external validity within this study, but could easily identify them, and note these limitations when disseminating the findings. For instance, although all participants were recent military veterans, they were of varying ages (18–56 years), and had different military career paths and experiences, thus making the data vulnerable to the threats of history and maturation. A threat to external validity evident to those with master's- and doctoral-level training is related to participant recruitment. We mailed surveys to all 6,400 veterans available from a list of those who had applied for a US$600 overseas service bonus offered by the State of West Virginia Division of Veterans Affairs (WVDVA). The researcher at the knowledge stage of competency might assume we had thoroughly sampled the population of interest by accessing a large number of WV veterans. Those at a higher stage of competency quickly realized that veterans who had not applied for the bonus were not represented in the survey. This could bias the sample by, perhaps, not including those with higher levels of depression (not sufficiently functional to have applied for the bonus) or a higher income (not sufficiently in need of the bonus).

Highly related to problem conceptualization and the identification of the variables under study, these latter issues bring up the need to fully understand the role of confounding and nuisance variables and to use one's skills to adequately design a study or apply appropriate statistical procedures that control for their effects as much as is possible. It is the perpetual bane of undergraduate students to learn about, and identify, IVs and DVs within a basic experimental design, such as one containing a control group and several levels of an IV (e.g., drug dose, hours of practice). One would not expect students at this level of training to have the skills to design more complex experimental manipulations with appropriate controls (e.g., three levels of

treatment × two levels of symptom severity × four assessment points), nor to know the strengths and limitations of such designs. At the graduate level of training, the student should be able to utilize more complex designs with greater control and be sufficiently familiar with research methodology in order to review and critique published studies and journal manuscript submissions. Within our research team, it was necessary for members to understand that, regardless of the type of analysis and assignment of specific variables to IV or DV status, the results would always remain correlational. Not being experimental research, all variables had equal status, and could easily be interchanged from IV to DV, depending on the question being asked. For example, a linear regression analysis showed that scores on the PCL were predicted by scores on the CESD ($\beta = 0.69$), level of combat exposure ($\beta = 0.23$), and rating of perceived family functioning ($\beta = -0.16$), adjusted $R^2 = .80$, $F(3, 916) = 1203.7$, $p < .001$. However, one can use the same four variables and change the DV from PCL score to rating of perceived family functioning. The result is that family functioning is predicted by PCL score ($\beta = -0.40$), and score on the CESD ($\beta = -0.29$), adjusted $R^2 = .44$, $F(2, 917) = 363.4$, $p < .001$; level of combat exposure does not enter into the model. The well-trained and experienced researcher would be sufficiently familiar with the existing literature and theory, and be able to make decisions regarding the status of any particular variable as an IV, DV, mediator, or moderator, such that the resulting findings contribute meaningful information to the knowledge base.

Additional Foundational Competencies. All team members, regardless of level of training, needed to know and put into practice the ethical requirements for human subject research as specified by professional, state, and national guidelines. All were certified through an online-training and testing process, and the research project, itself, was approved by the local university institutional review board (IRB). Further, being a multidisciplinary team, the specific professional guidelines regarding research differed among the disciplines, with those of the APA (2002) being the most explicitly defined. Additional competencies were evident in the ability of the researchers to build a relationship with the WVDVA that allowed a partnership in distributing surveys to a more diverse community of veterans than would have been possible through the federal VA system.

14.2.4 Core Statistics

Within the area of core statistics are included basic competencies such as probability and distributions, visual (i.e., graphing) and statistical description (e.g., central tendency and variability), basic and advanced inferential statistics (e.g., correlation, *t*-test, ANOVA, regression, and structural equation modeling), and nonparametric approaches (e.g., chi-square, Bayesian distributions, and rank-order tests). Someone at the bachelor's level should be able to use a statistical package to access a data set and provide descriptive statistics and related graphs for key variables, such as gender, age, education, income, etc. At increasing stages of competence, it would be expected that one could identify variables suitable for correlational analyses, group participants according to scores on key measures and perform an ANOVA, and identify (based on informed hypotheses) critical IVs and DVs for regression procedures. Within our study, specific team members with master's and doctoral-level training were able to take total scores on combat exposure, PTSD, and depression, and derive the following correlations ($n = 924$, $p < .001$): $r = .48$ between combat exposure and PTSD, $r = .29$ between combat exposure and depression, and $r = .85$ between PTSD and depression. At this level of training, the research

psychologist should be able to recognize that these correlations suggest a strong comorbidity between PTSD and depression, and that exposure, alone, is not necessarily a predictor of psychopathology. The psychologist with a greater degree of expertise (i.e., higher level of training and stage of competency) would be able to look at the covariance among these three variables and also conduct and interpret regression models that may show the contri-bution of other variables to level of PTSD and depression symptoms, such as age, education, rurality, income, and pre-military functioning. Further, those with higher levels of competency might develop and test these same variables in a path analytic or mediation/moderation model.

Additional Foundational Competencies. Competencies needed in this area in addition to scientific knowledge and methods include reflective practice, and the concept of ethical and legal standards. Although for some members of the team the statistical analysis procedures in the area of core statistics are among the most basic that are learned in undergraduate and graduate training, other members needed to quickly realize they were outside their level of competence. Regardless of the level of competence, one must be aware of, and follow, APA (2002) ethical standards when analyzing and reporting research results (Principle 8.10, APA) in order to avoid making false or deceptive statements (Principle 5.01, APA). Indeed, the team, as a whole, met to discuss the findings to ensure that all members understood the implications of the results, regardless of their knowledge of the statistical procedures utilized. This was done to ensure consistency of reports across multiple venues and so that findings would not be unintentionally misrepresented.

14.2.5 Specialized Statistical Procedures

Our study of returning veterans was a "one-shot" survey. One could easily imagine, however, following a sample of identified veterans over several months to years after their return from combat in order to evaluate physical and mental health and reintegration into the community. Such a study would require competent use with regard to structuring and implementing a longitudinal study, including fixed or variably spaced measurement occasions and multilevel systemic variables (e.g., the veteran, the family, the community), and understanding and using various advanced statistical models to describe change over time (e.g., growth curve modeling, latent growth models; cf. Singer & Willett, 2003). A longitudinal study would allow modeling of the interactions between the changes in the levels of PTSD and the depression symptoms in the veteran and the impact on family interactions and mental health over time, as compared to the static view provided by a single survey. Conduct of a study at this level of sophistication would require one to be at the use stage of competency, which likely would require training at the doctoral and postdoctoral levels. Bachelor-level students should know the basics of a longitudinal design, as compared, say, to a cross-sectional design. Graduate students should be able to more fully describe such designs, know their strengths and limitations, and be able to conduct related statistical analyses. They might, during their limited time as graduate students, be able to conduct a repeated measures or cross-sectional study, but time constraints would likely prevent conducting an extended longitudinal study. Coming full circle, bachelor-level and graduate students might function as research assistants on a longitudinal study, thereby enhancing their competency beyond that typically associated with level of training.

A research study of any type, be it a controlled laboratory study, a one-time survey, or more advanced designs, will, inevitably, have missing data. As noted by Aiken et al. (2008), two

thirds of the doctoral programs in their survey fail to provide any coverage of modern missing data treatments in their curricula. It follows, then, that most graduate-level students will not even be at the competency stage of knowledge and familiarity with such topics, and few will be competent in the use of such techniques. In the present study, with knowledge of the related limitations, we handled missing data via modal imputation. We were not sufficiently competent in the use of modern regression techniques for missing data, but we did know the method of imputation appropriate to the scales in the survey (i.e., mean imputation not being appropriate for ordinal data).

Those psychological researchers at doctoral and postdoctoral levels of training may be familiar with other concepts, such as bootstrapping and resampling (which can be computer-intensive procedures), but may not be competent in their use or be using them in their research products that contribute to the knowledge base. With a data set such as being discussed here, one would not typically conduct and report the outcomes of bootstrapping or resampling. However, such procedures can, and perhaps should be done to both avoid over-fitting a model and to add confidence in the characteristics of a sample (Tabachnick & Fidell, 2007). In doing a resampling procedure with our data set (taking four random samples of 250 out of 1,000 surveys), we found that the correlations among key variables were consistent across the samples. To illustrate the previously reported correlation between PCL and CESD scores ($r = .85$) for all 1,000 surveys, correlations between these variables only varied from 0.83 to 0.88 in the four random samples, lending confidence to the original estimate.

Additional Foundational Competencies. As under *Core Statistics*, competencies needed in this area in addition to scientific knowledge and methods include reflective practice and ethical and legal standards; we also note here a foundational competency in interdisciplinary systems. Because our research team was only at the stage of familiarity with modern methods of treating missing data, it was imperative that we assessed ourselves and used reflective practice. Attempting to use complex missing data procedures despite a lack of competency could result in the misrepresentation of our data, and potentially negatively affect our population base (veterans) through incorrect conclusions about their status and needs. Again, adherence to APA (2002) ethical standards when analyzing and reporting research results is critical. Lastly, in order to become familiar with and competently utilize advanced and specialized statistics, it is likely to be necessary to cross interdisciplinary lines and receive assistance and continuing education from researchers from other disciplines, including statistics and mathematics, sociology, and epidemiology.

14.2.6 Data Management

Within the area of data management are the topics of data entry, data recoding, data security, and data access, the details of which are typically learned at different levels of training. Data-entry skills are generally introduced to undergraduate students through course work or supervised research experiences. These students would be expected to be familiar with the procedures for creating a simple database using basic spreadsheet software. Some may be able, with guidance and a template, to use those skills to create a database with a specific statistical software package (e.g., SPSS, SAS). Master-level students would be expected to perform these tasks independently. In our study, trained undergraduate students entered survey data into a data

base that had been created, under supervision, by a senior undergraduate student who had several years of experience with the research group. Those students also learned how to "clean" the completed data set by checking that entered values were not outside the specified range for each variable, and by reentering a portion of the data to do a check on the accuracy of entry. It is interesting to note that recent versions of some statistical software packages (e.g., SPSS) now incorporate rather elaborate data checking and validation procedures. More advanced skills within data management, such as data recoding (e.g., recoding reverse-scored survey items), transformations (e.g., log transforms and other metrics), or imputation (including multiple imputation, cf. Rubin, 1987), typically are not introduced until graduate school. However, we again emphasize that increasing one's competency in any area is not dependent simply on progressing through the levels of academic training.

The topics of retention of research data and records, security, and sharing of data sets are probably only familiar to undergraduate students and even most graduate students, in terms of knowing and following IRB and HIPPA rules and regulations concerning privacy issues. They hopefully know to keep research records under lock and key (i.e., locked cabinets in locked rooms). The use of computers in research for data collection, storage, and analysis adds further security issues, especially when they are connected to the Internet. Researchers at all levels need to follow guidelines concerning records on Internet-enabled computers, and the use of passwords and encryption. Training, be it through academic programs or external sources (i.e., continuing education and ethics workshops), should bring all researchers – regardless of educational degree – to the stage of competence in which they know and follow basic privacy and security rules.

Beyond these important issues are those of data and record retention, and levels of access to research records. The Council on Governmental Relations (2006), which sets the rules for multiple governmental agencies (such as National Institute of Health [NIH] and National Institute of Mental Health [NIMH]), requires that data and research records to be retained for a minimum of 3 years. Local agencies and IRBs may require longer periods of retention, and journals may require additional periods of retention after publication. Further, granting agencies are requiring grantees to ensure accessibility of research records, including the posting of data through data-sharing portals. Even the Council of Science Editors (2009) recommends that the data sets should be available as part of the peer-review process (cf. Principle 8.14; APA, 2002). In short, there are increasing requirements on retention and access to which the present authors know many colleagues do not well adhere. Access to research records allows the scientific method to be truly self-correcting and also acts to discourage the possible reporting of fraudulent results. One of us (Joseph Scotti), for his part, has yet to destroy a single research record in his 30-year career; this well illustrates the storage problem that arises as a result of data retention and access requirements unless original data and records are converted to various electronic formats.

Additional Foundational Competencies. Competencies in the area of ethical and legal standards are well addressed above, particularly with regard to needing to be familiar with, and adhering to, local, state, professional, and federal standards. Data sharing, which is becoming the standard, especially for larger federal grants, is an important competency in both scientific knowledge and interdisciplinary systems, in that one is opening their data set to scrutiny and reanalyses by professionals in psychology and related fields. This process has the potential to generate information from existing data that the original authors did not examine and to build cross-disciplinary research.

14.2.7 Communication of Findings

Finally, one's completed research does not directly contribute to the field until the findings are communicated in some format, such as colloquia, conference posters and papers, theses and dissertations, grant and technical reports, Internet and electronic distribution, and book and journal publications. This represents the competency of dissemination, which includes release of findings through the sources previously listed, as well as being among the gate-keepers of which findings are published or not and the quality of the outlet. Thus, we have issues of authorship (Principle 8.12; APA, 2002), originality, avoidance of plagiarism, and the submission and peer-review process. Researchers reaching the stage of contribution, that is, who are publishing research that adds to the knowledge base, are among those who can become reviewers of the work of their peers. This may take the form of reviewing grant applications submitted to local, state, or federal agencies; or reviewing manuscripts submitted for publication in professional journals; and even being among those who set policies for the types of papers or grants that a journal or agency is seeking. These activities intersect with level of training, in that a typical undergraduate student might be fortunate to have their participation in a project recognized by a poster authorship. Graduate students are likely to present their thesis and dissertation research at conferences and may attempt to publish these products, while likely coauthoring works with their faculty mentors. Researchers at the doctoral and postdoctoral levels will be contributing to the general research knowledge base in their field of study. This reflects what Kuhn (1996) refers to as *normal science*, and does not necessarily generate new theories or directions; rather, it adds to the exploration of a restricted paradigm without expanding its boundaries or generating new paradigms. Individuals at the highest stage of competency, however, will be able to disseminate research of increasing sophistication, developing new theoretical, methodological, and statistical models that can then be utilized in normal science.

The example study falls into the category of normal science. The lead researcher has communicated the original findings of the group through the mediums of conference presentations, state and federal government testimony, and submission of manuscripts to peer-reviewed professional journals. Undergraduate students in the lab were able to attend a professional conference and assist in presenting the findings, while being recognized for their participation as poster coauthors. Graduate student members of the research lab are identifying and presenting additional findings, beyond the primary goals of the initial project.

For manuscripts or grants to be effectively disseminated, they must be written in a clear, unbiased manner and follow professional standards for language and format. In the field of psychology, writers must use APA style (APA, 2001) when communicating any piece of written work. Psychology majors in the field begin to be familiar with the basic standards early in their undergraduate careers, as papers and essays should require practice of the basics of APA style. As one moves on in their professional career, he or she should become able to use the APA manual independently in all of their professional writing. Further, at higher levels of training, one should be able recognize potential biases of his or her own work and actively avoid biases affecting the communication of findings. In our study, we have been particularly interested in rural veterans; as such, a possible oversight or bias could be an undue focus on the characteristics of rural areas as the major determinant of post-military reintegration.

Additional Foundational Competencies. Communicating research findings and implications across interdisciplinary boundaries is a good professional practice, both in the sense of promoting one's work and informing professionals in intersecting disciplines of work that they

might not otherwise be aware. Cross-fertilization pushes the boundaries of the established paradigms. We presented our psychological research on PTSD in groups of veterans to social work and rural health organizations. These professionals challenged us to think beyond the impact of trauma on an individual and their immediate family, and consider the broader impact on communities (e.g., loss of workers, drain on resources) and helping agencies (e.g., lack of awareness among primary care providers of PTSD symptoms and referral sources).

Additional ethical standards in communicating findings include reporting aggregate data to keep the identity of research participants confidential. Further, in case reports or qualitative investigations, extra care must be taken to guarantee this ethical standard, as a great amount of individual information is typically provided in these reports. One would have to ensure that no identifiable information (e.g., reporting minority status in a city with very few minorities) is reported.

14.3 Summary

14.3.1 Competence in the Training and Practice of Clinical Psychologists

We have presented an elaboration of the Competency Cube model of Rodolfa et al. (2005) by broadening the levels of training being considered and introducing the concept of the stage of competency (knowledge, use, and contribution). We linked the resulting model to specific research and statistical and data analysis skills that should be acquired at different levels of training. Noted again, however, is the point that skill acquisition is not fully dependent on the linear progression through academic degrees, nor does the notion of acquisition ensure competency in terms of *use* and *contribution*. Readers may – and even should – disagree with the specific skills that we have included in ❯ Table 14.1, and with the points in training at which these skills should be acquired. ❯ Table 14.1 is offered as a starting point; it is an empirical question as to when these skills are actually being taught throughout colleges and universities, and when and in what sequence they would best be learned. An initial question to ask at this point is whether the current system is "broken," or are we actually producing graduates who are competent in research skills? If they are competent, we might assume the current system is working pretty well in terms of sequence and timing of teaching research skills.

Fortunately, this question is well addressed by Aiken et al. (2008) in their survey of Ph.D. programs in psychology. Their findings are, in our view, disheartening; they go as far as saying they are "profoundly troubled" by their results. One troubling finding is that training in psychological statistics, measurement, and methodology appears to be no better at the top 25 psychology programs in the country than at lesser-ranked departments. This lack of a difference is due to a demonstrated deficiency in the coverage of specific topics and the judged competence of graduates across the 201 programs in their survey. For example, the Aiken et al. (2008) survey shows that while most programs report coverage of core statistical analysis procedures, such as ANOVA (95%), multiple regression (95%), and multivariate analysis (80%), coverage of more specialized content quickly declines as one moves to structural equation modeling (52%), nonparametric statistics (50%), longitudinal data analysis (30%), and treatment of missing data (24%). Similarly, while basic research designs are covered in most programs (92%), survey research, program evaluation, and survey sampling procedures are

covered in less than one third of the programs. More troubling is the low percentage of programs that report that *most or all of their graduates* (≥75%) are competent in applying a wide variety of critical skills to their own research (Aiken et al., 2008). For example, only 30% of the programs reported most or all of their graduates as being competent to apply classical test theory. Figures for some other important areas are: 46% for field research, 11% for longitudinal designs, 10% for program evaluation, 9% for generalizability theory, 8% for single-subject designs, and less than 7% for a variety of missing data approaches.

Recommended curricular coverage exists for undergraduate psychology programs (APA, 2007, 2008b), and even for high schools (APA, 2005). Surveys have been done to document adherence to recommended research and statistical analysis coursework and experiences at the undergraduate level (Friedrich, Buday, & Kerr, 2000; Tomcho et al., 2009). These surveys have generally found undergraduate curricula to have low – even poor – adherence to the 18 undergraduate learning objectives related to methodology and statistics as outlined by the APA (2007; Tomcho et al.). We located one older study evaluating student competence in research design and data analysis at the master's level of training in counseling psychology (Watkins, Schneider, Manus, & Hunton-Shoup, 1990). Similar to the later work of Aiken et al. (2008), Watkins et al. found that the master's program faculty rated their graduates rather low (using a nine-point scale, where 1 = *very little* and 9 = *very much*), especially as contrasted with the comparison group of doctoral programs in their study, on: (a) having been effectively trained in certain areas, and (b) having an interest in certain areas. For example, training and interest in test construction received mean scores of 4.1 and 2.7, respectively. Also relevant here are the respective ratings for independent research in counseling (M = 5.4 and 4.4) and program evaluation (M = 4.2 and 3.9). Finally, on the same nine-point scale, faculty rated their master's-level graduates as having low interest in contributing to the literature (M = 3.6). We did not find any studies evaluating competence in research design and data analysis related to continuing education experiences following one's terminal degree. Whether and to what effect clinicians and researchers continue to develop their skills and competencies in research design and statistical analysis seems like a promising avenue for investigation, but one likely to be equally unsettling, to say the least. A related issue goes beyond when, and in what sequence, these skills should be acquired: There is no consensus on which skills should be presented at what point in training and to what stage of competency.

Further, there is no consensus on how to evaluate or measure stage of competency in these various skills (Elman, Illfelder-Kaye, & Robiner, 2005; Leigh et al., 2007; Lichtenberg, 2007; Roberts, Borden, Christiansen, & Lopez, 2005; Rodolfa et al., 2005). We would argue that evaluation should depend on the particular stage of competence being measured (knowledge, use, contribution), as well as the context in which a particular skill is being learned (undergraduate versus graduate school versus continuing education seminar) and used (to pass a course versus to earn a doctorate versus to publish a research article). This does not presently appear to be the case. For example, undergraduate psychology majors will need to demonstrate knowledge of, and familiarity with, core statistical issues and procedures, such as probability, random group assignment, correlation, *t*-test, and ANOVA, primarily through written examination, including hand calculations and laboratory reports. This method does not evaluate the ability to apply this knowledge independently, raising the question of whether *use* of these skills is actually more than just a *desired* outcome of the undergraduate degree. Likewise, the primary demonstration of research competence for entering most graduate programs is the knowledge needed to pass the psychology subject test and the quantitative component of the

Graduate Record Examination. One could argue that an applicant's portfolio should include documentation of involvement in research, and interviewers may ask about research experience and knowledge. No interviewee, we imagine, is handed a data set and asked to complete a *t*-test as evidence of independent use. Further, and as clearly supported by the research of Aiken et al. (2008), even doctoral-level students largely demonstrate only the knowledge and familiarity stage of competence through course examination. Although they should be progressing toward independent use by the time of completion of their theses and dissertations, the measurement of this outcome is the vague and unstandardized "committee consensus" as to whether or not the student has demonstrated competence. We question whether the competence to apply these skills *independently* is actually being evaluated, and whether independent use is a *functional* outcome of the doctoral degree. In the same vein, professional licensing exams are written demonstrations of knowledge, and not of competence to use or contribute. Further, licensing exams are focused on clinical issues; the research design and statistical analysis questions are at a rather basic level of knowledge.

As clinical psychologists are the primary group who must pass credentialing examinations, one may ask how important research design and statistical analysis are to clinical practice if only demonstration of knowledge and familiarity are required. We would argue that the well-trained clinician *must* be familiar with a range of research design and statistical analysis procedures. This will enable the clinician to be an informed consumer of the research literature on effective intervention and assessment strategies, thereby making judgments about the quality of supporting research. Evidence-based practice requires good evaluation. To engage in evaluation-informed practice (cf., Bloom, Fischer, & Orme, 2009), the clinician should be familiar with a range of ideographic and nomothetic assessment procedures, single-subject research designs, and the ability to construct reliable and valid measures and observational procedures. This active use of research design and analysis skills will assist in determining the success or failure of interventions. Although the gateway to licensed practice is demonstration of knowledge and familiarity, the competent clinician must be a demonstrably competent user of these skills. However, competent *use* is not presently a component of licensure.

One may argue that the clinician needs only to be familiar with core design and analysis procedures, and competent in the use of methods that adequately demonstrate that interventions are working. Such adequate demonstrations are for the purpose of feedback to clients, adjusting intervention components, and documenting progress for insurance companies. This need not be documentation at the level of publishable clinical research. Still, how will the clinician who reads books and journals and attends continuing education workshops separate adequate from inadequate research on promising interventions and assessments? The practicing clinician need not be a demonstrated expert in randomized clinical trials and specialized statistical procedures, but she or he should be sufficiently familiar to make an informed decision about such research without relying completely on the opinion of "experts" (who may not themselves be as competent in research as might be generally assumed).

Looking back at the veterans research study presented earlier in the chapter, the practicing clinician should be able to use their knowledge of research design and statistical analysis to evaluate and question the overall study and what information should be taken as useful in her or his clinical practice. Although a strength of the study is the inclusion of help-seeking and non-help-seeking veterans, the clinician may be more interested in the help-seekers as they are the ones most likely to present themselves to the clinician for assistance. The clinician should be able to evaluate the adequacy of the psychometrics of the primary measures, and recognize

the potential difficulties with author-developed measures. Knowledge of the limitations of survey research, cross-sectional versus longitudinal designs, and anonymous self-report data are also needed. Consumers of research should also be familiar with issues of effect sizes versus the historical standard of reporting significance levels (*p* values; Grissom & Kim, 2005), and whether one can generalize from a particular study to the context in which one practices. This is of particular importance in the dissemination of empirically supported treatments and empirically based professional practices.

On the other hand, perhaps, Goldfried and Wolfe (1998) stated: "It is unrealistic to expect that the practicing clinician will be in the position to evaluate the methodological adequacy of our research findings; nor are they interested in doing so" (p. 149). This is a statement that we do find "profoundly troubling." The implication here is that graduates of doctoral programs do not have sufficient research skills to evaluate published research. Other sources also suggest that, indeed, clinicians are not interested in doing so (see Cohen, 1979; cf. Nathan, 2000). Never mind the issue of whether research is even *read*, a debate between Persons and Silberschatz (1998) raises (and does not settle) the question of whether the results of randomized controlled trials (RCTs) are even *useful* to practicing clinicians. Whether or not clinicians can read and understand the research, perhaps the research is simply not relevant to daily practice; thus the importance of moving from RCTs to empirically supported treatments to empirically based professional practices. However, we do not know if the latter are being read or used, either.

The movement toward establishing evaluations of competence at the level of use is a complex issue well beyond the scope of this chapter. A series of articles in *Professional Psychology: Research and Practice* well address the multiple challenges. First, among these, is developing adequate, valid, and feasible demonstrations of the competence to use a range of research design and statistical analysis procedures. Leigh et al. (2007) and Lichtenberg et al. (2007) focus on these issues with regard to professional psychology, largely meaning the practice of psychology with clinical populations. The issues, however, are equally relevant to the multiple disciplines of psychology, from applied clinical research to experimental psychopathology research to basic animal laboratory research, and from the study of populations and cultures to social behavior to normal and abnormal behavior and personality. Although these volumes focus on clinical psychology competencies, we should be evaluating *all* psychologists at *all* levels of training at a higher level than knowledge and familiarity with their subject matter.

14.3.2 Competence in the Training and Practice of Research Psychologists

We feel that research psychologists must be held to a different, one may say higher, standard of research competence than applied clinical psychologists, in general. ❯Table 14.1 reflects this perspective by rating the expected level of competence for nearly all research and design skills as 3 (competent in *use to contribution*) for those with a research career path. In contrast to this, our ratings for those on the clinical career path reflect our hope that they at least maintain the skills acquired in graduate school, rather than acquiring additional research skills. Oddly, the clinical psychologist takes a licensing exam that includes some basic research design and statistics questions; the research psychologist is not similarly "certified." For most clinical psychology positions licensure to practice is a requirement for being hired (such as university faculty).

This is not the case where research is the required focus of the job. Instead, employers rely on academic degrees, vitae, and professional references to document expertise in research design and statistical analysis. We were unable to locate any professional organization (other than academic programs) that provides certification of expertise in this area, including the American Board of Professional Psychology and the APA College of Professional Psychology (both of which, admittedly, are clinical-/applied-oriented), and also relevant APA Divisions and related Societies. Interestingly, the National Association of School Psychologists (2003) gives credit toward certification renewal (75 h of professional development over 3 years) for publication of research and for the hours of participation in a research project (up to 25 h per project).

So, how does one document competence in research at the level of use and contribution? Currently, one does so by successful submission to research grant agencies and research journals, both of which have statistical and research design experts on their review boards. Of course, those who become members of these review boards arrived there by having their own successful history of publication and receipt of grants under similar review requirements. The assumption is that the published researcher understands the design and statistics in their study, so much so that they could critique the work of others. However, a researcher might simply be the head of a team of associates who actually conduct the design and analysis components of the research. The automatic assumption of competence to review the work of others may thus be faulty. Although this bootstrapping approach has generally served us well, it may be time to document competence in design and analysis through more empirical means. This would include an objective examination of knowledge, but should be extended to demonstration of design and analysis skills with a prepared data set or identification of flaws and inconsistencies in a prototypical manuscript. Thus, actual skills would be demonstrated and criteria for serving on review boards could be set. We know from experience as journal manuscript reviewers that all reviewers are not equally knowledgeable about research design and statistical analysis issues. Documentation of competence would reduce this knowledge differential and avoid the not uncommon experience of one reviewer finding multiple design and analysis flaws, while another reviewer finds no problem at all. The importance of documenting research competencies beyond the ability to obtain grants and publish papers lies in the establishment of criteria of excellence that should raise the overall quality of both conducting and teaching about research. Presently, at our colleges and universities, we rely on academic degrees and curriculum vitae as documentation of expertise. This may no longer be sufficient. (In fact, it is *not* sufficient: One of us recently asked a biostatistician with a quantitative psychology doctoral degree to conduct a power analysis for a research grant application, that person could not do it.)

Developing a system of documentation of knowledge, skills, and performance indicators for certifying competence as a research psychologist would bring with it the requirement of continuing to enhance one's skills. Just as clinical psychologists are required to obtain continuing education units to maintain licensure, a similar system could be put into place for professional development and research skills. This may not be practical in the short run for the field as a whole, but could initially be developed to recognize expertise in just the same way that diplomat status is awarded in the clinical arena. Such a system would assist in the hiring of research faculty and provide assurance that consulting research psychologists and biostatisticians are, indeed, competent in their advertised skills.

An overarching problem of research psychology in general is that the number of individuals graduating with a focus on quantitative psychology is declining, as documented by Aiken et al. (2008). These authors discuss both the decline in the number of students focusing in the

quantitative area, as well as the number of programs, both having decreased by about half over a 10-year period. In fact, APA has a task force to increase the number of quantitative psychologists (APA, 2008a, 2009). Their data show three to eight times as many job advertisements per available candidate in quantitative psychology versus other major areas (e.g., cognitive, developmental, or social positions). This is important because if we are to increase the rigor with which we train graduate students in research design and statistical analysis, we will need faculty to do so. Aiken et al. (2008) report that 16% of the psychology department faculty teach statistics, research design, or measurement, with the majority of those faculty having been trained in a substantive area other than quantitative methods. Only half of all programs had at least one quantitative psychologist on faculty. We cannot count on faculty to teach their substantive area and be expert instructors in research design and analysis as well, particularly as the competency movement is fast spreading across all areas of psychology, placing greater demand on all.

14.4 Conclusion

The prior section brings us back to the question of whether psychology is a science. If we are, or are seeking to be, we need the expertise in research design and statistical analysis that will support that science. The foregoing discussion suggests that the field is in difficult straits. We have a weak system for evaluating the research design and statistical analysis competencies of graduates at all levels. The system primarily focuses on tests that demonstrate knowledge rather than use. Aiken et al. (2008) have well documented that doctoral programs are not up to date in the quantitative skills that they teach, and they provide low ratings for how competent they feel their own graduates are in independently utilizing these skills. Clinical psychologists appear not to be keeping up with the research base in an era when it has become increasingly important to use empirically (i.e., research) supported treatments. Unless the goal is for clinical psychologists simply to become technicians who follow intervention manuals, we must ensure they remain skilled at reading and interpreting the research literature and understanding the conceptual and theoretical bases for interventions – even manualized ones. Finally, quantitative psychologists, who should function to support the training needs and scientific goals of the field, are in increasingly short supply.

To remedy this difficult situation, we recommend turning to the Competency Cube, as developed by Rodolfa et al. (2005), and elaborated here. Our table of skills provides the functional competencies that psychologists at various levels of training, degrees, and career paths should acquire through lifelong learning. Likewise, the foundational competencies outlined by Rodolfa et al. are critical to the development of the functional competencies and should similarly be acquired and developed over one's career.

Careers. This brings us to a reflection on the research careers of the authors themselves. Author Stanley Cohen is the only true quantitative psychologist amongst us. He and the other senior (read "older") author (Joseph Scotti) were trained at a time where all statistical analyses were done by hand with, perhaps, the assistance of a slide rule or a 60-pound "desktop" *calculator*. This necessarily limited the ability to do the advanced statistical analyses that are now commonly available at the click of a virtual button through software programs such as SPSS and SAS. As such, we maintain an appropriate suspicion of what is actually going on "behind the curtain" when selecting analyses by clicking boxes. Our junior author (Vanessa Jacoby) is being trained in the "clicky-box era" (Kaschak & Moore, 2000), finding hand calculations

helpful in learning the conceptual aspects of simple analyses, while deeply appreciative of the availability of desktop *computing*. Authors Stanley Cohen, Joseph Scotti, and Julie Hicks Patrick are lifelong learners of research design and statistical analysis, keeping up with books and journals and attending specialized methodology workshops. Thus, their skills have been acquired over decades of learning, teaching, and using. Author Joseph Scotti notes that attendance of specialty workshops and conferences (e.g., *Conference on Innovative Trauma Research Methods;* Sonis, Palmieri, Lauterbach, King, & King, 2008) has not only sharpened and developed research and design skills more commonly used within psychological research, but have helped him learn designs outside of the field of psychology that can be brought into the next generation of psychological research, such as multilevel ecological models for understanding the social, geographic, and other contexts within which various samples of participants are functioning (Kawachi & Subramanian, 2006).

Author Vanessa Jacoby, on the other hand, is in the midst of a steep learning curve as a first-year doctoral student, coming out of the undergraduate research and statistics curriculum and into three graduate courses in research design and statistics, classical test theory, and generalizability theory. Her knowledge is being quickly brought up to the stage of semi-independent use in the design of a thesis research project. The careers of incoming graduate students are likely to be more similar to the experience of Vanessa Jacoby than to that of the other authors, given the explosion of statistical analysis procedures and research designs that increasingly sophisticated software programs allow. We hope this new generation continues lifelong learning in their development of functional and foundational competencies.

Final thoughts. Are we asking too much? Clinical psychologists need to be competent in their substantive areas of focus, being well acquainted with the knowledge base in their areas of interest. As practicing clinicians, they must also be competent in the skills needed to provide effective consultation and intervention. Must they also remain expert enough in research design and data analysis to evaluate *critically* the literature that recommends to them the use of specific intervention and consultation procedures? If they are to be more than technicians, we emphatically say, "*Yes, of course! Being conversant in the scientific bases of psychology is the very heart of a doctoral degree.*"

How we are to evaluate such competencies in research design and statistical analysis remains an open question. However, any movement beyond the status quo will take a major culture shift in the education and training of professional psychologists (Roberts et al., 2005). This shift in ensuring the competencies in research design and statistical analysis is occurring concurrent with a similar shift that is being recommended in the clinical training aspects of professional psychologists, as witness the other volumes of this series. Clearly, there is much work and clarification ahead before a major impact on the current system of education and training of psychologists occurs. We hope that this chapter adds to the growing base upon which to build this new structure for the field.

15 Single Subject Research

Kurt A. Freeman · May Lim

Abstract: In this chapter, we describe basic and expert competencies for the use of single subject designs. Basic competencies include repeated observation of behavioral phenomenon of interest, the participant serving as his or her own control, and utilizing measurement and visual analysis strategies that allow one to determine whether change occurs over time. Expert competencies include basic competencies plus repeated demonstration of experimental effect and altering only one variable at a time when introducing treatment. Through the use of numerous examples, we illustrate how single subject research designs lend themselves well to various aspects of research, including the stage of theory development (Level 1 research) and more formal and systematic tests of said theories (Level II and Level III research). We also describe how basic and expert competencies of single subject designs can be incorporated into clinical practice to evaluate effects of intervention. The reader will learn how single subject designs are unique approaches to scientific inquiry due to several features, including repeated observation of the dependent variable(s), replication of treatment effects, intrasubject and intersubject comparisons, visual analysis of individual participant data, and systematic manipulation of independent variable(s). This chapter will likely be useful for clinicians and researchers alike who are interested in answering questions about clinical phenomena in a manner that meets the requirements of the scientific method.

15.1 Overview

As evidenced by the adoption of the scientist-practitioner or local clinical-scientist models by graduate programs in clinical and counseling psychology, it is clear that the role of research is vital in graduate training. Thus, whether planning a career as a researcher or practitioner, graduate students are expected to gain an understanding of, and an appreciation for, research methodology. This chapter focuses on single-subject designs (SSDs), an idiographic approach for describing, examining, and comparing the performance of an individual against his or her own performance at different points in time or in different settings (Blampied, 2001; Leary, 2001). An introduction to the various SSDs is provided in terms of the processes involved in their utilization, as well as the benefits and weaknesses of each are provided. Clinical examples are used to illustrate the basic competencies needed to effectively apply SSD strategies in the clinical realm. This chapter also includes a discussion of the expert competencies related to SSDs in the context of psychological research that forwards our understanding of the human behavior and the treatment of problems that arise.

While training in various research methodologies is a standard course in doctoral-level psychology programs, many graduates who chose to work primarily as clinical practitioners rarely apply rigorous research methodologies in their clinical work (Holttum & Goble, 2006; Phelps, Eisman, & Kohout, 1998). Therefore, we aim to demonstrate that single-subject methodologies are useful for the clinician interested in creating and

documenting behavioral change for a given client without aspirations for contributing the scientific literature as well as for the social scientist interested in systematic research approaches.

To demonstrate how SSDs can be applicable across research and clinical contexts, we review how they can be applied at various levels of research (i.e., Levels I, II, and III; Hawkins & Mathews, 1999). Level I research typically is a less systematic approach to research that usually requires nothing more than what Hawkins and Mathews identify as "continuous" data collection. Emphasis is on demonstrating change and not on empirically verifying the specific elements that led to the change. Level II research is mostly concerned with the semi-scientific evaluation of treatments. This type of research focuses on experimental control, systematic application of the dependent variable (DV) on the independent variable (IV), and constant monitoring of the data. In short, Level II research also emphasizes behavioral change and experimental control, usually reflected in the documentation of data at pre- and post-phases of treatment, but without a need for replication of treatment effects. Finally, Level III research includes all the activities related to Level II research with the additional aim of identifying replication and generalizability of treatment effects.

15.2 Basic Competencies

15.2.1 Characteristics of Single-Subject Designs

In order to appreciate the complexity and utility of the various single-subject designs, their fundamental premises and characteristics are reviewed in the following sections. The following basic competencies associated with SSDs reflect the specific skills needed to conduct Level I type research (Hawkins & Mathews, 1999). The basic SSD skills associated with Level I research call for a higher level of detail than often used by most clinicians. Inherent in SSDs are organized and unique skill sets useful for practitioners because they aid in case conceptualization and allow the clinician's assumptions to be more precise by converting them into testable hypotheses. We propose that the fundamental characteristics of SSD at all levels of research can be very useful for practitioners because of the emphasis on specificity with regard to measurement and goals.

15.2.1.1 Repeated Observation of Phenomena of Interest

SSDs involve repeated observation of the phenomena of interest across time under standard conditions (Holcombe, Wolery, & Gast, 1994). Specifically, measurement of the DV occurs multiple times, across at least two separate conditions, usually referred to as *baseline* and *intervention*. Such a method of data collection is based on the perspective that determining whether the DV differs from one condition to the next in a meaningful way requires multiple data points within each condition. Doing so allows one to investigate if desired trends in the data are evident (see "Visual Inspection" section below) and protects against making assumptions about differences that may be spurious or the result of natural variation in the DV of interest.

Often in research, the dependent measure utilized is some form of observable behavioral phenomena (e.g., aggressive behavior of a young child, out-of-seat behavior of a child with Attention-Deficit/Hyperactivity Disorder, duration of crying by a depressed adolescent). However, there is nothing inherent within the SSDs that require the DV to be of such form. End products (e.g., weekly weight loss for overweight children), scores on questionnaires (e.g., obtained scores on the *Children's Depression Inventory*), or subjective ratings (e.g., measurements of anxiety using the Subjective Units of Distress Scale) could be repeatedly obtained within SSD research or in application of the principles of SSDs to clinical practice, allowing for inferences regarding the impact of the IV on measures of outcome. In fact, multiple examples abound regarding the use of various types of dependent measures within a single-subject research paradigm (e.g., Glicksohn, Gvirtsman, & Offer, 1997; Nugent, 1992).

In clinical practice, repeated observation can serve as an important role in the therapeutic process. Specifically, if data are gathered in a systematic and repeated manner, decisions can be made regarding: (a) the impact of treatment and (b) whether to alter interventions when monitoring suggests a lack of progress. How one goes about making changes in clinical interventions will determine whether the practitioner adheres to methods that retain sufficient experimental rigor so as to empirically demonstrate causal relations between changes in the DV and IV(s). However, because the goal of most clinical endeavors is not to demonstrate experimental control, but rather is to document change in the clinical phenomena of interest, any deviations from scientifically rigorous approaches may be less important than when engaged in research practices.

15.2.1.2 Participants as Their Own Experimental Controls

Similar to what occurs in within-subjects group designs, participants serve as their own controls in SSDs. The main analytic process used to determine experimental control involves comparing an individual's behavior across experimental conditions, rather than comparing across individuals. This is viewed as the relevant comparison, because in the naturalistic world, and certainly in the context of clinical practice, the primary question of interest is whether an individual's behavior has changed as a result of treatment relative to pretreatment behavioral presentation (Morgan & Morgan, 2001). For instance, a child psychologist is more concerned with whether depressive symptoms of an adolescent have changed as a result of therapy relative to pre-intervention level of symptoms rather than whether the client's symptoms changed relative to a statistically derived group mean. Note that intrasubject comparison across experimental conditions as a test of the effect of the IV on the symptoms of interest is different from completing a normative assessment (i.e., comparing a particular individual's performance or behavioral level to normative data) to determine if a person's current level of functioning is within normal limits. This latter practice is often an important issue clinically, and has some relevance to determining whether changes observed are clinically significant or meaningful (Atkins, Bedics, McGlinchey, & Beauchaine, 2005).

15.2.1.3 Measurement and Analysis

Now that the two of the fundamental characteristics of SSDs necessary for their implementation within Level I research have been presented, the discussion is extended to issues related to

basic measurement competencies when applying SSDs. We review basic competencies such as measuring behavioral characteristics of interest, evaluating baseline data patterns so as to make decisions regarding when to implement treatment, and methods for introducing the IV to allow for an evaluation of treatment effects.

Measurement Strategies

Critical to using SSDs within clinical practice and research is defining in clear terms the target phenomena of interest and developing methods to systematically track those events. The goal is to develop a definition that allows for repeated and reliable documentation of the target variables of interest over time. As mentioned earlier, there is nothing inherent in the use of SSDs that demands one to measure actual behavioral events. Rather the point here is that whatever the DV, be it aggressive acts or scores on a standardized rating scale, defining the variable in a manner that allows for objective, repeated measurement is critical.

As with defining clear DVs, it is necessary to create a clear operational definition of IVs so that one can ensure implementation of treatment with high fidelity. Consider an example of a parent attempting to increase a child's ability to play quietly by him/herself. Using this example, perhaps the IV is the access to a preferred activity (e.g., play with father) contingent upon a specified duration of "playing by self."

This approach to specificity with both the DVs and IVs essentially reflects a focused and consistent effort to understanding the relationship between two events. There is tremendous value in specifying the particular behaviors that need to be learned, increased in frequency, or decreased in frequency. This approach will yield a better chance of identifying a clearer relationship between the IV and DV as compared to an unfocused or shifting approach (Hawkins & Mathews, 1999). Once phenomena of interest have been identified the next step is to choose the measurement method that is most appropriate for capturing important dimensions of those phenomena. Various methods of recording behavioral targets that are commonly used in SSD research are reviewed below.

Time-based methods. Three time-based methods of measurement are commonly used in social science research. Duration as a measure, which is simply a documentation of the length of time that a behavior occurs (e.g., seconds, minutes, hours of continuous behavioral occurrence), is well suited for target behaviors involving sustained performance. For example, a parent concerned about the length, but not the frequency, of his or her daughter's tantrums may measure the duration of each tantrum using a simple stop watch. Duration can be used to track variables of interest that are either targeted for increase (e.g., length of time staying calm or playing quietly) or decrease (e.g., length of child's tantrums, arguments between parent and adolescent, amount of time spent in bed by patient with depression).

Latency refers to the time taken for a behavior to occur following a specified antecedent or cue or the time between the identified cue and the completion of a task. For example, a parent may want to determine the length of time it takes for a child to begin getting ready in the morning following a verbal reminder or the caregiver may be interested in the time between the verbal reminder and completion of the morning routine.

Inter-response latency refers to the passage of time between two contiguous occurrences of a target behavior. For example, a teacher concerned about how frequently a child asks for help may measure the length of time between each instance of the child is raising his or her

hand. Or, a couple with frequent arguments may wish to track the amount of time that passes between arguments using a dimension of time that is most appropriate (e.g., minutes, hours, days) to determine whether the couple's oriented therapy increases inter-response latency.

Event-based methods. Event-based recording methods involve simply tallying the occurrence of a specified discrete behavioral event. Determining frequency of a specified behavior is the simplest form of event-based measurement. Determination of the rate of behavior (i.e., frequency divided by some unit of time) is used more often, however. Event-based recording methods are most appropriate when the target behavior is relatively short in duration, can be easily observed and counted, and occurs regularly or often enough that significant changes are detectable. If the behavior occurs at a high frequency it may be useful to identify a time during the day to measure the behavior and identify for how long the data collector will observe the frequency of a behavior (i.e., in the morning from 9:00 a.m. to 9:30 a.m.).

Interval methods of recording behavior. At times it is impractical to record exact dimensions of a behavioral response (e.g., frequency, latency) because it occurs too often and/or over an extended period of time. For example, measuring "talking" or the number of words per conversation may be a difficult endeavor, especially if the speech is rapid and lengthy. Interval recording methods are useful for occurrence of a behavioral response when more specific measurements are impractical.

Various methods of interval recording are available to assist observers in estimating the occurrence of behavioral targets. Partial interval recording is used to document whether a behavior occurred at any time and at any frequency during a specified period of time. For example, a teacher who is testing a program to improve on-task behavior of an inattentive student may simply document whether the student was on task at any time during each 1 min interval of math instruction. Partial interval recording is most useful when responses are continuous (i.e., do not have a discrete beginning or ending), observation time is limited, and/or when recording several behaviors at the same time.

Momentary time sampling involves documenting whether a behavioral event is occurring at a predetermined interval. Using the example above, a teacher may check on a student at 10 random minute intervals during a 1 h period to see if he or she is on task. Both partial and momentary interval recording have the advantage of unburdening the observer with an excessive or time-consuming data collection process. The primary disadvantage is that by estimating the occurrence of behavior of interest, one may find it harder to document whether change occurs as a result of treatment.

Graphical Representation and Visual Analysis of Data

In SSDs, data are presented for individual participants and information is typically presented in real-time, graphical representation, allowing the researcher to easily examine the data. Data are represented in the manner that most accurately captures the variable of interest (e.g., rate, duration of the behavior), typically with each data point representing one observation period (e.g., 1 day, one class period, one session).

Although data gathered using SSDs can be subjected to statistical analysis (for attention to this issue, see Parker et al., 2005; Todman & Dugard, 2001; see also Perone, 1999 for argument on experimental control versus statistical control), traditionally analysis involves

visual inspection of data attending to level, trend, and variability within and across phases (Horner et al., 2005; Kazdin, 2003). *Level* refers to mean performance within a condition or phase; *trend* refers the rate of increase or decrease in the hypothetical "best-fit" line of the variable being measured within a phase or slope; finally, *variability* refers to the amount that data vary around the mean or slope within a phase. Hayes, Barlow, & Nelson-Gray (1999) suggest that *course* is also an important consideration when analyzing data gathered via SSDs. They define course as a more flexible method of investigating trend, allowing for a determination of whether data follow a linear or curvilinear pattern. Finally, *latency* to change in the DV after changes in the IV is also important for understanding the impact of the latter on the former (Kazdin). Specifically, the closer the time between the introduction of the treatment and the change in the DV, the more confident one is in the source of the change. By attending to each of these variables while visually inspecting data obtained, one can make determinations about the reliability and consistency of the intervention effect.

Compared against statistical analysis of data, visual inspection focuses much more heavily on clinical significance than statistical significance (Kazdin, 2003; Zhan & Ottenbacher, 2003). In clinical psychology, there has been increasing focus on clinical significance of intervention effectiveness versus simply statistical significance. Clinical significance refers to value or meaningful difference that an intervention has on a person's functioning or everyday life (Kazdin, 1999). Criteria have been suggested regarding how to determine clinical significance when using group designs (e.g., Jacobson & Truax, 1991; Jacobson, Roberts, Berns, & McClinchey, 1999), some of which argue that in order to determine clinical significance one must analyze the data at the level of the individual (Jacobson & Truax).

SSDs are well suited for focusing attention on clinical significance of intervention effects. Because analysis relies on visual inspection, emphasis is placed on ensuring that there is a large effect present in order to say with confidence that the IV produced a meaningful change in the DV(s). That is, in order to "trip the belief operant" there is an effect present, single-subject researchers demand notable changes in DVs from baseline to intervention phases. Of course, for clinical purposes, there still may be valid reasons to complete norm-based assessment using standardized instruments so as to determine whether the change altered behaviors of interest so that they are now within typical, or nonclinical limits (Hartmann, Roper, & Bradford, 1979).

15.2.1.4 Choosing a Baseline

With few exceptions, the experimenter utilizing a SSD initiates the process by completing a period of observations of the DV as it occurs in the absence of the IV. Conventionally, this first phase is referred to as the *baseline* and is labeled with an "A" when representing the data on a graph. The data pattern that emerges during this phase of the research serves as the point of comparison for patterns of data during other (often intervention) conditions. Thus, careful attention to the patterns that develop during baseline data collection is important, with particular attention to level and trend (Bailey & Burch, 2002; Kazdin, 2003).

In contrast to basic research paradigms (see Perone, 1991; Sidman, 1960), use of SSDs in applied contexts typically involves collecting baseline data during naturally occurring conditions (Barlow & Hersen, 1984; Hersen, 1982). Further, applied researchers and clinicians

because they are often working with people who may be experiencing significant distress may not have the luxury of continuing baseline observations until a narrowly defined pattern of data emerges. As such, the definition of "stability" or "pattern" is typically viewed differently when in the applied context as compared to a basic research context. This is not to suggest that applied researchers should not be vigilant in minimizing or eliminating variability in data patterns due to measurement errors or other extraneous variables that are controllable (and for which control over is warranted). Rather, the point is that the acceptable amount of control, and thus the amount of variability, differs considerably across basic and applied research environments. The remaining discussion will focus on issues primarily relevant to applied situations.

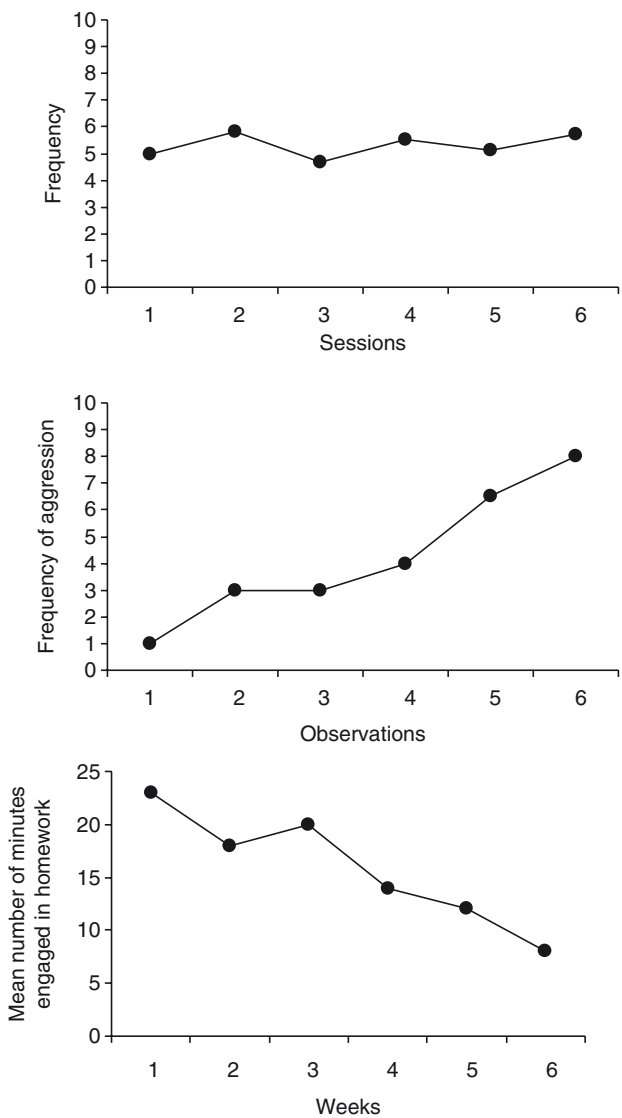
When conducting baseline observations, applied researchers and clinicians are interested in gathering a sample of the DV sufficient to serve as a standard against which to compare patterns of data produced during other conditions. To date, there remains no definitive criterion for the "right" length of baseline. The most important consideration when determining whether one's baseline observation period is adequate is that of consistency in data patterns, which then allows you to predict future data patterns in the absence of any change in experimental conditions (Kazdin, 2003). Once a pattern of consistency in the desired direction has developed one can introduce the IV and obtain interpretable findings. Although most single-subject researchers strive for a minimum of three baseline data points (Barlow & Hersen, 1984), the ultimate criteria of being able to adequately assess the impact of the IV prevails.

Although various combinations and permutations could occur, several basic baseline patterns have been described (Barlow & Hersen, 1984; Hersen, 1982). Each has particular implications for the interpretation of the impact of the IV on the DV. ❯ Figure 15.1 (top graph) depicts a stable baseline using a six-point baseline observation period with hypothetical data. Here, there is minimal variation with no significant increasing or decreasing trends across observations. Introducing the IV following this baseline period would result in unambiguous interpretation of its effect, easily determining whether there is no change (i.e., pattern remains the same during treatment), improvements (i.e., data patterns either increased or decreased depending upon the goal of the intervention), or worsening (i.e., again, data pattern either increased or decreased depending on the goal of intervention).

In contrast, the middle graph in ❯ Fig. 15.1 illustrates an increasing baseline pattern where the frequency of aggressive acts displayed by a youth at recess is increasing as baseline continues, suggesting that the behavior is worsening over time. Alternately, the bottom graph in ❯ Fig. 15.1 depicts a decreasing trend in the mean number of minutes spent completing homework per evening across successive weeks, which is also indicative of a worsening of the problem during baseline. Both baselines are acceptable patterns for treatment comparison because meaningful interpretations of the impact of the IV can be made. Specifically, if the IV produces a reversed pattern of data (i.e., decrease in the number of aggressive acts or increase in minutes spent on homework), then the original pattern serves as an adequate comparison. An increasing or decreasing baseline trend becomes problematic, however, when the IV does not produce a reversal in the direction of the behavior pattern. Specifically, such trends may mask whether an intervention has a detrimental effect, such as a worsening of the problem (Hersen, 1982).

In contrast to increasing or decreasing trends that represent a worsening in the dependent measure, baseline data patterns that indicate improvements are also problematic. Returning to the above examples, one would not want a baseline that indicates a decreasing trend in

◻ **Fig. 15.1**

The stable baseline (*top graph*): hypothetical data demonstrating slight, but negligible variation in data patterns; the increasing or decreasing baseline (*middle graph*): hypothetical data on aggressive acts demonstrating an increasing baseline and (*bottom graph*) hypothetical data on the number of minutes per evening spent engaged in homework, both representing decreasing baseline trends (Copyright 1999 by *Archives of Pediatric and Adolescent Medicine*. Reprinted by permission)


aggressive acts or an increasing trend in number of minutes spent engaged in homework. These patterns are problematic as points of comparison because one could not determine whether continued improvements following the start of treatment are the result of naturally occurring factors (i.e., those that were resulting in the initial improvement) or of the treatment.

The fourth pattern is relatively common in applied research and is called the variable baseline (see ❯Fig. 15.2). Although one could aggregate the data in a manner that minimizes the variability (e.g., by averaging the data collected over two sessions), this simply masks the variability and does not alter the basic pattern. Sidman (1960) recommended that when a researcher is faced with such a pattern in baseline data, one should seek out and eliminate the extraneous factors that produce such variability. However, as has already been mentioned, this may be difficult or excessively time-consuming for the applied researcher.

The utility of the variable baseline as a point of comparison depends on the impact of the IV. If the treatment produces a decrease in the variability of the data pattern *and* a change in the desired direction, then it is appropriate to conclude that the treatment had the desired impact. However, if variability is reduced, but the problem remains at unacceptable levels, then interpretation of the IV as useful would not be warranted. In this latter situation, although the dependent measure is impacted by the IV, the impact is not in the desired direction. Thus, one would not want to retain the treatment.

Another pattern of baseline is the variable-stable baseline. Here, the pattern is initially variable, but then becomes stable. Such a pattern may be achieved by extending the baseline observation period until it reflects a stable baseline pattern. Because the IV is introduced following a period of stability, interpretation of its impact is the same as with the stable baseline – unambiguous. While this approach is often ideal, practical and/or ethical constraints may limit the applied researcher's ability to extend the baseline to a sufficient length to establish stability (e.g., as in the case of a brief inpatient hospitalization, or when the dependent measure is severe self-injurious behavior).

Although unstable patterns of baseline data are not in and of themselves problematic, the stable-variable pattern highlights the influence of extraneous variables. This may make it difficult to evaluate the impact of treatment as the extraneous variable may interfere with the IV. In these instances, attempts to seek out and control (or at least identify and describe) these outside influences are important.

The variable baseline
15.2.1.5 Exploratory or Quasi-experimental Designs

There are times when it is not necessary or impractical to utilize rigorous experimental SSDs when attempting to gather useful information about clinical phenomena of interest. Clinical psychology, as well as many other fields, is replete with many examples of interesting anecdotal descriptions of unique cases or systematic yet nonscientific observations of unusual phenomena. Gathering information using "exploratory" methods contributes to our understanding of phenomena of interest and often serves as the impetus for more in-depth and thorough analysis. In this section, we review two types of SSDs that allow for exploration of phenomena of interest without applying rigorous experimental criteria.

15.2.1.6 The Case Study

A case study is the "detailed study of a single individual, group, or event" (Leary, 2001, p. 321). The field of clinical psychology abounds with case studies of interesting, unique, or challenging clinical cases. And while case studies lack attention to systematic or replicable collection of information, and are without controls to threats to validity, they have several beneficial characteristics (Kazdin, 2003). They serve as a source for information and ideas about clinical problems, as well as a source for developing therapy techniques. Further, they can be a beneficial way of studying phenomena of interest that are rare. A well-documented case study can also be used to challenge principles or practices that are considered well established, by describing how they did not appear to apply to a given individual. Thus, though case studies are not experimental in nature, they play an important role in clinical psychology.

15.2.1.7 The Simple A-B Design

As was previously mentioned, the hallmarks of SSDs include repeated observation of the behavior(s) of interest across time and systematic changes in IVs. The least complex SSD utilized to accomplish these goals is the A-B design. With this design, one collects measures of the DV during baseline and then again during the treatment condition. The specific goals of the A-B design are to document change and show only once the effect of the IV. The A-B design also moves beyond the clinical case study in regards to experimental rigor because of its reliance on repeated and systematic collection of data on the DV of interest. To that end, applying simple A-B designs in clinical practice can play an important role in clinical decision making.

The A-B design emphasizes continuous data collection and observing small or large changes in behavior and thus is an example of Level I research. The A-B design can be used to demonstrate treatment effectiveness or provide information to stop an intervention strategy altogether. Specifically, if the data indicate a good rate of progress during the B phase in the form of an increase in compliant behavior for a previously disruptive child or, conversely, a decrease in tantrums then such information implies the intervention in question is working. Data from this hypothetical A-B design would encourage a clinician to persist with treatment. However, a poor rate of progress in the B phase may provide compelling information to stop treatment or examine the conditions in which these negative trends are occurring. Lastly, no change at all in behavior is also useful information that can aid in clinical decision making. For instance, in

this last scenario a clinician may consider stopping treatment, persist with treatment, or wait in order to observe changes in behavior.

The simple A-B design lacks experimental rigor as compared to other SSDs, and thus may be most appropriate for use in clinical rather than research contexts. Specifically, inclusion of only one phase of each of the components (i.e., baseline and treatment) decreases the ability to adequately assess experimental control or internal validity. Although multiple threats to interval validity exist when using the simple A-B design (e.g., maturation, statistical regression to the mean, spurious introduction of noncontrolled variables affecting individual coinciding with introduction of treatment), its use by practitioners interested in documenting intervention effects is appropriate. Further, the A-B design is appropriate when practical or ethical limitations decrease one's ability to remove the intervention as a means of demonstrating experimental control (e.g., treating severe, life-threatening behavior). In these situations, the scientist-practitioner is at least gathering data to document whether change is occurring, regardless of whether effects can be fully ascribed to the specified intervention.

15.3 Expert Competencies

Having reviewed the fundamental competencies related to SSD and the two most basic types of SSDs, attention is now turned to more elaborate SSDs which allow one to examine specific effects of the independent/criterion variable on the dependent/outcome variables. First, additional critical features of SSDs necessary for increasing their experimental rigor are discussed. Then, "classic" single-subject withdraw designs and variations of these designs that allow for experimental control over the DV as well as alternatives to the withdrawal designs are reviewed.

These types of research methodologies reflect expert competencies, or Level II and Level III type of research (Hawkins & Mathews, 1999), useful for experimentally demonstrating the relationship between the introduction of treatment and changes in behavioral targets. Expert competencies in SSD reflect more rigorous analysis of cause-and-effect relationships and using SSD in a controlled methodological approach for research purposes. In particular, advanced application of SSD research strives toward a systematic explanation of observations with a particular emphasis on replication of treatment effects, measurement issues, interpretation of results with a consideration for validity issues or limitations, and expertise in the production of visual graphs to convey results concisely and accurately.

15.3.1 Additional Characteristics of SSDs

15.3.1.1 Replication of the Experimental Effect

The role of experimental replication of observed effects is one of the primary principles of scientific inquiry (Morgan & Morgan, 2001). Through replication, scientists are able to provide information about the reliability of observed effects as well as to self-correct when initial findings are not consistently obtained. Unfortunately, replication studies are lacking in behavioral sciences, including clinical child and adolescent psychology. This is likely due to a host of reasons, an important one being the energy and expense of replicating studies that rely on large groups of participants.

A hallmark of experimentally sound SSDs (i.e., those that allow for a determination of the functional relation between the IV and changes in DVs) is replication. That is, SSDs set as the standard repeated demonstration of the impact of the IV as the measure of experimental control. Support for the interpretation of the IV (e.g., training parents in methods of giving clear instructions to their children) as the cause of the change in the DV (e.g., rate of child compliance to adult instructions) increases each time one demonstrates that the latter changes as a function of a change in the former. Because of this, each participant in single-subject research is repeatedly exposed to baseline and treatment conditions. How this happens will vary depending on the specific SSD chosen.

Replication occurs across participants as well. The nomenclature describing SSDs implies that only one participant is involved (e.g., SSD, *n* of one designs). However, most research using these designs involve multiple participants (Horner et al., 2005; Leary, 2001), though there is no gold standard for the number of individuals who should be included in a single study to allow for adequate assessment of intervention effects across individuals. Each time an intervention effect is observed with a different participant, confidence that the IV is responsible for the change increases. Thus, when there is a small effect, researchers strive to have more participants so as to increase confidence in interpretation of the source of the effect. The number of participants needed may be fewer if the effect is large.

There are instances in which repeatedly introducing and removing an intervention are impractical or unethical. For instance, one may implement an intervention focused on skills acquisition (e.g., teaching a child with an intellectual disability how to tie his or her shoes). In this instance, maintenance of the behavior is probable even if intervention is withdrawn because of the naturally rewarding properties of engaging in the behavior. Or, perhaps the intervention is designed to address a serious or threatening behavior (e.g., suicidal self-harm) and thus removing an effective intervention may be considered unethical. In these instances, researchers will rely on SSDs that more heavily focus on intersubject replication and, in some cases, cross-situational replication as a means of investigating experimental control of the IV on changes observed in the DV (see "Multiple Baseline Designs" section below). Regardless of the type of SSD used, however, the goal is always to demonstrate multiple instances of the effect of the IV on the DV.

15.3.1.2 Changing One Variable at a Time

Another essential tenet of SSDs, especially research conducted at the Level II and III, is that only one variable should be altered at a time when moving from one phase of the experiment to the next (Barlow & Hersen, 1984; Hersen, 1982). For example, if a researcher was determining effective interventions for treating chronic pain, the investigator would want to introduce only one intervention (e.g., deep breathing) at the start of the treatment phase. If more than one variable is changed, then it becomes impossible to determine which variable is producing change in the DV. Continuing the above example, using two strategies such as deep muscle relaxation *and* introducing a particular cognitive intervention (e.g., meditation) at the same time would result in a situation in which it would be impossible to determine which produced any noted improvements that occur. Thus, unless the investigator is actually evaluating an intervention with multiple components (see discussion

below), standard practice is to hold all variables constant except for one IV as the investigation moves from the baseline to the treatment phase.

Although the general guideline is to only change one variable at a time when transitioning from baseline to treatment, as with any rule there are exceptions. If a researcher is interested in the combined effect of several IVs, as is often the case with many empirically supported interventions (Kazdin & Weisz, 2003; Mash & Barkley, 2006), then it is acceptable to vary more than one variable. For example, consider a hypothetical investigation where researchers are interested in the effects of a combined intervention for treating childhood depression (i.e., individual sessions, parent sessions, group sessions), and therefore introduced several strategies as a "package" intervention. In this way, the authors were able to determine the impact of the combined treatment on the targeted behavior. It should be noted, however, that if investigators are using such an approach to experimentally demonstrate control over the DV, all IVs should be introduced simultaneously, rather than progressively. In this way, the package intervention essentially becomes one IV. Although by using a package treatment it is impossible to determine which component of the intervention is producing the change, or whether it is the components in concert, such an approach allows one to determine if the combined intervention impacts the DV.

With regards to Level I research in the clinical realm, the goal is typically to demonstrate clinically relevant change in the target behavior, rather than showing experimentally validated cause–effect relations (Hawkins & Mathews, 1999). At this level of research, the purpose is not to prove empirically that an intervention is effective and clinicians need not necessarily change one variable at a time. In contrast, if the package intervention is implemented such that all components are introduced simultaneously clinicians practicing at Level I or II research would systematically withdraw components of treatment and track the DV over time to evaluate which components are essential (Kazdin, 2003; see also Jones, 1993).

15.3.2 "Classic" Single-Subject Withdrawal Designs

One of the most common categories of SSDs used in research involves systematically and repeatedly introducing and withdrawing an intervention and documenting the impact of those changes on the DV(s) of interest. This group of designs has been referred to as equivalent time-samples designs (Campbell & Stanley, 1966), withdrawal designs, and reversal designs (Kazdin, 2001). In this section, we describe common designs that are the result of permutations of the basic procedure of introducing and withdrawing intervention.

15.3.2.1 The A-B-A Design

The A-B-A design corrects the primary limitation of the A-B design by including a return to the original baseline conditions. This serves as a means of confirming experimental control over the dependent measure by allowing for repeated demonstration of experimental effect. If the dependent measure returns to a pattern that is similar to the original baseline, then stronger assumptions about the causal role of the IV can be made. In contrast to the A-B design, one is less concerned that some extraneous variable(s) coincided with the introduction of the

treatment phase. Although this may happen once, the possibility of another change in extraneous variables occurring at precisely the same time that the intervention is both introduced and withdrawn is so remote that it does not constitute a realistic threat to internal validity.

Although the A-B-A design corrects for problems of the simple A-B design, it has limitations. Most importantly, for the clinical researcher, completing an investigation while the participant is exposed to baseline conditions is problematic. Let us return to the example above of the adolescent client with depressive symptoms. Assume that an A-B-A design was used in which the B phase consisted of effective use of behavioral activation strategies. Ending the investigation while the participant was exposed to baseline conditions would be problematic if those conditions produced a return in data patterns similar to the original baseline. In this example, the client would be left to deal with his or her problems without the aid of intervention. Although perhaps not required to demonstrate experimental control, clinically and ethically reintroducing the intervention so as to address the presenting complaint would be prudent.

15.3.2.2 The A-B-A-B Design

By introducing an additional treatment phase, the investigator creates the A-B-A-B design. This design controls for the limitation of the A-B-A design and is more methodologically rigorous due to the fact that three opportunities occur to compare the behavior patterns during baseline and treatment conditions (that is, A to B, B to A, and A to B).

To illustrate the A-B-A-B design, consider Friman et al. (1999), who investigated the impact of an intervention for bedtime behavior problems exhibited by two children, ages 3 and 10 years. Both children exhibited bedtime problems in the form of calling out from their bedrooms and leaving their rooms after their parents had put them to bed. Baseline data were collected across 15 days, during which time parents were instructed to respond to the bedtime problems as they would typically. Treatment began on the 16th day and involved parents providing each child with a "bedtime pass" good for one free trip outside of the room past bedtime (e.g., get a drink of water, get another hug). Once the pass was used, it was relinquished to the parents, and no further trips were allowed. The pass was returned to the child the subsequent night. During intervention, the parents were instructed to ignore all crying and simply physically guide the child back into his or her room if he or she were to leave without the use of the pass.

Results of the experimental analysis are presented in ❯ Fig. 15.3. Somewhat variable, but increasing trends are noted in the dependent measure for both participants during the initial baseline. Following introduction of the intervention, a marked decrease in the targeted behavior occurred, to zero for the 10-year-old participant. Thus, it was demonstrated quite clearly with both participants that the behavior changed in the desired direction during the initial intervention phase. This is tempered slightly, however, with the 3-year-old participant. For him, as intervention continued, the behavior problems began to increase again after the initial decrease. Reintroduction of the baseline conditions (i.e., withdrawal of the bedtime pass) resulted in the increased occurrence of the bedtime behavior problems, which decreased to zero for both participants upon the re-administration of the intervention. Obtaining zero rates of behavior with the 3-year-old participant during the second intervention phase adds strength to the determination of experimental control given the initial variability in the first intervention phase.

Nightly frequency of crying and leaving the room for the 3-year-old child (*top*) and the 10-year-old child (*bottom*). (From Friman et al., 1999)
15.3.2.3 The B-A-B Design

Although single-subject research typically starts with an initial baseline period, there may be instances in which this is not feasible. For example, perhaps the investigator is only able to gather data after some form of intervention is put into place. Or, perhaps a person's clinical issues are so severe that attempts at intervention are needed immediately, such as the case when consultants are requested to provide immediate interventions for individuals in an inpatient unit who are engaged in frequent self-injurious behaviors. In either case, it is possible to use the B-A-B design. Although not as complete as the A-B-A-B design (i.e., because it does not allow for as many repeated comparisons of the experimental effect), it is more advantageous than the A-B-A design because it ends on a treatment phase (Hersen, 1982).

15.3.2.4 Variations of the Withdrawal Designs

The underlying strategy employed to demonstrate functional control using the various withdrawal designs (e.g., A-B-A, B-A-B) – the repeated introduction and withdrawal of the

intervention – allows for various extensions of the basic designs. Thus, perhaps endless permutations or formations of the basic components of the designs can be created to address particular questions of interest. Several examples of such designs are considered next, although the list is not meant to be exhaustive.

15.3.2.5 A-B-A-B-A-B Design

The basic components of the A-B-A design can be extended resulting in multiple withdrawals and administrations of the IV (e.g., the A-B-A-B-A-B design). Using such a design adds further support for the demonstration of functional control of the IV over the DV. By demonstrating multiple times that the data patterns change in the expected direction when the treatment is added and withdrawn, the researcher can be more confident that the effect is due to the particular treatment variables. Although this might not be necessary when the treatment effect is large (i.e., when there is a significant difference in the data pattern between baseline and treatment conditions), repeatedly demonstrating the desired effect may be necessary when the effect is small (i.e., when the difference between the two conditions is small). Observing minimal or moderate changes multiple times may provide more convincing evidence that the IV is producing the impact, above and beyond natural variability.

15.3.2.6 A-B-A-C-A-C Design

Introducing a condition in which the effects of a second IV are assessed, as with the A-B-A-C-A-C design, also can extend the basic A-B-A design. In such a design, the investigator compares the impact of treatment conditions B and C on the DV. However, with such a design, one is not able to compare the *relative* effects of the different IVs because they are confounded by the extraneous variable of time (Hersen, 1982). Further, order effects may confound the findings. Perhaps the conditions present in C only have an impact after the participant is exposed to the conditions present in B. With such a design, one is unable to determine whether this is the case, and thus there is a threat to the internal validity of the study. If completing intersubject comparisons, one can control for this by using a counterbalancing technique (i.e., participants 1 and 3 are exposed to the conditions in the following order: A-B-A-C-A-C, whereas participants 2 and 4 are exposed to them in the following order: A-C-A-B-A-B). By using counterbalancing, the researcher is able to determine whether the IVs produce similar effects regardless of order of presentation. Thus, if all participants respond to condition C in similar ways regardless of when they were exposed to this condition, then one has greater confidence in the effect of C alone.

15.3.2.7 Interaction Designs

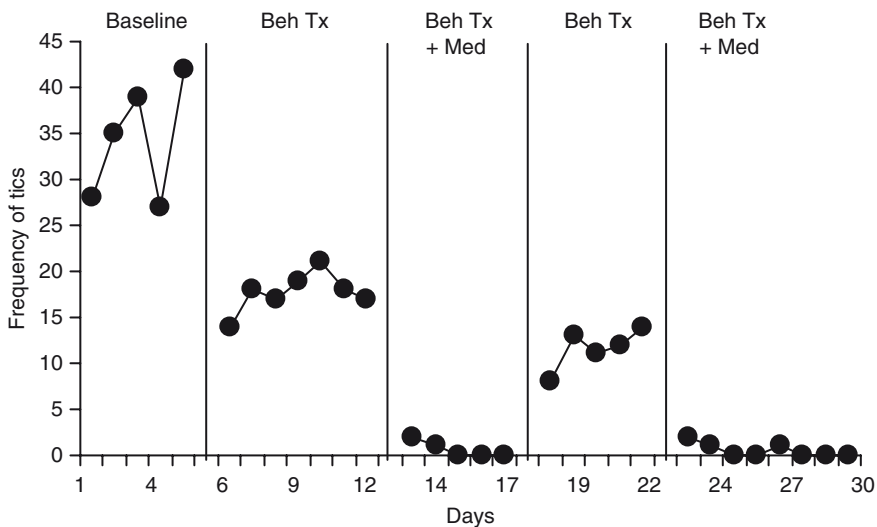
As stated earlier, single-subject research typically involves a change in only one variable at a time across conditions. This rule can be applied in a way that allows the investigator to evaluate the combined effects of multiple IVs by using a withdrawal design. Specifically, by introducing a condition in which two IVs are present, it becomes possible to assess the impact of the

combined intervention relative to a single intervention. In some situations, a particular treatment may produce minimal impact, or may produce an impact that is less than that which is desired. By extending the basic components of the A-B-A design, one can assess the impact of adding additional treatment components.

Assume, for example, that a researcher is interested in treating a severe tic disorder. ❯ Figure 15.4 shows hypothetical data in this scenario. After establishing a baseline of the number of tics during a 1 h period of the day, the impact of a behavioral treatment is evaluated. As is shown, although the number of tics decreases somewhat due to treatment, the desired goal of zero tics is not achieved. Thus, the investigator adds an additional pharmacological component to the intervention – the use of an antihypertensive medication. This results in a condition labeled "BC" because it involves both components (i.e., behavior treatment + medication). As shown in ❯ Fig. 15.4, the combined intervention results in decreases in the DV leading to zero. When the investigator withdraws the medication, the data patterns return to being similar to the original treatment phase. Finally, the combined intervention is reintroduced, resulting in the elimination of the tics. As illustrated, it is possible to demonstrate the impact of the combined intervention with such a design. Put another way, one is able to investigate the relative impact of condition C over condition B. The number of combinations is theoretically endless, potentially resulting in conditions such as B-C-D, B-C-D-E, and so forth.

15.3.3 Stage-Process Designs

Although withdrawal designs have proven remarkably useful in scientific inquiry, partly because of the flexibility in applying the basic concepts of repeated observations and replication

◼ **Fig. 15.4**
Number of tic behaviors during a 1-h period. Hypothetical data of the assessment of intervention for tics


of experimental effect in multiple ways, there are situations in which their use is not appropriate (e.g., treating serious, life-threatening behavior; intervention results in behavior supported by variables beyond intervention). In situations in which repeated withdrawal and reintroduction of the intervention is either impractical or unlikely to influence behavior in expected ways, various other SSDs are used. These include the multi-elements design, multiple baseline designs, and changing criterion designs.

15.3.3.1 The Multi-elements Design

The multi-elements design (also referred to as the simultaneous treatment design or the alternating treatments design) differs from other SSDs in that multiple conditions (i.e., baseline and treatment conditions, two or more treatment conditions) are conducted in rapid succession, with the order of presentation typically determined through random selection, and compared against each other (Miltenberger, 2001). For example, perhaps baseline conditions are in effect on 1 day, treatment conditions the next, and so forth. Thus, unlike withdrawal designs, the effects of the different experimental conditions are evaluated across the same time frame. This helps eliminate the possibility of extraneous influences on the DV during only one experimental condition. In other words, any extraneous variable is going to impact the DV during all conditions because they are occurring essentially in conjunction. One is able to rule out the extraneous as the cause of any differences noted across conditions.

With the multi-elements design, often there are three phases: baseline, comparison (rapid alternation between two or more conditions), and the use of the effective intervention (Holcombe et al., 1994). In some situations, however, the baseline might not be necessary. This may be particularly true if one of the comparison conditions is a baseline condition. One treatment condition is judged to be superior if it produces data patterns in the expected direction at a level that is greater than other conditions. Another component of the multi-elements design is that an equal number of sessions of each condition should be conducted. To ensure discriminated responding across conditions, researchers often pair separate but salient stimuli with each condition. This design may be particularly useful if the investigator is comparing interventions that have an immediate effect, and when the dependent measure is particularly sensitive to changes in stimulus conditions (i.e., reversible; Holcombe et al.).

The multi-elements design can be used to compare a variety of different variables of interest. For example, the design can be used to compare different assessment conditions, such as in functional analysis research (e.g., Anderson, Freeman, & Scotti, 1999). In addition, this design can be used to compare a treatment condition to baseline (e.g., Freeman & Piazza, 1998), or to compare multiple treatments (e.g., Kahng, Iwata, DeLeon, & Wallace, 2000). Such an approach allows the investigator to assess which intervention may prove to be the most effective in changing the targeted DV. The benefit of such a design over other designs is the ability to make such treatment comparisons in a relatively short amount of time.

15.3.3.2 Multiple Baseline Designs

There are three types of multiple baseline designs: (a) multiple baseline across behaviors, (b) multiple baseline across persons, and (c) multiple baseline across settings (or situations)

(Hersen, 1982; Miltenberger, 2001). With the multiple baseline design across behaviors, the impact of an intervention across different behaviors emitted by the same person is evaluated. As such, this is a within-subjects design. The intervention is applied sequentially to the different (presumably) independent behaviors. An example might be evaluating the use of a particular reward strategy to treat pediatric obesity, where a reward is provided each time a child makes a healthy choice during the day (i.e., walking or biking to school, choosing water over juice at meals, and choosing a healthy meal option when eating out). The second design – multiple baseline across persons – involves the evaluation of the impact of a particular intervention across at least two individuals *matched* according to relevant variables who are presumed to be exposed to identical (or at least markedly similar) environments. For example, the investigator may compare an intervention across two students who attend math class with a particular teacher, one who attends in the morning and one who attends in the afternoon. Finally, with the multiple baseline across settings design, a particular intervention is applied sequentially to a single participant or group of participants across independent environments (e.g., home and school).

Technically, there must be at least two separate dimensions (i.e., behaviors, settings, or persons) present to utilize a multiple baseline design, although convention suggests a minimum of three or more. Multiple baseline designs are characterized by the presence of only two conditions: baseline and treatment. However, unlike the simple A-B design, treatment is introduced in such a way that one is able to evaluate experimental control of the IV. Specifically, the baseline condition is extended for increasing lengths of time as the intervention is introduced with the other DVs. Thus, these designs are particularly useful for studying irreversible effects, because replication is achieved without withdrawal and reintroduction of the IV (Perone, 1991).

An assumption underlying the multiple baseline designs is that the dependent measures (i.e., behaviors, persons, settings) are functionally independent. If this is the case, a change in one DV as a result of the IV should not produce changes in the other DVs. Treatment effects, therefore, are inferred when the dependent measure changes only when the intervention is applied to it. Variables still exposed to baseline conditions should show little to no change when the treatment is introduced with the other DVs. In this way, the multiple baseline designs are weaker than other designs (Barlow & Hersen, 1984; Hersen, 1982). Specifically, experimental control is inferred based on the comparison of nontreated DVs as compared to the treated variables, as well as the replication of the effect across behaviors, persons, or settings.

If the DVs are not functionally independent (i.e., treatment with one variable produces changes in the other variables), then the ability to establish experimental control is compromised. Determining a priori whether DVs are independent can be difficult, however. Take, for example, a situation in which the dependent measures are three problematic behaviors of a student in a classroom (i.e., talking out of turn, throwing spit wads, getting out of seat without permission). As an intervention, the investigator instructs the teacher to respond in a particular way to the behaviors (e.g., differential reinforcement of competing behavior), and evaluates the impact of the intervention using a multiple baseline design. The student may well learn to change each of the behaviors simply by exposure to the treatment for one behavior (e.g., differential reinforcement when the student talks out of turn affects other behaviors). As this example illustrates, as an artifact of the lack of independence, intervention with one DV may produce changes in the other variables, resulting in the *inability to demonstrate* experimental control. This is problematic because the intervention may be the controlling variable in this situation, but this cannot be demonstrated in a convincing manner.

Kazdin and Kopel (1975) provided three recommendations for addressing problems of dependence across DVs. First, they recommend selecting dependent measures that are as topographically distinct as possible as a means of increasing the likelihood that they are independent. However, such an approach still relies on successful "guessing" as topographically distinct behaviors may still be functionally related. Second, they suggest that investigators utilize four or more baselines as compared to two or three. They argue that by increasing the number of baselines, one is increasing the likelihood of selecting measures that are independent. However, as pointed out by Hersen (Barlow & Hersen, 1984; Hersen, 1982), the probability of interdependence may be enhanced with a larger number of DVs. Finally, Kazdin and Kopel recommend that, when faced with the occurrence of dependence across variables, the investigator withdraws and then reintroduces the IV. By doing so, it may be possible to demonstrate adequate experimental control. Although the investigator originally may have selected the multiple baseline design to avoid using a withdrawal design, this may be necessary to adequately demonstrate control.

To a certain extent, there are competing clinical and research goals when considering multiple baseline designs. From a research standpoint, the goal is to identify target DVs that are less likely to be influenced by changes in other targeted DVs. However, clinically, one is often interested in designing interventions that address not only targeted behavior patterns, but are also likely to produce change that generalizes to other relevant behaviors or contexts. For instance, as a therapist working with an adolescent with social anxiety is likely to be interested in implementing interventions that not only address anxious responding in the classroom setting, but also in the lunchroom, during extracurricular activities, and so forth. The clinical goal is to teach skills that will generalize to relevant contexts. Of course, whether generalization happens naturally (e.g., teaching use of relaxation skills in the classroom results in the person also using those skills in the lunchroom) or must be programmed explicitly (e.g., prompting adolescent to use skills across settings) will only be determined as one progresses.

15.3.3.3 Nonconcurrent Multiple Baseline Design

The presumption of the multiple baseline designs is that the measurement of the different DVs occurs simultaneously. In this way, the designs control for threats to internal validity as such as history effects. However, there may be situations in which it is particularly difficult to obtain simultaneous observations on multiple individuals who meet the specified criteria, thus limiting one's ability to utilize the multiple baseline across persons design. This may be particularly true in applied or clinical research (Hayes, 1985). In such situations, it may be possible to utilize the nonconcurrent multiple baseline design, originally described by Watson and Workman (1981).

With the nonconcurrent multiple baseline across persons design, each baseline length is predetermined (e.g., 3, 6, 9 days). Then, when a participant with the requisite features is available, she or he is exposed to a randomly selected baseline period. From this point, the methodology is conducted in the same manner as the simple A-B design – baseline observations are conducted for the predetermined length, followed by the application of treatment. In this way, baseline and treatment data are obtained from multiple participants, allowing for adequate between-persons comparisons. If a participant fails to display an acceptable baseline pattern, that individual would be dropped from the investigation, although their eventual reaction to treatment may still be useful as a replication (Watson & Workman, 1981).

Some (e.g., Harris & Jenson, 1985a, b) have argued that the nonconcurrent multiple base-line design across persons is equivalent to a series of A-B designs with replication. This nomenclature has been recommended because multiple baseline designs rely on simultaneous data collection as a means of demonstrating adequate control over threats to internal validity. As described earlier, by showing that the change in the DV occurs only when the treatment is introduced, the investigator has confidence in the causal relationship. This is strengthened when data with several individuals are collected simultaneously because the design controls for history effects. Harris and Jenson (1985a, b) argued that the nonconcurrent multiple baseline design does not control for such effects because the data are not collected across individuals simultaneously; thus, the individual is not exposed to the same environment.

By varying the length of baseline, however, the nonconcurrent multiple baseline design does control for threats to internal validity (Hayes, 1985; Mansell, 1982). Specifically, each time that the investigator demonstrates that the dependent measure changes when the treatment is introduced, regardless of the length of baseline, the likelihood that an extraneous variable produced the change for each participant is greatly reduced. Further, by using increasing lengths of baseline, the researcher controls the possibility that the exposure to baseline conditions naturally produces changes in the dependent measure. Thus, although generally considered one of the weaker SSDs, the nonconcurrent multiple baseline across persons design can serve as a useful methodology if other factors limit the ability to utilize a more stringent design.

15.3.3.4 Changing Criterion Design

The changing criterion design shares features with both the simple A-B and the alternating treatments designs (Hersen, 1982; Miltenberger, 2001). Specifically, it is characterized by the presence of only one baseline and one treatment phase. However, what differentiates this design from the A-B design is that the treatment condition is defined by the sequential introduction of different performance goals. In other words, the treatment phase is applied until the targeted DV achieves a specified level of performance. At that time, the goal (i.e., criterion) of performance is altered and the intervention continues until the behavior again achieves the desired level. Changes in the criterion occur until the dependent measure is occurring at the desired terminal level. As such, the changing criterion design is particularly well suited for situations in which the investigator is interested in evaluating shaping programs that are expected to result in increases or decreases in the dependent measure (e.g., decreased cigarette smoking, increased level of exercise; Hersen). Evaluation of the intervention as the causal agent occurs through two comparisons: between the occurrence of the dependent measure during baseline and treatment, and between the occurrence of the dependent measure across the different levels of the intervention. If the DV changes in the desired direction only when the criterion changes, then the investigator can have confidence in the controlling nature of the IV.

15.4 Moving from Basic to Expert Competence in Use of SSDs

As should be evident from the discussion thus far, moving from basic to expert competence involves developing an understanding of the methodological structure of the various

single-subject research designs and how they can be used to successfully investigate relations between particular interventions and behavior change. Additional knowledge and skill sets are important for transitioning from novice to expertise.

Developing an understanding of how SSDs address issues of internal and external validity is important as one moves to expert competence. Except for quasi-experimental SSDs (e.g., the simple A-B design), SSDs adequately address issues of validity in multiple ways. Regarding internal validity, through use of repeated measurement across time, repeated demonstrations of the impact of IVs, and intra- and inter-participant comparison, single-subject methodologies control for threats such as maturation and history effects, for example. Extraneous variables that threaten internal validity are assumed to be constant across baseline and treatment conditions, and thus any notable differences across the conditions can be attributed to the IV.

External validity is addressed through two types of replication: direct and systematic replication (Sidman, 1960). Direct replication is accomplished by demonstrating the impact of the IV across participants with similar characteristics. As the number of replications of the impact increases across participants, the extent of generality is identified. Systematic replication, or replication that involves varying some aspect of the original experimental conditions, is also used to address external validity. That is, using single-subject methodologies to demonstrate replication of treatment effects across clinical disorders, patient populations, settings, clinicians, and so forth allows for the assessment of the extent to which the findings are externally valid.

Another important skill set demonstrating expertise in the use of SSDs is the ability to appropriately select the design based on DVs of interest and interventions to be used. For example, withdrawal designs are particularly relevant for testing interventions that are expected to have a relatively rapid effect on the DV, as well as those that can be introduced and removed (e.g., reward system). Further, they may be best suited for behavioral patterns that are likely to remain influenced primarily by the intervention. To illustrate, consider an intervention designed to teach young children the skills needed to tie their shoes. Once established, subsequent decrease of the skills is unlikely when treatment is withdrawn as the skills are now maintained by their outcome – shoes that are tied. Thus, one would not be able to demonstrate intrasubject replication of treatment effects by documenting that behavior changes in expected directions with intervention is repeatedly introduced and withdrawn. Instead, stage-process designs may be best when testing interventions that focus on skills acquisition. However, if the intervention is designed to increase compliance with the instruction to tie one's shoes with children who have learned how to do so (i.e., have acquired the skills) yet are defiant when requests to tie one's shoes are issued, withdrawal designs may be appropriate to test whether a contingency management system increases compliance.

Several additional skills are unique features of a researcher or clinician with expertise in the use of SSDs. First, an expert researcher or clinician who utilizes SSDs should be able to produce visually appealing and accurate graphs, avoiding visual distortions that may generate biased results (Krishef, 1991). Second, experts in SSD should be able to effectively communicate data results in language that is simple and clear enough for the average audience to appreciate. Third, the expert researcher or clinician should be able to discriminate features of the data, such as variability, level, and trend (Horner et al., 2005). Fourth, as a consumer of research products the expert researcher or clinician should be able to decipher meta-analytic studies of single-subject

research (Morgan & Morgan, 2001; Scruggs & Mastropieri, 1998). Fifth, expertise in SSDs involves the ability to utilize said designs within one's own research agenda, consulting with others regarding how to apply SSDs and training others (e.g., graduate students) in their use. In other words, demonstrating expertise involves both knowing how to use SSDs and knowing how to train others in their use.

Students interested in SSD research and its application in clinical practice will need support in the form of mentorship and supervision in order to put skills into practice and move from novice to experts. It should be noted that support may be difficult because of existing bias toward group-design research over single-subject research in doctoral training programs (Blampied, 2001). Specifically, "[i]f the training environment is ignorant or hostile, trainees' opportunities to integrate single-case based clinical work into their growing experience of the practice of clinical psychology will be impaired" (Blampied, p. 161). Students who choose the route of single-subject research methodology for their master's theses, dissertations, or for other research and publication activities will need training directors, advisors, and mentors to be alert to barriers that impede the single-subject research approach. Additionally, students will need guidance from skilled supervisors who are, at best, knowledgeable about the single-subject approach, and, at the very least, supportive and tolerant of the single-subject approach.

15.5 Summary

SSDs are unique approaches to scientific inquiry due to several features, including repeated observation of the DV, replication of treatment effects, intrasubject and intersubject comparisons, visual analysis of individual participant data, and systematic manipulation of IVs. Further, direct and systematic replications are used to establish the generality of the findings. Together, these features allow the investigator to guard against, or to detect when present, threats to internal and external validity. Thus, their use in psychological and psychotherapy research can allow investigators to answer questions of interest in a manner that meets the requirements of the scientific method (Hayes et al., 1999; Hilliard, 1993; Morgan & Morgan, 2001).

Single-subject research designs lend themselves well to all areas of research, beginning at the development of a new theory, hypothesis, or intervention (Level I) to a formal and systematic test of said theories, hypotheses, and interventions (Level II and Level III; Hawkins & Mathews, 1999; see ❯ Table 15.1). In this way, SSDs are useful not only in the context of psychological research, but also in the context of demonstrating the effectiveness of clinical interventions (Hayes et al., 1999; Hilliard, 1993; Kazdin, 2003). Psychotherapy as a process involves first hypothesis building (i.e., developing reasonable explanations for the client's current conditions) and then hypothesis testing (i.e., assessing the effectiveness of an intervention expected to be effective based on the original hypothesis). Initial interventions may not be effective, and thus clinicians may experiment with others until improvements are noted. Flexibility of SSDs can allow clinicians to collect data and manipulate variables in a way that allows for adequate demonstration of therapeutic outcome as a result of specific interventions. Therefore, their use within psychotherapy can facilitate a clinician truly operating as a scientist-practitioner.

⬛ **Table 15.1**
Single-subject designs within all levels of research

	Goal	Defining features	Examples from SSDs
Level I	Document or create change	Baseline data is collected Data is collected continuously New variables or new measurement tools added based on clinical judgment Reliable and valid measurement tools and methods Graphical representation of data Findings from Level I research may lead to hypotheses that may be tested in more rigorous Level II research	The case study Simple A–B design
Level II	Semi-scientific evaluation of a treatment	Hypotheses are stated clearly Predictor and criterion variables in the hypotheses are clearly defined Reliable and valid measurement tools and methods Data is evaluated Conclusions are drawn about whether the research hypothesis was supported or should be rejected	Simple A–B design applied to a treatment found to be previously efficacious
Level III	Scientific research	Goal is to replicate previous treatment findings (research question: *Will we find the same thing?*) Goal may be to generalize findings to another population or context (research question: *Will we find the same thing with this new group or in this new situation?*)	Withdrawal designs A-B-A, A-B-A-B, A-B-A-B-A-B, A-B-A-C-A-C Stage process designs multi-element design multiple baseline design nonconcurrent multiple baseline changing criterion design

Rigorously applying SSDs to clinical practice presents challenges, however. Specifically, as articulated at various places throughout the chapter, the requirements needed to experimentally demonstrate that changes in the DV are the result of an intervention using SSDs can be at odds with the realities of clinical practice. A fundamental issue is identifying the variables (e.g., context, type of behavior, question being asked, population being served, resources available) for deciding which SSD is most appropriate for use in a particular clinical context for a specific purpose. For instance, if a treatment has already been established as evidence-based, then a simple A-B design may be appropriate as a mechanism of monitoring change. Further, reporting to the scientific community multiple applications of an intervention's effects using simple A-B designs will help support clinical application of the intervention that was originally tested in highly controlled conditions. On the other hand, since many interventions (including those identified as empirically supported according to APA criteria; Chambless & Hollon, 1998; Chambless et al., 1996; Task Force on Promotion and Dissemination of Psychological Procedures, 1995) have not been subjected to effectiveness trials or used with special populations (e.g., rare disorders, with individuals with comorbid disorders), the use of SSDs provides an opportunity to establish effectiveness of the treatment in a clinical context and with variations of client characteristics that were not included in randomized clinical trials. One can envision a multistage process in which SSDs are initially used in clinical contexts to establish treatments as evidence-based. Following this, treatments can be used more clinically in a single-case decision making framework that meets certain purposes (e.g., case formulation, treatment design, monitoring progress), but would not require withdrawal or multiple baseline designs in part because the intervention had been established as effective in previous research.

The issue of how to successfully incorporate SSDs into clinical practice is complex and full attention to it is beyond the scope of this chapter. We raise the issue here to encourage people to consider how to integrate SSDs into clinical practice, and how the pursuit of doing so is beneficial for not only clinicians and their clients (e.g., through documentation of change, better-informed decision making) but also for the research community (e.g., by verifying previous outcomes with unique populations, by raising additional questions to be addressed through more comprehensive or precise research).

In conclusion, SSDs have critical underlying assumptions and basic characteristics that separate them from group designs, while still ensuring that data are collected and analyzed in an experimentally rigorous manner. Although historically SSDs are aligned with operant traditions of behavioral psychology (Sidman, 1960; Skinner, 1974) (e.g., Hayes, 1981), these designs are largely theory-free (e.g., Hayes) and can be useful for any investigator (whether a researcher or practitioner) who gathers time-series data in a systematic fashion. Thus, regardless of theoretical premise of a given researcher or practitioner, SSDs may be appropriate for determining causal or functional relations between changes in the DV(s) and introduction of the IV. This is not to suggest that solid training in the philosophical and theoretical context in which these designs were developed is not important (Blampied, 1999), but instead to support their broad utility in the diverse field of clinical child psychology. Further, their utility is exemplified by the fact that there are frequently calls for more single-subject research in various fields of psychology and beyond (e.g., Cook, 1996; Hrycaiko & Martin, 1996; Lundervold & Belwood, 2000). Not only are they useful for explicit research purposes, they can also be used to assist practitioners in determining the impact of their efforts. Because of this, understanding the SSDs is important for both researchers and clinicians alike.

16 Qualitative Research

Donald E. Polkinghorne

Abstract: Qualitative research refers to the group of inquiry approaches developed to produce knowledge about the experiential realm of human beings. The focus of these approaches is on describing and understanding the meanings people attach to their encounters with other people, their cultural environment, and material objects. Qualitative research holds that the organization and content of the human experiential realm more closely resembles that of natural language rather than numbers. Qualitative studies generate data in the form of participant descriptions of their experiences and use literary analytic procedures to produce higher-order descriptions and understandings of the investigated experience. Qualitative studies produce a different kind of knowledge than quantitative studies. Its studies are concerned to examine the depth and fullness of its topic of interest. Because of the kind of knowledge produced by qualitative research, it is grounded in a different ontological and epistemological base than quantitative research. Understanding and practicing qualitative research requires that students do not simply transfer quantitative research principles to qualitative studies, but approach gaining competency in qualitative research from within its own perspective. There are two levels of competency in qualitative research – the basic level and the expert level. Basic level competency includes knowledge about qualitative research including its philosophy of knowledge, its area of study, the tools and techniques it uses, and its traditions. A student who achieves a basic level competency should be able to read and understand a qualitative research report. Expert level competency is an advance beyond the basic level in that, in addition to understanding, it concerns mastery of the skills needed to conduct a qualitative study. These are practice skills and include mastery of in-depth qualitative interviewing and observation, mastery of analytic skills of data in linguistic form, and mastery of communicating results transparently. Mastery of expert competency is achieved by advancement through various stages of skill development to reach a level of expertise. A student who has achieved expert competency should be able to conduct a worthy qualitative study.

The term *qualitative research* refers to a collection of linguistically based social science research approaches that focus on the study of the human experiential realm. The modern-day practice of qualitative research can be traced to its emergence in the 1970s as part of a reform movement in the social sciences (Schwandt, 2000). The reformers were interested in studying the meanings and values through which people understood and made sense of their encounters with the world, with others, and with themselves. They held that the then current mainstream social science methods, with their commitment to a numeric form of data and to statistical analyses, were inadequate for understanding human existence as it was experienced by persons. The reformers proposed that a research approach that was language-based, rather than numeric-based, would allow for deeper and more nuanced knowledge of human experience. In their development of language-based research, the reformers retrieved and revised earlier attempts at such a research, for example, anthropological field studies and University of Chicago symbolic interaction studies. In the decades since 1970, qualitative- or

linguistic-based research has become an important component in the repertoire of social science inquiry methods.

16.1 Overview

Since its re-emergence in the 1970s, qualitative researchers have developed multiple linguistic-based approaches to the study of the experiential realm. They have produced a diverse set of procedures and tools for their inquiries. Already by 1990, Tesch (1990) could list 46 terms used to refer to various qualitative approaches. As textbooks on qualitative research began to appear, the variety of approaches was culled down to the eight or so most used. For example, Camic, Rhodes, and Yardley (2003) in their *Qualitative Research in Psychology* include chapters on discourse analysis, narrative psychology, grounded theory, phenomenological psychological method, ethnographic methods, and action research. Although textbooks have often treated the field as if it were a collection of different intact methods, an alternate treatment whose focus is on the theory and principles underlying the diverse approaches is possible. When looked at as various, distinct methods, competency in qualitative research would consist of mastery of several of the methods. However, when the field is viewed as a common enterprise based on shared assumptions about how to study the experiential realm, competency involves understanding the rationales that inform the linguistic processes used across the various methods. From this perspective, the different approaches to data generation and analysis that are called for in the various methods are seen as ssimply alternate ways to implement the principles of a language-based approach to the study of human experience (see Patton, 2002). In this chapter, the basic competencies in qualitative research are identified as understandings of its principles and rationales. Expert competencies are defined as including the mastery of the skills needed to carry out qualitative studies.

The number of social science research projects aimed at the study of the experiential realms employing a qualitative approach has increased each decade since the 1970s. This increase has primarily occurred in the disciplines of sociology, education, nursing, and business (in focus group research). In addition, anthropological studies have turned attention to the experiences of their research participants. Among the social sciences, it is the discipline of psychology that has least employed qualitative approaches in its research in the recent decades. However, earlier seminal works have been produced on psychological topics employing qualitative approaches, for example, James' *Varieties of Religious Experience* (1902), Freud's case studies (e.g., 1895/1966), Piaget's theory of cognitive stages in children (1954), Maslow's hierarchy of needs (1943), Kubler-Ross' *Death and Dying* (1969), and Greenberg's (Hanna Green) *I Never Promised You a Rose Garden* (1964), a case study about the experience of schizophrenia.

In recent decades, the use of qualitative approaches in psychology has progressed more in European psychology (especially in Great Britain and Scandinavia) than in American psychology. American psychology has, in general, retained cautiousness about the use of qualitative research. For example, the proposal in 2007 for a new division in the American Psychological Association for qualitative research was not approved. Nevertheless, the use of qualitative approaches in American psychology, especially in counseling psychology, appears to be increasing. Ponterotto (reported in Azar, 2008) noted that over the past 12 years the proportion of qualitative studies published in mainstream counseling psychology journals increased from 13% to 18% and that qualitative approaches make up 10% of psychology dissertations.

The largest increase in publications based on qualitative methods, however, has occurred in social science disciplines other than psychology. The demand for textbooks on how to conduct qualitative research has increased dramatically during the last 4 decades. Sage publications has been the leader in producing these textbooks and now has an extensive library devoted to qualitative research, for example, its three editions of the *Handbook of Qualitative Research* (Denzin & Lincoln, 2008), an edited volume on qualitative research practice (Seale, Gobo, Gubrium, & Silverman, 2004), and Creswell's popular textbook (Creswell, 1998). Most of the textbooks are not discipline-specific, but address the general use of qualitative methods.

However, there have been textbooks published that address the specific use of qualitative research in psychology. To date, most of these have been authored by British psychologists. Included among these texts are: Banister, Burman, Parker, Taylor, and Tindall's *Qualitative Methods in Psychology* (1994), Willig's *Introducing Qualitative Research in Psychology* (2001), Smith's *Qualitative Psychology: A Practical Guide to Research Methods* (2003, second edition, 2008), Parker's *Qualitative Psychology: Introducing Radical Research* (2005), and Willig and Stainton-Rogers' *The Sage Handbook of Qualitative Research in Psychology* (2008). In addition, the British journal *Qualitative Research in Psychology* began publishing in 2003 (David, Gough, & Parker, 2003–2008). Written in English, this literature has been adopted by American psychologists. An early publication by American authors was *Qualitative Research in Psychology* (Ashworth, Giorgi, & de Koning, 1986). Appearing more recently is the important edited volume *Qualitative Research in Psychology* (Camic et al., 2003) by the American Psychological Association.

16.1.1 The Realm of Inquiry for Qualitative Research

Qualitative approaches are specifically devised to study the human experiential realm. The experiential realm is a production of people's brain activity, but while neurological studies focus on where in the brain various activities take place, qualitative studies focus on the experiential content generated by these activities (Petitot, Varela, Pachoud, & Roy, 1999). The generated content includes people's thoughts, understandings, emotions, beliefs, remembrances, imaginations, perceptions, and other mental performances. Although the term *experiential* can be used to refer only to perceptual products, in qualitative approaches it is used to refer to all the productions of mental activity. People have the capacity to be aware of some of their mental activity, but not all of it. At times, the term *consciousness* has been used to connote the experiential realm. However, *consciousness* has also been used to refer to only the productions that appear in people's awareness. In this chapter, I will use *consciousness* in the broad sense to refer to all the products of mental activity whether or not they are available to awareness (Thompson, 2007).

One of the activities of the experiential realm is the presentation to awareness of the objects and activities of the external environment. Since the publications of Kant (1781/1965), it has been recognized that the phenomena that appear in awareness are not simply mirrored reflections of objects in the external world; rather, they are the products of mental activity which organize and consolidate sense data into the recognizable objects that appear in consciousness. The world that appears in human consciousness is the result of specific human processes and differs from the world that appears in other species (e.g., the world as experienced by bats, Nagel, 1970). Jonas' (1966) study of the particular sensory apparatus through which human

beings interact with the world limits and focuses the received perceptual data available to people's mental construction. Thus, the experiential realm, which is the focus of qualitative study, is composed of constructed appearances representing the things in the world. In everyday experience, people's focus is turned toward the things in the world that are represented by their appearances in consciousness, not to the things themselves. Husserl called this focus the *natural attitude* (1937/1970). The study of the experiential realm requires the refocus of attention to the appearances themselves.

These appearances do not show up in consciousness as isolated and meaningless perceptual fragments. Instead, they show up as meaningful in relationship to their effect on accomplishing tasks and fulfilling desires. Which meaning is embedded in an appearance is derived from the effect of past similar appearances and the personal and social context in which they show up. The appearances in consciousness include more than the presentation of current perceived objects; memories and imaginations also appear as well as thoughts. Qualitative studies have most often focused on the meanings that accompany the appearances in people's consciousness. Different people may understand the meaning of the same appearance in different ways depending on their experiential social environment and personal histories.

Individuals, because of their unique life-events and various interactions with others, can attach their own exclusive meanings to appearances. For example, one person, who had been previously bitten by a dog, when seeing a dog approaching interprets its appearance as threatening and moves away; another person, who has a dog as a pet, interprets the dog's appearance as pleasantly appealing and may reach out to touch the dog. Meaning-giving, at times, depends on a person's practical needs. If a person needs something to keep the wind from blowing his or her papers off the desk, a large book sitting on the desk may be understood as a possible paper weight; without the need, the book may not be noticed. The significance of what meaning people give to their appearances is that their actions follow from the meanings they give to them. Human actions are not simple reactions to stimuli, but are responsive to the meanings that people connect to the appearances of the events and happenings in their lives.

In addition to personal experiences, people make use of the meanings assigned to appearances by their social environment. Cultures supply a common core of meanings to be linked to particular appearances. These cores vary among cultures, and people from one culture may identify the meaning of an appearance differently from people from another culture (Lakoff, 1987). For example, in some cultures the experience of having a sitting person show the soles of their shoes is insulting; although in other cultures exposing one's soles has no meaning. People who are members of a culture share a large overlap about what meanings are to be attached to various kinds of events and happenings. The overlap provides a shared interpretation of similar appearances and, thus, allows people to understand one another.

People's experiential realms are not things; they are historical processes and their primary dimension is time. They are continuously engaged in making meaningful what appears. Appearances stream and flow into people's experience as they encounter their physical and social environments, remember past experiences, and engage in imagination (James, 1890/1950). But as new experiences occur, they, along with the meanings and emotions attached to them (Damasio, 1994), are retained. Consciousness is not simply a momentary phenomenon consisting only of immediate appearances flowing by on its surface. Rather, it has a temporal depth made up of its accumulated experiences. The experiences are not stored as merely one thing after another, but they become somewhat organized into inter- and multi-linked configurations. The work of the experiential realm includes the organization of appearances as well as

their production. New appearances are given meaning by becoming linked to stored experiences of a similar kind. Thus, over time, people come to build a reservoir of somewhat consistent interpretative patterns used to assign meaning to the various types of events and happenings that appear. As ever new appearances enter into experience, they are used to refine or reorganize the operating patterns of interpretation into finer levels of distinction.

People's experiential realms present appearances in different modes – perceiving, remembering, and imagining. At times the focus of attention is on memories of past appearances. Past experiences are recalled and reexamined, not only for review of what happened in the past, but also to reinterpret the past in the light of subsequent events. Sometimes memories appear in awareness without the effort to recall them. Some of these are filled with disturbing emotional content and it is difficult to repress them out of awareness (Ricoeur, 2004). Consciousness can also engage itself in the construction of imagined scenarios. Often possible actions are played out in imagination before deciding what to do to achieve a desired result. A person's experiential realm moves seamlessly through these various modes, and, at times, it appears to be operating in different modes at the same time.

16.1.2 Studying the Experiential Realm

Studying people's experiential realm is problematic. As a mental phenomenon the kind of reality it is has different attributes than those of physical things. Physical things are available for public inspection through the senses, either directly or inferentially with instruments such as cloud chambers and temperature gauges. A person's experiential realm is not available for public inspection and, therefore, it cannot be known objectively (i.e., agreement by two independent observers about what is seen). It is also a complex phenomenon consisting of the activities that produce the objects and meanings that appear in consciousness. Only the person whose consciousness it is can observe, although only partially, his or her experiential processes and contents. Despite the difficulties in investigating people's experiential realms, it is that aspect of human existence that is of greatest importance for understanding human beings. Study of the realm displays the ways the physical world, the social environment, other people, and one's self appear in a person's life and the perspective from which a person interacts with them. Husserl (1937/1970) called people's experiential realms their *life worlds* distinguishing it from the world as it is independent of people's experience.

The life world is the world of personal consciousness in which people conduct their lives. People's emotional responses, decisions, and actions are based on the meanings given to what appears in their experiential realms. Thus, understanding people's life worlds is central to understanding human beings and, therefore, is of fundamental interest to psychology.

The discipline of psychology began as the study of the experiential realm. In the early decades of psychology, its research interests concerned the relationships between changes in the physical environment and changes in perceptual experience. Physical stimuli were altered and participants were asked to report what they experienced. It was established that stimuli, such as audition and vision, have to reach certain intensity before they make an appearance in a persons' experience. The studies also found that changes in the magnitude of stimuli were not apparent in experience until they passed a certain threshold (Fechner, 1860/1966). Although Wundt continued the experimental research on the relation between changes in stimuli and changes in experience, he believed this research could study only immediate experiences, but

such research could not give access to deeper mental processes such as thinking, attention, and mental synthesis. In his ten-volume *Völkerpsychology* (1900–1920), Wundt's studies of these deeper processes employed historical analysis, naturalistic observation, and attention to language usage (Hergenhahn, 1997). Brentano (1874/1995) agreed with Wundt that the search for mental elements implied a static view of the experiential realm. He developed a psychology that approached the mental realm as consisting of the activities of judging, feeling, and valuing, which he called *act* psychology. Brentano employed a method of "inner viewing" to study the activities of the experiential realm.

Early American psychology did not adopt Wundt's and Brentano's interest in the deeper, integrated productions of experience, but focused instead on identifying the static experiential elements (Titchener, 1896). In reaction to the search for elements, some psychologists (e.g., James, 1890) began to study the functions of the experiential realms' processes in aiding the human organism to adapt to its environment. However, with the advent of behaviorism and adoption of the unified science model of research, study of the experiential realm was abandoned. The behavioral model of research limited study to only those aspects of reality that were publically observable. Although behaviorism recognized the existence of people's experiential realms, it looked on them as "black boxes" because knowledge about them could not be acquired by the methods of their science. What was publically observable (i.e., what was objective) about humans was the relation between the stimuli that affected them and their bodily responses. In the 1960s (see Gardner, 1985), psychology renewed its interest to what was happening in the "black box," that is, it turned to the study of cognition and experience. The invention of the computer provided a model for how the experiential realm operated. Although psychology's cognitive turn opened up this non-publically observable realm for study, the model of science that guided behavioral research was retained.

A basic problem for research directed at the experiential realm is that researchers do not have direct access to participants' experiencing. Because participants do have partial access to their own experiencing, a solution to the research problem is to have participants produce languaged descriptions about their experiencing. Languaged descriptions offer only an approximation of participants' actual experiencing. It is difficult to establish the accuracy or completeness of descriptions because they cannot be compared to the experiencing itself. Thus, the production of the descriptions is subjective in that they are the personal views of participants on their own experiences. However, once produced, the descriptions themselves are open to public observation and can be treated as "objective" data. Research becomes transformed from study of the experiential realm to study of descriptions about the experiential realm. The data that serve as evidence in the research are the descriptions themselves.

When mainstream psychology turned to study of the experiential realm, it continued to employ the model of science that had guided behavioral research. The model assumed that scientific knowledge took the form of relationships among variables. Whether or not a relationship held between variables could be determined by submitting a proposed relationship to statistical testing. Such testing required prior selection of variables and a way to establish scores representing varying amounts of the variables. Then items or participants are examined to establish scores that represent the amounts of the variables they possessed. The collections of scores on the variables are then presented to statistical testing. The testing exposes whether or not the projected relationship is affirmed by the collected scores. Statistical tests operate by calculations of information in numerical form. This model of knowledge and its method of

testing relationships were retained by mainstream researchers for study of the experiential realm. The model required that participant's descriptions of their experiences be about selected variables and be gathered in numeric form. Or, if the descriptions were originally given in linguistic form, that they be translated into numeric form. The use of scales (e.g., Likert scales) allowed for participant descriptions to be recorded directly in numeric form. The use of codes by raters permitted the translation of descriptions originally given in languaged form into numbers. Relationships among the variables in experiential realm are tested by statistical procedures.

Qualitative research, with its interest in the study of the experiential realm, was part of psychology's cognitive turn. However, qualitative researchers proposed that simply adapting the mainstream model of knowledge development to the experiential realm was not adequate to deal with its unique attributes. Qualitative approaches are presented as an alternative model of knowledge development for the experiential realm.

There are important aspects of the realm that are difficult to grasp when parts of it are abstracted out in the form of measurable variables. The depth and breadth of the realm are complex and dense, and the meanings of its contents are derived from their connectedness of other experiences. The relationships among its contents are not static and permanent; rather, they are realigned as new experiences are incorporated. Describing these relationships as fixed and expressible in mathematical formulas covers over the flux and evolving characteristic of the realm. Also the content of the realm varies across individuals in irregular ways. Although there are shared contents related to people's common biology and their internalization of culture, each person's experiential realm has additional unique characteristics. Small differences in people's life events and happenings, as well as the order in which they occurred, can produce significant differences in the meanings people attach to their life events. These individual differences are not often distributed in a normal variation around a mean; thus, making inferences of population characteristics of the experiential realm from random samples is dubious at best. In order to study the experiential realm in its depth and interconnectedness, qualitative researchers have proposed new inquiry approaches that use natural language as data and linguistic-based analytic tools. To emphasize that qualitative researchers employ a different approach to knowledge generation than that used by mainstream researchers, they often refer to their research as *inquiries*, *studies*, or *explorations*. Nevertheless, because qualitative approaches seek to generate appropriate knowledge about the human realm and make use of empirical accounts and reasoned arguments, I will identify them as a type of *research* in this chapter.

A problem for both mainstream and qualitative researcher is how to make participant descriptions more closely represent the processes and contents of the experiential realm. Qualitative researchers maintain that the attributes of natural language are more able to represent participants' experiential realm than variable scores. Thus, qualitative researchers generate data by gathering languaged descriptions about an aspect of a single person or several persons' experiential realm that is the topic of the investigation. They thoughtfully examine and analyze these descriptions to produce a synthesis that uncovers the structural constituents that coordinate the descriptive elements. The descriptions are produced by participant interviews, researcher observations, document searches, and examining photographs and videos. The worth of the generated descriptions depends on the skill and talents of the researcher for noticing and drawing out nuanced and comprehensive descriptions about an experience. The process of generating a qualitative text is not rule governed and lacks the exactitude of the

administration of a survey questionnaire. The analysis and synthesis of the text also depends on the researcher's ability to conceptualize and notice patterns.

The competencies of qualitative research can be divided into two levels: basic competencies and expert competencies. Basic competencies are concerned with knowledge about qualitative research including its theories and principles and its history and traditions. Mastery of the basic competencies is demonstrated when one is able to read and understand qualitative articles. Expert competencies are concerned with mastery of the skills required to carry out a qualitative study. Mastery of the expert competencies is demonstrated by ably conducting and reporting a qualitative study and by the production of a critical evaluation of a qualitative study.

16.2 Basic Competencies

One who has mastered the basic competencies of qualitative research: (a) will know and understand the principles that guide the conduct of qualitative research; (b) will know and understand the rationales that inform the processes used by qualitative researchers to generate data, to analyze and synthesize the data, and to communicate results; and (c) will know about the history and traditions of qualitative research. ❯ Table 16.1 provides an outline of the basic competencies for understanding qualitative research.

16.2.1 Theory and Principles of Qualitative Research

The theory of qualitative research is based on the premise that the processes and interactions within the experiential realm more closely resemble those operating in naturally spoken languages than those operating in mathematical functions. This premise underlay the kind of data it gathers, the kind of analysis it uses, and the way it frames its reports. Three topics make up this theory section: (a) Differences between linguistic- and numeric-based research, (b) language and the study of the experiential realm, and (c) the place of researcher bias.

◻ **Table 16.1**
Basic competencies – understanding qualitative reports

Area of competency	Sub-competencies
Theory and principles	Linguistic and numeric data
	Properties of language
	Views on bias
Rationales for processes	Data generation
	Analysis-synthesis
	Communication of results
History and traditions	Grounded theory
	Ethnography
	Phenomenology

16.2.1.1 Differences Between Linguistic- and Numeric-Based Research

Qualitative research operates by a different set of principles of inquiry than those that direct inquiries using statistical analysis. Quantitative studies collect or transform information into numbers. In part, this choice is informed by a philosophical position that reality is ordered in a manner that can be described best mathematically. In addition, data in numeric form are required in order to use the descriptive and inferential power of statistical analyses. These analyses provide numeric relationships among groups of scores and can produce a probability estimate that the mean score of a population of scores can be inferred from a randomly selected sample scores from the population. Qualitative studies generate information in the form of spoken and written naturally used language. This choice is based on the idea that certain areas of reality – for example, the experiential realm of human beings – are more closely organized on linguistic, rather than mathematical principles. Linguistic principles of organization allow inter-relationships of meaning to be grasped by conceptual hierarchies and by metaphorical relationships of similarity. Data in linguistic form require their own type of analysis-synthesis processes for producing a comprehensive and comprehensible understanding of the generated data.

One of the most difficult problems in attaining competency in the theory of qualitative research is the background assumptions students hold about what constitutes "real" research. The prior understandings about research by many students are derived from their prior schooling and quantitative research classes. These classes have emphasized that researcher involvement with participants will bias the data, that to count as knowledge findings must be generalizable, that following a method will assure a valid outcome, that replications of a study will produce the same findings, that there is one proper way to assure a causal relationship – the gold standard of random experimentation, etc. When qualitative research is judged using these assumptions, it does not fare well. A response to these assumptions that appears sometimes in qualitative studies is to try to make qualitative research "be more like" quantitative research. Attaining competency in the qualitative principles of inquiry involves coming to understand that qualitative approaches produce a different type of knowledge than that produced by quantitative studies. The qualitative focus is on developing intensive knowledge about individuals rather than about populations. Qualitative knowledge does not provide an answer as to whether or not a hypothesis is supported by gathered data. Qualitative knowledge qualitative demands intensive interaction with participants who have been intentionally selected for their particular experiences.

The kind of knowledge produced by qualitative research is related to the kind of understanding one has about how a friend is experiencing an event or happening. It has a kinship to the knowledge gained by clinicians about the manner in which clients understand and approach their life events. A well-done qualitative study can enlarge the sensitivity of clinicians to the possible range and complexity of clients' experiences. The findings of qualitative research are not simply intended as accurate descriptions of participants' experiential realms, but are meant to offer lenses through which others can look to notice possible experiential subtleties and nuances. In this way, the findings or what is learned in a study serve to sensitize one to notice differences and variations in people's experiences of similar events. Thus, qualitative research can encourage looking below the surface impressions of people's experiences. The conceptually refined lens offered as a qualitative finding can bring to the foreground aspects of another's

experiential realm that had been an unnoticed aspect resting in the background. In this way, qualitative findings serve as instruments of disclosure.

Qualitative findings function in a way similar to findings offered by a creative examination of a literary production. For example, in an analysis of Shakespeare's *As You Like It*, it may be argued that a theme of the play is the contest between the agrarian way of life and the emerging urban life style at the turn of the sixteenth century in England. The examiner provides text from the play, from other works of Shakespeare, and from the historical period to demonstrate the operation of the theme. Using the examiner's findings as a guide, one might now notice how the theme is operating in the play. In previous readings, the reader may not have noticed the theme; but looking through the lens of the examiner's interpretation, passages that had been passed over in previous readings, now become meaningful. The findings have allowed for an increase in the understanding and meaning of the play. Learning about the operation of the deeper theme in the play can also lead a reader to look for such themes in other plays of Shakespeare.

The findings are not a projection on the play by the examiner. They are based on evidence from the text, from comparisons with other texts, and from historical documents. The legitimacy of the findings is dependent on the reader's recognition that the agrarian–urban theme actually shows through the text. What was not noticed before now becomes apparent. What is transferable about the finding is the possibility that the agrarian–urban theme may appear in other plays; that is, it is something that could be looked for. Or more generally, one could look to see if themes of a different kind are operating in other plays.

Qualitative research is a rational enterprise. It employs cognitive processes, such as contrasting and comparing textual elements, and it makes and defends inferences by demonstrating that the conclusions it offers about the meanings and patterns are supported by the data elements in the descriptions. The kinds of reasoning processes used in qualitative analysis differ from those that compose mathematical reasoning; nevertheless, they are part of the common stock of cognitive inferential tools used by people to gain understanding of the meanings and values experienced about themselves, others, and worldly happenings.

16.2.1.2 Properties of Language and the Study of the Experiential Realm

Qualitative research tools are designed to generate and analyze–synthesize linguistic data. The organization and relationships of the experiential realm more closely reflect the properties of languages rather than mathematics. Language relates to auditory knowing and has distinctive features that differentiate it from visual knowing. Beginning with the classical Greek philosophers, western culture has assumed the primacy of visual knowing. It is through the visual sense that we come to know what is real. The superiority of visual knowing is expressed in the value contemporary science places on data that can be publically observed. Levin's (1993) edited volume traces the hegemony of visual knowledge in the metaphors used to talk about knowledge. When we to want to express that we know what someone meant, we say *I see what you mean*; when something is understandable, it is *clear*; a profound remark is *insightful*. In spite of the wide spread use of visual metaphors to expression knowing through all of the senses, differentiating the attributes of auditory knowing from those of visual knowing can assist in "clarifying" qualitative principles.

The descriptive data generated by qualitative research is in linguistic form. Understanding these data draws on the attributes of auditory knowing. Language is at base an auditory

phenomenon. It is first of all spoken and heard and is known through the auditory sense. Even written texts are representations of auditory communication. In the phonetic-based alphabets, the written letters stand for the spoken sounds. Thus, when interview data are transcribed, they retain their auditory attributes. Auditory knowing is primarily interpretative. Its knowledge is not about the sounds that are sensed, but about the meanings the sounds stand for. Moving from the hearing of sounds to the realm of meanings they point toward includes knowing how the language being listened to has linked certain noises to meanings. A language's first level of relating sounds to meanings is the combining of sounds into words. When listening to someone talk in a language not known to the hearer, the words that are heard are devoid of meaning. Except for a few onomatopoeic words – such as *bow-wow* and *meow* in English – sounds have no intrinsic relation to the meanings they represent. The meanings referred to by words are a function of its relation to the other words in its language system (Saussure, 1907–1911/1966). In addition to words, languages contain grammars that generate meanings by combining words into kinds of sentences. For example, a propositional sentence communicates meaning about a state of affairs (*He is sad.*). Sentences can be combined into prose paragraphs to express relations among state of affairs (e.g., the narrative *He is sad. His father died*).

Ferreting out the meaning of any particular expression is a complex mental operation, although it is an everyday accomplishment. Words have a flexible relationship to the realm of meanings. The meaning intended by an expression depends on the context in which it is used. Auditory knowing takes into account the particular situation, the historical setting, the intonation, and style of the speaker, and other considerations in understanding the meaning intended by a speaker's utterance. Knowing what an element of a description means requires knowing its relation to the whole description; and knowing what the whole description means requires knowing the meaning of its elements. Interpreting a description involves the to-and-fro from parts to the whole and whole to the parts. Taking part in the process of producing and understanding by moving back and forth from parts to the whole is termed entering the *interpretative or hermeneutic circle*. The attributes of flexibility and context dependence of the auditory knowing of the meaning of a languaged expression distinguish it from the attributes of sameness over time and context independence that serve visual knowing.

16.2.1.3 Views on Researcher Bias in Qualitative Research

It is a tenant of mainstream research that findings are to be unbiased and objective. Anyone who studies the same phenomenon should come to the same conclusions. Findings are to be protected from the influence of researchers' cultural backgrounds, personalities, desires, and expectations. When any of these factors affect a researcher's findings, the findings are considered biased, and, thus, are unworthy. Many of the rules and methods for conducting mainstream research are intended to separate researchers from their personal perspectives and expectations so as not to influence the responses of research participants. The goal is to produce data that represents real differences in participants' responses, not differences in the stimuli or treatment. For example, in double-blind experimental research neither the administrators of a treatment nor the participants know whether they are receiving the active or the placebo treatment. In survey research presentation of the question is to be constant across participants to eliminate the effect of differences in questioner dress, gender, voice inflection, etc. on participant answers (Mishler, 1986). Findings are said to be objective when they are undistorted by

the researcher's personal perspective; they are said to be subjective when they are a consequence of the researcher's perspective.

In qualitative approaches, researchers are directly involved with participants in data generation. The qualitative interview is a person-to-person interaction and the statements given by participants are influenced by the way questions are asked and by what is asked. Unlike the administration of survey questionnaires, questions in qualitative interviews arise in the flow of the interview and are tailored to the situation. In addition, the personal style of the interviewer, the occasion, and the setting influence participants' descriptions. Because of this close interaction, qualitative interviews are described as co-creations between researchers and participants. However, it is the personal involvement, whether in interviews or in observations, that is necessary to generate rich and robust descriptions that include the complex and layered interactions that are part of the experiential realm.

Qualitative researchers also affect the outcomes of the analysis-synthesis processes. Unlike statistical analysis, which is performed by a computer, the analysis-synthesis of linguistic data is performed by the researcher. It is a process that depends on the skill and persistence of the researcher. The organization of data into meaningful topics and patterns depends on the researcher's insightfulness and creativity. Although techniques have been developed to assist researchers in the analytic process, the quality of the findings depends on researcher characteristics.

Because qualitative researchers are involved in the data generation and analysis-synthesis process, qualitative findings inherently are open to researcher influence and bias. Within qualitative research, there are different positions on how to deal with the operations of researcher bias. The positions line up on a continuum from the attempt to eliminate as much bias as possible – positivism – to acceptance of bias as an aspect of all research – constructionism. Those closer to the positivist position use techniques such as member checks (participants' review of their interviews to verify that the interview accurately reflects what they meant) and expert reviews of the researchers' analyses-syntheses findings (expert researchers' review and agree that the findings are faithful renditions of the data). Closer to the middle of the continuum are researchers who recognize their possible influence, but expect that by being aware of their prejudices and positions they can avoid them. Those who hold this position include a section in their reports, usually called *reflection*, where they describe how the possible influences their backgrounds and assumptions could affect their findings. Toward the constructionism end of the continuum are those who hold that all knowledge reflects the values and assumptions of the researcher and is a construction of the method used. They view findings as what are noticed from the particular perspective of the researcher through the lens of his or her method. Findings are not objective in the sense that anyone who would investigate a topic would arrive at the same results; but, rather, a finding provides a description of aspects of the topic noticed from the subjective perspective of the researcher. Such aspects may not have been noticed from the perspectives of other investigators. Constructionist findings invite the reader to view the topic from the perspective of the researcher.

Readers can recognize the position taken by researchers regarding the role and affect of bias in qualitative studies by the manner in which knowledge claims are stated. Claims that state that the findings represent what is actually the case about the experiential realm are closer to the positivist pole; those that state that findings represent the researcher's view are closer to the constructionist pole. Historically, qualitative research has tended to move from the positivist toward the constructionist pole (Charmaz, 2000; Corbin & Strauss, 2008).

16.2.2 Rationales and Purposes of Qualitative Research Processes

The rationale for the processes used in qualitative research is based on its commitment that the experiential realm is better understood linguistically rather than mathematically. Qualitative approaches operate within a linguistic milieu. They gather and generate a variety of linguistic descriptions about the aspect of experience that is the topic of the study. They carefully analyze these descriptions using techniques and tools appropriate for clarifying and refining the understanding of texts. They then communicate and justify the derived understanding through linguistic-based arguments.

16.2.2.1 Data Generation

The purpose of qualitative data is to provide a basis for increased understanding of aspects of the participants' experiential realms that are being studied. To serve this purpose, the data need to be descriptions that are rich in detail, vivid, and nuanced about instances when participants experienced the feeling or response under investigation. The data should contain fully articulated, concrete examples of instances when participants had the experience. Participants' commentaries about the topic under investigation are much less helpful than amply fleshed out examples that include the context and content of the studied experience. For the analytic work to produce a well-developed description of the attributes of the investigated experience, its data need to be a collection of robust examples of the occurrences of the experience. Generating data consisting of brief answers to a list of pre-designed questions or brief interviews does not provide enough detailed information to interpret the meanings embedded in the data.

The problem faced by qualitative researchers is to generate information that more closely and fully reflects the operations and content of consciousness. One concern about participants' descriptions is the limit of their access to their own experiential realm. Not all the activity of consciousness is present in or available to people's awareness. Freud located aspects of mental activity that were unavailable directly to awareness, and Derrida (1990/2003) criticized Husserl's idea that all the operations of a person's consciousness were available to his or her own reflective inquiry. In addition, much that participants are asked to report about concerns past experiences; but the activity of recollection does not reproduce mirrored images of past experience. Recollections are reconstructions filling in with details that were not part of the original experience and leaving out parts that were included in the original experience (Polkinghorne, 2005). However, people do have the capacity to observe aspects of their own present conscious activity and to bring into their awareness pre-conscious and remembered activity. An analogy used by Merleau-Ponty (1945/1962) to describe access to one's own consciousness activity and contents involved looking into a deep well with a search light. The light of awareness can only penetrate the darkness to a certain depth; what is beyond that depth cannot show up in awareness, but what can be seen is expressible in language.

Most of the data of interest to qualitative researchers is not simply lying around to be collected and gathered; rather, they require the involvement of researchers to develop or generate it from participants through interviews and careful observations. The qualitative approaches make use of skillful interviewing as a means to assist participants in exploring and reporting their experiences. In the context of open and trustworthy interactions, participants are able, over time, to reflect on and talk about their experiences in some detail and with subtlety. Their

prose descriptions allow for accounts that capture the synergistic relations of meanings within their experiential realms. Qualitative approaches also make use of observations of participants' gestures and actions from which they infer the experiential meanings that informed participant responses to events and happenings. Qualitative researchers are data scavengers and make use of any source that can advance the development of their database. They search documents, emails, letters, photos, and other resources to expand details about the examples of the experience they are investigating. The aim is to capture as much of the subtleties and intricacies of the topic under study as possible.

In qualitative research, the data generation, analysis, and communication processes are not carried out by completing one before beginning the next one. Unlike quantitative research where all the data must be collected before conducting the analysis, qualitative researchers move back and forth among data generation and analysis and preparation of public communication. During a study, each process inter-relates with and informs the others. The analysis of the initial data uncovers aspects and layers of the experience that need further exploration and elaboration. The next round of data collection follows up on the questions raised by prior analytic work. The follow-up may involve re-interviewing or re-observing originally selected participants or sites or selecting new participants or sites to gain further details and examples that fill in the gaps and deepen the developing analysis. There is no built-in rule or formula to determine when enough data have been generated for a study. The notion of saturation, in which additional data are no longer provide new information, has been employed as a means for deciding when enough data have been gathered. However, the notion of saturation has come under criticism (see Morse, 2007). Often, the amount of data generated in a study is influenced by pragmatic concerns about limited resources and time. In general, the iterative movement between data generation and analysis continues until sufficient data are accumulated to allow a concluding substantive analysis-synthesis to be achieved.

The logic of selecting participants to interview and observe reflects the need to produce dense and satiated descriptions of an experience. This requires participants who have had the experience being investigated and who can reflect on and articulate the experience. Selection criteria in qualitative research are not determined by the need to randomly select enough participants from a population in order to calculate the probability that what holds for the examined participants also holds for the unexamined members of the population. Thus, although the term *sample* is commonly used, participants in a qualitative research are not selected to create a random sample of a population. Rather, they are purposefully selected persons who can provide revealing descriptions of an experience. In addition, the number of participants is not determined by a desire to produce statistical significance. The number of participants is decided on by the quality and fullness of the descriptions required to produce an understanding of the topic. If qualitative researchers want to make a claim that their particular findings hold for people who were not part of their study, they need to argue for the extension. The argument needs to establish that the topic investigated is so basic to human experience that understanding its attributes in one or a few people allows the inference that this understanding would hold for all people or for all members of a group. Most qualitative studies are not intended to produce generalized knowledge; instead, the aim is to yield particular knowledge about an individual's or several people's experience. When the study includes more than one person, the findings describe the differences across the participants as well as the common elements.

The gold standard for the selection of participants in a qualitative study is *theoretical sampling*. In theoretical sampling, selection is not done in advance of the study, but takes place as the study is underway. As initial analyses raise specific questions and open up areas of inquiry, new participants are selected who can address these questions and who can add new variations within the studied experience. The quality of the generated data depends not only on who are selected as participants, but also on the amount of time given to the encounters with participants. Seidman (2006) suggests at least three interviews with a participant. He points out how more than a single (one hour) encounter allows for rapport to develop between the researcher and participant and for deeper and richer descriptions to emerge over time. Although theoretical sampling and extensive time with participants yields the most useful qualitative data, practical issues in the actual carrying out a research project have required researchers to use other strategies. Patton (2002, pp. 230–246) describes 16 alternate selection strategies. The data generated in many published studies involved only single, one hour interviews with participants.

For the final analysis, the generated data are transformed into a composite written text. Interviews are transcribed, observation notes collected, selections from documents gathered, and researcher notes and memos are brought together in a single extended text. It is not unusual that the combined text takes up 500–1,000 pages (Kvale, 1996). The assembled text appears as a disjointed collection of various transcribed interviews, assorted observational reports, unstructured notes from other textual sources, and researcher notes and memos. The text presents the data as they were originally generated and retains their original formats. As a composite, it lacks thematic coherence and conceptual order. Although some organizational scheme related to the research topic was developing during the iterative data generating-analysis process, the task of drawing out a clear and insightful description of the experiential topic remains. The need is to develop organizational schemes that will bring together the ideas and understanding of the topic that inhere in the textual mass.

The final assembled large text is the database for a qualitative study, and qualitative findings are the product of the analysis and synthesis of the text. However, there is a gap between the experiential realm itself and data about it, whether the data are gathered in linguistic or numeric form. Because the experiential realm is not open to public observation, it cannot be studied directly; instead studies of it rely on self-reports of participants about their experiences. Thus, what is analyzed in qualitative (and quantitative) research is the content of self-reports and researcher observations, not direct observations of the experiential realm. Quantitative studies may develop constructs about unobservable aspects of the experiential realm – such as self-esteem. Because the experience of self-esteem is not directly observable, instruments are used that produce self-report data in numeric form. These data are considered to represent variations in participants' experienced self-concept. The analysis is of the scores, which are reckoned to correspond to the aspects of participants' unobservable experiential realm. Although the self reports used in qualitative studies are in linguistic form, they share the difficulty that their data are representations of the experiential realm, not direct observations. The concern about data representing participants' experiences is not whether or not they are completely accurate descriptions of experience, but how close their descriptions come in their representation. It is the qualitative research position that languaged descriptions offer the possibility of data that come closer to an adequate expression the experiential realm.

16.2.2.2 Analysis-Synthesis

The purpose of qualitative analysis-synthesis is to glean from the assembled textual examples an essential understanding of the experience under study that will help readers to appreciate the depth and complexity of the experience for the selected participant or participants. When the research interest is in the experiences of various participants, the analysis needs to explicate the common and disparate aspects of the examined experience among the participants. Understanding of an experience does not simply emerge from the text; rather, it is a skilled production by the researcher. It requires multiple careful reviews of the text by the researcher. The researcher needs to tarry and linger over the text so that the less obvious meanings in the examples become noticed. The process involves both breaking down the text into its parts (analysis) and gathering together the parts that are similar under a concept or name (synthesis); that is, the text is decomposed into parts and recomposed into a conceptual understanding. Parts of the originally disjunctive examples take on additional meaning by being understood as instances of a concept or theme; that is, they are understood as kind of something. Producing a new concept or using an existing one that brings conceptual ordering to linguistic data requires a developed capacity of similarity and analogical reasoning (see Vosniadou & Ortony, 1989). The conceptual synthesizing process proceeds by trial and error. Concepts that are thought to link similar data units are tested to determine if the concepts adequately separate the data into meaningful kinds. With each test, the concepts are further refined until a conceptual pattern is constructed that displays the data examples as instances of the organizing concepts.

The synthesizing work continues by ordering the derived concepts into higher-order categories. For example, examples in the data might have been ordered under the concepts *feeling hot*, *feeling weak*, and *feeling achy*. These concepts could then be understood as attributes of the higher-order category *feeling ill*. The synthesis builds a structure that shapes the data into an understandable form. The process of refining concepts and categories until there is a good fit between data and the constructed organizing structure continues until researchers are confident that the result elaborates the experience with sufficient detail and clarity. Often the data are susceptible to being understandable through different constructed structures. A structure that frames the data in an unusual way can often bring into view ordinarily missed aspects of an experience. Rather than employing a preconceived structure from the literature, qualitative researchers are to approach their data with "innocence" and to creatively derive a structure that reveals the experience in a new light. Qualitative synthesis derives a cognitive structure from the collected data that delineates the attributes and relationships that make up the studied participants' experiences.

Data in various qualitative studies have been organized using different kinds of structures. The following are the examples of different organizing schemes. Meeker's (2004) study of surrogate decision makers for dying patients used a stage pattern to describe the changes in roles that the surrogates experienced over time. The roles of the examined surrogates moved from the beginning stages in which they experienced themselves as information brokers between health-care providers and the patient to a concluding stage in which they experienced their role as decision makers about the patient's termination. Martin, Sadlo, and Stew's (2006) study of boredom organized the analysis around attributes that made up their participants' experience of being bored. Carter's (2006) study of positive interpersonal emotions organized his interview generated data into a typology matrix. The matrix included different aspects of these

emotions, different levels of the intensity of feeling, and differences in the directionality of the emotions (directed toward others, coming from others, and shared with others). Of the possible matrix cells, Carter located examples in 45 of the cells in his database. McCabe (2003) studied the process of her grieving after her mother's death using personal journals she had written during the 2 years after the death. She organized her findings around the changing ways her mother appeared in her memory and the fluctuations in the way time was experienced in the recollections of interactions with her mother. She developed a model of grieving in which the relationship with the lost loved one is retained through memories and one experiences an ongoing and positive experience. She compared her model to the DSM-IV-TR (American Psychiatric Association, 2000, pp. 740–741) notion that bereavement which lasts beyond 2 months is pathological. Pak (2006) produced a study that organized her interview data into narrative case studies of three Korean–American women. The stories traced the ways these women experienced the conflict between their immigrant families' values and American values in the choice of and preparation for their careers.

There are a number of computer software programs designed for use in qualitative analysis. They are extensions of word processing programs and allow researchers to manage the large database with which they work (Lewins & Silver, 2007). The software programs do not synthesize the data; the synthesis is the result of the cognitive effort and skill of the researcher. The software does assist the researcher by allowing parts of the text to be cut and pasted under different concepts while retaining their links to their original position in the large text. The software is an extremely helpful replacement for paper-based methods formerly used by qualitative researchers. However, unlike statistical software, qualitative software does not involve simply entering data and pushing keys to direct the computer to produce a structural synthesis (see Fieldling & Lee, 1998; Lewins & Silver).

16.2.2.3 Communication of Results

The purpose of qualitative write-ups is not only to report the results of the analysis-synthesis process, but also to demonstrate that the results fit the assembled data. Write-ups need to include a full description of the data generating and the analysis-synthetic processes that produced the results. The choices made during the conduct of the research need to be spelled out, including decisions made about participant selection and the unsuccessful conceptual trials. The reader should be able to go from the reported structure to the database and see how the structure fits the data. The communication should make transparent the processes used to produce the results. To accomplish this task, it requires a report of monograph or book length. Journal length articles can only be abbreviated reports that do not provide sufficient detail for a reader to confidently accept the reported descriptive structure (Polkinghorne, 2007).

There is a particular problem with reporting qualitative findings in journals using the APA format (American Psychiatric Association, 2000) for articles. The format was developed in the 1960s to organize the write-up of quantitative research. The format assumes that results were produced by mathematical analysis and that there was no need to describe how the analysis produced its results from the data. The format also assumes that all the data will be gathered before the analysis. The APA journal format works as a short-hand approach to reporting quantitative research because it assumes that readers have a background understanding of how quantitative studies produce results (Bazerman, 1987). Qualitative researchers, however, need

to explain what they did and why and to spell out the trials and errors that occurred in developing a synthesis. They also need to demonstrate that the structure is derived from the data by including data examples in the write-up.

16.2.3 History and Traditions of Qualitative Research

In addition to comprehension of the theory and principles of qualitative research, the basic competencies include factual knowledge about its historical development. The mainstream social science environment of the late 1960s into which the qualitative research re-emerged was committed to a unified view of science; that is, there was only one kind of knowledge that could be called *scientific* (Hempel, 1965). Scientific explanations were those that accounted for people's behavior by understanding it as governed by a general law. The accepted method for establishing such laws was to propose a possible law (hypothesize) and deduce from the hypothesis what people's behavior would be like if the hypothetical law actually operated. Then collect data to determine if the observed behaviors matched those predicted by the hypothetical law. If the observed behavior was what was predicted, then the hypothesized law was confirmed and added to the inventory of scientifically established laws (Smith, 1986).

The problem confronting the renewal of qualitative research was acceptance by the mainstream as a viable and legitimate alternative means to produce knowledge. Addressing this problem has remained an important part of the history of qualitative research literature (e.g., Giorgi, 1970a; Polkinghorne, 1983). Over the decades since its renewal, qualitative research has gained acceptance in the social sciences as an alternate, although not equal (see Shavelson & Towne, 2002) approach to research. The early strategies for gaining acceptance were to adapt qualitative research so that it appeared more like mainstream research. For example, mainstream terms, such as *data*, *sampling*, *analysis*, and *validity* were employed to describe qualitative processes, which resembled, but were not the same as, mainstream processes. The monograph format for reporting qualitative research was converted to the APA journal format. Recent qualitative literature has been less concerned with justifying the qualitative approach and more concerned with clarifying its principles and increasing the skills of its practitioners.

Basic competency in the history and traditions of qualitative research includes knowledge of its development in three social science disciplines – sociology, anthropology, and psychology. Over time, processes that were developed in one of these disciplines have been used in other disciplines and have lost the disciplinary identity. They have become available as implements for use by qualitative researchers of all disciplines.

16.2.3.1 Grounded Theory – Sociology

With the renewed interest in the study of human experience in the late 1960s, there was concern to find an acceptable research method that would accomplish the task. In 1965, Glaser and Strauss published a study on nurses' experiences of the death of a patient using a qualitative approach. Two years later, they published *Discovery of Grounded Theory: Strategies for Qualitative Research* (Glaser & Strauss, 1967), which described the method they had used in the 1965 study. Glaser and Strauss were professors at the University of California medical school in San Francisco, and their publications provided an early legitimacy to qualitative research as well as

a method for conducting it. In subsequent years, both Glaser and Strauss have published a series of books elaborating procedures for generating and analyzing qualitative research (see Bryant & Charmaz, 2007a). Strauss published three editions of *Basics of Qualitative Research* (Corbin & Strauss, 2008), which is the most widely used text on conducting qualitative studies.

The term *Grounded Theory* was used by Glaser and Strauss to refer both to the product of their research and the techniques they used to produce their results. A grounded theory is one that is derived inductively from data generated about a topic instead of from armchair thinking. The grounded theory process is focused on the generation of theory instead of testing and validating hypothesized theories. Glaser and Strauss introduced the notions of theoretical sampling for data generation and the application of coding for qualitative analysis. Grounded theory research is rooted in the symbolic interactionism (Blumer, 1969; Charon, 2004) perspective in sociology developed at the University of Chicago in the 1930s. Grounded theory originated in the discipline of sociology; however, most or all disciplinary and general textbooks on qualitative research include a chapter on grounded theory.

16.2.3.2 Ethnography – Anthropology

Anthropology engages in ethnographic studies of cultures. In recent decades, anthropology has expanded its studies beyond the investigations of foreign cultures to domestic groups of all kinds (e.g., the classroom and business organizations). Early ethnographic research approached the study of cultures from a third person perspective. Research investigated the rules that informed the behavior of a culture's members in certain preselected spheres of activity; for example, marriage and kinship, ceremony, and leadership hierarchy. More recently, anthropological studies have focused on group members' experiences from a first person or emic perspective. This change of focus was influenced by Geertz' (1973) criticism of the imposition of Western structures on foreign cultures. Geertz introduced the idea of thick description for qualitative data generation. Rather than limiting data gathering to predefined variables, thick description calls for recording the context, strategies, motivations, intentions, and meanings of participants' actions. Anthropological research tools, such as field study and observational processes, have been adopted by qualitative researchers of various disciplines, including psychologists (Griffen & Bengry-Howell, 2008).

16.2.3.3 Phenomenological Psychology

Mainstream psychology has been more resistant to qualitative research than the other social science disciplines. However, one of the principal qualitative approaches, phenomenology, was first developed in psychology. There are two different branches of phenomenological qualitative research – empirical phenomenology and interpretative phenomenology. The first branch was based on the philosophical studies of the structures of consciousness initiated by Husserl in the early decades of the twentieth century (e.g., 1925/1977). Giorgi (1970b) formulated a qualitative research approach making use of methods developed by Husserl; for example, the method of reduction (the focus on the processes and content of consciousness rather than with identifying the properties of the "real" objects that exist in world external to consciousness). While in Husserl's studies, data came from reflections by the researcher on their own experiences, Giorgi

modified Husserl's approach to include interviews of participants about their experiences (see Polkinghorne, 1989). Giorgi hoped that by using interview data his phenomenological research approach would be considered more empirical and, thus, more acceptable to mainstream psychology. Giorgi was a professor at Duquesne University, which served as the center of phenomenological psychology research in the 1970s and 1980s and published the *Journal of Phenomenological Psychology* and annual collections of phenomenological psychology articles.

The second branch of phenomenological qualitative research, interpretive phenomenology, draws upon the existential philosophies of Heidegger (a student of Husserl's) and Merleau-Ponty. The focus of interpretative phenomenology is on the experiences of everyday life events rather than on the basic structures of consciousness. It is concerned about the interpretative meaning people attach to their interactions with other persons and worldly items. The use of interpretive phenomenological research has been prominent in the health sciences (Patricia Benner, 1994).

In current qualitative research, the distinctions between grounded theory, ethnography, and phenomenology are often not maintained. At times, the individual terms have been used to encompass qualitative research in general. Processes first developed in a particular tradition have been extracted and now serve as an amalgam of techniques and tools from which researchers of any discipline can select and use. The selection of what processes to employ in a particular qualitative study is now guided by the needs of that study, rather than its connection to one of the traditional approaches (Patton, 2002).

16.2.4 Summary of Basic Competencies

When these basic competencies are mastered, students will be able to read and understand qualitative research reports. They will be equipped with knowledge of the basic assumptions and terminology of qualitative reports. The kind of knowledge that makes up the basic competencies is propositional; that is, it is factual knowledge about qualitative research. The sources for this knowledge are the qualitative handbooks (Bryant & Charmaz, 2007b; Clandinin, 2007; Denzin & Lincoln, 2008; Gubrium & Holstein, 2002; Willig & Stainton-Rogers, 2008) and textbooks (see Section 16.1) dealing with qualitative research. A valuable source for learning the terminology used in qualitative research is Schwandt's *Dictionary of Qualitative Inquiry* (Schwandt, 2007). The basic competencies could be covered in a one or two semester graduate course.

The basic competencies are not sufficient to conduct a qualitative inquiry or to perform an effective critical analysis of a qualitative study. Carrying out a qualitative study requires development of expert competencies, including the mastery of skills needed to generate worthwhile qualitative data and mastery of skills needed to analyze-synthesize these data. Engaging in a pseudo-study without mastery of the skills can be counter-productive in mastering the theory and principles of qualitative research. Mastery of the expert competencies also enables a student to critically evaluate a study and to propose alternatives that might improve it.

16.3 Expert Competencies

The basic competencies involve propositional knowledge about qualitative research, and with their mastery students are able to read qualitative studies with understanding. For the most

part, reading a report affects only the reader him or herself. However, conducting a qualitative study affects the lives of participants whose time and effort are used. In addition, the results of a qualitative study are presented to the public as a knowledge claim that can be used to assist decision making. Engaging in activity that impacts other people is a significant step up from the solitary activity of reading; thus, it requires a higher order of competencies to assure the production is worthwhile and trustworthy. The higher-order competencies are referred to as *expert competencies* in this chapter because they require mastery of skills and procedural knowledge beyond those that make up the basic competencies. Mastery of the expert or practice competencies occurs at varies levels. These levels of mastery move from the lowest level of novice mastery to the highest level of expert mastery. The term *expert* is used in the chapter to refer to both the area of practice mastery and to the highest level of practice mastery. The areas of practice or expert competencies include mastery of skills involved in the generation of qualitative data, analysis of the data, communication of results, and in the design of a qualitative study. ❯ Table 16.2 provides an outline of the expert competences for conducting a qualitative study.

16.3.1 Levels of Practitioner Mastery

Conducting research is a practice and, as such, requires proficiency in the use of three kinds of knowledge – personal, propositional, and procedural: (a) Personal knowledge is knowledge by acquaintance. Researchers have first-hand knowledge about the processes and contents of their own realm of experience, which they can draw on in conducting studies of participants' experiences. The area qualitative researchers study is not alien or unfamiliar, but is one they already know and talk about. (b) Propositional knowledge is knowledge about facts. Researchers need to know and make use of the facts about the philosophical assumptions, rationales, and history and traditions of qualitative research. The basic competencies are concerned with mastery of the propositional knowledge about qualitative research. However, the expert competencies include mastery of a deeper and broader knowledge of the facts related to qualitative research. (c) Procedural knowledge is knowledge for conducting a qualitative study. This knowledge is practical or "how-to" knowledge whose mastery is demonstrated by skillful performance. All three types of knowledge are needed to produce high-quality qualitative research results.

■ **Table 16.2**

Expert competencies-conducting qualitative research

Area of competency	Sub-competencies
Designing qualitative research skills	Proposed design
	Modifications
Data generating skills	
	Gaining access to sites and participants
	Interviewing
	Observing
Analysis-synthesis skills	
Communicating results skills	

Development of the practice skills used in qualitative research can be seen to progress through a number of stages of mastery. Dreyfus and Dreyfus (1980) developed a model of skill acquisition based on the study of chess players and airline pilots. Benner (1984) adapted their model to describe the stages through which nurses progressed in the development of skillful practice. The model is applicable as a description of the levels of practice mastery through which qualitative researchers can advance. ❯ Table 16.3 lists the Dreyfus and Dreyfus levels of practitioner mastery.

Novice. The novice researcher has learned a set of textbook-provided abstract rules to be adhered to in carrying out a qualitative study. The rules are codified as imitations of what it appears advanced qualitative researchers have done in their studies. Novices focus on correctly following a set of rules and are concerned about whether or not they "did it right." In a sense, they merely go through the motions of doing research rather than actually conducting research. Qualitative studies involve ongoing adjustments and creative decision making in response to the changing circumstances that occur as the study is underway. Simply following a predetermined set of rules is likely to produce poor results. Novices may know what the rule says to do, but they have not attained the skills required to carry out the rule. For example, one may know the rule "conduct interviews with participants," but not have the skills to accomplish the task.

Advanced Beginner. Researchers in the advanced beginner stage have gained experience in actually conducting studies and begin to develop an understanding of aspects of the contexts in which studies are conducted. The researcher begins to operate on maxims of what to do rather than rules. Maxims are principles to be adapted to various circumstances and features in which the research is conducted. For example, the researcher has learned the maxim "make the interviewee feel at ease," and tries to decide what to say to accomplish this for this kind of interviewee.

Competence. As the researcher becomes more experienced, the number of circumstances and features to be noted in deciding what to do can become overwhelming. The problem is to know which of the possible situational differences are important to the conduct of the research. In response to this problem, competent qualitative researchers learn to develop a perspective or plan which allows them to distinguish between which aspects of the study's environment are important and which can be ignored. Researchers operate from a plan of what needs to be attended to in carrying out a particular study to achieve worthwhile results. For example, the competent researchers develop a series of topics they want the interviewee to respond to. These preset topics allow the researcher to recognize when the interviewer is saying something relevant to the study. When the interviewee deviates from the desired topics, the interviewer needs to decide what to do to get them back on topic.

🔹 **Table 16.3**

Levels of mastery of expert skills

Level of mastery
1. Novice
2. Advanced beginner
3. Competent
4. Proficient
5. Expert

Proficient. Performers of research in the first three stages approach the study from a somewhat detached point of view; their attention is focused on deliberating about which maxim to follow or what perspective to take for the study. The proficient researcher becomes more attached and involved in the purpose of the study. Past experiences have become assimilated and function as a large repertoire of intuitive perspectives. Researchers come to perceive the study as a whole rather than as a series of independent steps. From this perspective, the significance and relevance of occurrences during the research process "present themselves" intuitively without deliberative thinking. Rules and maxims have been replaced by situational discriminations. With proficiency, what is salient in the research circumstance stands out; however, determining how to respond requires stepping back from the situation to consider how to respond. For example, an interviewee mentions something about their experience that had not been anticipated. Proficient researchers recognize, without thinking about it, that it may be important to explore further this statement. They then have to step back and deliberate on how they can accomplish this.

Expert. Like proficient researchers, the past experiences of experts have resulted in their capacity to recognize and attend to what is salient during a research process. However, experts, unlike proficient research practitioners, are able to see immediately how to respond and to have the skill required for the response. Experts are not only able to recognize that an off-hand remark by an interviewee opens up an area for further exploration, but is also able to respond at the time in a way that leads the interviewee to discuss the area in more detail.

There is a discontinuity between the competent level and the proficient and expert levels. Up through the competent level researchers approach a study as if were a series of disconnected steps. Their attention is focused on their own actions, which keeps them from becoming immersed in the study. In advancement to the proficient level, researcher attention is focused on the study as a whole. From all that is going on in a study, they are able to differentiate what is salient to moving the study along from what is background noise. Happenings in the research process are understood from the perspective of the effect on the study as a whole. Their actions are no longer informed by rules or maxims but by their past experiences. Benner (1984, p. 37) wrote: "If experts are made to attend to the particulars or to a formal model or rule, their performance actually deteriorates." Benner says that advancement to an expert level of performance takes at least 3 to 5 years of practice; however, mere experience does not guarantee that a researcher will advance through the stages. Progression requires the integration of experiences and attention to the nuances and shades of differences that appear as research practitioners conduct a number of studies. Not all researchers progress to the level of expert practitioner. Many, even those with extensive propositional knowledge and much experience, do not attain the expert level of practice mastery. Advancement to the level of expert researcher follows a developmental path through stages. Advancement from a stage occurs as the knowledge and skill a researcher has already accrued are not adequate to deal with studies of the next level of complexity. A higher level of skill is required to solve the problems presented at next level.

When students have mastered the basic competencies they know what tasks are engaged in to conduct a qualitative study, but they do not have the skills necessary to perform the tasks. This prompts the move to develop the skills necessary to perform the tasks prescribed in the textbooks. A course designed to develop the skills required to conduct a qualitative study (data generation, analysis, and communication of results) could be offered. The course might use

graduated practice exercises to increase students' level of performance. When students have attained a sufficient mastery of the skills, they are able to conduct a qualitative study at advanced beginner stage. In deciding what to do and when to do it, they are able to follow a plan laid out by a tradition or copy the steps used in a previous study. They remain dependent on external authorities to tell them what to do.

With more experience, students can move to the level of a competent qualitative research practitioner. The advancement to the level of competent performer can take place through closely supervised experiences, such as participating in a qualitative research practicum, conducting pilot studies, serving as an apprentice in a faculty member's study, and finally producing a qualitative dissertation. On reaching the level of a competent practitioner, students can understand that to accomplish their research goals, they need to make adjustments to prescribed steps and to make their own situated judgments about what processes should be carried out. They also are able to be flexible in application of these processes. When an opportunity or problem is encountered in a study, they are able to disengage from the flow of the study to think through how to respond.

Process beyond the competency level to the expert level usually occurs after graduating from a doctoral program. Movement to these more advanced levels occurs through the situated learning (Lave & Wenger, 1991) that happens in carrying out qualitative research projects of increasing intricacy and difficulty. Advancement is assisted by working with a mentor or supervisor and with participation in a local or web-based community of advanced qualitative research practitioners (Wenger, 1988; Wenger, McDermott, & Snyder, 2002).

This chapter has presented the expert competencies in qualitative research as the skills and knowledge needed by practitioners to conduct a qualitative study. The full achievement of the expert competencies is demonstrated by conducting complex and complicated studies in which what to do and when to do it is informed by the practitioners accumulated background understanding. Advancement to full expertise occurs through a series of steps from novice practicing through competent practicing to full expert practicing. Attaining full mastery of the expert competencies requires experiences beyond doctoral level training in psychology programs. However, doctoral programs can advance students toward the competency level of practice. Presently, most doctoral programs do not offer sufficient course work, qualitative research practica, or substantial support and supervision for qualitative dissertations to allow students to attain the level of competent qualitative researchers. In the past decades, many doctoral programs in psychology did not offer any courses in qualitative research. Their curriculum offered and required only courses related to quantitative-based research. If students were allowed to use a qualitative approach in their dissertations, they did so without sufficient understanding and necessary skills, and, often, without adequate supervision by experienced mentors. In recent years, many psychology doctoral programs seem to be more open to qualitative approaches. Ponterotto's survey of counseling psychology programs (reported in Azar, 2008) found that 95% of them allowed qualitative dissertations, although only 10% of the students produced them. Ramesh's (2005) study of eight elite APA accredited counseling programs found that all eight espoused methodological diversity in their web sites, program documents, and interviews with program directors. Nevertheless, only one of these programs required a course in qualitative research for graduation. The other programs allowed students to take a course in qualitative research, but the course was not required, nor could it be taken as a substitute for one of the five or six required courses in quantitative methods.

If psychology programs are to assist students in achieving a competent level of qualitative research practice, it will require a minimum of two semester courses, a qualitative research practicum and a well-supervised dissertation. The tasks of generating worthwhile qualitative data and their insightful synthesis require specialized knowledge and skills; data generation is not a simple extension of everyday conversations and observations; nor is qualitative analysis a matter of following a set of rules or entering data in a software package. Because qualitative research works in the medium of language rather than mathematics, much of what is mastered in quantitative courses is not applicable to qualitative research. In some ways, the attempt to transfer quantitative methods and values to qualitative research interferes with attaining competency in qualitative methods.

It is generally understood that studies with numerically based research require training in sophisticated skills before they can be undertaken. Ordinary and everyday understanding of mathematics is not sufficient to conduct a quantitative study. However, students sometimes try to conduct a qualitative study with only their everyday understanding of how to talk to people and how to make sense of what they read. Conducting a worthwhile qualitative research project also requires the mastery of sophisticated knowledge and skills. The following sections offer a brief overview of topics that could be addressed and resources that could be used to help students attain a competent level in the expert competencies.

16.3.2 Designing Qualitative Studies

A qualitative research project begins by defining its goal; for example, to find out the attributes and structures of the experience of being cared for. The design is first of all pragmatic. Given the time and resources available, the level of skills of the researcher and the access to appropriate sites and participants, decisions have to be made about how the goal could be achieved. The qualitative traditions have developed a set of tools that other researchers have found helpful in previous studies. However, these tools may not be useful for achieving the goal of a new study. Researchers are, then, expected to create new data gathering approaches that can work in for the particular study. For example, if the goal of a study is to understand the experience of relating as an avatar to other avatars in the Second Life computer simulation, face-to-face interviews are not available. Designing a qualitative study is not completed when the proposal is written. It remains flexible and changeable as problems and opportunities occur in the pursuit of the research goal.

Carrying out a research process because it was acceptable in another study or because that is the way a book said it should be done, demonstrates a novice level of skill in the design process of a study. Participants and sites should be selected because they are needed to accomplish the research goal. The number of participants interviewed should not be predetermined but decided on the basis of the research goal; for example, learning in great depth about the experience in one or two people or in learning about the variation in the experience over a larger number of participants. An originally selected participant may be found to not be articulate about the experience and, thus, someone else should be selected.

Qualitative researchers who function at the expert level need to "think on their feet," make adjustments in the midst of the study, change directions when what is being done is not advancing the study to its goal, and even change goals when a different opportunity arises while the study is underway. Movement through the levels of performance in the expert competencies

comes from practice and experience. As researchers move up through the levels of the practice competencies, they are able to make better decisions for moving the study along. Those functioning at the expert level are able to notice when changes are needed and to make the appropriate changes that move the study to its goal.

16.3.3 Data Generating Skills

The purpose of data generation in qualitative research is to produce fully elaborated examples of the experience being investigated from participants. The examples need to include descriptions of the historical and social context in which they occurred, the thoughts and feelings the participants had, and the relationship of the example to other events and happenings in the participants' lives. The generation of examples is primarily accomplished through interviews and observations.

Access to Sites and Participants. The first skill needed to generate data is ability to negotiate access to relevant participants and sites. Administrators of sites and individual participants are often leery of being open to researchers. Researchers need to be able to present what they want from the sites and participants in a way that respects their concerns and honors their time. They need to adapt their study designs to take account of the concerns of the sites and participants, yet allow them to meet the goals of their studies. There is no formula to be learned on how to negotiate access. What is done is situation–specific, although role play sometimes will help to improve the skill.

Interviewing. The most used skill in data gathering is interviewing. Even when generating data through observation, researchers engage in informal and formal interviews with participants. To generate a complete description of a participant's experience requires establishing a trusting relationship that allows the participant to feel free to explore all facets of an experience. Some participants are resistant to talking to strangers (including researchers) about their personal lives; some only share with the researcher the parts of their experience that present them in a good light; and others try to figure out what the researcher wants to hear and then limit what they say to what they think will please the researcher. Researchers need to have the skills to move beyond these resistances. Some of these skills are similar to those needed by clinicians in their work with clients which involves the building of rapport and a working alliance (Gelso & Hayes, 1998). The aim of the qualitative research interview, however, differs from therapeutic interviewing. The purpose of the qualitative interview is to gain examples of the investigated experience, not to serve the needs of the participant. The participant needs to buy into the worth of the time and effort they are giving to share their experiences.

The time spent with a participant is limited, so the researcher must make efficient use of the time available. Group interviews (focus groups) can generate more data in less time than one-to-one interviews. However, conducting focus groups requires its own set of specialized skills (Barbour & Kitzinger, 1999; Morgan, 1997). To make effective use of the limited time available for one-to-one interviews requires preparation by the researcher. Researchers need to develop main questions and possible follow-up questions in advance. For part of their preparation, they may engage in mock interviewers with associates. The course of the actual interview may move in unanticipated directions and the researcher needs the skill to explore the new direction or to move the interview back to areas of importance for project. Researchers have to notice when a

salient area is approached and have to be able to follow up and probe further in this area. A number of qualitative interviewing texts are available which describe these interviewing processes and skills (Kvale, 1996; Mishler, 1986; Rubin & Rubin, 2005; Seidman, 2006; Weiss, 1994). However, reading about conducting a qualitative interview to generate descriptions rich in detail, with vividness, and containing nuanced differentiations is only a supplement to practicing interviewing. Students can be given graduated interview assignments to be recorded and transcribed. In reviewing the transcripts, attention is directed at what the student said rather than the interviewee's responses. From these assignments students can reflect on and discuss what they said and did; for example, when what they said closed off the interviewee, what they could have said to have enabled the interview to move forward, and what they did say that produced valuable descriptive statements.

Gaining interviewing skill also involves an increased sensitivity to the ethical nature of the interview. The ethical dimension in interviewing involves more than enacting the research codes: for example, maintaining confidentiality, not engaging in deception, and honoring the right of participants not to continue. Participants open their lives to another person during an interview and need to be treated with respect and courtesy. The interviewer is in a power position to the interviewee. When an interviewee is not performing to the expectations and needs of the interviewee, unless there is genuine care for the interviewee, interviewer comments, gestures, and facial expressions can communicate disappointment in the interviewee. The rewards for producing a successful interview favor the interviewer in terms of grades, graduation, publication, and perhaps promotion. The interviewees receive only appreciation for their time and effort and perhaps a gift or small payment. A researcher who begins a study without appropriate preparation and adequate development of skills, simply to complete a class assignment, takes from participants their time and effort and gives little or nothing in return.

Observation. Patton (1980) opens his early chapter on observation with the story about a man with a gun chasing another man rushing through a meeting of researchers. When the researchers were asked to write a report of what they observed, most were more than 40% mistaken. Although the story was meant to show that observational data cannot be trusted, Patton wrote that what the story really demonstrates is that one cannot trust observations by untrained and unprepared observers. Patton ends the discussion of the story by writing:

► First, the popular wisdom about observation being nothing more than selective perception is true in the ordinary course of participating in day-to-day events. Second, the skilled observer is able to improve the accuracy, validity, and reliability of observations through disciplined training and rigorous preparation. (p. 72)

Preparation includes becoming clear about of all that can be observed at a site, what is important to attend to in order to provide worthy data for the study. What is significant for a study is not obvious at first glance. Keeping track of what is seen over a period of time requires the development of skills for taking orderly notes. Observational data generating also includes decisions about how an observer relates to the site. Do they assume the role as an ordinary member of the site and engage in its activities along with the other members? Do they place themselves outside the membership as an onlooker? A number of books on participant observation point out the issues to consider in making these decisions (e.g., Jorgensen, 1989).

16.3.4 Analysis-Synthesis Skills

The findings of qualitative research are derived from a meticulous examination of the gathered data. Noticing an underlying pattern or theme is not a mechanical process, but is largely dependent on the cognitive capacities and skills of the researcher. Just as not all students are able to skillfully perform in the numeric area, perhaps not all students are capable of the level of cognitive skill to conduct a qualitative analysis with its need to make fine textual distinctions and uncover underlying patterns. The analytic-synthetic skills are the most difficult to teach. Practice on short stories, poems, and other literature can increase skill in analysis of languaged data.

Techniques have been developed to assist the creative work of producing a synthesis that calls attention to aspects and relationships in an examined experience; for example, coding the text. The first step is open coding in which the text is broken apart into units and each unit is identified as an instance of a concept. Next is axial coding in which the identified concepts produced in the open coding are gathered around a higher-order concept (an axle) as attributes of the higher-order concept. The next step is to gather the axial concepts together in an overall concept that represents the general thrust of the data (Holton, 2007). Some researchers do not break the text apart before the synthesizing work, but work with the whole text. As researchers gain experience and read more studies, they accumulate a repertoire of conceptual schemes that they can try on the data.

An important part of the analysis-synthesis process is testing the proposed schemes as to how well they fit the data. This follows the logic of the hypothetical model of quantitative research. Except that it is an ongoing process in which the data that did not fit the proposed scheme are used to alter the scheme in the direction of a more comprehensive fit. The process continues until a scheme is tweaked to the point that it accounts for most all of the data. The testing depends on the integrity of the researcher to not force data, which does not fit, into a proposed scheme.

Analysis requires considerable preparation before it is carried out. Researchers need to be acquainted with the theories and research that appear in the literature on the topic and the organizing schemes and models offered in the literature. One of the reasons for conducting a qualitative study is dissatisfaction with the models proposed in the literature. Qualitative research generates data containing full descriptions of an experience in order to derive a more useful descriptive model of an experience. This requires researchers to develop the capacity to not only know what others have said about the topic, but to also be able to come innocently to the data without preconceived notions of what they will find. It involves the ability to start from the beginning and take a fresh look at the data. There are texts available that address the process of qualitative analysis (e.g., Boyatzis, 1998; Coffey & Atkinson, 1996; Dey, 1993; Potter, 1996; Wolcott, 1994).

Qualitative researchers at the competent level need to be practiced in the use of at least one of the qualitative software packages. The packages are very helpful in working with the mass of data generated in a study; however, mastering all the ways in which they can assist in conducting an analysis takes time and practice. A student should be already skilled in the use of a qualitative software package before beginning a dissertation.

16.3.5 Communicating Results

The write-up or report of a qualitative study is framed for the readers of the report (Wolcott, 2001). Because implementing the sequence of steps from traditional qualitative method does

not necessarily produce worthy or believable results, a qualitative report has to lay out what was done and why. The report has to take the reader along on the journey traveled by the researcher. The reader should be told about what decisions were made and why. The write-up should provide the reader with a transparent view of the research process. The researcher should approach the write-up as if the reader needs to be convinced of the results.

The form of the write-up is an argument intended to show the reader how the results are derived from the data and that the data are trustworthy and sufficient to support the results. Because the evidence for the results is the collected data, the researcher needs a careful and detail descriptions of how the data were generated, and how efforts were made to locate data that would correct or elaborate the initial interpretations. Excerpts from the data that were significant for the development of the results can be quoted and their importance explained. The trial and error process engaged in establishing a structure which fits the data should be part of the write-up. Readers are not expected to accept results simply because the researcher carried out a study.

There is no prescribed format for reporting qualitative results at the current time. Writing a report that anticipates and answers readers could have as they go through the texts and that presents the argument in a logical and supported way is a skill that qualitative researchers are required to develop. Associates and supervisors, as well as prospective readers, can provide feedback on drafts. As with any writing skill, report writing improves with experience and feedback. A researcher at the competent level should be able to write a well argued report with supporting evidence and with detailed explanations of the processes used in the study.

Qualitative research does not follow the logic assumed by the APA journal format. In some doctoral programs, qualitative dissertations are expected to be written using chapters that follow the APA format. Because many journals expect that researchers (both quantitative and qualitative studies) use this format, qualitative write-ups are often without sufficient detail and appear to the reader as thin and unconvincing. With the advent of web journals, it may be possible for researchers to publish reports of adequate length to include the details of a study's process and to present arguments that clarify how the results were derived from the data. Perhaps the highest level of skill in report writing is to present a transparent description of what was done and why and a convincing argument for the results within a journal length article that uses the standard APA format.

16.4　Summary

It may be that the first doctoral dissertation in the United States using what would be referred to today as a qualitative method was produced by Adrian van Kaam in 1958 at Case Western Reserve University (portions reprinted in 1969, pp. 305–340). His study was about the experience of "really feeling understood," a notion taken from Roger's theory of therapy. Van Kaam wrote about the use of his results:

▶ Regarding the application, the results of phenomenal [qualitative] psychology seem to be of greater use in reaching the deeper layers of common human existence which is the concern of the present study. To the extent that phenomenal psychology is also and primarily interested in the explication of an experience in its individual givenness, its results are useful in problems of therapy and counseling, interpretation of personality tests, development of personality, creativity, and

human relationships....It is apparent, then, that the results of both kinds of psychology [traditional academic psychology and qualitative psychology] do not exclude but complement each other. (van Kaam, 1969, p. 340).

Qualitative psychology is an alternate form of research designed to study the experiences of persons. It is based on the premise that the organization of the human experiential realm more closely resembles natural language than mathematics. Its results are in linguistic form as are its processes of data gathering, analysis, and communication of findings. Understanding qualitative studies requires knowledge of the logic and rationales that underlay their processes and the cognitive operations. Mastery of the basic competencies will enable students to make sense of the studies. However, the capability to conduct a qualitative study requires mastery beyond the basic competencies. These additional competencies are the special skills used for language-based research. Mastery of them is gained through practice and experience and can proceed from a beginning, novice level of performance to an expert level.

17 Epidemiology

David L. Streiner · John Cairney

Abstract: Epidemiology is the study of the distribution and determinants of health-related conditions in the population. As such, it is concerned with issues such as the total number of cases of a specific disorder in the population (prevalence) and the number of new cases that arise within a given time frame (incidence). These data are most often derived from cross-sectional surveys, which have become increasingly sophisticated over four "generations" of epidemiological research, and now consist of nation-wide studies involving interviews with thousands of randomly-selected individuals. In addition to counting individual cases, epidemiology is concerned with quantifying the degree to which certain factors may predispose people toward certain disorders, while others may be protective. These effects are captured with statistics such as the relative risk and the odds ratio. There are specific research designs that are used to gather these data, including case-control and cohort studies. In designing and evaluating such studies, it is important to be aware of a variety of biases that can distort the results. These include the fact that those who volunteer to be in a study are different in systematic ways from those who do not enter studies; that those who are more chronic are likely to be over-sampled compared to people who remit quickly; and that people drawn from certain settings, such as the workplace, are not representative of the population in general. Finally, epidemiology attempts to quantify the risk of adverse outcomes associated with disorders, such as the risk of premature death.

17.1　Overview

When one of the authors gave a copy of his book *PDQ Epidemiology* (Streiner & Norman, 1996) to his mother, she said, "That's nice, dear, but what do you know about skin diseases?" The answer is "Nothing," but fortunately, despite this common misperception, epidemiology is not the study of the epidermis.[1] Rather, the term comes from the Greek: *epi*, meaning "among," and *demos*, meaning "people." Terms that are related to epidemiology are *epidemic* (the outbreak of a disease in a localized group of people) and *demography* (the study of vital and social conditions of a group). These other terms begin to tell us what epidemiology is about – the study of the distribution and determinants of health-related conditions in the population.

　　Epidemiology has a long tradition, dating back to the middle of the seventeenth century, when John Graunt, who was a haberdasher, published the *Natural and Political Observations Made upon the Bills of Mortality* (Graunt, 1662/1939). Graunt gathered "Bills of Mortality"

---

[1] The confabulation of epidemiology with epidermis is not isolated; the other author (JC) was once asked about his vocation by an overly inquisitive cab driver. When the driver was told "psychiatric epidemiologist," he replied, after a pause, "… so, the study of the effect of mental problems on skin disease?" At the present time, the field of psychiatric dermatology is still in its infancy.

(which we would now call death records) from parishes in and around London in order to determine factors that affected when and why people died. He discovered that more boys were born than girls; that while male deaths exceeded female ones, men had less morbidity while they were alive than women; that one third of children died before the age of 5; that the number of deaths increased in the autumn; and that various diseases followed different temporal trajectories: death rates from rickets and "a stopping of the stomach" increased over time, while gout stayed the same, and "the stones" tended to decrease over the years. These findings do not appear surprising today (although some of the diseases may), but in one way they were revolutionary: for the first time, data about individuals were combined in order to draw broad conclusions, and general laws could be deduced from the patterns of death.

About 2 centuries later, there was an outbreak of cholera in London. At that time, drinking water was delivered by private companies, which drew it from the Thames River. John Snow, a local physician, drew a map of the city, showing where each person had resided before dying of the disease. The deaths were clustered in an area supplied by the Southwark and Vauxhall Company. However, there was a reduction in cholera deaths from drinking water supplied by the Lambeth Company after the company had relocated its pipes to a less polluted section of the river. He confirmed his hypothesis that drinking water was the culprit by famously removing the handle of the Broad Street pump (which still stands in central London) and noting a drop in the death rate (Snow, 1855/1936).

Around the same time, mental health epidemiology was taking its first, faltering steps. European psychiatry of that era was dominated by a biological perspective, spurred by the discoveries that "general paresis of the insane" (tertiary syphilis) was caused by a spirochete and "pellagra psychosis" by a deficiency of nicotinic acid in the diet, leading to the hope that a physical cause could be found for all mental disorders. However, in the United States, the dominant perspective was a psychosocial paradigm, looking at society and the family as the source of the pathology (Klerman, 1990). As Grob (1985) has pointed out, nearly all of the psychiatrists in the United States in the nineteenth century were both hospital superintendents and Protestants, who believed that gathering data would uncover the laws underlying disease, including mental illness, and that inductive science would validate their religious beliefs. One of the most prominent of the superintendents was Edward Jarvis, who found that the further people lived from psychiatric hospitals, the less they used them. This led him to argue against large, centralized hospitals, and in favor of small, geographically distributed ones (Jarvis, 1850). In 1854, Massachusetts established a Commission of Lunacy, which was headed by Jarvis, to determine the number of mentally ill patients in hospitals. His report (Jarvis, 1855/1971) pointed to the role of stress and social factors such as poverty, rapid social change, and urban anomie as key elements. To a large degree, the report was limited by the absence of a reliable diagnostic schema, a problem that would persist until the mid-1960s. Further, despite its length (over 200 pages), he did not use its census-like statistics in an epidemiological manner, and many of his conclusions were independent of the data (Grob). For example, the religious beliefs of Jarvis (and nearly all other superintendents of the time) led them to extol the virtues of farm and small-town life, and to view the growth of large cities with some degree of alarm. Thus, the Commission on Lunacy was convinced that increasing urbanization would result in a rising incidence of insanity, a conclusion reached in the report despite their own data which showed no such trend. Interestingly, the advances in mental health epidemiology between the 1850s and the 1920s came not from psychiatry, but from the social sciences. The

census of 1840 tried, unsuccessfully, to count the insane for the first time. However, it was severely compromised by the racial bias of the enumerators, who overstated the number of "insane" and "idiotic" free Blacks in the Northern states; even towns that were all White and psychiatric hospitals that did not admit Blacks were reported to have high numbers of them (Maultsby, 1982). Over the next 30 years, Jarvis worked with the superintendent of the census, Francis Walker, to improve data collection. The tenth census, in 1880, resulted in 25 volumes of findings, including one by Frederick H. Wines on "dependency," a term that included the mentally ill, the retarded, and criminals (U.S. Bureau of the Census, 1888). In keeping with the established beliefs of the time, the increase in "dependency" was related to organized society. There were special censuses in 1904 and 1910 that focused on the mentally ill but, as with the previous enumerations, they were severely hampered by the lack of a reliable and valid nosological framework.

From the turn of the century until the end of World War II, psychiatric epidemiology continued to be dominated by social scientists (Grob, 1985). Psychiatry itself was divided into two opposing camps, which still exist in various guises. The American Medico-Psychological Association (the forerunner of the American Psychiatric Association) tried to devise a uniform system of diagnostic categories that would be used in all hospitals. However, Adolph Meyer, who can be considered one of the founders of American psychiatry, and the chair at Johns Hopkins, resisted "one-word diagnoses" and the attempt of statistics to solve psychiatric and social problems. Ironically, the last resident he trained was Alexander Leighton, who is arguably one of the leading figures in the development of modern psychiatric epidemiology.

According to Klerman (1990) and Weissman (1995), the second generation of mental health epidemiology entered its "golden age," in the era after World War II, with the notable examples of the Midtown Manhattan Study (Srole, Langner, Michael, Opler, Rennie, & Leighton, 1962) in New York and the Stirling County study in Eastern Canada (Leighton, 1959). These studies featured large, representative samples of the general population, high response rates, and measures of overall impairment, rather than the unreliable, psychoanalytically based diagnoses of *DSM-I* (American Psychiatric Association, 1952). Again, the studies highlighted the causal role of social factors in the genesis of mental disorders, reflecting what Srole and Fischer (1980) called the "Mental Paradise Lost" doctrine: that "mental health in the population at large has long been deteriorating, and at an accelerating tempo during the modern era" because of urbanization (p. 209).

The third generation of research, such as the Epidemiologic Catchment Area (ECA) study (Regier et al., 1984), was marked by large, community-based samples; the use of structured interviews administered by lay interviewers; and the more reliable diagnoses found in the Research Diagnostic Criteria (Spitzer, Endicott, & Robins, 1978) or later editions of *DSM*. The fourth generation, in which we are now, has built on the methodological advances of the previous generation. However, rather than sampling from a limited number of communities (the ECA, for example, was conducted in five cities in the United States), representative samples were drawn from the entire country, using sophisticated, multistage sampling techniques to ensure representativeness. Exemplars of this generation are the National Comborbidity Survey in the United States (Kessler, 1994) and the Canadian Community Health Survey, Cycle 1.2 (CCHS; Gravel & Béland, 2005). Weissman (1995) believes that the fifth generation of mental health epidemiology will focus on one group generally excluded in the previous

generations: children.[2] There were a number of valid reasons for this omission, including legal (e.g., varying definitions from one jurisdiction to another regarding the age at which a child could consent to be in a research study), nosological (definitions of diagnostic criteria for childhood disorders are still somewhat in a state of flux), and methodological (the paucity of well-standardized, age-appropriate structured interviews). Now that many of these problems have been resolved, we are starting to see epidemiological studies of children, but none in North America that meet the criteria for fourth generational studies in adults.

In order to be able to understand the results of epidemiological studies, it is necessary to learn some terminology of epidemiology. In the next section, we will introduce some of the basic concepts and, following that, some other terms that will allow you to sound more like a maven.

17.2 Basic Competencies

17.2.1 Research Designs Used in Epidemiology

Cross-sectional surveys. The studies we have described so far are *surveys*, in which information about the disorder, and possible contributing and protective factors, is gathered at the same time. If this is done just once, as with the CCHS 1.2 (Gravel & Béland, 2005), it is called a *cross-sectional survey*, because it looks at the population at one slice in time. In light of the amount of data that is gathered, it is a relatively inexpensive type of study (although the emphasis is on the term "relatively"). The major drawback is that, because information about the outcome (diagnosis) and putative causes is gathered simultaneously, it is impossible to definitively establish causation. People are notoriously inaccurate regarding when symptoms first began, or when other events occurred (Streiner & Norman, 2008). This is particularly true in psychiatric epidemiology, where the onset of a disorder is often very slow and insidious, so that it is difficult to say when it actually began. For example, early theories about the etiology of autism implicated "refrigerator" mothers, who were emotionally frigid (e.g., Bettelheim, 1967; Kanner, 1943, 1949). Later studies showed a strong genetic basis for autism (Folstein & Rutter, 1977), implying that the coldness may be a reaction to having an emotionally nonresponsive child, not the cause. This illustrates the difficulty in being able to say with any assurance that cause X preceded disorder Y based on data gathered at one time point.

Longitudinal surveys. The logical solution is a *longitudinal survey*, in which the same people are interviewed a number of years later, as was done in both the Stirling County (Leighton, 1959) and the Midtown Manhattan (Srole et al., 1962) studies. Its advantage is the ability to disentangle cause and effect for some outcomes, but at the expense of an increase in cost, and the loss of participants over time, due to deaths, moves, refusals, and so forth. For example, in the National Longitudinal Study of Children and Youth, based in Canada (Willms, 2002), only about 62% of respondents were available for follow-up 10 years later at wave 6. Not only does this affect the sample size (and hence the power) at later times, but it also raises the specter of differential attrition: that those who drop out are different in some systematic way from those who do not, possibly biasing the results. Another problem with longitudinal surveys, especially those that span many decades, is that the field may change quite fundamentally within that

---

[2] We use the term "generally" because although it is true in the main, that children have not been the focus of most community studies of mental disorder, notably exceptions to exist (see Boyle et al., 1987).

time period, so that constructs, such as personality or depression, and the ways in which we measure them, may change, making it problematic to reconcile "old" forms of assessment with "new" ways of thinking. Early surveys on the development of children of the great depression offer one such example (see for example, Clausen, 1993). The strength of some of these surveys was that they followed the same group of children from childhood, through adolescence, into adulthood, spanning several decades. One of the central constructs, however, was personality, which was assessed at baseline using the Rorschach. It is extremely difficult to use these data to understand personality development from childhood to adulthood given the dubious validity, not to mention reliability, of the ink blot test.

Ecological surveys. In some situations, we do not have data at the individual person level, and must rely on aggregated data, gathered from entire regions. This type of design, called an *ecological survey*, is widely used in fields such as oncology and cardiology, linking countries with a high dietary fat intake to a high incidence of disorders such as breast cancer and coronary artery disease. An example in the mental health field is a series of studies by Sakinofsky (Sakinofsky & Roberts, 1987). In one example, for instance, it was found that Canadian provinces with high suicide rates also had high rates of alcohol sales and deaths from cirrhosis of the liver or other alcohol-related liver diseases, pointing to a link between suicide and alcoholism. The major advantage of ecological surveys is that they are very inexpensive and can be done quickly, because they rely on data that are usually readily available through public records. But, there are also a number of problems. First, while we may know how many people in each region were exposed to the risk factor (in this case, alcohol) and how many had the outcome (suicides), we do not know how many exposed individuals had the outcome. That is, it may not be the drinkers who are committing suicide; alcohol consumption may be a marker for some other variable, such as poverty, that is the causative agent, so that some people may drink, but it is different people in the same region who take their lives. This is known as the *ecological fallacy*. The second problem is that even if the correlation is between the correct variables, such *ecological correlations* are usually higher – and often much higher – than the correlation that would be found on an individual person level.

Surveys are used most often when we are interested in a broad range of outcomes, such as counting the number of people with various psychiatric diagnoses. There are times, though, when we want to focus on a specific outcome, such as depression, suicidal ideation, or adaptation following a significant loss. Because these conditions are relatively rare, it is more efficient to specifically sample these cases, rather than to survey the general population. For example, we may want to determine if people who have made a life-threatening suicidal attempt are more likely to have suffered the loss of a parent early in life than have people who have not attempted suicide (e.g., Adam, Lohrenz, Harper, & Streiner, 1982). To simplify matters, let us assume we will classify people into two groups: those who have attempted suicide and those who have not. Similarly, we will dichotomize loss into present (one or both parents died before the person was 15) or absent. This will result in a 2 × 2 table: suicidal with early loss, suicidal without loss, non-suicidal with loss, and non-suicidal without loss, and we will count the number of people in our sample who fall into each of the four cells.

Case-control studies. There are two ways we can go about doing our study. One way is called a *case-control* study. We begin by finding people who have a history of suicidal attempts (cases) and a group of people who do not (controls), and determine how many in each group suffered parental loss. This is not a particularly powerful design for determining causality, but may be the only possibility when the prevalence of an outcome is extremely small. The major challenge in this design lies in choosing the correct control, or comparison, group. Cases and controls

must be matched for other variables that may affect the outcome, such as age or gender. If the groups differ with respect to these factors, then group differences may be due to them rather than to parental loss. For example, we know that women attempt suicide more often than men (although men actually commit suicide at a higher rate; Gibbs, Beautrais, & Fergusson, 2005). If for some reason more men experienced early loss than women, then this could lead to the paradoxical result that those with loss attempt suicide less often. Variables that are related to both the outcome and the grouping variable are called *confounders*, and interfere with our ability to establish causality.

On the other hand, we do not want to match on other variables that may be related to the causal factor. For example, we may be tempted to match the groups on the basis of depression, because this is associated with suicidal risk. However, because parental loss may result in depression, making the groups equivalent on the basis of this variable may conceivably wipe out real group differences in terms of the outcome; this is an example of *over-matching*. In these two examples, depression differs from age or gender in that it is part of a possible *causal chain*, leading from loss to depression to suicidal attempt; whereas age and gender are not part of the chain. Determining whether a variable should be controlled for (matched) or not is not an easy decision; it must be made on the basis of theory or your knowledge of the field. One major problem with case-control studies is that the groups may differ with respect to other confounding variables that we are not aware of.

Cohort studies. The second way of conducting the study is called a *cohort* design. Instead of finding cases and controls, and looking backwards in time to see how many had or did not have the probable cause, we sample people on the basis of the putative cause and follow them forward in time. In this study, we would locate one group (or cohort) of people who had lost a parent by the age of 15 and a second group of people who had not lost a parent, and then look at the proportion of each group who had attempted suicide by the age of, say, 50. However, to say that we "follow" them does not necessarily mean that we have to sit around and wait for 35 years (although some studies, such as of the survivors of Hiroshima or the offspring of schizophrenic parents, involve just that). If suitable records exist, we can locate in the present people who have lost a parent 35 years ago, and use other records or self-report to determine how many have made serious suicide attempts. Cohort studies are often superior to case-control ones, because they do away with the need to recall events, and all the biases that accompany it. By the same token, though, cohort studies also require careful consideration of the variables that should be used to match the two cohorts; and are susceptible to biases due to the fact that the groups may differ on variables we cannot control for.

17.2.2 Biases Affecting Studies

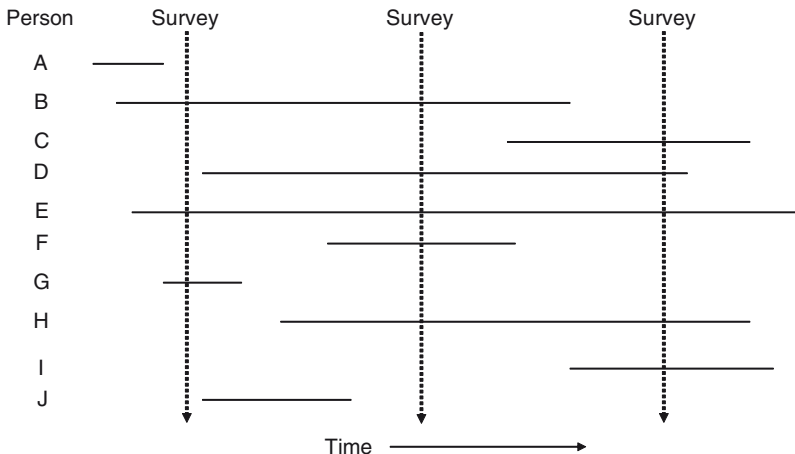
All of the designs mentioned previously are susceptible to various biases that affect who gets into a study and, consequently, what conclusions are drawn from it. What follows is far from a comprehensive enumeration of all possible biases. Sackett (1979) lists 35 of them, and with little imagination, many more can be proposed. The biases mentioned here are the major ones that affect the types of studies most often used in epidemiological research.

Volunteer bias. Ideally, surveys, case-control studies, and cohort studies would enroll a random selection of people drawn from the populations of interest. However, ethical considerations require that people consent to being in a study, and not all do. The question, then, is whether

those who do volunteer are representative of the larger group, or if they differ in some ways that may affect the outcome. The literature is not promising; volunteers are different from refusers. In the National Diet-Heart Study (American Heart Association, 1980), volunteers were more likely than nonvolunteers to be nonsmokers, more concerned about health matters, more highly educated, employed in skilled and professional jobs, Protestant or Jewish rather than Catholic, living in a household with children, and active in community affairs.

Healthy worker bias. Many studies sample people from the workforce for obvious reasons. They are easier to find and recruit than people in general; we know where to find them, companies maintain computerized lists of employees, and mass mailings can be sent out through internal e-mailings. However, those who are working are not representative of the population as a whole; by definition, they are healthier. The entire adult population consists of those who are working and those who are unable to work because of disabilities and other health-related problems. Consequently, as a group, the health of the general population must be worse. The problem is exacerbated when the workers must pass a physical examination, such as those in the military, police officers, fire fighters, or garbage collectors. Seltzer and Jablon (1974), for example, found a lower mortality rate among those discharged from the Army than among people of similar age and gender in the population at large, even 23 years after discharge. (This may also be due to the fact that if one can survive a steady diet of Army food, one can survive anything.)

Incidence–prevalence (Neyman) bias. When we do a cross-sectional survey, two groups of people will be systematically under-represented: those who die from the disorder and those in whom the condition resolves quickly. For example, a survey to measure the prevalence of suicidal ideation in the general population will naturally miss all those who successfully acted on their thoughts. Similarly, a survey looking at point prevalence will disproportionately sample those whose conditions are more chronic. This is seen in ❯ Fig. 17.1, which shows the duration of illness for ten patients. Although the length of illness is long for only four of them (B, D, E, and H), at any of the three survey times, anywhere from 50% to 80% of those captured will be

▣ **Fig. 17.1**
Illustration of the incidence–prevalence bias


more chronic cases. For many years, the prognosis for schizophrenia seemed extremely pessimistic, because the studies did not include those for whom only a short hospitalization was necessary. Similarly, a cross-sectional survey of women receiving Aid for Families with Dependent Children (AFDC) found that 93% had been on welfare for 3 or more years, and 65% had been getting it for more than 7 years, reinforcing the beliefs of some that AFDC leads to chronic dependency. However, when women were followed longitudinally from the time they first applied for AFDC (thus avoiding the incidence–prevalence bias), the numbers dropped to 70% for 3 or more years, and only 30% who received it for more than 7 years (Duncan, Hill, & Hoffman, 1988).

17.2.3 What Is a Case?

We have been using the term "case," and much of epidemiology involves the counting of them (i.e., people who have one or more designated conditions) over time or, as in Snow's study of cholera, over a geographic area. But, who is considered to be a case? For some disorders, the definition is fairly straightforward – a person who clearly meets all of the criteria. Even in medicine, though, the number of conditions that can be clearly and unambiguously defined is relatively small. Especially in the general population, most disorders exist along a continuum. Cancer, for example, is not a present/absent phenomenon; a person may have cellular abnormalities and growths (dysplasias) that may or may not progress to become cancerous. It is a definitional issue to decide when the dysplasias become large enough to be considered a cancer. This is even more true for psychological disturbances, in which it is more accurate to ask, "How depressed is this person," rather than, "Is the person depressed or not?" In psychiatry, "caseness" is usually defined as meeting some set of criteria. In the United States, these criteria are spelled out in the *Diagnostic and Statistical Manual*, the latest version of which is *DSM-IV-TR* (American Psychiatric Association, 2000); while psychiatrists in Europe use the tenth version of the *International Classification of Diseases and Related Health Problems* (ICD-10; World Health Organization, 1992); some countries, such as Canada, confusingly, use both systems.

Bear in mind, though, that many aspects of the definitions found in *DSM* and *ICD* are arbitrary. For example, to meet the *DSM* criteria for generalized anxiety disorder (GAD), the person has to have at least three of six criteria (e.g., easy fatigueability, irritability) for at least 6 months. But why 6 months as opposed to, say, 3 or 12 months; and why three symptoms instead of two or four? We can also argue that a person who meets all six criteria has more GAD, or a more severe type of GAD, than one who meets only three of them. Taking a disorder that exists on a continuum and dichotomizing it can result in two types of errors: false positives (those who meet the criteria, but may not suffer from a clinical disorder) and false negatives (those who suffer from GAD, but do not meet all of the criteria).

17.2.4 Finding Cases

Accepting these problems in defining a case, the next problem is finding them. Perhaps, the easiest way is to use registries of in- and out-patients in general and psychiatric hospitals. In fact, this was the method used in the earliest surveys, such as those by Jarvis (1855/1971) in the United States and Koller (1895) in Switzerland. However, there are many problems with this approach. First, receiving services is highly dependent on their availability. For example,

Joanette, Lawson, Eastabrook, and Krupa (2005) found that the probability of hospitalization for schizophrenic patients was directly related to the availability of beds, and fewer than half of those with a major depressive disorder receive any form of help (Parikh, Lesage, Kennedy, & Goering, 1999). In the United States, a large proportion of people do not have health-care insurance, and even for those who do, many insurance plans have only limited coverage for psychiatric disorders. The result of these, and other factors, is that registries will not capture a significant number of people with mental health problems. The other side of the coin is that many who do see a mental health professional do not have a diagnosable disorder, at least not one of the major disorders typically measured in epidemiological surveys (Lin, Goering, Lesage, & Streiner, 1997).

If the determinants of contact with the mental health-care system were randomly distributed in the population, then the result would "only" be an undercounting of the number of cases. However, they are far from random. Who seeks help; who is admitted as opposed to being seen on an out-patient basis; and who actually gets to see a therapist is dependent on a host of demographic and social factors, such as gender, socioeconomic status (SES), marital status, rural versus urban residency, age, willingness to admit to psychological problems, and so forth. Consequently, samples drawn from patient lists would be extremely biased with respect to the general population.

The case-finding procedure used in almost all studies since the 1950s involves random samples drawn from the population at large. The original surveys, such as the Midtown Manhattan and the Stirling County studies mentioned previously, used mental health professionals, such as psychiatrists and clinical psychologists, to conduct face-to-face interviews with those selected to be participants. This was required because the relatively objective and reliable criteria used in the latest versions of *DSM* and *ICD* did not exist then, necessitating reliance on expert opinion to make a diagnosis. Paying professionals to conduct interviews, though, is an extremely expensive proposition, so later surveys have relied on structured interviews such as the Diagnostic Interview Schedule (DIS; Robins, Helzer, Croughan, & Ratcliff, 1981) and the Composite International Diagnostic Interview (CIDI; Robins et al., 1988) administered by trained lay interviewers, either in person or over the telephone.

Structured interviews consist of a series of questions that are read to the participant. In most diagnostic schedules, various modules assess different disorders. In order to save time and reduce the burden on the respondent, there are often two or three screening questions (probes) in each module. If the person answers negatively to them regarding the presence or severity of symptoms, then that module is skipped; otherwise, the entire module is administered. The structured format is used to increase the inter-rater reliability of the questionnaire, and this indeed seems to work (e.g., Andrews & Peters, 1998). However, some people have argued that their inflexibility, combined with the lack of clinical experience of the interviewers, results in the under-diagnosis of some disorders (e.g., Brugha et al., 1999). In the case of the DIS and the CIDI, substantial differences were obtained when Kessler and his colleagues changed the format for asking probes for the diagnostic modules. In the DIS, respondents were asked "entry" or "probe" questions serially for each disorder. Depending on the response, Yes or No, a series of follow-up questions were asked, related to the disorder being assessed (e.g., depression). Once the module was complete, the interviewer moved on to the next disorder module. It is easy to imagine that subjects might become "test-wise" and learn to say No instead of Yes in order to end the interview more quickly; the consequence of this are much lower prevalences of disorders, especially comorbid ones. Kessler et al. reasoned that if all the entry questions for the disorder modules were asked first, this would reduce the likelihood of this

kind of response bias (interviews could then go back and ask follow-up questions for each module as before, based on the initial affirmative responses). The result of this modification, among other things, was to produce a lifetime prevalence of any disorder in the first NCS study close to 50%, a figure more than double that of earlier work which used the old format (Kessler et al., 1994). However, while it is tempting to conclude that the modification to the presentation of questions resulted in a more "accurate" estimate of prevalence, other concerns (over-inclusiveness of diagnostic criteria, high sensitivity, and low specificity) remain a problem with these kind of structured interviews. In short, minimizing response bias does not address more fundamental problems with validity – can half of the population really have suffered from a clinically significant mental disorder at some point during their lifetimes?

17.2.5 Counting Cases: Incidence and Prevalence

Now that we have defined and found cases, we can move on to the meat of epidemiology, which is counting cases. Depending on the type of information we want, we can count either *incident cases* or *prevalent cases*.

- *Prevalence* refers to the number of people who have the condition at any given time.
- *Incidence* refers to the number of new cases within a given time frame.

In order to set the scene, imagine that we want to determine the number of cases of a disorder first described by Norman and Streiner (2003), but which, for some unexplainable reason, has not yet made its appearance in *DSM*: photonumerophobia, or the fear that one's fear of numbers will come to light. We randomly sample people in a small community of 100 individuals, determining whether people meet the criteria for this dread disorder currently or at any time in the past and, if the latter, when the disorder began and ended. ⊙ Figure 17.2 shows the time of onset and, for some people, remission of this disorder for the 12 people who are or were cases. Only persons D and G developed the disorder during the sampling window, and would be deemed to be incident cases. Thus, the incidence of photonumerophobia is:

$$Incidence = \frac{Number\ of\ New\ Cases}{Number\ at\ Risk} = \frac{2}{100} = 0.02.$$

On the other hand, A, B, D, F, G, I, K, and L have the disorder during this period and would be prevalent cases. Note that all of the incident cases are also prevalent ones, but not vice versa. The prevalence is therefore:

$$Prevalence = \frac{Total\ Number\ of\ Cases}{Number\ at\ Risk} = \frac{8}{100} = 0.08.$$

⊙ Figure 17.2 raises two questions: How wide should the window be? And should person G be considered an incident case, because she had the disorder previously, which went into remission before the survey was done? The answers are, "It all depends," and "It all depends." Part of the ambiguity stems from the fact that the methods and terminology of epidemiology come from the study of infectious diseases, and predate the time that most of them were treatable. For the most part, the onset of these was relatively rapid and easily identifiable; and once a person contracted the disorder, he or she either died (e.g., cholera), developed an immunity against further

⬛ **Fig. 17.2**
Onset and duration of photonumerophobia among 12 people
infections (smallpox or measles), or had it forever (tuberculosis). Thus, it made sense to keep the window fairly narrow and to not worry about people who had had the disorder previously.

Most psychological disorders, though, do not adhere to either of these properties. First, with the exception of a few diagnoses, such as panic disorder and post-traumatic stress disorder, the onset of conditions, such as depression, schizophrenia, or GAD, is slow and insidious. People may be able to say their problem began or ended some time within a given year, for example, but cannot be more precise than this. Second, some disorders may disappear or be successfully treated, only to reappear a number of months or even years later. For these reasons, we commonly use a 6- or 12-month window, and would measure, for example, the *6-month prevalence* of a disorder; that is, the proportion of people who have had the disorder within the past half year. Another index that is frequently used is *lifetime prevalence*, or the proportion of people who have had the disorder at any time in their lives. The problem with these indices, especially lifetime prevalence, is that they are relatively insensitive to change. Even when new treatments emerge that can successfully treat specific disorders, the lifetime prevalence will not change until a significant proportion of those who previously had had the disorder die off (Streiner, Patten, Anthony, & Cairney, in press).

The second issue, whether to count as incident cases those who have had the disorder previously, is a more difficult problem to resolve. In a large measure, the answer depends on our underlying model of a disorder. For example, if we believe that schizophrenia, like rheumatoid arthritis or multiple sclerosis, is a life-long illness, interrupted by periods of relatively better functioning, then we would answer in the negative; any current diagnosable disorder is simply a worsening of a chronic, underlying condition. On the other hand, if we believe that the affective or anxiety disorders can be successfully treated, then whether or not a person has had it previously is irrelevant insofar as counting the current episode as a new one is concerned. Often,

the researcher may create decision rules, along the lines of, "The current disorder is considered to be a continuation of a previous episode if that episode ended less than XX months ago; and a new episode if the previous one ended more than XX months ago." Needless to say, the length of this period is somewhat arbitrary, although it may be based on studies of the natural history of the disorder. There is a danger, though, that these definitions, arbitrary as they are, may influence how the disorders are conceptualized. If we say that any reemergence of symptoms after 6 months is a new episode, then we may not uncover evidence of long-term consequences of a disorder. Conversely, if one, brief episode means that a person is placed in the lifetime prevalent category, then we may become unduly pessimistic about the prognosis of a disorder.

Because researchers differ among themselves regarding the width of the window and the definition of prevalent cases, readers have to be very careful in comparing the results of various studies. It may look as if estimates vary widely from one study to the other, but this may be caused by some studies using 6-month prevalence and others using 12-month, or even lifetime, prevalence rates with differing criteria of what constitutes separate episodes (e.g., Anderson, Freedland, Clouse, & Lustman, 2001).

If we use the same time window, then incidence rates and prevalence rates are related to each other. In particular,

$$Prevalence = Incidence \times Duration.$$

So, for example, if the 6-month incidence rate is 5/100,000 and the duration of the disorder is 5 months, then the 6-month prevalence rate is 25/100,000. Similarly, we can determine the duration of a disorder, as:

$$Duration = Prevalence/Incidence.$$

Incidence and prevalence rates are used for different purposes. Health-care planners, for instance, are more interested in the prevalence of a disorder, since this determines the need for clinical services. Researchers, on the other hand, are often more interested in incidence rates, as these give an indication of how disorders change over time or from one age group to another. A prime example of this can be found with the recent AIDS epidemic. Those who run hospitals, clinics, and manufacture anti-retroviral medications need to know for how many cases they must plan for the coming fiscal period (i.e., prevalence), and this keeps growing each year. Incidence data, though, show that the peak of the epidemic likely occurred around 1998 and has been declining since then, leading to hypotheses about the putative causes of the decrease.

17.2.6 Factors Affecting Incidence and Prevalence

Not only are we interested in how many people have a disorder, epidemiology concerns itself with factors that influence incidence and prevalence rates. Very roughly, we can divide these into *individual* and *group* factors. By individual factors, we mean attributes such as social support, the presence or absence of comorbid disorders, ego strength, and so forth, which vary from one person to the other. These are considered to be *predisposing* factors, which make a person more likely to have a disorder and *protective* factors, which make it less likely. For example, having one psychological condition, such as anxiety, increases the chances that a person will also suffer from another one, such as depression (Kessler et al., 1994). Conversely, social support is seen as a protector (or buffer), in that those who have more of it are less likely to develop depression in the face of stress (Aneshensel & Frerichs, 1982). Often, protective effects form complex

associations with other risk factors. So, in the example above, if stress were associated with depressive symptoms, but only for individuals who lack a supportive network of family and friends, then epidemiologists (and other scientists) would call this an interaction effect or an effect modification; this is illustrated in ❯ Fig. 17.3. Both factors need to be considered simultaneously, because the effect of one variable (stress) is contingent on the other social support.

The discussion above highlights the inherently multivariate nature of modern epidemiology. Mental disorders, like most chronic health problems, are not the result of one single causative factor, but rather a constellation of multiple risk and protective factors working together in complex ways. Multivariate risk analysis is a complex subject, quite beyond a single chapter such as this. Moreover, many other excellent works exist in this area that could be consulted (e.g., Aneshensel, 2002). It should at least be pointed out, however, that understanding "multiple" causes for single disorder is a complex issue, and a number of considerations need to be at the forefront of study design. First, the selection of possible putative risk and protective factors for a disorder must be derived systematically from one or more of the existing literature, clinical experience, and theory. Our particular bias is that a theory – biological, psychological, or social – should guide the selection of possible variables for study and analysis. Next, the specification of the nature of the association between the variable and the disorder must be made clear prior to the analysis. We have already identified at least three possible associations so far – risk factors, protective effects, and confounders – but other designations are also possible. For example, some variables are best described as *intervening* or *mediating* effects rather than confounders or effect modifiers. A variable is said to mediate the association between two other variables when, according to a given theory, the variable in question "explains" or "accounts for" the association itself. Poverty, stress, and depression could serve as an example. A popular theory in the sociology of mental health is that poverty or SES is associated with poorer mental health because individuals from low SES groups suffer disproportionately greater exposure to stress than individuals higher up the socioeconomic ladder (e.g., Turner, Wheaton, & Lloyd, 1995). In this example, stress is the mechanism (intervening or mediating effect) that explains why individuals from lower SES groups suffer higher rates of disorder and distress. Of course, other factors may also be operative. A variety of sophisticated

⬛ **Fig. 17.3**
Interaction among stress, social support, and depressive symptoms
statistical techniques exists for testing mediating and/or moderating associations such as linear regression analysis, path analysis, and structural equation modeling. However, these topics are beyond the scope of this chapter.

Another way of looking at factors that influence incidence and prevalence is to examine groups (usually called "cohorts" in epidemiology) of people who share common attributes. This is usually called *APC analysis*, which stands for Age-Period-Cohort. We know that some disorders, such as Alzheimer's Disease, are more prevalent among the elderly, and that the probability of the disorder increases with age (Ferri et al., 2005). Depression, on the other hand, peaks in the mid-1940s, and then decreases with age (Streiner, Cairney, & Veldhuizen, 2006). Needless to say, this is referred to as an *age effect*. Age effects are due to the physiological effects of aging on the body, or changes in a person's circumstances that accompany the aging process, such as losses of social supports through death, changes in the person's role due to retirement or the "empty nest," and so on. In contrast to this, period and cohort effects reflect the influence of external factors on groups of people.

Cohort effects are often due to historical events that occurred at specific times. For example, people born in the 1920s were subjected to (at least) two major influences – growing up during the Depression and then living through World War II. These could affect the people in either negative or positive ways. It has been postulated that the severe famines that periodically affect sub-Saharan Africa result in protein-calorie malnutrition, and that this adversely affects cognitive development in infants (Konczacki, 1972). Conversely, having survived the Depression may have led to greater psychological resilience in the face of later stresses (Elder, 1974). Thus, a specific age cohort (i.e., people born around the same time) was exposed to factors early in their lives that have a persisting influence on their health over time (Yang, 2007).

Period effects are similar to cohort effects in that they are external to the individual. However, they affect people of all ages. A recent example is Hurricane Katrina; the trauma due to the death of family members, loss of one's home, forced relocation to another city, loss of one's job, and so forth affected everyone living in New Orleans at the time, irrespective of age. As with cohort effects, it is assumed that the effects are prolonged and have mainly negative consequences on a person's physical and/or mental health. Some period effects, though, may be positive: the introduction of anti-psychotic and anti-depressant medications in the 1950s and 1960s would have benefited people of all ages who suffer from these disorders.

Age effects are due to a person's chronological age; *cohort effects* affect people who were born around the same time; and *period effects* involve people of all ages who have lived through some change that affects their lives.

These distinctions among age, period, and cohort effects sound fairly straightforward, but they are difficult to disentangle in reality. To begin with, they are not independent from one another, because:

$$Cohort = Period - Age,$$

that is, given the calendar year (period) and the person's age, one can determine the year of birth (the cohort). Further, the results of any one study are often open to multiple interpretations. For example, ❯ Fig. 17.4 shows the 1-year prevalence of any mood disorder for people 55 years of age and older (Streiner et al., 2006). Is the overall decrease in prevalence with age due to the fact that older people are less likely to be depressed than younger ones (an age effect); or that those who were 75+ in 2002 (when the survey was conducted) were the people who were made resilient by living through the Depression (a cohort effect)? There is no way we can

Lifetime prevalence of any psychological disorder
differentiate between these explanations with just these data. What would be needed is another survey, done 10–20 years earlier, so that those who were 75+ when it was conducted are in a different birth cohort.

17.2.7 Types of Risks

We have been using the term "risk factor" without adequately defining it, and indeed, although the concept seems simple at first glance, it is actually quite difficult to define. In his *Dictionary of Epidemiology*, Last (2001) defines a risk factor as

▶ an aspect of personal behavior or lifestyle, an environmental exposure, or an inborn or inherited characteristic which on the basis of epidemiological evidence is known to be associated with health-related condition(s) considered important to prevent. (p. 160)

Note, though, that this definition talks about the "association" of a risk factor with an outcome, and says nothing about causality. For this reason, some authors (e.g., Burt, 2001) differentiate among various types of risk. A *risk determinant* is a factor that is causally related to the outcome; for example, exposure to a traumatic event, which, in some people, leads to post-traumatic stress disorder. A *risk marker* is some attribute or exposure that is related to a higher prevalence of the outcome, but may not be causally related to it. It has been known for a long time that the prevalence of schizophrenia is inversely related to SES (e.g., Hudson, 2005). However, low SES may not be the cause of schizophrenia, but may either be a marker for stresses in the person's life which trigger the psychotic episode or the result of an inability to cope, resulting in a decline in social status. Finally, a *modifiable risk factor* is a determinant of an outcome that can be ameliorated, reducing the probability of the disorder. For example, children from low SES backgrounds have less exposure to books before kindergarten, resulting in poorer reading skills which persist throughout their school experience and may lead to them not completing high school. The Head Start program, which was created in 1965, tried to

remedy this through early interventions (Children's Defense Fund, 1992), although its effects are still being debated (e.g., Barnett, 1992). Bear in mind, though, that these terms are not universally used, and it is often difficult to determine whether an author is referring to a risk factor (modifiable or not) or a risk marker.

17.2.8 Quantifying Risk: Relative Risk and Relative Odds

Data about incidence and prevalence tell us how many people have a given disorder at any given time. ➤ Figure 17.4, for example, shows us that there is a higher prevalence of depression among those who are between 55 and 59 years of age than those who are over 75; and from this, we can infer that the risk of depression decreases with age. Our next job is to quantify those risks. Two different indices are used, *relative risk* (RR) and *relative odds* or the *odds ratio* (OR), depending on the type of study that was used. We will change the example somewhat, and ask whether depressed men or women are at a higher risk for committing suicide.

If we try to answer this with a cohort study, we would start with one group of depressed females and another of depressed males (gender, in this case, is likely a *risk marker*), follow them for a period of time, and count the number of suicides in each cohort. For example, Mattisson, Bogren, Horstmann, Munk-Jörgensen, and Nettelbladt (2007) began with a group of 1,823 men and 1,740 women, and followed them from 1947 until 1997. Of the 116 men and 228 women who had their first episode of depression during this interval, 17 committed suicide. The results are shown in ➤ Table 17.1. Note that, by convention, the risk factor (gender) defines the rows and the outcome (suicide) is shown in the columns. For males, the risk of suicide is 12/116 = 0.1034; and for females, it is 5/228 = 0.0219. Therefore, the RR is the ratio of the two risks, or 0.1034/0.0219 = 4.72. In other words, men are at nearly five times the risk for committing suicide as are women. If we label the four cells A, B, C, D in the usual manner, then:

$$RR = \frac{Risk\ in\ Group\ 1}{Risk\ in\ Group\ 2} = \frac{A/(A+B)}{C/(C+D)} = \frac{12/116}{5/228} = 4.72$$

Were we to do a case-control study, we would look for one sample of people who committed suicide, a matched group of people who had not, and then determine the number of males and females in each group. The results of such a study by Qin, Mortensen, and Agerbo (2000) are presented in ➤ Table 17.2. They searched a database for people who committed suicide (cases) and then assembled a much larger group of those who did not (controls). Even though

◘ **Table 17.1**

Results from a cohort study showing the relationship between gender and suicide[a]

Risk factor	Outcome		Total
	Suicide	Non-suicide	
Male	12	104	116
Female	5	223	228
Total	17	327	344

[a]Data taken from Mattisson et al. (2007).

🔲 **Table 17.2**

Results from a case-control study showing the relationship between gender and suicide[a]

Risk factor	Outcome		Total
	Suicide	Non-suicide	
Male	541	39,890	40,431
Female	270	39,981	40,251
Total	811	79,871	80,682

[a]Data taken from Qin et al. (2000).

the layout of the table is the same as for ⊙ Table 17.1, we cannot calculate the RR as we did previously. The reason is that in a cohort study, the ratios of cell A to cell B and of cell C to cell D are determined by the risk factor. However, in a case-control study, these two ratios are determined by researchers, not by the effect of the risk factor. That is, the researchers can decide to recruit any number of controls – one for each case, five for each case, or, as in the Qin study, as many as they could find. So, rather than working out the proportions across the rows, we have to use the columns. In this case, though, we will not work with risks, but with *odds*; numbers much beloved by horse racing enthusiasts. A proportion, as we saw, has the number of those with the condition in the numerator, and the total of those with and without it in the denominator; for odds, the denominator is only those without the condition. So, the odds among those who committed suicide is 541/270, or 2.004:1 in favor of males. That is, among those who took their lives, slightly more than two thirds were men. Similarly, the odds among those who did not commit suicide was 39,890/39,981, or 1.000:1, reflecting an even division between men and women. The OR, then, is 2.004/1.000 = 2.004. Writing this out:

$$OR = \frac{A/C}{B/D} = \frac{AD}{BC} = \frac{541 \times 39,891}{39,890 \times 270} = 2.004.$$

If we calculated the RR instead of the OR, we would get 1.98. This illustrates two points. First, when the prevalence of a disorder is very low (say, under 5%), then the OR provides a fairly good estimate of the RR. Second, the OR is larger than the RR. Moreover, as the prevalence increases, the OR overestimates the RR to an increasing degree, making it a less accurate estimate of what we really want to know, which is the RR.

17.3 Advanced Competencies

17.3.1 Measuring Treatment Effectiveness

The outcomes of studies that look at interventions can be measured in one of two ways: as a continuous variable (e.g., scores on a scale) or dichotomously (improved/not improved). From a measurement perspective, it is usually better to measure phenomena on a continuum, because it is more powerful and results in less loss of information than splitting people into two (or more) groups (Streiner, 2002). However, clinicians often want to know the "bottom line" – what proportion of patients actually improved enough so that they can be considered cured or functional? Simply saying that the treated group improved by ten points on a scale does not

give enough information, because even with this amount of improvement, they may still be impaired; hence, both types of outcomes are often useful. In both cases, we usually represent the difference between groups by an *effect size* (ES).

In looking at a continuous outcome, it is common to express the difference between the groups as a *standardized mean difference*, which is also referred to as *Cohen's d* (Rosenthal, 1994):

$$d = \frac{M_T - M_C}{SD},$$

where M_T is the mean of the Treatment group, M_C the mean of the Control or Comparison group, and *SD* is the pooled standard deviation of both groups. For example, assume obsessive-compulsive disorder (OCD) patients are randomly assigned to receive either cognitive behavior therapy (CBT; the treatment group) or group psychotherapy (the comparison), and the outcome is their score on the Yale-Brown Obsessive-Compulsive Scale (Goodman et al., 1989). At the end of treatment, the CBT group has a mean of 10, the group therapy condition 13 (lower scores are better), and the pooled SD is 2.5. The standardized mean difference is therefore:

$$d = \frac{10 - 13}{2.5} = -1.2.$$

This is equivalent to a *z*-score, and indicates that the treatment group's mean is 1.2 SDs below the comparison group's mean. Is this good or bad? According to Cohen's (1992) criteria, an ES of 0.2 is considered to be small; that of 0.5 is moderate; and 0.8 is large. Consequently, this would be seen as a large difference between the two treatment conditions.

When the outcome is measured as a dichotomy, the outcome is expressed as a *relative benefit*, or RB. An RB is exactly the same as an RR, except for the second word. Because we are determining how much more likely patients in the treatment group are to improve compared to the comparison group, it would be somewhat strange to define this as a "risk," but the concept and the formula are the same. As with RR, a value of 1.0 indicates no difference between the groups; numbers over 1.0 show a benefit in favor of the treatment group; and less than 1.0 shows that the comparison group did better. Let us make up a fictitious example, again using OCD treated with CBT or group psychotherapy, but now we will classify the patients as either improved or not improved according to some criteria; the results are shown in ▸ Table 17.3. The relative benefit of CBT is:

◻ **Table 17.3**

Fictitious results of treating obsessive-compulsive disorder with either cognitive behavior therapy or group psychotherapy

Treatment	Outcome		Total	Proportion improved
	Improved	Not improved		
Cognitive behavior therapy	40	10	50	0.8
Group psychotherapy	25	25	50	0.5
Total	65	35	100	

$$RB = \frac{40/50}{25/50} = \frac{0.8}{0.5} = 1.60.$$

In other words, those in the CBT condition are 60% more likely to improve than those in the group therapy condition.

While this sounds very impressive, there is a large problem with RB. Let us assume that instead of 50 subjects per group there were actually 5,000; but the number of people who improved remained the same – 40 in the CBT condition and 25 in the group-treatment condition. The RB would be:

$$RB = \frac{40/5,000}{25/5,000} = \frac{0.008}{0.005} = 1.60.$$

Again, patients receiving CBT are 60% more likely to improve, but there is a major difference. In the previous example, 80% of CBT patients got better, and with an RB of 1.6, we would be strongly inclined to adopt this form of therapy for this disorder. In the second example, we have the same RB, but fewer than 1% of the patients improved with CBT, and we would be foolish to offer patients this form of treatment (or group psychotherapy, for that matter). Obviously, the RB is masking as much as it is telling us.

What we need, then, is some statistic that takes the actual *numbers* of improved patients in both groups into account, and that statistic is the *number needed to treat* (NNT; Laupacis, Sackett, & Roberts, 1988). We have to calculate it in steps. First, rather than taking the ratio of the benefit in each group, we take the *absolute difference* in the proportion who benefited. For the first example, it would be 0.8 − 0.5 = 0.3; and for the second, it is 0.008 − 0.005 = 0.003. The NNTs are then simply the reciprocals of these:

$$NNT_1 = \frac{1}{0.3} = 3.33 \quad NNT_2 = \frac{1}{0.003} = 333.3.$$

What this means is that, in the first example, four patients need to be treated with CBT in order for one to improve more than if treated with group therapy; and in the second example, 334 must be treated for one person to benefit more with CBT than group treatment. (When there is a fraction, we always round up in order to be more conservative.) Ideally, the NNT should be 1, but it never is for two reasons. First, not everyone in the treatment group derives benefit from the therapy; in the first example, only 80% did. Second, people in the comparison group also improve, even when the control condition is placebo. The NNTs therefore tell us (a) whether the intervention under study is better than the comparison or control condition and (b) the actual number of people who are expected to do better. Thus, RBs should *always* be accompanied by NNTs.

As a rough guide, most of the behavioral therapies for depression have NNTs in the range of 2–4 when compared against wait-list controls. On the other hand, preventative medical interventions, such as medication to prevent strokes or death from hypertension or heart attacks, have NNTs that are between 100 and 1,000.

17.3.2 Counting Negative Outcomes

Various psychiatric disorders result not only in increased suffering on the part of the patient, but also in an increased probability of premature death. There are a number of different

indices that are used to express this increased risk, depending on what aspect of the risk one is interested in.

Case-fatality rate. The case-fatality rate (CFR) is the proportion of people with a specific disorder who die because of it within a given time. That is, the 1-year CFR is:

$$CFR_{1Year} = \frac{Number\ of\ Deaths\ in\ a\ Year}{Number\ of\ People\ with\ the\ Disorder}.$$

Saha, Chant, and McGrath (2007) did a meta-analysis of 37 studies of mortality in schizophrenia, and found that the CFR was 95.4 per 100,000 population. This means that in every year, slightly under 1% of schizophrenics die, either because of the disorder or (in this case) partly because of the treatment. They hypothesized that the CFR has been increasing since the 1990s because of the introduction of the atypical antipsychotic medications, which treat the disorder, but also lead to significant increases in weight and the prevalence of Type II diabetes.

Proportional mortality rate. A difficulty with the CFR is that we do not always know what the denominator is. For example, to test Saha et al.'s (2007) hypothesis that the increased mortality rate is due to the parallel increase in the use of atypical antipsychotics, we would really need to know the number of patients with schizophrenia who are taking this class of drugs. Such data rarely exist at a nation-wide level, so we would have to do a study simply to get that number. We may be able to get funding to do this once, but it is impractical if we want these data on a regular basis, in order to look at trends over time. Data that do exist through the census and other national surveys are the total number of deaths in a year, and the number of deaths from a particular cause. We can use these to calculate the *proportional mortality rate* (PMR), which is the proportion of deaths due to a specific disorder:

$$PMR = \frac{Number\ of\ Deaths\ from\ a\ Particular\ Cause}{Total\ Number\ of\ Deaths}.$$

Thus, if we knew the total number of deaths among schizophrenic patients, and the number that are due to diabetes (and such data are available through various registries), we could determine if the proportion dying from this disorder has changed significantly since the atypicals were introduced. There is, though, one problem with the PMR. It may increase for two reasons: (1) there are, in fact, more deaths from this disorder or (2) there are fewer deaths due to other causes. An unfortunate fact of life is that over the long haul, the case fatality rate is 100% – everyone is going to die from something. As we get better at treating heart disease, cancer, infectious diseases, and so on, the PMRs for the other, chronic and untreatable disorders, such as Alzheimer's Disease or diabetes will of necessity increase.

Standardized mortality ratio. One problem with the CFR is that it is difficult to interpret what the number means. Is a CFR of 95 per 100,000 people high or low? In the Saha et al. (2007) study, the interest was in the change in the CFR over time, so the absolute value was of secondary importance, but we still do not know whether the final value is anything to be concerned about. One solution is to calculate the *standardized mortality ratio* (SMR), which is the ratio of the number of observed deaths to expected deaths for a specific disorder:

$$SMR = \frac{Number\ of\ Observed\ Deaths}{Number\ of\ Expected\ Deaths}.$$

An SMR of 1 indicates that the observed mortality rate is exactly equal to the expected rate; a number above 1 shows that the observed mortality rate is higher and less than 1 indicates that it is lower. Most often, the number of expected deaths is derived from the general population. Saha et al. found that the median SMR for all causes of death in people with schizophrenia was 2.58, meaning that their mortality rate was 2½ times higher than for the population at large. They were also able to calculate cause-specific SMRs; that for suicide was the highest (12.86), indicating that those with schizophrenia committed suicide at a rate nearly 13 times higher than in the general population.

Age-standardized rates. There are times when standardizing with reference to the general population is not specific enough. This may occur when the population of those with the disorder differs from the general population in terms of some key demographic variables, such as age or gender. For example, Fernquist and Cutright (1998) were interested in whether suicide rates are comparable across 21 developed countries. The problem is that the probability of committing suicide increases with age, and the age distribution of the population differs from one country to the next. If one country has a higher rate of suicides than the others, it could mean either that (a) the suicide rate is, in fact, higher in that country or (b) it has a higher proportion of older people, who are more likely to commit suicide. For example, the rate of suicides among people 60 years of age and older can be the same in two different countries, but if the first country has proportionally more elderly, then it would appear to have a higher suicide rate in comparison to the second. The solution is to *age-standardize* the rates by comparing them all to a reference population, broken down by age. The choice of the reference population can be critical, because using different standards can result in different conclusions. When comparisons are made within a given country (e.g., looking at differences across states or provinces), the population of the entire country is used. For international studies, a number of "reference populations" have been proposed. The "European" standard was developed in Scandinavia; it is appropriate for studies in developed countries, but is weighted toward the upper end of the age spectrum (Doll & Cook, 1967), reflecting the demography of northern Europe. The "world" standard, proposed by Segi (1967), is based on 46 countries world wide, and is not as heavily weighted by the elderly. More recently, the World Health Organization (WHO) has issued standards based on the population of the world, and broken down by both age and gender. In addition to its scope, an advantage of the WHO standard is that the data are updated every 5 years (United Nations, 2006).

To illustrate the procedure, let us compare two countries, each with a population of 1,000,000 people, that have very different age structures. Country A is a typical developing country with a large proportion of people under 30 years of age and Country B is a developed country with an aging population. The data are shown in ❯ Table 17.4.

If we look at the bottom row, we see that Country A has had 19,300 suicides in the year (column d); whereas there were 43,500 suicides in Country B (column h). So, just examining the crude number of suicides, it looks as if there are 2.25 times as many in Country B than in Country A. However, if we compare the suicide rates within each age decade (columns e and i), we see they are the same in both places. Multiplying these age-corrected rates by the population weight (column b), which reflects the proportion of people around the world, we find that the age-corrected suicide rates are the same, as are the age-standardized rates for the countries as a whole (2.50). Thus, age-standardization has removed the effect of the different age structures, giving us a more accurate picture of what is happening in the two places.

Bear in mind, though, that all of the indices we have discussed – ORs, RRs, NNTs, and the rest – are point estimates derived from studies. As with all point estimates, they are accurate

■ Table 17.4

Age-standardization for suicide rates in two fictitious countries

Age group	Wt.	Country A				Country B			
		Population	No. of suicides	Suicide rate	Weighted rate	Population	No. of suicides	Suicide rate	Weighted rate
(a)	(b)	(c)	(d)	(e)	(f)	(g)	(h)	(i)	(j)
0–9	22	300,000	0	0.00	0	50,000	0	0.00	0
10–19	18	250,000	2,500	0.01	0.18	50,000	500	0.01	0.18
20–29	16	150,000	3,000	0.02	0.32	100,000	2,000	0.02	0.32
30–39	12	90,000	2,700	0.03	0.36	100,000	3,000	0.03	0.36

Total	100	1,000,000	19,300	0.0193	2.50	1,000,000	43,500	0.0435	2.50

only to the degree that the studies themselves were well executed. That means that there should be no systematic biases regarding who did and did not get into them that may distort the findings, and that the sample sizes were large enough so that the confidence intervals around the estimates are relatively small. The old adage of "garbage in – garbage out" applies in full force in epidemiology; sophisticated analyses cannot correct bad design.

17.4   Summary

Epidemiology is a branch of research that focuses on counting the number of cases of a disorder in the population, with the aim of discovering those factors that influence its incidence and prevalence. As we have seen, "counting" is not always an easy or straightforward proposition, and requires a knowledge of research design, sampling, measurement theory, and statistics. Further, psychiatric epidemiology is heavily influenced by theory, especially (at least in North America) by theories arising from the social determinants of health. It is a relatively new field of study in psychology, but one that promises to grow in scope and influence over the coming decades.

18 Literature Reviews and Meta Analysis

Joseph A. Durlak

Abstract: This chapter discusses the most common research methodology in psychology: the literature review. Reviews generally have three purposes: (1) to critically evaluate and summarize a body of research; (2) to reach some conclusions about that research; and, finally, (3) to offer suggestions for future work. The basic and expert competencies required for completing a high quality literature review are described by discussing seven major components of reviews along with relevant questions that should be answered to assess the successful completion of each component. A major focus is on meta-analysis, but guidelines are pertinent in assessing the quality of various types of reviews including reviews of theories and clinical applications. Readers are directed to additional helpful resources in order to aide them in becoming critical consumers or producers of good literature reviews.

18.1 Overview

What is the most common research method in psychology? Is it a correlational study, a qualitative case study, an *N* of 1 within-subject design, a quasi-experimental design, or a randomized true experiment? It is none of these. Without question, the most common research method used in psychology is the literature review. Everyone who does any type of study or prepares any type of research report begins with a literature review. This is as true for every author of a professional publication, a technical report, or a grant proposal as it is for every graduate student who does a masters thesis or dissertation. The type and depth of these reviews vary depending on the circumstances, but reviews generally have three general purposes: (1) to critically evaluate and summarize a body of research, (2) to reach some conclusions about that research, and, finally, (3) to offer suggestions for future work.

Literature reviews have become a highly valued research method. Some highly respected journals publish only reviews (e.g., *Annual Review of Psychology, Psychological Bulletin, Review of Educational Research*), and many journals publish reviews periodically. A conservative estimate is that over 300 published literature reviews appear in the social sciences each year. Some reviews become highly influential and receive many citations as others have recognized the important contributions that reviews have made in different research areas.

The fifth edition of the Publication Manual (American Psychological Association, 2001) describes review articles, including meta-analyses, as critical evaluations of previously published material:

▶ By organizing, integrating, and evaluating previously published material, the author of a review article considers the progress of current research toward clarifying a problem. In a sense, a review article is tutorial in that the author: defines and clarifies the problem; summarizes previous

investigations in order to inform the reader of the state of current research; identifies relations, contradictions, gaps, and inconsistencies in the literature; and suggests the next step or steps in solving the problem. (p. 7)

Three qualifications should be made with respect to these statements.

First, reviews often evaluate unpublished as well as published materials. Second, although this chapter focuses on research reviews, it is also possible to review theories, policies, and aspects of clinical practice. For example, one might review therapeutic techniques used with certain types of clients, or assessment procedures for different problems or clinical situations. Many of the comments offered with respect to research reviews also pertain to other types of reviews. In other words, has any review been conducted and reported carefully enough so that its major conclusions and implications can be accepted with confidence? Third, for the first time, the next edition of the APA Manual will include detailed guidance on the conduct and reporting of meta-analyses (H. Cooper, personal communication, August 21, 2007).

Because a literature review is a bona fide research strategy, one can focus on the general methodology for doing reviews, and reviews can be evaluated according to how well this methodology has been followed. Just like any other research method, literature reviews vary in quality; some are very well done, whereas others are not. The term quality as used here refers to the scientific rigor of the review or to the extent to which the reader can place confidence in the major conclusions and implications of the review. A poorly done research study does not inspire much confidence in its findings and neither does a poorly done literature review. However, a well-done review makes a major contribution by its up-to-date evaluation of past research and suggestions for what type of future research can best advance the field.

The major purpose of this chapter is to discuss the basic and expert competencies related to conducting and reporting literature reviews. This is done by discussing the major components of reviews along with relevant questions that should be answered to assess the successful completion of each component. Space does not permit discussion of all the relevant issues, but useful resources on different aspects of literature reviews are offered throughout this chapter.

This chapter devotes its attention mainly to meta-analysis, which is one type of a literature review, but many comments are applicable to all types of reviews including those done as part of a student's thesis or dissertation. The following section provides an overview of meta-analysis. Then, the major components of a review are discussed along with the relevant questions that pertain to the quality of a review. The last sections of the chapter describe the basic and expert competencies required for conducting and reporting literature reviews and the typical processes whereby these competencies are acquired.

18.2 What Is Meta-analysis?

In the past 2 decades, research on meta-analysis has become increasingly sophisticated as researches have continued to refine the technique and examine how it can be applied and modified, if necessary, depending on the specific characteristics of the studies and outcome data being reviewed. Therefore, this chapter focuses only on the basics of meta-analysis. The reader is referred to several user-friendly resources that contain further explanations of meta-analyses (Durlak, 1995, 2000, 2003; Durlak, Meerson, & Ewell-Foster, 2003) as well as texts that also contain explications of more advanced statistical issues and analytic procedures (Hedges & Olkin, 1985; Hunter & Schmidt, 2004; Lipsey & Wilson, 2001; Wolf, 1986).

Also called a quantitative review, a research synthesis, or a systematic review, a meta-analysis is a quantitative analysis of a research area in which the findings from studies are transformed into a common metric, the effect size, which is then pooled and analyzed. The overall goals of a meta-analysis are the same as any review which were noted earlier (i.e., critically evaluate and summarize a body of research, reach some conclusions about that research, and offer suggestions for future work). The unique feature of a meta-analysis is its ability to quantify the magnitude of the findings via the effect size. Although there are many different types of effect, the three most commonly used indices are standardized mean differences (SMDs), the product-moment correlation, r, (see Rosenthal, 1991) and the odds ratio (see Fleiss, 1994; Haddock, Rindskopf, & Shadish, 1998). Product moment correlations are primarily used to synthesize the findings from correlational studies, and the odds ratio is preferred when outcome data are truly dichotomous (e.g., meeting diagnostic criteria, graduation, or arrests). This chapter focuses on treatment-meta-analyses that is, reviews that evaluate the impact of one or several different types of treatments or interventions based on studies involving treatment versus control group comparisons. These types of meta-analyses usually use SMDs as the index of effect although the statistical properties of the data set must be considered in the choice of the most appropriate index of effect (McGrath & Meyer, 2006; Ruscio, 2008).

An SMD is usually calculated by subtracting the mean of the control group at post from the mean of the intervention group and dividing by the pooled standard deviation of the two groups (Hedges' g or Cohen's d, depending on the exact method of calculation (see Durlak, in press). When means and standard deviations are unavailable, there are other ways to estimate an effect size from a study (Lipsey & Wilson, 2001). Dividing by the pooled standard deviation thus creates a "standardized" metric that can be used across studies, and SMDs are usually given a sign suggesting the superiority of the intervention over the control group at post. Therefore, an SMD of +0.50 from one treatment study is similar in magnitude to an SMD of +0.50 drawn from another study. Each SMD represents one half of a standard deviation and suggests the interventions in two studies were equally effective.

It is important to keep in mind that there is no straightforward relationship between the statistical significance of an outcome that might be attained in a study and its effect size. A statistically significant finding can yield an SMD that might be low, medium, or high in magnitude. In other words, SMDs convey information that is different from that of customary tests of statistical significance; SMDs in treatment with meta-analyses describe the *magnitude* of the difference between two groups (Vacha-Haase & Thompson, 2004).

The ability of an effect size to transform the unique data from different studies into a common metric creates the opportunity for the reviewer to examine several potentially important research questions. For example, what is the overall mean effect averaged across all interventions? What factors or variables might affect this overall result? Does this mean effect differ for young or older clients, for those with different problems, and so on. Carefully conducted meta-analysis can be a powerful tool for assessing a research area.

18.2.1 Components of a Scientifically Rigorous Review

❯ Table 18.1 lists seven major components of a scientifically rigorous review and poses several primary questions to be asked and answered regarding the review. These components and their accompanying questions have been synthesized from a variety of sources as noted

◼ **Table 18.1**

Major components of a scientifically rigorous literature review

1. Is the review well-written?
  A. Does the review contribute new knowledge to the field?
  B. Is the review well-organized to tell a logical, coherent, convincing story?
  C. Is the prose clear, coherent, and concise?
  D. Is the take-home message clear and emphatic?

2. Formulation of a good research question
  A. Is the purpose of the review described clearly?
  B. Is the research topic important, empirically, theoretically, or practically?
  C. Are the research questions reasonable and testable?
  D. Are a priori hypotheses offered?*

3. Reviewing all the relevant literature
  A. Is the scope of the review appropriate?
  B. Is the review up-to-date?
  C. Are there explicit criteria about which type of studies were included or excluded?
  D. Are multiple search strategies used?
  E. Are unpublished studies included?*

4. Deriving maximal information from individual reports
  A. Was the influence of methodological features evaluated?
  B. Was the extent of missing or limited information acknowledged?
  C. Is a clear rationale presented for the coding of the major variables?*
  D. Is the coding of studies reliable?*

5. Conducting appropriate analyses
  A. Do the analyses competently address the major research question(s)?
  B. Are clear distinctions made between primary and exploratory analyses?
  C. Are discrepant or contradictory findings handled appropriately?
  D. Is one effect per study used per research question?*
  E. Were effects weighted before analyses*
  F. Were statistical outliers identified?*
  G. Were studies grouped appropriately for analyses?*
  H. Did the review consider and rule out some likely rival explanations for the results?

6. Reaching conclusions and advancing the field
  A. Is the take-home message emphatic and clear?
  B. Were the major conclusions clearly supported by the evidence?
  C. Were appropriate qualifications to the main conclusions offered?
  D. Was the practical significance of the findings assessed?
  E. Were the findings placed in an appropriate context?
  F. Were the implications for theory, policy or practice discussed?
  G. Does the review identify critical directions for future research?

The features marked with an * apply to meta-analyses while the others apply to all types of reviews. Material is drawn from Bem (1995), Drotar (2000), Durlak (2000, 2003), Durlak et al. (2003), Galvan (2004), Oxman (1994), and Sternberg et al. (1997).

at the bottom of the table. In effect, the questions in ❯ Table 18.1 can be used as criteria to judge the quality of a review, keeping in mind that quality is not an all-or-none construct but something that lies along a continuum that ranges from very low quality to the highest quality. The list of questions is not exhaustive but do pertain to the major aspects of reviews.

Another perspective concerning good reviews comes from data reported by Sternberg, Hojjat, Brigockas, and Grigorenko (1997) as to what qualities of reviews are associated with their eventual publication. These authors analyzed reviewers' quantitative ratings of manuscripts, and a factor analysis suggested the presence of three separate dimensions: analytic, creative, and practical. These dimensions overlap with those presented in ❯ Table 18.1. For example, the analytic dimension consists in answering the major question: How well does the author analyze the relevant literature (components 3D, 3E, 5A, and 5C in ❯ Table 18.1). The creative contribution revolves around the question: Does the review make an important contribution to the field (related to components 1A and 2B in ❯ Table 18.1). Finally, the practical dimension is relevant to how well the review is written (components 1B, 1C, 1D, and 3A). Each of Sternberg et al.'s (1995) three dimensions was important; each was a significant and comparable predictor of the eventual publication of review articles in *Psychological Bulletin*. In other words, it is helpful to keep in mind that the creative and practical aspects of a review are just as important as its technical aspects. The following sections discuss each of the components listed in ❯ Table 18.1 in an effort to describe what makes for a scientifically rigorous review.

18.2.1.1 Is the Review Well-Written?

The importance of good writing cannot be over-emphasized. A reviewer might have important findings to share, but if the purpose, conduct, findings, and implications of the data are not written up properly, the review's impact will be greatly diminished. In fact, the review might never be published. Reviews should be well organized to tell a logical, coherent, and convincing story to maintain readers' interest and to culminate in a clear and emphatic take-home message that makes a contribution to the field. Because reviews are designed to teach readers something new, the entire review should be composed to highlight the take-home message.

Sternberg (1991) offered this wise advice to would-be authors of reviewers:

▶ Literature reviews are often frustrating because they offer neither a point of view nor a take-home message. One is left with a somewhat undigested scattering of facts but little with which to put them together. I encourage authors to take a point of view based on theory and to offer readers a take-home message that integrates the review….. [reviews that are lively and maintain reader interest] need to make a point, not simply to summarize all the points everyone else has made. (p. 3)

Finally, the prose should be clear, coherent, and concise. As Bem (1995) indicates, good scientific writing is accurate, clear, simple, direct, and organized to tell a coherent story. Galvan (2004) also offers excellent suggestions on how to write and, most important, how to self-edit an effective literature review.

18.2.1.2 Reviewing the Relevant Literature

An important requirement for a good review is that the relevant literature has been reviewed, although a truly comprehensive review of every report is usually impossible to achieve. There are over 20,000 outlets for published and unpublished research (Cooper & Hedges, 1994) and new outlets appear each year, especially on the Internet. Therefore, the central task of the reviewer is to search carefully for as many relevant studies as possible in order to avoid bias in the identification and inclusion of studies.

The search for relevant literature should be based on reasonable inclusion and exclusion criteria that are articulated by the reviewer so that readers can understand what type of research is relevant or not. For example, at a minimum, the reviewer should specify the starting and ending dates of the literature search, and what are the characteristics of the samples, study designs, interventions, and outcomes of interest. The presence of clear and reasonable explanations for why some studies are included whereas others are not, allows for a focused review that can answer specific research question. For example, one reviewer might be interested in group treatment for school-aged youth who are anxious or depressed, and only evaluate reports that measure anxiety or depression as outcomes. Another reviewer might be interested in both individual and group interventions for young aggressive children (ages 3–10). It is up to the reviewer to justify why certain types of studies are being reviewed and others are not.

Multiple search strategies are essential for finding relevant studies and the three most successful strategies usually consist of: (1) manual searches of the abstracts or method sections of journals that have published relevant studies; (2) examination of the references of each obtained study; and (3) computer searches of multiple data bases. Although computer searches can be done quickly, they should *not* be the primary search strategy. Computer searches have been known to identify only a small minority of relevant studies (i.e., less than 20%) compared to the other two approaches mentioned earlier (Durlak, 2000). This is because computer databases do not include all possible outlets, often do not thoroughly sample books and book chapters, are modified over time (making a consistent search over the same data base more difficult), overlook the most recent studies due to a time-lag related to their updating, and may not contain the search terms that exactly fit a reviewer's requirements. One of the skills in reviewing depends on learning the standardized search terms and their variants that comprise each database and how to conduct overlapping computer searchers of these databases to assure more relevant studies are identified (Taylor, Wylie, Dempster, & Donnelly, 2007). Reference librarians are a useful resource for learning effective search strategies for different databases.

Reviews should strive to include unpublished studies due to the possibility of publication bias, which refers to the reluctance of editors to accept and authors to submit reports that contain nonsignificant results (Dickersin, 1997). In other words, a review of only published studies might over-estimate the true effect size because only published results with positive findings are reviewed and unpublished material with negative results are not included. However, unpublished studies (e.g., doctoral dissertations, conference papers, technical reports, and unsubmitted papers contained in researchers' file drawers) do not always contain lower effect sizes than published reports (Wilson, Gottfredson, & Najaka, 2001). One can never be sure about the existence of publication bias; much depends on the care taken to locate published and unpublished literature and the data they contain. Different methods to estimate the degree to which publication bias might influence the findings are available and authors have discussed the situations in which they should or should not be used (Peters, Sutton, Jones, Abrams, & Rushton, 2007; Terrin, Schmid, Lau, & Olkin, 2003).

18.2.1.3 Deriving Maximal Information from Individual Reports

The prime goal in coding studies is to capture all the potentially important information from each study (i.e., those independent variables that might affect the findings and conclusions of the review). Which variables should be coded?

Meta-analysts should rely on past research to guide their choices. Usually, meta-analysts develop a coding system (that is available to interested readers) that focuses on various theoretical, clinical, practical, and methodological features of each study that prior research or theory has suggested could be important. For example, coding might involve among other things, which types of treatment techniques were used, who were the clients, what was the nature and seriousness of their presenting problems, who administered the treatment, and what outcomes were assessed. The review should contain examples of how the major variables of interest (i.e., those related to the reviewer's a priori hypotheses) were coded and why these variables might be important.

The experimental features of the studies should also be coded for two important reasons: (1) the experimental rigor of the reviewed studies often affects the confidence that can be placed in the findings and (2) methodological features frequently affect study outcomes (Wilson & Lipsey, 2001). Exactly, which methodological aspects are important and how they affect findings are empirical questions that meta-analysts can ascertain through statistical analyses (see below). Moreover, there is no standard way to evaluate the experimental quality of each study; different issues might be important depending on the particular research area. Once again, prior research probably suggests which variables to consider. For example, outcomes might vary based on psychometric properties of the outcome measures, from where the data are obtained or who does the treatment. Therefore, it is important to assess if effects differ based on reliability and validity of the outcome measure, whether youth, parents, teachers, or independent observers provided the outcome data, or if the loss of participants during the course of the study (i.e., sample attrition) makes a difference. Several meta-analyses have documented that implementation influences outcomes so the extent to which the intended intervention was conducted as planned should also be evaluated (Durlak & Dupre, 2008).

Meta-analyses should calculate and report the methods used to code studies and the reliability of the coding system. Usually, the complete coding manual is made available to interested readers or posted on a Web site. Choice of a reliability estimate depends on the nature of the coding (e.g., continuous or categorical variables, their frequencies with the study sample, and the number of coders used). Hartmann (1982) offers useful guidance on choice of reliability methods.

18.2.1.4 Conducting Appropriate Analyses

Analyses can be complicated because the original research being reviewed is complicated, and this section focuses on some common strategies and situations. Variability is the challenge that faces most meta-analysts. There is often substantial variability in the outcomes of a research area. This is not surprising. If each researcher always obtained the same result, there would not be a need for any more studies. We would know very well what to expect from an intervention. However, there is also substantial variability in the ways researchers conduct their studies. They design their studies differently, recruit different size samples, involve different types of participants (e.g., in terms of age, gender, cultural background, and level of adjustment), work in different communities and contexts, measure outcomes in different ways, and modify or change

aspects of the intervention. The challenge for a meta-analyst (just as it is for anyone conducting a literature review) is to deal with the simultaneous variability in study characteristics and outcomes in a systematic, analytic way in order to arrive at scientifically sound conclusions and implications.

The effect size is the dependent variable in a meta-analysis and all the features of the reviewed studies are the independent variables. Each independent variable (i.e., study feature) could moderate the outcomes (i.e., be associated with lower or higher effect sizes). The challenge for the meta-analyst is to determine which independent variable or combination of variables, if any, affects the dependent variable.

Prime Considerations Concerning Effect Sizes. Studies usually vary in how many outcomes they examine, and it is important in a meta-analysis to use only one effect size per study in each analysis. Otherwise, a study with, say, six outcomes, automatically receives six times more importance in the analysis than a study with only one outcome. It is extremely helpful in most meta-analysis to divide the types of outcomes found in reviewed studies into different categories and analyze each category separately. For example, do treatments for students affect levels of academic achievement as well as they affect levels of depression or self-confidence?

However, meta-analysts should weight each effect size by the inverse of its variance before conducting any analyses (Hedges & Olkin, 1985). This procedure gives more weight to studies conducted with larger samples, which is important because such studies provide more reliable estimates of the true population effect than studies with smaller samples. Authors should also inspect the distribution for possible outliers, that is, very aberrant findings that are much higher or lower than the rest of the distribution and make and defend their choice of which type of statistical model (random effects, fixed effects, or a combination) was used in the analyses (see Lipsey & Wilson, 2001).

Importance of Confidence Intervals. Meta-analysts should also calculate confidence intervals (CIs) around all mean effects (Hedges & Olkin, 1985). Usually, 95% CIs are calculated, but intervals at other levels can be used with appropriate justification. CIs are essential in evaluating the precision of meta-analytic findings by providing the range of likely values around any obtained mean effect. When CIs do not include zero, the mean effect is statistically different from zero, and when different means are compared their corresponding CIs assist in determining (along with the *Q*-between statistic; see below) if the means differ significantly from each other.

For example, suppose in a meta-analysis the mean effect for one subgroup of studies (Group A) was 0.20 with a 95% CI from 0.05 to 0.35 while the mean of the other subgroup (Group B) was 0.60 with a 95% CI of 0.10–0.90. Although the mean effect for Group B is three times higher than for Group A, the two means do not differ significantly from each other because the CIs for the two groups overlap to a substantial degree. This is because the CI for Group A indicates that the mean effect is likely to range between 0.05 and 0.35, while the CIs for Group B (0.10–0.90) include much of this range. In this example, the CI for Group B includes 83% of the range of the CI for Group A. The large CIs obtained for Group B tell us that with repeated replications it is likely that the obtained means for the two groups could be very close together and not differ by a magnitude of three as found in this one meta-analysis.

Cumming and Finch (2005) have indicated that researches are often too conservative when interpreting the statistical difference between two means. They stress that if mean CIs do not overlap at all, the means should be interpreted as significant at the 0.01 level (even if 95% CI is used), and they have developed a procedure to determine if means differ at the 0.05 level by testing the degree of overlap in the CIs. In sum, CIs represent a range of plausible values for the true population effect compared to the estimate of the effect obtained in a meta-analysis.

Narrower CIs indicate more precision in the estimate of the true effect. Readers often have difficulty interpreting the meaning of CIs. If 95% CIs are used, then in 95 of 100 replications of the meta-analysis, the true population value of the ES would fall somewhere within the CI.

Grouping Studies for Analysis. Early criticisms of meta-analyses often focused on the "apples and oranges" problem. That is, the concern was that reviews were combining groups of studies that were so conceptually different that they should not be combined.

One preferred way to assess variability in a meta-analysis is to use the Cochran Q statistic which can be supplemented with another statistic, I^2 (Higgins, Thompson, Deeks, & Altman, 2003). The Q statistic assesses whether there is a statistically significant degree of variability present in a group of effect sizes. That is, is there more variability present than one would predict based on sampling error alone? If the Q statistic is *not* statistically significant, than the group of studies is likely to be estimating the same population effect. I^2 values assess the *degree* as opposed to the statistical significance of variability along a 0–100% scale and can be interpreted in the following fashion: 0% represents no variability at all; 25% low, 50% moderate, and 75% or more, a high degree of heterogeneity. Illustrations of the use of Q and I^2 can be found in Cuipers, van Straten, and Warmerdam (2007) and Durlak, Weissberg, and Pachan (in press).

When studies are subdivided into groups to test for moderation, the Q statistic is analogous to an ANOVA in the sense that total variability in effects for all the studies consists of the variability found within- and between-groups of studies. The desired finding in a test for moderation is to obtain statistically *nonsignificant Q* statistics *within groups* with accompanying low I^2 values but a statistically significant Q statistic *between groups* with high I^2 values. Inspection of the group means would indicate which group had the higher or lower effects. ❯ Table 18.2 offers some hypothetical data to illustrate how a hypothesis can be evaluated using the Q statistic and I^2 values. In this example, 66 studies were reviewed in which children and adolescents having symptoms of both depression and anxiety received cognitive-behavioral therapy. The reviewer provided a rationale for hypothesizing that adolescents would receive significantly more benefit from treatment than younger children. The data from Example A in ❯ Table 18.2 confirm the reviewer's hypothesis for measures of depression, but the data from Example B do not confirm the hypothesis for anxiety outcomes. Why?

Note that the reviewer first examined the variability in effects for both depression and anxiety outcomes across all studies and obtained a statistically significant Q statistic (76.75 and 21.96) and corresponding I^2 values reflecting a moderate (50% for Example B) or high degree of heterogeneity (75% for Example A). In other words, the total group of studies in each case was not estimating the same population effect and a search for possible moderators was justified. However, when the studies were divided according to the age of the participant sample, the hypothesis that adolescents would benefit significantly more than 10–12 year old children was confirmed only for depression outcomes.

In Example A, the Q-within statistics for each subgroup of studies ($k = 27$ and 39) were no longer statistically significant with accompanying low I^2 values (5% and 18%) and the Q-between was highly significant as predicted. The mean of the two groups was 0.07 for younger and 0.32 for older children with non-overlapping CIs.

However, in the case of anxiety, even though Q-within statistics were not statistically significant and I^2 values were low (0% and 7%), the Q-between statistics was *not* significant and there was no heterogeneity at all (0%) between the groups' effect sizes. Also note that although the mean effect for adolescents on anxiety outcomes was higher than for younger children (0.37 to 0.14, respectively) the mean CIs overlapped considerably (−0.26–0.54 and 0.24–0.46). Example B illustrates that one should not merely compare mean effects; CIs and additional

🔷 **Table 18.2**

Hypothetical findings illustrating confirmation (Example A) and disconfirmation (Example B) of hypothesized moderation

Example A: Outcomes for depression outcomes							
Studies	SMD	k	95% CI	Q-within	I^2	Between groups	
						Q-between	I^2
All programs	0.22[a]	66	0.10–0.45	76.75[a]	75%	NA	NA
10–12 year old children	0.07	27	−0.01–0.15	12.01	5%		
13–18 year old youth	0.32[a]	39	0.25–0.39	46.26	18%	18.48[a]	95%
Example B: Outcomes for anxiety outcomes							
All programs	0.33[a]	22	0.23–0.45	21.96[a]	50%	NA	NA
10–12 year old children	0.14	2	−0.26–0.54	0.67	0%		
13–18 year old youth	0.35[a]	20	0.24–0.46	20.36	7%	0.93	0%

[a] Denotes a finding that is statistically significant at the 0.05 level.

statistical analyses should be conducted to assess if any between-mean differences are statistically significant and to assess their magnitude.

The examples in ◉ Table 18.2 involve one possible moderator, two subgroups, and two outcomes, but analyses become more complicated with additional moderators, groups, and outcomes. Meta-regression can be used to test for multiple possible moderators, but before predictor variables are entered into the regression their correlation should be checked to avoid multi-colinearity.

18.3   Ruling Out Alternative Explanations

For both examples in ◉ Table 18.2, the meta-analyst should examine other possible variables that might influence effect sizes. Methodological features often are associated with effect sizes, although there is no standard way to determine methodological quality or rigor. Sometimes single variables, such as randomization to conditions, levels of attrition, or the reliability of the outcome, are related to effect sizes. Other times, a multivariate approach is used. Several method variables are combined in a scale and then the mean effects of studies categorized as high, medium, or low in experimental quality are compared. The reviewer should justify whatever approach is taken.

18.3.1 Reaching Appropriate Conclusions and Advancing the Field

Clearly stating and explicating the major conclusion of a review produces the take-home message, and the value of conducting and describing the steps of a review so as to present a coherent, logical, and convincing argument has already been noted. Reviewers should also offer

appropriate qualifications to their conclusions depending on the limitations found in the database, because such limitations should be a focus for future research. For example, notice that only two studies in ❯ Table 18.2 assessed anxiety outcomes for 10–12 year old children. The need for further research on this population would be pointed out.

Implications that findings have for theory and practice should be emphasized. Furthermore, the practical significance of the results should be discussed and there are now several ways a meta-analyst can illustrate the practical benefits of obtained effect sizes (Cooper, 2008; Hill, Bloom, Black, & Lipsey, 2008; Randolph & Edmondson, 2005; Rosenthal & Rubin, 1982; Valentine & Cooper, 2003). The magnitude of the effect is only one consideration; other factors include types of outcomes being modified, populations studied, findings from previous research, and the inherent value or "real-world" benefit of the types of changes suggested by the outcomes.

Interpreting Effect Sizes. A reviewer has to explain the meaning of the effect sizes obtained in a meta-analysis. What do average effects of 0.25, 0.55, or 0.60 mean (Durlak, in press; Vacha-Haase & Thompson, 2004; Volker, 2006)? It is essential to place current findings in a research context. Lipsey and Wilson (1993) provide one context for judging the effects of treatment meta-analyses. They analyzed the results of 156 meta-analyses assessing behavioral, psychological, and educational treatments. The overall mean from these meta-analyses that contained 9,400 studies and over 1 million participants was 0.48 with a standard deviation of 0.28, suggesting that two thirds of the mean effects fell somewhere between +0.19 and +0.75; 16% were higher than +0.75 and an equal percentage were below +0.19. However, Lipsey and Wilson's (1993) data were taken from reviews of treatments for individuals who had varying and often serious psychological, behavioral, or academic problems, so their findings do not apply to all types of interventions. For example, universal or primary prevention programs focusing on general populations who are not manifesting any initial problems tend to obtain lower mean effects on many outcomes (Durlak, Weissberg, Taylor, Dymnicki, & Schellinger, in press).

Furthermore, some outcomes are much more difficult to modify than others. One compilation of 76 meta-analyses of academic interventions indicated that mean effects were 0.23 for students in elementary school, 0.27 for those in middle school, and 0.24 for those in high school when achievement test scores were the outcome (Hill et al., 2008). While higher effects would, of course, be desirable, a mean effect of 0.24 translates into a 9.5 percentile gain in achievement for the intervention group over the controls. Many educators would welcome an intervention that might boost the academic performance of their student body by nearly 10 percentile points.

Many authors reporting effect sizes from individual studies or meta-analyses have invoked Cohen's (1988) convention that effects of around 0.20 are small in magnitude, those around 0.50 are moderate and those ≥0.80 are large; the corresponding figures for correlations as an index of effect are 0.10, 0.30, and 0.50. However, Cohen (1988) offered these conventions cautiously only as a general rule of thumb that could be used in the absence of prior empirical work in the field. Therefore, rather than simply invoking what are perhaps inappropriate criteria for judging the magnitude of effects in a particular area, authors should strive to compare their findings with previous research.

18.4 Strengths and Limitations of Reviews

It is important to acknowledge some general strengths and limitations that characterize most reviews. Several of the major strengths of reviews have already been noted. Reviews can bring

readers up-to-date regarding findings in an area and offer conclusions and interpretations of the accumulated data that increase others' understanding and stimulate them to advance the field. Meta-analyses can assess a large body of literature that involves hundreds of studies and thus bring a perspective and focus to bear on issues that is extremely valuable to others. Surveys indicate that many researchers and practitioners read and depend on reviews for keeping them up-to-date in their respective fields (Cooper & Hedges, 1994).

However, a review's strengths depend on how well it has been executed and reported. Each of the components of a review discussed in this chapter is important, and the failure to accomplish one component effectively can undermine the worth of the entire enterprise. For example, accurate analyses and interpretations can be undermined if the relevant literature is not included or up-to-date. Poor writing can cloud the impact and value of a review. Therefore, each major component of a review is a critical determinant of its final worth.

In addition to limitations that involve a poorly conducted component of a review, as a matter of course, all reviewers depend on the information contained in original research reports. Although some reviewers do contact authors and ask for additional information regarding their studies (and this strategy is recommended so that potentially important studies do not have to be excluded) many authors do not comply with these requests and obtaining additional data from authors whose studies were conducted many years ago is most difficult. Therefore, many reviews must rely on the data contained in the original research report.

The APA Manual (American Psychological Association, 2001) and guidelines offered by many journals describe the essential information that should be included in any study. For example, if interventions are being evaluated, at a minimum, it is critical to describe clearly who did what, to whom, and what happened as a result. Unfortunately, reports often omit some of this information. Several authors have noted that the literatures they examined fail to describe the participants sufficiently, particularly in terms of ethnicity and socioeconomic status, but sometimes also in terms of age and gender; others do not describe who conducted the intervention and their experience and training level, exactly what were the major elements of the intervention, and whether it was implemented as planned. In other cases, there is insufficient information on the psychometric properties of the outcome measures, why the ns vary across outcomes, and when attrition occurs, if it differentially affected the intervention and control groups or if the sample of participants that was evaluated differed in any important way from those who began the study (Durlak, Celio, Pachan, & Schellinger, in press; Durlak & Wells, 1998; Hahn et al., 2007; Haney & Durlak, 1998; Tobler et al., 2000; Weisz, Jensen-Doss, & Hawley, 2006; Wilson et al., 2001). The extent to which data are missing on different variables affects the adequacy of any analyses, their resultant interpretations, and how final conclusions must be qualified due to missing data. It is still true that ".... there has never been a meta-analysis in which the author has noted that all the needed information was available in all the studies" (Durlak, 2003, p. 207).

18.4.1 Basic Competencies

Basic competencies related to literature reviews essentially involve the abilities to act as an informed and critical consumer of research, that is, the ability to read and judge a review's value in understanding current findings or developments in a particular field. Basic competencies related to literature reviews refer to knowing what constitutes a good literature review. This is why the previous sections focused on the major components of literature reviews and how

these components can be used to judge the quality of a particular review. Mastery of basic competencies is demonstrated by the ability to critically evaluate a literature review. In other words, first one needs to understand the major criteria that can be used to evaluate the scientific rigor of a literature. These criteria were presented in ❯ Table 18.1 and described earlier in this chapter. Mastery of basic competencies is demonstrated when one can read a review and appropriately evaluate its strengths and limitations in order to draw the appropriate conclusions and implications from the reviewed literature. Note that the conclusions a reader draws from a review might not correspond exactly to those presented by the author of the review. The reader might recognize certain limitations in the review not fully acknowledged by the author and therefore reach a different and more correct view of the literature than the original author. In fact, reaching a different conclusion might propel the reader to re-analyze the same literature hoping to improve on the new review and correct some of its problems. This is not shocking. Researchers can and do disagree about the contribution of new work. Science often advances when researchers offer their work to the scrutiny of others who might then be motivated to conduct better research.

18.4.2 Expert Competencies

Expert competencies relate to the production of new research: that is, the ability to conduct and report good literature reviews. In terms of meta-analysis, there are additional expert competencies that are relevant. Because of its quantitative nature, the use of meta-analysis can be greatly advanced by methodological and statistical research on different techniques and methods. For example, valuable contributions have been made by many authors who have developed methods to calculate effect sizes, made statistical adjustments based on the characteristics of research studies (i.e., weight studies by sample size), or clarify which and how effects should be used to assess a specific research literature. There are too many of these expert contributions to cite, but meta-analytic texts and handbooks often acknowledge these multiple contributions (e.g. Cooper & Hedges, 1994; Hunter & Schmidt, 2004; Lipsey & Wilson, 2001; Rosenthal, 2001) and advancements that continually appear in journals.

18.4.3 Acquiring Basic and Expert Competencies

Achieving the necessary basic and expert competencies related to literature reviewing is usually achieved in the same ways as other competencies: through knowledge and practice. It is important to read thoroughly about literature reviews to attain sufficient knowledge and understanding of the properties of a well-done review. The reader has already started this process by reading this chapter and its references will direct him or her to further literature regarding different aspects of reviewing. Then one practices the basic competencies and receives feedback from an expert in the area.

18.5 Basic Competencies

For basic competencies, a student's learning phase usually occurs informally. Students become attached to researchers who guide their students to influential work in a research area. Several

journals now use student reviewers who are mentored by researchers on the journal's editorial board. This is an excellent way to master basic competencies because this editorial mentoring process allows the student to complete a review on a submitted paper and then compare his or her comments about the paper to those prepared by the reviewing mentor. Because every research report contains a literature review, the student can learn through reviewing others' work, how to discern if the introduction to an article (which contains the literature review of previous work) has been prepared appropriately. Once again, ❯ Table 18.1 or the other sources cited in the table can be used as a guide to evaluate reviews. Students can also visit the websites of different journals that provide detailed guidance to prospective authors on how to prepare manuscripts for possible publication.

18.6 Expert Competencies

Once basic competencies are attained, the most reasonable way to become an expert is to practice, obtain feedback from an expert, and practice some more (i.e., incorporate the feedback in successive drafts of the review). This is essentially the process involved in most graduate programs regarding literature reviews (the first major chapter or section of a thesis or dissertation). A student proposes his or her thesis or dissertation, prepares a draft of a literature review, and receives comments on the draft from the thesis or dissertation chair (and occasionally from other committee members before the proposal and final defense). Some students become discouraged over the necessity of repeated drafts of their thesis or dissertations, but expert competencies are not achieved overnight and usually require continual practice and refinement. Even after multiple drafts have been prepared prior to the defense of the thesis or dissertation, other committee members usually offer additional comments to improve the final product. Boote and Beile (2005) and Maxwell (2006a, b) offer an interesting discussion about the strengths and limitations often encountered in dissertation reviews.

How can young scholars judge how much progress they are making in acquiring needed competencies? While students can learn about conducting and reporting reviews through helpful feedback from faculty mentors, an expert reviewer is able to execute a high-quality review independently. Ideally, during their graduate career, students should manifest a progression of reviewing skills. Their efforts at a review for their dissertation should be better than the review section of their thesis in the sense that the number of drafts their dissertation chair might suggest or the amount of revision that is required is less than for their thesis. Basically, their first efforts at the review section of their dissertation should be better than their last efforts at the review section of their thesis. However, students should not be discouraged by the amount of time and revision needed; even experienced and frequently-published scholars do multiple drafts of their papers. Nevertheless, young scholars will probably not conduct a review independently until after they receive their final degree and are functioning as professional psychologists.

18.7 Summary

This chapter has discussed the basic and expert competencies related to conducting and writing literature reviews, including meta-analyses. Many researchers and scholars depend on reviews

to bring them up-to-date on findings and implications of developments in their field. The three general goals of reviews are to: (1) critically evaluate and summarize a body of work (theory, research or practice), (2) reach some major conclusions about the literature, and (3) offer suggestions to advance the field.

The seven major components of literature reviews were described and several central questions that should be answered in judging the scientific value of the review were discussed. Basic competencies related to literature reviews involve the ability to act as an informed and critical consumer of research, that is, the ability to read and judge a review's value. Expert competencies relate to the production of research: that is, the ability to successfully conduct and write up a high-quality review. To demonstrate basic competencies, one needs to understand what characteristics make for a good review and be able to apply this knowledge when reading and evaluating reviews. Expert competencies are attained by a series of practice and feedback cycles in which one attempts a review, receives guidance from a knowledgeable expert on the different steps of the review, and uses that feedback to improve one's work.

Professional Roles

19 Supervision

Robin L. Shallcross · W. Brad Johnson · Sarah Hope Lincoln

Abstract: As a central component in the training of graduate students in clinical, counseling and school psychology, the provision of clinical supervision has been undergoing an evolution and transformation in developing more explicit competencies. We review definitions of the terms of clinical supervision and competence, and define basic and expert levels of competence through a literature review and specific training examples of how to achieve these competency levels. The transformation this domain is experiencing can be summarized as a shift from learning how to supervise through observation or on the job training, to specific instruction and benchmarks of how to measure competence. This has implications of who is eligible to supervise by credentialing and licensing bodies, as well as capturing best practices in terms of providing excellent clinical, ethical and legal supervision.

19.1 Overview

Clinical supervision is a central component in the training of graduate students in clinical, counseling, and school psychology. In many respects, effective professional education in psychology hinges upon the supervisory process: "it provides the structure and framework for learning how to apply knowledge, theory, and clinical procedures to solve human problems" (Falender & Shafranske, 2004, p. 6). Good supervision allows trainees to develop competence as psychologists, as they progress across the continuum from novice to autonomously functioning professional (Holloway, 1992; Rosenbaum & Ronen, 1998). Clinical supervision achieves a number of salient purposes, including fostering supervisee's professional development, instilling and developing necessary skills and attitudes, ensuring that trainees who fail to develop sufficient skills and attitudes are not allowed to practice independently, monitoring and safeguarding client welfare, promoting ethical practice, and assisting trainees in the development of meta or higher-order competence as professional psychologists (Bernard & Goodyear, 2004; Falender & Shafranske, 2007; Vasquez, 1992; Watkins, 1997). Watkins summarized the importance of supervision this way:

> ▶ Psychotherapy supervision is important because, among other possibilities, it provides supervisees with feedback about their performance; offers them guidance about what to do in times of confusion and need; allows them the opportunity to get alternate views and perspectives about patient dynamics, interventions, and course of treatment; stimulates or enhances curiosity about patients and the treatment experience; contributes to the process of forming a therapist "identity" and serves as a "secure base" for supervisees, letting them know they are not alone in their learning about and performing psychotherapy. (Watkins, 1997, p. 3)

Numerous surveys in the professional psychology literature indicate that clinical supervision remains one of the most prevalent professional activities of clinical psychologists in both

academic and practice settings (Falender et al., 2004; Robiner & Schofield, 1990; Watkins, 1995). Most psychologists report that supervision is a key component of their professional identity and most of them provide some supervision during the average work week (Robiner & Schofield). Although supervision is central to the clinical psychologist's professional development and subsequent practice, very few training programs provide detailed training in supervision. As Watkins noted, "it seemingly is a process that is learned on the job or through some sort of osmosis; through witnessing countless hours of supervision – usually by several different supervisors or by undergoing one's own supervision" (p. 573). Further, the theoretical base for supervision has only recently begun to solidify (cf., Bernard & Goodyear, 2004; Falender & Shafranske, 2004); while the guidelines and standards for supervision remain elusive. For example, authors of the *Task Force on Supervision Guidelines* sponsored by the Association of State and Provincial Psychology Boards (ASPPB) expressed chagrin at the apparent failure of the psychology training system to standardize the process of supervision: "Given the critical role of supervision in the protection of the public and in the training and practice of psychologists, it is surprising that organized psychology, with few exceptions, has failed to establish a requirement for graduate level training in supervision" (ASPPB, 2003, p. 1). Although clinical supervision is a significant activity of practicing psychologists, less than 20% of supervisors have received formal training in supervision (Peak et al., 2002). To its credit, the profession of psychology has recently begun the process of carefully defining competence to supervise – most notably at the Competencies Conference held in Scottsdale, Arizona, in 2002 (Kaslow, 2004).

In this chapter, we distill and summarize the key elements of supervision competence. We begin with an overview of both supervision and competence and set the stage for the interface between these constructs. We will discuss some of the inherent challenges in providing training in clinical supervision at the predoctoral and prelicensure levels, given ethical and legal considerations. The model at the Pacific University's School of Professional Psychology (SPP), where the first author is part of the core faculty, will be used as an example of how a doctoral program surmounts these challenges. We will then offer suggestions for training of licensed psychologists in expert supervision competencies.

19.2 Introduction

19.2.1 Supervision

A review of the literature reveals numerous definitions of clinical supervision. We provide a sample of frequently cited definitions here, followed by a discussion of the most salient components of supervision.

▶ Supervision is an intervention provided by a more senior member of a profession to a more junior member or members of that same profession. This relationship is evaluative, extends over time, and has the simultaneous purposes of enhancing the professional functioning of the more junior person(s), monitoring the quality of professional services offered to the clients that she, he, or they see, and serving as gatekeeper for those who are to enter the particular profession. (Bernard & Goodyear, 2004, p. 8)

▶ It [supervision] involves observation, evaluation, feedback, the facilitation of supervisee self-assessment, and the acquisition of knowledge and skills by instruction, modeling, and mutual problem solving. In addition, by building on the recognition of the strengths and talents of the supervisee, supervision encourages self-efficacy. (Falender & Shafranske, 2004, p. 3)

▶ We define supervision as a working alliance between practitioners in which they aim to enhance clinical practice, fulfill the goals of the employing organization and meet ethical, professional, and best-practice standards of the organization and the profession, while providing personal support and encouragement in relation to the professional practice. (Kavanagh, Spence, Wilson, & Crow, 2002, p. 247)

These and other definitions of supervision share several key elements; we consider these as the salient features of clinical supervision. Below, we highlight the primary elements of supervision.

Supervision Is First and Foremost a Relationship. Supervision always occurs in a relational context (Watkins, 1997) and competent supervisors are attentive to the relational dynamics that shape the formation, course, and outcomes of supervision. In light of the relational foundation of supervision, it should come as no surprise that supervisees gravitate to supervisors with good interpersonal skills (e.g., empathy, respect, and genuineness) and who can effectively demonstrate support, empathy, and respect (Henderson, Cawyer, & Watkins, 1999). Effective supervisors see themselves as participants in the supervisory process rather than external observers of the therapy process (Whitman & Jacobs, 1998).

Supervision Extends Over Time. Supervisory relationships require some period of time – often several months – so that participants form a strong working alliance and begin the work of supervision (Bernard & Goodyear, 2004; Watkins, 1997). Many supervision relationships continue for years while others may be limited to several months because of the constraints of a training program.

Supervision Enhances Professional Functioning. The supervisory relationship exists for the express purpose of helping trainees to develop and hone the knowledge, attitudes, skills, and values essential for the competent practice of psychology (Bernard & Goodyear, 2004; Liese & Beck, 1997). Where formative supervision is crucial for instilling basic skills and competencies, ongoing supervision may minimize the likelihood that a psychologist's work will deviate from standards of practice or that a psychologist's knowledge and skills will become obsolete.

Supervision Helps to Ensure the Safety and Welfare of the Client. Supervisors are responsible for monitoring trainee's progress and performance as a way of protecting the public and preventing harm to individual clients (Vasquez, 1992). Monitoring the client care represents an essential ethical requirement for supervisors (American Psychological Association (APA), 2002); psychologists who supervise must balance attention between the trainee's development and vigilant concern for the best interests of all clients involved.

Supervisors Must Balance Developmental and Gatekeeping Roles. Supervision is a demanding role requiring psychologists to blend teaching, mentoring, and oversight roles with the perpetual obligation to evaluate trainees (Johnson, 2007; Watkins, 1997; Whitman & Jacobs, 1998). Like it or not, supervisors must constantly attend to quality control screening and ensure that trainees without sufficient skill or appropriate psychological fitness can be referred for remediation or even dismissal from the training program. Supervisors must maintain adequate objectivity and perspective so as to provide accurate formative and summative feedback to trainees.

Supervision Is Comprised of Multiple Supervisory Competencies. Although supervisory competency is a meta construct, competent supervisors are skilled at the delivery of numerous individual competencies (Falender & Shafranske, 2007; Johnson, 2007), many of which will be explored later in this chapter. Salient competencies include coaching and guidance in conducting therapy, bolstering a supervisee's professional identity, and communicating alternative views and perspectives (Watkins, 1997).

Supervision Is Distinct from Teaching, Psychotherapy, and Consultation. Bernard and Goodyear (2004) clearly articulate the contours between supervision and other roles commonly occupied by the psychologist. Like teachers, supervisors impart knowledge and engage in evaluation. Like psychotherapists, supervisors address supervisee's problematic thoughts, behaviors, and feelings and point out personal blind spots. Like consultants, supervisors attempt to help supervisees work more effectively as professionals. Yet, supervision is driven by the needs of the supervisee and the client (not a curriculum). Supervisors help supervisees to explore personal issues only if these relate to the efficacy of a client, and if supervision is more pervasive and enduring than consultation; supervision aims for broad development of the clinician, whereas consultation often addresses a specific deficit or a troubling case.

19.2.2 Competence

The term *competence* is now thoroughly intertwined with the literature on training and supervision in professional psychology (Kaslow et al., 2007). Both educational and training programs are expected to certify that their training "products" are competent to proceed to the next level of training or practice independently. Certainly, being competent is an ethical obligation for any member of the APA and psychologists licensed to practice psychology. For instance, Standard 2.01 of the Ethics Code, Boundaries of Competence, states that: "psychologists provide services, teach, and conduct research with populations and in areas only within the boundaries of their competence, based on their education, training, supervised experience, consultation, study, or professional experience" (APA, 2002, p. 1063).

Although psychologists have always demonstrated an interest in preparing competent professionals, ensuring competence is now framed as an ethical and professional obligation of psychologists engaged in training (Vasquez, 1992).

So, what is competence? Several authors lament about the fact that it is often easier to detect incompetence than it is to clearly delineate competence (Koocher & Keith-Spiegel, 1998), and that operational definitions of the competence construct are elusive at best (Ridley, Baker, & Hill, 2008). In an early effort to describe competence, Peterson and Bry (1980) conceptualized four dimensions of competence: professional responsibility, interpersonal warmth, intelligence, and experience. Pope and Brown (1996) reduced this model to two broad dimensions of intellectual and emotional competence.

Recently, definitions of competence in the field of professional psychology have become more nuanced and refined. We now provide examples of some of the more influential definitions of competence to date:

▶ [Competence is] the habitual and judicious use of communication, knowledge, technical skills, clinical reasoning, emotions, values, and reflection in daily practice for the benefit of the individual and the community being served. (Epstein & Hundert, 2002, p. 226)

► Competence refers to an individual's capability and demonstrated ability to understand and do certain tasks in an appropriate and effective manner consistent with the expectations for a person qualified by education and training in a particular profession or specialty thereof. (Kaslow, 2004, p. 775).

► Competence is a state of sufficiency relative to the specific performance or training requirements within the given setting in which such abilities are exercised. (Falender & Shafranske, 2004, p. 5).

Most authors now appear to agree that competence refers to the psychologist's suitability for the profession as reflected in the acquisition and appropriate expression of specific knowledge, attitudes, and skills (Rubin et al., 2007). But, if supervisors are responsible for helping to instill competence in trainees (Vasquez, 1992), at what point does a trainee cross the threshold from incompetent to competent? Recently, Elman, Illfelder-Kaye, and Robiner (2005, p. 368) attempted to define this process, which they term as *professional development*: "Professional development is the process of acquiring, expanding, refining, and sustaining knowledge, proficiency, skill, and qualifications for competent professional functioning that result in professionalism."

On the Distinction Between Competence and Competencies. When conceptualizing competence, it is important to carefully distinguish between discrete professional *competencies* – specific attitudes, knowledge, and skills – and *competence*, an integrated deep structure that hinges on the psychologist's ability to coordinate the application of specific competencies in a specific context with a specific client (Ridley et al., 2008; Wood & Power, 1987). While competence implies a broad or meta capacity, it is dependent upon many discrete competencies, and far from an absolute construct, competence reflects sufficiency of a broad spectrum of personal and professional abilities, given a specific clinical/professional requirement (Falender & Shafranske, 2004, 2007). Competencies are always elements of competence and as such should be observable, measurable, containable, practical, and flexible (Kaslow, 2004). As clusters of integrated knowledge, skills, attitudes, and abilities, competencies should be positively correlated with overall competence and should be measurable against well-established standards (Kaslow; Rubin et al., 2007). Wood and Power (p. 25) distinguish competence and competencies this way:

► Competence depends on the dynamic interplay of the various competencies … By skillfully managing the process, professionals can adapt to individual differences, special cases, and unforeseen circumstances. Essentially, the purpose of the integrated deep structure [competence] is to coordinate and integrate the subordinate competencies and related skills in order to attain the predetermined outcomes.

19.2.3 Toward Supervision Competencies

What makes a clinical psychologist competent to a mentor? For decades, psychologists have assumed that an adequate clinician will also be an adequate supervisor (ASPPB, 2003; Falender & Shafranske, 2004, 2007). Assumptions, such as a license to practice psychology implies competence in the supervisor role or experience as a supervisee equates to subsequent competence as a supervisor, are destined to undermine the importance of supervisor preparation. Such assumptions are also incongruent with research findings showing that, in practice, many supervisors fail to competently tailor their interventions and approach to fit distinct supervisees in unique contexts with different clients (Shanfield, Mohl, Matthews, & Hetherly, 1992). Moreover,

there is evidence that a great deal of supervision and mentorship is marginal at best; there is often a very significant difference between minimally adequate and superior supervisors (Ragins, Cotton, & Miller, 2000). For all these reasons, it is imperative that the psychology profession moves to establish supervision as a core competence area within the discipline. This would imply that training programs and individual psychologists should hold an ethical obligation to insure that those who supervise are well trained, knowledgeable, and skilled in the practice of clinical supervision (Falender et al., 2004; Vasquez, 1992).

There is another reason for establishing supervision as a core competency area. Many supervision theorists have begun to emphasize the importance of common factors across various supervision models (Holloway, 1992; Ladany, Ellis, & Friedlander, 1999). For instance, Falender et al. (2004) propose five supra-ordinate factors that are essential to and infuse all elements of supervisory competence. These factors include: (1) recognition that acquiring supervision competence is a lifelong, cumulative, developmental process, (2) recognition that diversity in all its forms relates to every aspect of the supervision process and requires specific competence, (3) recognition that attention to legal and ethical issues is essential, (4) recognition that training is influenced by both professional and personal factors including values, beliefs, interpersonal biases, and conflicts, and (5) recognition of the necessity that both self- and peer assessment occur regularly throughout supervisory development.

Becoming a competent supervisor requires a significant transition from being a clinician (Falender & Shafranske, 2004). In order to determine a psychologist's competence to supervise, educators and evaluators must establish explicit and measurable standards of competence. Then, supervisors in training must be prepared to supervise through immersion in relevant training, experience, and self-assessment opportunities (Getz, 1999). A competency-based approach to preparing supervisors should be quite similar to the competency-based approaches to training clinicians. Falender and Shafranske (2007, p. 233) offer a clear definition of competency-based supervision which can easily be applied to the supervision of supervision: "Competency-based supervision is defined as an approach that explicitly identifies the knowledge, skills, and values that are assembled to form a clinical competency and develops learning strategies and evaluation procedures to meet criterion-referenced competence standards in keeping with evidence-based practices and requirements of the local clinical setting."

In the remainder of this chapter, we seek to further the agenda of establishing a competency-based model of supervision (Falender et al., 2004; Kaslow, 2004) by enumerating the core or basic competencies required for competent supervision in clinical psychology. Core competencies, when applied judiciously to specific supervisees, training contexts, and clinical circumstances will translate into competent supervisory performance. We then propose several higher-order competencies that are manifest in clinicians with specific expertise in clinical supervision.

19.3   Basic Competencies

As referenced in the "Introduction" section, the 2002 Competencies Conferences began the process of defining competence to supervise (Kaslow, 2004). Another step in the direction of further defining core competencies for predoctoral training was accomplished in the creation of The Competency Developmental Achievement Levels (DALs) of the National Council of Schools and Programs in Professional Psychology (NCSPP). They were approved by the membership on August 15, 2007, for inclusion in the NCSPP educational and training model in

	Begin Practicum	Begin Internship	Complete Doctoral Degree
	Assuring Client and Organizational Welfare		
K	1. Understanding of need for supervision 2. Understanding that diversity plays a role in organizations 3. Knowledge of one's limitations in functioning within an organization	1. Knowledge of one or more models of supervision 2. Basic knowledge of how personal and cultural values can influence supervision and management 3. Knowledge of organizational operations and the functions and limitations of roles therein	1. Knowledge of supervision practices and agency policies that enhance client and staff welfare 2. Knowledge of at least one model or theory and associated research and applications. 3. Sophisticated knowledge of how diversity issues and personal and cultural values influence supervision and management
S	1. Demonstration of awareness of self and others in relationship to leaders 2. Articulation of the importance of diversity in organizations 3. Demonstration of self-control and flexibility in new situations	1. Demonstration of ability to think critically and analytically about self and others as a manager, supervisor, and as supervisee 2. Attention to issues of diversity within the organization 3. Demonstration of ability to determine when seek extra supervision is needed	1. Ability to implement at least one model of supervision 2. Integration of knowledge of diversity issues into supervisory and management process 3. Management and maintenance of own self-care and promotes the wellness of others 4. Effective work with organizational structure, hierarchical relationship, and multidisciplinary colleagues
A	1. Appreciation for diversity 2. Enthusiasm for learning to function in clinical role 3. Valuation of leaders and supervisors as guides for effective service delivery 4. Active approach to learning about self in systems	1. Awareness of self and role in larger system 2. Interest in learning about organizational systems and how they influence individuals within them	1. Concern for, and commitment to, well-being of supervisees' clients 2. Tolerance of role expectancies and ambiguities 3. Valuation of the incorporation of diversity issues in supervisory and organizational decision making

	Begin Practicum	Begin Internship	Complete Doctoral Degree
	Training/Mentoring		
K	1. Knowledge of the purpose of training and the roles of apprentice and supervisee	1. Knowledge of multiple roles in the supervisory process 2. Knowledge of research evidence relevant to supervision and management of organizations 3. Knowledge of individual and cultural differences in supervision 4. Knowledge of, and developing, expertise in clinical areas in which one is supervising	1. Basic knowledge of monetary implications of a healthcare service delivery system 2. Knowledge of at least one business model that lends itself to healthcare delivery systems 3. Understanding of the importance of training and mentoring in the professional development of individuals and in the quality Enhancement of Organization
S	1. Ability to articulate basic roles of supervisor and supervisee 2. Effective function within organizational context 3. Active search for opportunities to learn from clinical placement and supervisor 4. Acceptance and incorporation of feedback from instructors and peers	1. Demonstration of ability to think critically and analytically 2. Ability to establish a supervisory alliance 3. Ability to utilize and integrate feedback with in the supervisory relationship 4. Ability to apply research knowledge to health-care systems and supervision 5. Ability to articulate primary mission and limits of setting	1. Ability to take an active part in developing or changing public policy 2. Ability to apply research findings to suggest changes in organizational policies and planning 3. Ability to perform and balance multiple roles in supervision, e.g., teaching, evaluation, mentoring, and modeling. 4. Ability to provide effective formative and summative feedback 5. Ability to integrate and evaluate feedback within the supervisory relationship. 6. Ability to assess learning needs of trainees.
A	1. Demonstration of interest in learning 2. Demonstration of interest in self-reflection 3. Openness to considering advocacy as a professional responsibility	1. Desire to supervise others 2. Valuation of professional collaboration within supervisory relationships 3. Valuation of flexibility 4. Commitment to lifelong learning and quality improvement 5. Interest in advocacy efforts	1. Willingness to take an active part in developing or changing public policy 2. Valuation of training and mentoring as professional activities

	Begin Practicum	Begin Internship	Complete Doctoral Degree
	Evaluation/Gatekeeping		
K	1. Understanding of purposes of evaluation 2. Understanding of responsibilities of agencies to larger bodies for accreditation and approval	1. Knowledge of basic formative and summative methods of evaluating clinical work of supervisees 2. Knowledge of how diversity and individual differences can influence approaches to evaluation 3. Knowledge of evaluation and feedback methods used in organizations	1. Knowledge of "best practices" in evaluation 2. Knowledge of one's own value system and the implications for management 3. Knowledge of evaluation of healthcare delivery systems
S	1. Appropriate response to supervisor and agency expectations 2. Demonstration of constructive use of formative feedback 3. Provision of basic constructive feedback to peers 4. Provision of needed information in a timely manner	1. Assessment of clinical strengths and areas needing improvement for self and others 2. Evaluation of how issues of diversity impact the supervision process 3. Ability to seek, utilize, provide, and integrate feedback 4. Prompt response to supervisory requests	1. Development of new evaluative skills as needed to serve the health-care organization 2. Oversight of program evaluations with the aid of a more experienced manager 3. Modeling of an accurate and reflective self-assessment process 4. Stimulation of self-reflection and self-evaluation in others
A	1. Demonstration of non-defensive openness to both formal and informal formative feedback 2. Valuation of self-reflection and an active approach to self-discovery 3. Demonstration of cooperative attitude regarding supervisor's priorities and agency's policies and expectations	1. Interest in increasing self-knowledge and experience 2. Valuation of, and respect for, the dignity and autonomy of others 3. Valuation of own skills 4. Openness to providing and receiving feedback from peers and supervisors	1. Valuation of role in organizational system and the beginning comfort with role of manager/supervisor 2. Investment in offering others feedback 3. Investment in receiving feedback from others
	Ethics		
K	1. Basic knowledge of ethics codes 2. Understanding of need for, and purpose	1. Knowledge of professional ethics, statutes, and rules and regulations	1. Knowledge of legal and ethical requirements, case law, and risk management

	Begin Practicum	Begin Internship	Complete Doctoral Degree
	of, accurate record-keeping 3. Knowledge of own limitations in experience and skills	regarding supervision 2. Knowledge of limits of one's supervisory and clinical skills 3. Knowledge of differences between therapy, consultation, supervision, and management roles	relevant to supervision 2. Knowledge of limitations of one's own supervisory competence
S	1. Ability to recognize legal and ethical issues in clinical and organizational contexts 2. Ability to function within appropriate professional boundaries in an organizational context 3. Beginning skill in accurate and useful record-keeping	1. Demonstration of appropriate professional assertiveness related to ethical issues 2. Search for appropriate information and consultation about ethical issues in supervision 3. Evaluation of and appropriate response to ethical and legal issues associated with supervision or organizational demands 4. Ability to comply with legal requirements 5. Ability to promptly complete necessary records with minimal supervision of methods	1. Integration of legal and ethical awareness in planning and implementation of programs 2. Ability to help supervisees and others recognize ethical dimensions of clinical decision making 3. Ability to develop record keeping methods that aid the organization's functioning 4. Ability to resolve supervisory role conflicts.
A	1. Demonstration of appreciation for and commitment to ethical practice 2. Recognition of the influence of value systems to ethical decision making 3. Appreciation for the need to function within the policies and procedures of an organization	1. Commitment to ethical practice as supervisee and supervisor 2. Appreciation for professional and business codes of conduct that influence service delivery	1. Commitment to ethical practice in all aspects of supervisory behavior 2. Encouragement of supervisees and organizations in the development of ethical practices
	Health Care Leadership and Advocacy		
K	1. Basic knowledge about healthcare systems	1. Understanding of impact of reimbursement on treatment provided	1. Knowledge of systemic implications of financial issues for healthcare service delivery

	Begin Practicum	Begin Internship	Complete Doctoral Degree
		and service delivery system 2. Knowledge of one or more models of leadership/management 3. Basic knowledge of monetary implications in service delivery	2. Knowledge of leadership and management roles 3. Basic knowledge of healthcare service delivery system options 4. Knowledge of at least one business model that lends itself to healthcare delivery systems
S			1. Ability to take an active part in developing or changing public policy 2. Ability to apply research findings to suggest changes in organizational policies and planning 3. Beginning ability to provide leadership in program planning and development
A	1. Openness to considering advocacy as a professional responsibility	1. Interest in advocacy efforts	1. Willingness to take an active part in developing or changing public policy

professional psychology. Each core competency is divided in grid format across three levels of clinical training: Begin Practicum, Begin Internship and Complete Doctoral Degree. Five domains of Management and Supervision were developed: (1) "assuring the well being of the client or organization," which was placed first to emphasize the primary duty of supervisor to client welfare; (2) "training and mentoring of supervisees and those being managed," which refers to the educative/facilitative dimensions of the supervisor/manager role; (3) "evaluation/gatekeeping," which refers to the responsibilities associated with formative and summative feedback to supervisees and communicating evaluative messages to external groups such as academic programs, administrative personnel, and licensing boards; (4) "ethics," functioning within the standards of the profession which cuts across all aspects of the competency, and (5) "health care leadership and advocacy," which refers to the roles and functions associated with managing programs or organizations as well as influencing organizational, governmental, and societal values and policies in the health care arena. Each domain is operationalized by specific tasks and outcomes across the dimensions of knowledge (K), skills (S), and attitudes (A).

Initially, graduate students in clinical, counseling, and school psychology, start out on the receiving end of supervision. At the Pacific University's SPP, students begin practicum training under the supervision of a licensed faculty person, after an initial year of academic instruction. The model followed is that students continue to receive supervision through 2 years of required practicum experience, optional clinical fieldwork for advanced students, internship, and then depending upon the state or province the individual will practice in after graduation, some form of postdoctoral supervised training. The ultimate goal representing independent and

autonomous functioning, represented by a license being granted, is that supervision is no longer *required*. However, in keeping with the first of the five supra-ordinate factors mentioned by Falender et al. (2004) that acquiring supervision competence is a lifelong, cumulative, developmental process, lifelong supervision or consultation is encouraged after licensure is achieved.

What is prudent to mention at this point is the inherent challenge in training students to become competent at basic levels of supervision skill. These are the ethical and legal issues of who is eligible to supervise. Clinical supervision by definition is a professional relationship between a licensed psychologist and a psychologist in training (practicum student, intern, resident) who is not able to provide services independently (Thomas, 2007). Supervisors have professional responsibilities to the supervisee and to the client. Supervision implies the supervisor's clinical responsibility for the work being supervised, i.e., client welfare. The supervisor is also legally responsible for the supervisee's actions.

Training in how to supervise faces some challenges nonexistent in training graduate psychology students in how to become administrators, consultants, teachers, and/or researchers. There are numerous examples, most likely familiar to readers of teaching assistantships, research assistants, assigning classroom or seminar projects of program consultation or organizational evaluation, that do not conflict with ethics or state regulations of the practice of professional psychology. However, in most jurisdictions, it would be unethical and illegal to "turn loose" a student–clinician trainee to independently supervise.

To address this issue, in the fourth year of training at SPP, students are required to take a two-semester Professional Roles class. In the first semester, they are introduced to the foundational seven competencies required for entry-level practice in professional psychology as promulgated by the NCSPP: relationship, assessment, intervention, diversity, research/evaluation, management/supervision, and consultation/education. This is in addition to other non-purely clinical domains of roles professional psychologists can engage in, i.e., administration, management, academic teaching, continuing education (CE) workshop provision, coaching, political action and advocacy, etc. In the second semester, Professional Roles is paired with a Supervision of Supervision (SOS) course, in which students are introduced to the multiple theories of supervision and are able to "supervise" master's students in our Counseling Psychology program. The class is taught by a licensed faculty and each doctoral student is paired with one to two master's students who are learning how to do assessment and therapy with each other as "pseudo-clients." Thus, no actual clients are involved in this training experience. Doctoral students receive feedback from the faculty person on their "supervision" of the master's students' role plays with each other. They also discuss assigned readings in their text and journal articles. Additionally, they are evaluated by their "supervisees" and asked to self-evaluate.

In our APA-approved internship at our in-house training clinic, the Psychological Service Center (PSC), interns are able to provide consultation to the practicum and clinical fieldwork students, and are under the supervision of their licensed faculty supervisor(s). They attend a weekly seminar in which theory and practice are discussed in a variety of domains they are being trained in. Thus, no student–clinician at any level of predoctoral training is independently supervising, but is offered gradual exposure to the skill sets required for basic competence in providing supervision.

Essentially, then, a "tandem" experience is occurring simultaneously for these predoctoral students: continuing to receive hopefully competent required supervision up to the point of completion of their internship, while learning how to provide competent supervision themselves. Such learning is a combination of role modeling, didactic instruction, exposure to research and literature in the theory and practice of supervision, and supervised practice in

providing supervision to less experienced students than themselves. The pre-internship students practice with less experienced students seeing pseudo-clients, while the interns are practicing with practicum students seeing real clients. However, in the latter instance, no intern acts independently of his or her own assigned supervisor in this consultative role.

Another challenge in the continuity of training psychologists to provide competent supervision is the requirement of several years of licensure prior to being eligible to supervise. The ASPPB Supervision Guidelines recommend that the supervisor has at least 3 years of post-licensure experience and has had training and/or experience in supervision (ASPPB, 2003, p. 3). This varies by each state's licensing board, but in Oregon, the minimum number of years of licensure required for predoctoral and postdoctoral supervision eligibility is 2 years. There is no requirement to provide documentation demonstrating proof of training in how to supervise. Ironically, this is in contrast to the Licensed Professional Counselor (LPC) Board in Oregon, which requires documentation of 30 clock hours of training in supervision prior to being eligible to supervise an eligible candidate toward the LPC credential. The majority of LPC's practicing in Oregon are master's prepared mental health therapists, as opposed to doctoral level practitioners.

In a personal communication from the former chair of the Oregon Board of Psychologist Examiners (OBPE) to the first author, the concern expressed for a requirement to document proof of formal training in how to supervise the licensed psychologists, is that it would further draw down the limited pool of psychologist eligible, willing, and available to supervise in Oregon. (S. Dale, June 20, 2007, personal communication). In the past several years, the OBPE has developed elective trainings, offered several times a year, in what is called Orientation to Psychologist Residency Supervision. Continuing education credits are available to those who attend.

To further illustrate SPP's model, the ten core and part-time faculty who are involved in direct supervision of service provision by the predoctoral student–clinicians in our in-house training clinics meet twice a month for a 1 hour meeting that is also entitled SOS. While some administrative issues regarding clinic policies and procedures are discussed, the meeting exists to support the supervisors in their complex and demanding roles as such.

A subset of this group attends a once a month Journal Club meeting, in which articles in the literature relevant to the various domains of professional psychology are read and discussed. Articles on the topic of supervision are frequently selected. In November 2008, the first author presented a 4 hour continuing education workshop to 45 core and part-time supervisors entitled Ethical Supervision: Best Practices, as another example of supporting supervisors to provide competent and ethical supervision.

In weaving back and forth between the theory and practice in achieving competence in supervision, the question still remains of basic competencies and how they are assessed. As the DALs have been so recently issued by the NCSPP, the structure of how to teach to supervise is still evolving, but does have a base in the literature.

Holloway, 1995, developed a *Systems Approach to Supervision* (SAS) as an example of a trend toward understanding how supervisors can be trained to do supervision rather than solely focusing on how supervision has been done. Her work addresses the contextual factors of the supervisor, the trainee, the setting in which supervision is provided and the cultural elements of each of these three factors. C. Edwards Watkins Jr. in his 1997 *Handbook of Psychotherapy Supervision* has chapters on how to provide supervision from the perspective of the following theoretical schools: Psychoanalysis, Psychodynamic Psychotherapies, Interpersonal, Dialectical Behavior Therapy, Rational Emotive Behavior Therapy, Cognitive Therapy, Client Centered, Gestalt, Experiential Model of On the Job Training, Developmental Perspective,

Integrative and Systemic Cognitive-Developmental Supervision. Bernard and Goodyear (2004) illustrate how most models of clinical supervision can be organized into four primary categories: (a) developmental models, (b) social role models, (c) psychotherapy-based models, and (d) integrative models. Aten, Strain, and Gillespie (2008, pp. 6–7) propose a transtheoretical model of supervision which includes ten supervisor processes of change: consciousness raising, dramatic relief, self-reevaluation, environmental reevaluation, self-liberation, stimulus control, counterconditioning, contingency management, social liberation, and helping relationships.

19.3.1 Case Example

To illustrate the SPP introduction to the basic competencies in clinical supervision, the first author provides the following "case example." Alice is a composite example of a fourth-year SPP student taking the required course of Professional Roles I in Fall Term of any given academic year. She is exposed to multiple competencies in a variety of domains professional psychologists can practice in, and this class emphasizes non-purely clinical roles to help students "diversify their vocational portfolio." In a vocational interests assessment survey conducted in the beginning of the course, about one third of the students indicate intention to become supervisors in their professional careers. In class, they are introduced to theories of clinical supervision, ethics involving supervision, and the DALs, through lecture and readings. They are assigned a "Shadow Knows" project, completed individually; and in group format, a Capstone Project is started that will be brought to completion in the second semester, or during the following Spring Term, in Professional Roles II. The Shadow Knows project involves shadowing a professional psychologist in the community at a non-purely clinical aspect of their job (supervision, consultation, coaching, administration, teaching, etc.) and interviewing them about job preparation and how they became interested in this aspect of the profession. AG would turn in a written report and give an oral presentation to the entire class, to permit vicarious learning.

The Capstone Project involves a small group of typically four students who contact an outside institution or agency, to explore more fully the nonclinical role and engage in active provision of that role. The contact and contract are made during Fall Term, and then the students complete the project in Spring Term. For those who choose clinical supervision, a typical activity is a review of the literature and a survey of student–clinician attitudes about positive and negative aspects of supervision, with a confidential report made to the supervisors of the results. Another example is the Capstone Group teaching to a class of Master's in Counseling Psychology students at another graduate school on ethical and competent supervision. The students self-evaluate their projects, give an oral presentation to the entire class on what they did and how they felt the project went. They are also evaluated by an independent, third party, typically a contact person at the agency or institution, who sends his or her evaluation to me to include in the overall grade.

As Professional Roles II (PR II) is a two-credit course, it is paired with a one-credit course of SOS, taught by a fellow faculty member. It is offered in both Spring and Summer Terms of any academic year, and the PR II students are paired with one to two Master's in Counseling Psychology students to "supervise" their role plays with each other as pseudo-clients in learning therapy and assessment techniques. The PR II students meet weekly with the faculty member in class format for lecture and readings discussion on clinical supervision, and weekly with their "supervisees" in group. The PR II students set training goals, review videotapes of the "sessions" their students have made of their role plays, and are evaluated by the master's students.

The texts we have used in the SOS class include Haynes, Corey, and Moulton's (2003) *Clinical supervision in the helping professions*: *A practical guide*, New York, Brooks/Cole-Thompson. In 2009, we are using Falender and Shafranske's (2004) *Clinical supervision: A competency-based approach*. Thus, AG would have the benefit of practicing basic competencies in clinical supervision prior to starting his or her internship.

19.4   Expert Competencies

The 2003 ASPPB Supervision Guidelines are meant to assist jurisdictions and supervisors by providing recommendations for: the supervision setting, supervisor qualifications, the duration and frequency of supervisory contact, the conduct of supervision, evaluation, regulation, and enforcement issues. Qualifications of supervisors are: Supervising psychologists shall be licensed or certified for the practice of psychology and must be aware of and abide by the ethical principles and state statutes pertaining to the practice of psychology in general and to supervision in particular. Supervisors have adequate training, knowledge, and skill to render competently any psychological service which their supervisees undertake. In instances when the needed service of a client is beyond the areas of expertise of the supervisor, supervision may be delegated to another psychologist whose competence in the delegated areas has been demonstrated by previous education, training, and experience. They shall not permit supervisees to engage in any psychological practice which they cannot perform competently themselves. The supervisor has the responsibility to interrupt or terminate the supervisee's activities whenever necessary to insure adequate training and the protection of the public. The supervisor has at least 3 years of post-licensure experience and has had training and/or experience in supervision (ASPPB, 2003, p. 3).

No specific training or experience requirements are indicated. While the first author has been continually supervising predoctoral and postdoctoral psychologists, as well as practitioners from other disciplines in the mental health field, in a variety of inpatient and outpatient clinical settings since 1987, she had no formal academic training in supervision during her years in graduate school from 1981 to 1985. Her skills and expertise have been predominantly acquired on the job, by attending professional development workshops, and through consultation from more senior mentors. In offering SPP's model and herself as an example of an expert supervisor in a setting conducive to supporting expertise, the reader is asked to accept this in the spirit of humility and as one possible model. The first author is very aware this model could be described as derivative of a prospective template based on a retrospective review of experience acquired while not necessarily following a prescriptive or formal training model at the time.

19.4.1 Supervisor Preparation

The following are recommendations to help make more standardized the definition of expert competencies in clinical supervision (Haynes, Corey, & Moulton, 2003):

- Formalized training in supervision which would include preparation to conduct clinical supervision. Components include self-assessment, ethical competence, knowledge of diversity and multicultural competence, and continuing professional development.
- Knowledge of formal contracts and agreements.

- Ability to initiate and maintain a positive supervisory relationship.
- Ability to assess both supervisees and all clients they will serve.
- Multiple modes of direct observation of the supervisee's work, i.e., video, DVD, one-way observation mirror, etc.
- Policies and procedures for practice.
- Knowledge of proper documentation methods.
- Specific feedback and evaluation plans.
- Good risk management practices.

Pragmatically, the first author, to the extent she is capable given the supervisory setting, does the following:

- Interviews the supervisee to determine mutually compatible interests.
- Signs supervision contract.
- Establishes training goals.
- Reviews evaluation form at the start of supervision to acquaint supervisees with the domains they will be evaluated in.
- At semester midpoint conducts an informal check in using the evaluation form completed "blind" meaning without prior discussion with supervisor and supervisee. Upon review, can discover if a "course correction" is needed in terms of how close or far apart perceptions of a student–clinician's work are.
- Formal evaluation at the end of each semester for both student–clinician and supervisor. Good supervision should mean there are no "surprises" at the end of the term.

The expertly competent supervisor has a supervision theoretical model to operate from, is familiar with the literature on supervision, checks malpractice coverage to ensure coverage of vicarious acts of supervisees, ideally has a support group of other supervisors that meets regularly, and attends periodic update professional development trainings on supervision that can also ideally earn continuing education credits.

19.4.2 Ethics

The first author teaches an Ethics course annually each Summer Term for first-year doctoral students prior to their entering practicum training in the Fall Term. She also teaches peers and colleagues in a continuing education workshop format on Ethical Supervision: Best Practices. A review of the 2002 Ethical Principles of Psychologists and Code of Conduct reveals that there is no separate section devoted exclusively to supervision. The pertinent codes extracted from the subsections are the following: 2.01 Boundaries of Competence; 2.03 Maintaining Competence; 2.05 Delegation of Work to Others; 3.05 Multiple Relationships; 3.08 Exploitative Relationships; 7.04 Student Disclosure of Personal Information; 7.06 Assessing Student and Supervisee Performance; and 7.07 Sexual Relationships with Students and Supervisees (APA, 2002, pp. 1060–1073). She has also volunteered as an orals examiner for the Oregon Board of Psychologist Examiners, which covers ethics and jurisprudence regulatory statutes for psychologists desiring licensure in Oregon. She also is an American Board of Professional Psychology examiner for clinical candidates. Again, this is another avenue to stay abreast of ethics developments in the field.

19.4.3 Diversity

The first author is fluent in Spanish and is the Director of the Latino Bilingual Track for the Pacific University's SPP. She developed a training model for fluent Spanish-speaking doctoral psychology students to participate in international study as well as to serve in clinics for practicum and internship training where Spanish-speaking populations are served. Additionally, she attends diversity training workshops offered annually by SPP for core and part-time faculty. Each syllabus, whether for a class or a supervision team, addresses diversity as follows: This course/supervision honors the diversity of individuals and organizations. Client services, readings, presentations, and discussions will be respectful to all people from the variety of personal ecologies. This includes race, class, nationality, regional identity, ethnicity, religion, age, sexual preference, gender, and abilities.

19.4.4 Structuring Supervision

To illustrate one model of conducting supervision, the first author currently supervises a team of four practicum students at one of the two in-house training clinics at the Pacific University's School of Professional Psychology, called the Psychological Service Center. It is located at the heart of downtown Portland, OR, and thus is in a metropolitan, urban area. There are 12 supervision teams: ten for providing therapy services and two for providing assessment services. In Spring Term of each academic year, about the month of February, each doctoral student ranks their choice of practicum placement from approximately 45 community sites, working in concert with the Director of Clinical Training (DCT). The goal at SPP is to keep as many first-year practicum students as possible in our two in-house training clinics, to provide close supervision and engage in a concerted attempt at gatekeeping, in addition to fostering student development. Most first-year practicum students are transitioning from the initial year of academic course work to their first clinical rotations. Some have come with past work experience in the mental health or chemical dependency field, and some have current, part-time positions working to supplement income while in graduate school. Some have had no related paid work experience in the field, but may have volunteered in their communities during their undergraduate years staffing a "hotline," or working in a crisis center. Some have been resident advisors in their college dormitories.

I supervise from a psychodynamic perspective and students who are assigned to my team as practicum or clinical fieldwork student–clinicians are aware of that orientation during the ranking time frame in the Spring. They are assigned to me by the PSC Director and the DCT.

If I am accepting a psychologist resident for postdoctoral supervision or someone from another discipline in the mental health field into my private practice, I will have a face-to-face interview to determine mutual compatibility and assess for ethical comportment. I have turned down requests for supervision from candidates only interested in a "rubber stamp" supervisor or for whom I did not feel confident about their integrity. If there is a mutual decision to enter into a supervisory relationship, we follow the stipulations and requirements as determined by the Oregon Board of Psychologist Examiners (OBPE) for a contractual arrangement, which requires approval by the Board prior to the start of the postdoctoral hours to count toward ultimate licensure. These forms are available for review at the OBPE Web site at www.obpe.org.

For an example of the contract I use when supervising or consulting with someone from a related field, please see Appendix A.

The clinical training year for practicum student–clinicians and interns extends from late August to the following year mid-August. The students have access electronically to the syllabus for each academic year, and know the dates we will be meeting, my expectations for supervision, and assigned readings for the year. The majority of the month of September is spent in group team meetings for 3 hours, as their caseloads are typically low, and I can spend time in orienting them to clinic policies and procedures (this is also done in weekly trainings by SPP administrators and staff), discuss psychodynamic theory, and get a feel for their knowledge and experience base, engage in team building exercises, and establish a baseline of knowledge I would like them to have at the beginning of our work together. We discuss their training goals and I orient them to the evaluation forms used at the PSC and quality assurance measures for charting. For examples of the Practicum Evaluation Form and the Intern Training Goals and Evaluation Form, please see Appendices B, C and D. I also have a handout of What to Bring to Supervision:

What to bring up in supervision; or, how to know which cases to ask about when you only have a limited time frame for supervision (in no particular order):

1. Any suicidal client, suicide ideation, suicide risk factors
2. Any homicidal client
3. Any time you hear threats to another person
4. Any time the client mentions violent fantasies, song lyrics, thoughts, etc.
5. Any time you hear about possible harm to a child (under age 18), including physical, sexual, or emotional abuse
6. Any time you hear about possible harm to an elderly person (65 or older)
7. Any time you hear about possible harm to a developmentally delayed adult
8. Any time you hear about possible harm to a mentally ill adult
9. Any unusual feelings about particular clients
10. Any times you told personal information
11. Any "out of office" contacts with clients, including telephone calls after work hours and any planned or unplanned meetings
12. Any physical contact with clients
13. Any times gifts are given or received
14. Any bartering or different fee arrangements with clients
15. Any time a client threatens a complaint or lawsuit
16. Any time the client brings up court or legal issues
17. Any time the client asks you to write a letter for him or her
18. Any time you receive a request for information about the client
19. Any time the client asks to see his or her file
20. Any time you employ an assessment device, even a behavioral checklist
21. Any time you stray from the agreed-upon treatment plan

We then move into a schedule of alternating weekly 3 hour group supervision meetings with 45 min individual supervision times, to allow a balance between vicarious learning in the group and more privacy for specific feedback in individual meeting times. We establish if there is an urgent client situation, i.e., suicidal, homicidal, abusive to attend to as a priority. Next, we move on to the other clients in each student's caseload. The student–clinician presents a client and

comes with consultation questions formulated, has a portion of a DVD of the actual session to show, and then a discussion ensues. The initial emphasis is on helping students to establish a therapeutic working alliance, recognize positive and negative transferences, clarify diagnoses, establish appropriate treatment plans to match the client's presenting concerns and learn to recognize various levels of defensive functioning and to make conducive interpretations. An overarching goal is to establish a safe and trusting environment in which the students can feel comfortable sharing their mistakes as well as their superb accomplishments. A favorite quote from a previous supervisee is that supervision from me would often challenge her in ways she could not always understand at the time, but put her on her "growing edge."

19.4.5 Evaluations

Evaluations, both informal and formal, are always done in individual meetings for confidentiality and Family Educational Rights and Privacy Act (FERPA) reasons. FERPA is a federal US law to protect students' privacy and confidentiality. Midpoint through each semester I do an informal evaluation with each student–clinician. I have them complete the evaluation form independently of me, and I also fill one out for them. We then compare our ratings to see how closely they match. If there are significant discrepancies in our perceptions of their performance in each of the domains evaluated, this offers the opportunity for a "course correction." At the end of each term, a formal evaluation is conducted, I sign off on their accumulated hours, and this becomes a part of their SPP student evaluation file. At the end of each term, they are offered the opportunity to complete an evaluation of me anonymously through Survey Monkey electronically, and the aggregate ratings are sent to me by the DCT's administrative assistant for my review. These reviews are included in each faculty supervisor's personnel file for inclusion in the annual performance appraisal.

19.4.6 Case Example

The following will illustrate the first author's clinical supervision of a team of Practicum I or Practicum II students in one of SPP's in-house training clinics. In August, I send a welcome and introductory e-mail to the student–clinicians assigned to me. I include a copy of the syllabus, with assigned readings and dates we will be meeting for Fall Term. They sign their contracts during the first week of orientation, which are returned to the DCT. The orientation is being conducted by a variety of faculty and staff to assist the student–clinicians in "learning the ropes" of agency policies and procedures. In our first group meeting as a team, I have each of them complete a training goals survey and discuss what their experiences to date have been in either volunteer or paid work positions. I ask them at this point in their training, what they envision doing with their degree, and in what settings they would like to work. As the majority of my fellow faculty teach and practice using Cognitive-Behavioral Theories, I know that as a psychodynamic practitioner and supervisor I will have some basic teaching tasks during the first month of our supervision meetings to bring the team to a "baseline" level of understanding various terminologies and techniques. Primarily, I am introducing or reviewing the concepts of conducting good interview assessments, accurate diagnosis, building rapport, establishing therapeutic working alliances with clients, transference, countertransference,

case conceptualization, and formulating treatment plans. I give them copies of the evaluation forms used by the PSC, and how I will work with those tools, both for midterm informal (mutual check in) evaluation and formal end-of-the-term evaluation. I explain to them the difference in formative and summative evaluation, and also gently remind them I have a gate-keeping responsibility to the profession and consumers. One helpful way to introduce this delicate concept is to remind those of them who have participated in the admissions committee process that they have actually been involved, in part, in giving input to who is admitted versus rejected from the SPP program.

I very clearly explain my expectations of how they are to come prepared to use supervision time, that I am ultimately responsible for their actions and the safety and well-being of their clients, and that they are practicing under my license. They are given a copy of the previously described What To Bring To Supervision. I have found in teaching ethics that the model of Berry and Sam (1997) of acculturation, originally to ethical identity, is usefully applied to acquire a professional identity. The idea of "culture shedding" is a helpful concept in understanding and shaping student–clinicians. New graduate students and student–clinicians vary widely in their knowledge and understanding of professional comportment, and can undergo a period of confusion and resistance as they adapt to the values, traditions, and behaviors of an unfamiliar profession. Where I see this most concretely occur is in the areas of jurisprudence and understanding how and why psychologists have discretion as abuse reporters in Oregon in privileged and confidential settings. If students worked in a setting prior to training with us, or are currently working in a setting where they are considered mandated reporters, there is a shedding of one role to adopt another. I also explain to them how I will review their written work, to complete it in a timely fashion, for client files and quality assurance reviews.

And so the training year begins, and I am looking for the qualities of openness to feedback, receptivity and eagerness to learn new ideas and try out techniques, compassion and empathy, willingness to discuss mistakes as well as accomplishments, and support each other as team members. The student–clinicians attend twice the monthly trainings by a variety of faculty and community professionals, attend once the monthly Grand Rounds, and work with the interns as consultants to cases. We have three semesters during the training year, so three formal evaluations are conducted at the end of each term.

During the training year, the first Term is typically helping students building caseloads, with their first clients typically transfer clients from previous student clinicians. Thus, working with attachment-loss-and reattachment issues conceptually and technically to retain clients is a theme. Making students feel comfortable and knowledgeable with clinic policies and procedures, and less performance anxious, is also an initial training goal. The second Term is about consolidating theoretical knowledge and understanding and creating useful treatment plans that connect theory to techniques in accomplishing clients' treatment goals. By the third Term, preparing students for transfer and termination of clients, as well as their own departures from the clinic, is a predominant theme. Many client terminations are determined by the student–clinician's training goals as opposed to the clients finishing treatment on their own. So, sensitivity to perceptions of rejection and abandonment on the part of some clients is thoroughly discussed.

Throughout the year, I will be participating in SOS meetings with fellow supervising faculty, attending CE workshops, and staying abreast of the literature. This description and case example has emphasized working with beginning student–clinicians in their first year of Practicum training. If I am supervising a postdoctoral fellowship, I follow a developmental model of less teaching, didactics, and direct instruction through role-modeling to help prepare

the more advanced supervisee for a greater level of independence and autonomy granted through licensure.

19.5   Summary

Our overview provides an acknowledgement of the seminal and continuing importance of clinical supervision to the field of professional psychology. In recognition that the field is moving in the direction of establishing competencies in the domains reflected in this handbook, this chapter has elucidated an understanding of a distinction between competence and competencies. As the field moves from a belief and practice that learning how to supervise was based on an apparent apprenticeship model of observation and "osmosis," benchmarks are now being established to help guide training programs toward a more standardized process of teaching how to supervise. One graduate school's model was discussed as an example of incorporating the DALs into required coursework and experiential training in how to conduct clinical supervision.

In discussing basic and expert competencies, it is apparent that there are inherent challenges in reaching consensus given the multiplicity of theoretical approaches, settings and populations supervision is provide, as well as the pragmatic challenges of ethical and legal prohibitions against nonlicensed supervision.

A review of the DALs for predoctoral training and recommendations for post-licensure-continued acquisition and enhancement of clinical supervision knowledge and skill provides examples of support and ongoing development of the supervisor. Professional development in the domain of clinical supervision is truly an ongoing, lifelong developmental curve. The ethically and legally compliant supervisor will find that the bulk of preparation and experience will continue to occur post licensure.

Robin L. Shallcross
Diplomate in Clinical Psychology, Portland, Oregon, USA

Supervision/Consultation Contract

Introduction

Welcome to my practice. I look forward to our work together in either a supervisory or consulting relationship. There is a distinction between these two terms; we will establish which type of relationship we have entered to be clear about the nature of our work together. If I am supervising your work, you are practicing under my license, and we share the responsibility for the work you do. If I am your consultant, I act in the capacity of an advisor only. You are not compelled to follow my suggestions and I am not legally held responsible for your work. The professional decisions you make as an advisee are solely your own.

I have been a licensed psychologist in Oregon since 1992 and earned my Diplomate in Clinical Psychology from the American Board of Professional Psychology in 1990. I have been supervising and consulting with a variety of mental health professionals since 1987. My theoretical orientation is psychodynamic and my professional experience includes therapy work and assessment in inpatient and outpatient settings: individual, couples and group work, public speaking engagements, workshop presentations, administrative and program development in academic settings. I work primarily with an adult populaion and do not consider myself trained to work with children or adolescents under 16. I am also not qualified to conduct neuropsychological testing, other than brief screening instruments.

Confidentiality

Our supervision/consultant relationship and the work that takes place are considered confidential with the following exceptions:

- If you work at an agency we will need to discuss communications with your supervisor at the agency. We will need to establish frequency and type of contact between myself and your supervisor, responsibilities of your agency, me and you for communication about professional activities and evaluations. All clients need to know you are in supervision (it is your choice whether to advise clients of retaining a consultant) and that they will be discussed confidentially. Please have clients sign permission to audio/video tape sessions after discussion with them and before you tape. This should be considered part of informed consent.

Initials_____

- If you are working towards licensure or are presently licensed you are expected to abide by the Code of Ethics of your professional board. If I believe you are endangering clients by unethical practices, I will need to report those practices to the appropriate board.

- If you are a student, evaluations will be shared with your school. We will also need to follow their requirements for standards and practice.

Expectations for Our Work Together

We will discuss and set goals for professional growth in supervision/consultation on an ongoing basis. You are expected to prepare for each session by thinking through these goals, your cases and deciding what case presentation and questions would be most pertinent for us to focus on.

We will have formal written evaluations every _____. These will be shared with _____. Your evaluation will be based upon the goals we are meeting and the ongoing feedback in each session. I expect you to evaluate how supervision and or consultation is meeting your needs and what I can do to change to better help you.

We will discuss suicide assessment, risks and procedures and duty to warn information to prepare you for a suicidal or violent client. This information is to assist your clients and support your professional knowledge and independent functioning if an emergency arises. You will be asked to sign that we reviewed this information.

You are expected to follow all ethical rules for informed consent and confidentiality for clients. We will review the forms you use for release of information with other professionals and to discuss when you have contacts with professionals about clients.

You are expected to maintain clear professional boundaries with clients. Throughout supervision/consultation we will focus on ethics and deepen your understanding of ethical practice. We will discuss professional boundaries and possibilities of dual relationships. This serves as notice I consider sexual relationships harmful to clients, unethical and prohibitive.

Feelings as they arise with and about clients are important information relevant to the therapeutic relationship. I expect these feelings to be discussed in supervision/consultation.

We will need to discuss all "out of office" contacts with clients. This includes telephone calls to your home by a client, telephone calls after work hours to or from your client, and any planned or unplanned meetings (i.e., at the grocery, social events, movies, school or professional functions, etc.)

Initials_____

We need to discuss any physical contact with your client, even if you consider this touching therapeutic.

We need to discuss any bartering arrangement you may consider with a client instead of a set fee. In addition, we need to discuss any acceptance or giving of gifts.

Information About You

Have you ever had a complaint of any kind filed against you by anyone, including but not limited to clients, colleagues or the lay public? This complaint may have been to a supervisor, administrator, licensing board or professional organization.

_____yes _____no

If yes, what was the outcome of the complaint? Were you disciplined? Please elaborate using an extra sheet if necessary.

_____
_____
_____
_____
_____
_____

Do you have malpractice insurance? Malpractice insurance is a requirement for supervision or consultation and coverage must be maintained throughout our work together. Please provide a copy of your current coverage including the name of the carrier, limits and dates of coverage. In the event you change insurers, have your insurance cancelled and/or have a claim made against your professional insurance, you must disclose these changes or events immediately. If our agreement lasts over time, I may request you provide me with an update of your professional liability coverage.

We have agreed to meet _____ for the dates beginning _____ through _____. My fee for each one hour session is _____. Please pay me at the time of our appointment, unless we make other arrangements.

This supervision/consultation relationship may be terminated by either party at any time. In such an event, we will document the termination agreement in writing.

I have read all the above exceptions to confidentiality and expectations. I have discussed this contract consisting of four pages and agree with all of its provisions. A copy of this contract has been provided to me.

I have read and understand the terms of this agreement. I am retaining Robin L. Shallcross, Ph.D., ABPP as a supervisor/consultant.

SCHOOL OF PROFESSIONAL PSYCHOLOGY
Clinical Psychology Program, Pacific University, Portland, Oregon, USA

Student Name	**Grade Recommended by Supervisor (P/F)**
Semester (Spring, Summer, Fall) & Year	Supervisor Name
Training Level	Site

SITE'S EVALUATION OF TRAINEE

We recommend that evaluation be done collaboratively with the trainee by the primary supervisor. This form is due to the Clinical Training office by the last day of classes in the term.

INSTRUCTIONS: Using the scale below, give an overall rating for each area of competency and add any explanatory comments regarding strengths or concerns. **Rate students relative to other students at the same level of training.**

6	Exceptional
5	Excellent
4	Very Good
3	Good
2	Fair
1	Poor
0	Unacceptable

RELATIONSHIP: INTERPERSONAL SKILLS

- Remains pleasant and accessible towards others
- Maintains professional boundaries with others
- Aware of impact of own behavior on others
- Communicates understanding of other's positions, concerns
- Adapts behavior appropriately based on feedback
- Articulates points clearly to others
- Maintains positive, enthusiastic attitude
- Interacts with others in a professional and courteous fashion
- Tolerates ambiguity/uncertainty
- Presents a professional image (dress, grooming, demeanor)
- Is comfortable in supervisory role
- Provides helpful, accurate guidance
- Provides balanced, sensitive feedback
- Seeks supervision to augment supervision/consultation of others

Interpersonal Skills Rating	
Comments:	

SUPERVISION (RECEIVE) SKILLS

- Reviews/prepares for supervision
- Identifies and works on supervision objectives
- Hears and implements feedback
- Communicates clearly in supervision
- Is aware of personal biases/impact on clients and supervisors
- Is developing professional counselor identity

Supervision Rating	
Comments:	

CASE MANAGEMENT SKILLS

• Maintains chart documentation in timely, complete fashion	• Knows when s/he needs consultation
• Writes useful, intake, transfer, termination reports	• Consults when needed with other agencies with documentation
• Keeps updated, useful, behaviorally specific treatment plans	• Manages time & caseload sensitively & effectively
• Maintains accurate, complete case notes	• Follows agency rules/procedures
• Refers to treatment notes when writing case notes	• Completes paperwork on time

Case Management Rating	
Comments:	

INTERVENTION: THERAPY SKILLS

- Establishes warm, caring relationship quickly
- Is sensitive to how their behavior may affect client
- Is empathetic and accepts client's feelings
- Confronts difficult issues sensitively
- Is able to respond effectively in a crisis situation
- Formulates and implements behaviorally specific TX goals
- Makes useful conceptualizations and TX plans
- Implements TX plan in session
- Monitors clients progress
- Uses data collected to guide treatment decisions

Therapy Skills Rating	
Comments:	

- Understands personal limits and competencies
- Makes appropriate referrals
- Maintains confidentiality, secures appropriate releases

- Articulates and resolves ethical dilemmas
- Represents self correctly
- Avoids dual relationships
- Understands and uses informed consent

ETHICS SKILLS

Ethical Values Rating	
Comments:	

- Is aware of personal biases and worldview
- Brings up issues of diversity in supervision
- Shows sensitivity to cultural values
- Incorporates issues of diversity into conceptualization & treatment plan

- Sensitively handles issues of diversity clinically & proffesionally
- Incorporates professional diversity guidelines into work
- Operates from an appropriate frame of multicultural competency
- Attends to client's cultural context in assessment & treatment

DIVERSITY SKILLS

Diversity Rating	
Comments:	

CONSULTATION/EDUCATION SKILLS

- Elicits appropriate consultation question
- Clearly establishes who the client is
- Develops consultation contract
- Completes consultation as designed (or revised)
- Prepares appropriate report (if applicable)
- Maintains clarity about consultation/education role

Consultation/Education Skills Rating
Comments:

MANAGEMENT/SUPERVISION (GIVE) SKILLS

- Is comfortable with role of appropriate authority
- Communicates appropriately with other supervisors
- Offers useful & helpful feedback

Management/Supervision Skills Rating
Comments:

RESEARCH: LOCAL CLINICAL SCIENTIST SKILLS

- Seeks out appropriate literature to aid in case conceptualization & treatment planning (both internal & external validity)
- Discusses the literature in supervision
- Incorporates empirical knowledge into treatment planning
- Conducts treatment according to plan (unless appropriate to revise)
- Uses outcome measurement therapeutically
- Revises treatment plan according to outcome measurement

Research/LCS Skills Rating
Comments:

ASSESSMENT SKILLS CHECKLIST

- Elicits appropriate referral question
- Selects and uses outcome measures
- Incorporates outcome measures into treatment plan
- Establishes appropriate baseline
- Conducts effective initial interviews

- Produces readable reports in a timely fashion
- Integrates findings into useful conceptualization
- Administers/scores/interprets competently (intellectual, objective, projective, outcome)
- Other (specify)

Assessment Skills Rating	
Comments:

TRAINING OBJECTIVES FOR INTERN

</div>

15 domains of intern competence are listed below along with examples of specific items in each domain.

- At the beginning of each term, the intern and supervisor **collaboratively** develop a list of personal goals in each category.
- Not every area in each domain need be addressed, though each intern should have **three goals** within each category.
- Goals should be **behaviorally specific and relevant** to areas that need improvement. Examples of ways to make goals measurable follow. This is not a comprehensive list:

  - KNOWLEDGE: Test of knowledge in new area
  - INTENSITY: Rating of comfort or skill in acquiring skill in a new area (e.g. rate comfort and skill with functional analysis from 0–10)
  - FREQUENCY: State number of times you plan to accomplish a particular goal behavior (e.g. plan to read 3 articles about treating panic; or plan to complete notes within 24 hours 90% of the time)
  - DURATION: State planned duration of new behavior (e.g. plan to review the referral notebook for 10 min daily)

- Goals will be reviewed between supervisor and intern at the end of the term
- Results of this review will be considered in the supervisor's ratings of the intern at the end of the term.

<div align="center">

ASSESSMENT

</div>

- Successfully administers assessments
- Correctly scores assessments
- Makes clinically relevant and accurate interpretations

- Writes concise, well-organized, thorough reports
- Provides clinically sensitive, appropriate feedback to clients

GOAL #1	
GOAL #2	
GOAL #3	

INTERVIEWING

- Conducts accurate, clinically sensitive intake interviews
- Balances information gathering with rapport building
- Identifies and clarifies presenting concerns
- Assesses history, impact, and current level of functioning
- Conducts mental status evaluations when appropriate
- Gathers diagnostic information efficiently and accurately
- Makes accurate diagnoses based on intake interview
- Selects, uses, scores, and interprets screening instruments
- Completes interview within the specified time-frame
- Completes intake reports in a timely manner

GOAL #1
GOAL #2
GOAL #3

CASE CONCEPTUALIZATION

- Develops cohesive case conceptualizations
- Conceptualizes cases according to a theoretical orientation
- Considers and appropriately addresses cultural issues in conceptualization
- Identifies causal, maintenance, and intervention factors
- Considers research in case conceptualization
- Identifies client strengths
- Writes well-organized, thorough comprehensive case conceptualization reports
- Uses case conceptualization to guide treatment

GOAL #1
GOAL #2
GOAL #3

TREATMENT PLANNING

- Collaborates with client in development of treatment plan
- Develops treatment plans that are consistent with conceptualization
- Prioritizes client concerns according to client wishes and feasibility
- Develops specific, measurable treatment goals
- Identifies interventions for each goal
- Considers research in selection of interventions
- Selects clinically appropriate outcome measurements for each goal

GOAL #1
GOAL #2
GOAL #3

INDIVIDUAL ADULT CLIENT INTERVENTIONS

- Competently treats depression, anxiety, and relationship problems
- Knows and applies empirically supported treatment interventions with adults
- Effectively motivates clients

- Follows treatment plan and works directly on treatment goals
- Effectively identifies and intervenes with in-session clinically relevant behavior
- Quickly builds a caring, warm therapeutic relationship

GOAL #1
GOAL #2
GOAL #3

GROUP INTERVENTION

- Competently treats adult concerns in a group setting
- Knows and applies knowledge of group stages and roles.
- Effectively motivates clients in groups

- Follows treatment plan and works directly on treatment goals
- Effectively identifies & intervenes with group members' clinically relevant behavior
- Quickly builds a cohesive group

GOAL #1
GOAL #2
GOAL #3

CHILD AND FAMILY INTERVENTIONS

- Competently treats both internalizing and externalizing behaviors
- Applies empirically supported interventions with children & parents
- Effectively motivates children and parents

- Follows treatment plan and works directly on treatment goals
- Effectively identifies & intervenes with in-session behavior
- Quickly builds a relationship with children and parents

GOAL #1
GOAL #2
GOAL #3

CLIENT PROGRESS

- Identifies appropriate outcome assessment
- Incorporates outcome assessment into the treatment plan
- Documents outcome assessments into the chart notes

- Uses outcome assessment to inform treatment
- Regularly administers outcome assessment
- Sensitively shares outcome assessment results with client

GOAL #1
GOAL #2
GOAL #3

THERAPEUTIC ALLIANCE

- Quickly develops therapeutic rapport
- Successfully repairs ruptures to the alliance
- Attends to and appropriately uses the interpersonal process
- Avoids premature client-initiated therapy termination
- Communicates empathy, respect, and genuineness
- Appears competent and relaxed

GOAL #1
GOAL #2
GOAL #3

SUPERVISION/CONSULTATION

- Is comfortable in supervisory role
- Provides helpful, accurate guidance
- Provides balanced, sensitive feedback
- Seeks supervision to augment supervision/consultation of others

GOAL #1
GOAL #2
GOAL #3

USE OF SUPERVISION/CONSULTATION

- Reviews/prepares for supervision
- Identifies and works on supervision objectives
- Open to feedback
- Brings up pertinent issues in supervision
- Communicates clearly in supervision
- Is aware of personal biases/impact on clients and supervisors
- Implements feedback

GOAL #1
GOAL #2
GOAL #3

PRACTITIONER-SCHOLAR MODEL

- Knows and uses relevant research to guide treatment
- Independently seeks clinically relevant research

GOAL #1
GOAL #2
GOAL #3

PRACTICE IN DIVERSE CULTURAL COMMUNITIES

- Integrating knowledge of diverse populations in case conceptualization & treatment planning
- Awareness of personal biases
- Attends to culturally relevant issues in session

- Adjusts psychotherapy methods to culture specific norms and therapy needs
- Addresses cultural issues in supervision
- Works clinically with ethnic minority populations

GOAL #1
GOAL #2
GOAL #3

ETHICAL AWARENESS AND SKILLS

- Understands personal limits and competencies
- Makes appropriate referrals
- Shows sensitivity to cultural values
- Maintains confidentiality, secures appropriate releases

- Articulates and resolves ethical dilemmas
- Represents self correctly
- Avoids dual relationships
- Understands and uses informed consent

GOAL #1
GOAL #2
GOAL #3

SELF AWARENESS

- Is aware of emotional reactions to clients
- Understands the impact of his/her behavior on others

- Knows biases and prejudices
- Open to self-exploration and feedback

Assessment	N/A to this rotation	Ready for Postdoctoral Practice	Needs Occasional Supervision	Needs Regular Supervision	Needs Remedial Work
The intern promptly and proficiently administers commonly used tests in his/her area of practice, autonomously choosing the tests to be administered appropriately. All interns demonstrate competency in administering intelligence tests and MMPI-2.		Proficiently administers all tests. Completes all testing efficiently. Chooses appropriate tests to answer referral question.	Occasional input needed regarding fine points of test administration. Occasionally needs reassurance that selected tests are appropriate.	Needs continued supervision on frequently administered tests. Needs occasional consultation regarding appropriate tests to administer.	Test administration is irregular, slow. Often needs to recall patient to further testing sessions due to poor choice of tests administered.
The intern autonomously interprets the results of psychological tests used in his/her area of practice. All interns demonstrate competency in interpreting intelligence tests and MMPI-2.		Skillfully and efficiently interprets tests autonomously. Makes independent diagnostic formulations on a variety of syndromes with confidence. Accurately interprets and	Demonstrates knowledge of scoring methods, reaches appropriate conclusions with some support from supervision.	Completes assessments on typical patients with some supervisory input, occasionally uncertain how to handle difficult	Significant deficits in understanding of psychological testing, over-reliance on computer interpretation packages for interpretation.

Assessment	N/A to this rotation	Ready for Postdoctoral Practice	Needs Occasional Supervision	Needs Regular Supervision	Needs Remedial Work
		integrates results prior to supervision session.		patients or unusual findings. Understands basic use of tests, may occasionally reach inaccurate conclusions or take computer interpretation packages too literally.	Repeatedly omits significant issues from assessments, reaches inaccurate or insupportable conclusions.
The intern writes a well-organized psychological report, answering the referral question clearly and providing the referral source with specific recommendations for patient care.		Report is clear and thorough, follows a coherent outline, is an effective summary of major relevant issues. Relevant test results are woven into the report as supportive evidence. Recommendations are related to referral questions.	Report covers essential points without serious error, may need polish in cohesiveness and organization. Readily completes assessments with minimal supervisory input, makes useful and relevant recommendations.	Intern uses supervision effectively for assistance in determining important points to highlight.	Inaccurate conclusions or grammar interfere with communication. Or reports are poorly organized and require major rewrites.
Interviewing	**N/A to this rotation**	**Ready for Postdoctoral Practice**	**Needs Occasional Supervision**	**Needs Regular Supervision**	**Needs Remedial Work**
The intern gathers relevant interview data promptly, appropriately evaluating immediate concerns such as suicidality, homicidality, and any other safety issues. The intern makes appropriate contingency plans with client regarding safety issues if		Intern continuously demonstrates above professional competencies.	Intern needs guidance regarding interview of complex cases. Intern is aware of how to cope with safety issues, but continues to need	Intern recognizes potentially problematic cases, but needs guidance regarding detailed evaluation. Detailed	Intern delays in questioning client about immediate concerns. Intern forgets to ask about important safety issues or makes

Interviewing	N/A to this rotation	Ready for Postdoctoral Practice	Needs Occasional Supervision	Needs Regular Supervision	Needs Remedial Work
needed. The intern discusses all confidentiality issues openly with clients.			reassurance in supervision. May occasionally forget to discuss confidentiality issues promptly.	discussions are needed to cope with safety issues; intern handles them well. Occasionally needs prompting to discuss confidentiality issues with patient.	inadequate assessment or plan. Intern does not remember to address confidentiality issues, needs frequent prompting.

Case Conceptualization	N/A to this rotation	Ready for Postdoctoral Practice	Needs Occasional Supervision	Needs Regular Supervision	Needs Remedial Work
The intern formulates a useful case conceptualization, including both transference issues and dysfunctional cognitions, that draws on theoretical and research knowledge.		Intern independently produces good case conceptualizations within own preferred theoretical orientation, can also draw some insights into case from other orientations. Overt emotional issues are accurately and consistently identified, plans and reflects appropriately on deeper issues between sessions.	Reaches case conceptualization on own, recognizes improvements when pointed out by supervisor. Readily identifies emotional issues but sometimes needs supervision for clarification.	Reaches case conceptualization with supervisory assistance. Aware of emotional issues when they are clearly stated by the patient, needs supervision for development of awareness of underlying issues.	Responses to patients indicate significant inadequacies in theoretical understanding and case formulation. Misses or misperceives important emotional issues.

Treatment Planning	N/A to this rotation	Ready for Postdoctoral Practice	Needs Occasional Supervision	Needs Regular Supervision	Needs Remedial Work
The intern formulates appropriate therapeutic treatment goals in collaboration with the patient. The intern collaborates with patients in crisis to make appropriate short-term safety plans, and intensify treatment as needed.		Consistently sets realistic goals long-term in accordance with patients' needs and desires. Can autonomously work with patient in crisis to establish appropriate short-term plan.	Sets appropriate goals with occasional prompting from supervisor, distinguishes realistic and unrealistic goals. Shows good professional skills, but needs occasional reassurance after coping with patients in crisis.	Requires ongoing supervision to set therapeutic goals aside from those presented by patient. Needs to refine crisis plans in collaboration with supervisor.	Fails to set any goals without prompting from supervisor. Fear overwhelms abilities in patient crises.
Adult Client Interventions	**N/A to this rotation**	**Ready for Postdoctoral Practice**	**Needs Occasional Supervision**	**Needs Regular Supervision**	**Needs Remedial Work**
The intern presents interventions that well-timed, effective and consistent with empirically supported treatments.		Interventions and interpretations facilitate patient acceptance and change. Demonstrates motivation to increase knowledge and expand range of interventions through reading and consultation as needed.	Most interventions and interpretations facilitate patient acceptance and change. However, intern requires supervisory assistance with the timing and delivery of more difficult interventions.	Many interventions and interpretations are delivered and timed well. Needs supervision to plan interventions and clarify interpretations.	Most interventions and interpretations are rejected by patient. Has frequent difficulty targeting interventions to patients' level of understanding and motivation.

Group Interventions	N/A to this rotation	Ready for Postdoctoral Practice	Needs Occasional Supervision	Needs Regular Supervision	Needs Remedial Work
The intern appropriately copes with group therapy challenges and complications such as conflict, scapegoating, premature termination and challenges to leadership.		Consistently manages issues as they arise in group, builds cohesiveness while dealing with complications. Aware of own strengths and weaknesses as a group leader.	Seeks input on group process issues as needed, then works to apply new knowledge and skills. Needs occasional feedback concerning strengths and weaknesses.	Welcomes ongoing supervision to identify key issues and initiate group interaction. Actively working on identifying own strengths and weaknesses as a group leader.	Responses to patients and management of group process indicates significant inadequacy in the theoretical understanding and implementation of group process. Defensive or not insightful when discussing strengths and weaknesses.
Child Family Interventions	**N/A to this rotation**	**Ready for Postdoctoral Practice**	**Needs Occasional Supervision**	**Needs Regular Supervision**	**Needs Remedial Work**
The intern presents interventions that well-timed, effective and consistent with empirically supported treatments.		Interventions and interpretations facilitate patient acceptance and change. Demonstrates motivation to increase knowledge and expand range of interventions through reading and consultation as needed.	Most interventions and interpretations facilitate patient acceptance and change. However, intern requires supervisory assistance with the timing and delivery of more difficult interventions.	Many interventions and interpretations are delivered and timed well. Needs supervision to plan interventions and clarify interpretations.	Most interventions and interpretations are rejected by patient. Has frequent difficulty targeting interventions to patients' level of understanding and motivation.

Client Progress	N/A to this rotation	Ready for Postdoctoral Practice	Needs Occasional Supervision	Needs Regular Supervision	Needs Remedial Work
The intern identifies, collects, documents, and explains appropriate outcomes		Appropriate outcomes selected, collected, interpreted, documented and used.	Occasionally needs help selecting or interpreting an instrument	Occasionally forgets to give an instrument or frequently needs help selecting an instrument	Does not use outcome measurements regularly and/or uses them inappropriately
*Therapeutic Alliance		**Ready for Postdoctoral Practice**	**Needs Occasional Supervision**	**Needs Regular Supervision**	**Needs Remedial Work**
The intern consistently achieves a good rapport with clients.		Establishes quality relationships with almost all clients, reliably identifies potentially challenging patients and spontaneously makes adjustments.	Generally comfortable and relaxed with patients, handles anxiety-provoking or awkward situations adequately so that they do not undermine therapeutic success.	Actively developing skills with new client populations. Relates well when has prior experience with the population.	Has difficulty establishing rapport, alienates clients or shows little ability to recognize problems when they occur.
*Supervision/Consultation (receive)		**Ready for Postdoctoral Practice**	**Needs Occasional Supervision**	**Needs Regular Supervision**	**Needs Remedial Work**
The intern seeks consultation or supervision as needed and uses it productively.		Actively seeks out professional consultation as needed when treating complex cases. Makes generally accurate self-appraisal, recognizes tendencies to misjudge abilities and shows	Open to feedback when offered, tries new ideas and behavior with varying degrees of comfort and success. Shows awareness of strengths and weaknesses, uses supervision	Accepts supervision in many areas, but occasionally shows defensiveness. Needs supervisory input for determination of readiness to try new skills.	Frequently defensive or confused by feedback, resists use of important and necessary feedback, overly dependent on habitual ideas and behavior. Seriously misjudges

*Supervision/Consultation (receive)		Ready for Postdoctoral Practice	Needs Occasional Supervision	Needs Regular Supervision	Needs Remedial Work
		particular care in those areas.	well for clarification of areas of uncertainty.		strengths and/or important limitations.
Supervision/ Consultation (provide)	N/A to this rotation	Ready for Postdoctoral Practice	Needs Occasional Supervision	Needs Regular Supervision	Needs Remedial Work
The intern performs an assessment of the client referred for consultation, incorporating mental status exam, structured interview techniques or psychological assessment, as needed, to answer the referral question.		The intern is able to choose appropriate means of assessment to respond effectively to the referral question; reports and progress notes are well-organized and provide useful and relevant recommendations with minimal supervisory input.	Occasional input is needed regarding appropriate measures of assessment and effective write-up of report or progress notes to best answer the referral question	Needs continued supervision regarding appropriate assessment techniques to complete consultations as well as input regarding integration of findings and recommendations.	Consultation reports and progress notes are poorly written and/or organized. Fails to incorporate relevant information and/or use appropriate measures of assessment necessary to answer the referral question.
Practitioner-Scholar Model		Ready for Postdoctoral Practice	Needs Occasional Supervision	Needs Regular Supervision	Needs Remedial Work
*The intern seeks out professional writings regarding treatment cases as needed to enhance knowledge about the patient's psychological status.		Intern independently seeks out and reads professional writings pertaining to cases at hand.	Intern identifies areas of knowledge that need enhancement with a particular client and asks for suggestions regarding readings.	Intern readily accepts and reads professional writings as assigned by the supervisor.	Intern procrastinates regarding professional readings assigned by supervisor to learn essential treatment-oriented competencies.

Practitioner-Scholar Model		Ready for Postdoctoral Practice	Needs Occasional Supervision	Needs Regular Supervision	Needs Remedial Work
The intern is able to develop a plan for research or other professional writing.	N/A to this rotation	The intern, alone or in conjunction with a colleague, is a full participant in development of the plan.	The intern provides substantive input into the plan.	The intern provides helpful suggestions regarding design and implementation of a colleague's plan.	The intern does not follow-through with responsibilities in development of plan.
The intern demonstrates professional skills sufficient to accomplish the goals of the research and/or writing project.	N/A to this rotation	The intern, alone or in conjunction with a colleague, is a full participant in the progress of the project.	The intern demonstrates the ability to execute at least one aspect of the project independently.	The intern provides significant assistance in the accomplishment of the project.	The intern does not follow-through with responsibilities in accomplishing the goals of the project.

*Diverse Populations	Ready for Postdoctoral Practice	Needs Occasional Supervision	Needs Regular Supervision	Needs Remedial Work
The intern maintains sensitivity to cultural and other individual differences.	Spontaneously raises issues relating to individual differences with clients as appropriate, conveys ease in working with a range of backgrounds, aware and sensitive to individual differences, accurately self-monitors own responses to differences.	Initiates supervisory discussion regarding areas of inexperience in personal differences when needed.	Has discomfort with some clients, resolves such issues effectively through supervision.	Has difficulty recognizing or working around prejudices, holds some beliefs which limit effectiveness with certain clients, unable to surmount these problems to date in supervision.

*Ethical & Humane Practice	Ready for Postdoctoral Practice	Needs Occasional Supervision	Needs Regular Supervision	Needs Remedial Work
The intern demonstrates good knowledge of ethical principles and consistently applies them appropriately, seeking consultation as needed.	Spontaneously and consistently identifies ethical issues, effectively resolves issues using consultation and supervision as needed	Consistently recognizes ethical issues, appropriately asks for supervisory input.	Generally recognizes situation where ethical issues might be pertinent, is responsive to supervisory input	Often unaware of important ethical issues, disregards supervisory input.

*Self-Awareness & Professionalism	Ready for Postdoctoral Practice	Needs Occasional Supervision	Needs Regular Supervision	Needs Remedial Work
The intern interacts professionally and appropriately with treatment teams, peers and supervisors at all times. The intern seeks peer support as needed.	Develops smooth working relationships, effectively relates to team members in accordance with their unique roles, effectively uses team format in the service of treatment needs. Develops positive alliances with other interns and colleagues, handles differences openly.	Actively participates in team meetings, but input is circumscribed. Seeks input from supervisors to cope with rare interpersonal concerns.	Progressing well on providing input in a team setting. Effectively seeks assistance to cope with interpersonal concerns with colleagues.	Personal characteristics or dysfunctional behaviors significantly limit the intern's ability to participate in team model, e.g. withdrawn, overly confrontational, insensitive. Has hostile interactions with colleagues.
The intern takes on responsibility for key client care tasks, autonomously ensuring that tasks are completed promptly. The intern demonstrates the necessary self-direction, in gathering	Takes initiative in ensuring that key tasks are accomplished, seeks responsibility. All reports and progress notes are filed promptly. Deadlines not needed. Fully dedicated to expanding knowledge and skills, seeks out	Systematically attends to all details with few prompts. Occasional deadlines needed to complete tasks. Shows initiative, eager to learn, beginning to take steps to enhance own learning.	Completes work effectively when given prompts or deadlines. Open to learning, waits for supervision to present ideas.	Overly dependent on prompts or deadlines or frequently misses deadlines. Needs too much direction from supervisor, uninvolved.

*Self-Awareness & Professionalism	Ready for Postdoctoral Practice	Needs Occasional Supervision	Needs Regular Supervision	Needs Remedial Work
clinical and research information, to practice independently and competently as a postdoctoral psychologist.	and takes specific steps to follow-through on learning opportunities.			
The intern demonstrates positive coping strategies to manage personal and professional stressors to maintain professional functioning, so that quality patient care continues uninterrupted. The intern copes with professional challenges such as new responsibilities or client crises.	Exhibits good awareness of any personal and professional problems, impact of stressors on professional practice is limited to subtle effects such as ineffi-ciency. Seeks supervision and/or personal therapy to resolve issues if needed. Level of confidence accurately matches current abilities, experi-ences minor stress handling crises or major new responsibilities.	Has good insight into the impact of stressors on professional functioning, seeks supervisory input to minimize this impact. Confident in practiced areas of competence, needs supervi-sory encourage-ment to venture into new areas.	Intern needs significant supervision time to minimize the effect of stressors on professional functioning. Confidence fluctuates, seeks reassurance from supervisor.	Ongoing stresses significantly hamper professional functioning. Personal problems significantly disrupt professional practice, intern denies problems when brought up by supervi-sor. Lack of confidence is communicated to others in a manner that undermines the quality of work.
The intern understands and uses own countertransfer-ence produc-tively in the treatment.	Intern uses countertransfer-ence to formulate hypotheses about client's current and historical social interactions during session to patient as appropriate. Consultation sought as needed for complex cases.	Intern can use countertransfer-ence to formulate hypotheses during supervi-sion sessions. Interventions generally presented in the following session.	Intern under-stands basic concepts of countertransfer-ence. Intern is able to identify own emotional reactions to patient as counter transference. Supervisory input is frequently needed to process the information gained.	Intern holds on to anger, frustration or has other intense emotional response to the patient, blaming patient and unable to see countertransfer-ence issues, even with supervisory input.

Supervisor Comments

Summary of Strengths:

_____
_____

Areas of Additional Development or Remediation, including Recommendations:

_____

Conclusions

Competency Goal for evaluations done at 3, 6, or 9 months: All competency areas will be rated at a level of competence of **Needs regular supervision** or higher. No competency areas will be rated as **Needs remedial work.**

Competency Goal for evaluations done at 12 months: At least 80% of competency areas will be rated at level of competence of **Needs occasional supervision** or higher. No competency areas will be rated as **Needs remedial work**. Note: exceptions would be specialty area rotations that would take a more intensive course of study to achieve this level of competency and the major supervisor, training director and intern agree that a level of **Needs regular supervision** is appropriate for that particular rotation, e.g. a neuropsychology major rotation for a general track intern.

_____ The intern HAS successfully completed the above competency goal. We have reviewed this evaluation together.

_____ The intern HAS NOT successfully completed the above competency goals. We have made a joint written remedial plan as written below, with specific dates indicated for completion. Once completed, the rotation will be re-evaluated using another evaluation form, or on this form, clearly marked with a different color ink. We have reviewed this evaluation together.

Supervisor Signature	Date	Intern Signature*	Date

*I have received a full explanation of this evaluation. I understand that my signature does not necessarily indicate my agreement.

20 Consultation

Jon Frew

Abstract: Not long ago the vast majority of clinical psychologists practiced in relatively restricted roles providing assessment and therapy services. There has been a pronounced shift in the field and today most psychologists are moving into expanded roles and activities. One of these roles is organizational consultation. In this chapter some of the requisite competencies to provide consultation services to organizations are outlined at both the basic and expert levels. As there is no uniformity or agreement about the number or definition of consultation competencies, a case study approach was employed to identify the range of competencies that were employed by the author in two organizational consulting projects.

20.1 Overview

In 1990, I designed and taught a course entitled "Organizational Consultation" in a PsyD program at a university in the Pacific Northwest. The class was a popular elective in a doctoral program curriculum replete with required courses which prepared students to assume the traditional roles of a clinical psychologist. In that era, the vast majority of students in that program aspired to a career trajectory that would ultimately land them in private practice, in which they would provide assessment and psychotherapy services.

Despite the popularity of the organizational consultation class, which was offered once a year until 1998, it was viewed by most students as a "boutique" course, a curious diversion from the program's rigorous clinical training and as a class that provided a skill set that would probably never be utilized. In 1999, I launched a new course in that PsyD program entitled "Professional Roles." This course was designed to reflect the educational model of the National Council of Schools and Programs of Professional Psychology (NCSPP) first outlined in the landmark article written by Peterson, Peterson, Abrams, and Stricker (1997). Organizational consulting as a role and a set of competencies was transplanted into the Professional Roles course, joining others including supervision, teaching, management, and administration.

Over the course of the past 10 years, as I have continued to modify and teach the Professional Roles class, I have noted a dramatic shift in the attitudes and perspectives of current clinical psychology students, concerning the place of organizational consulting (and other nonclinical roles) in their career aspiration portfolio. The vast majority of students now understand that their future as a professional psychologist will be more financially rewarding and personally satisfying, if they are trained to carry out both clinical and nonclinical activities in a variety of roles. This shift in the recent and current students' career visions is evident as well in the broader field of psychology. Levant et al. (2001, p. 80) encourage psychologists to envision and access new roles.

▶ For professional psychology to continue to grow and flourish, psychologists must identify and conceptualize roles that they are well suited to take up in the near and more distant future. …

[T]hese roles are not really new. What is new, however, is thinking of these roles as aspects of psychology's core identity.

With the expansion of roles and activities carried out by clinical psychologists comes a concurrent effort to identify the basic competencies required to be proficient in these roles. Graduate training programs in psychology have been forced to take a step back and consider this question: "What are the competencies requisite for professionals who refer to themselves as clinical psychologists?" The organization that has been most active in the discussion of expanded professional roles, curriculum revision, and the identification of competencies has been NCSPP. They have identified the following core competencies: relationship, assessment, intervention, research and evaluation, consultation, education, management, supervision, and diversity. These nine terms can be sorted into three categories (Frew & Machell, 2007):

Roles	Activities	Competencies
Consultant	Assessing	Relationship
Educator	Intervening	Assessment
Supervisor	Evaluating	Intervention
Manager	Consulting	Research and evaluation
	Teaching	Consultation
	Managing	Education
	Supervising	Management
		Supervision
		Diversity

Despite the role performed by a clinical psychologist (clinical or expanded), the work almost always requires the skill set to form relationships, to accurately assess, choose and deliver appropriate interventions, to evaluate the impact of the intervention, and to have some level of multicultural competence. NCSPP's identification of core competencies was a good start, leaving much work to be done. The Association of Psychology Postdoctoral and Internship Centers (APPIC), with the support of American Psychological Association (APA) and 30 other groups, convened a conference entitled "Competencies Conference, 2002: Future Directions in Education and Credentialing in Professional Psychology," which was attended by more than 130 psychologists. They grappled for 3 days, attempting to address the thorny issues of how competencies are defined, taught, and assessed in graduate psychology training. Kaslow, Thorn & Pate (2005) provided a summary of the conference. In 2007, the membership of NCSPP approved the Competency Developmental Achievement Levels (DALs) to be included in the education and training model. The DALs were a work product of the NCSPP 2007 conference and will be discussed later in this chapter.

This current volume(s), *The Handbook of Clinical Psychology Competencies*, is a significant contribution to the efforts to sharpen the focus of a competency model. The topic of this chapter is consultation.

The term "consultation" in the field of psychology often has a different connotation than it does in the business world. Psychologists (and physicians) frequently think of consultation in terms of clinical consultation. You have a question about your patient's diagnosis and you call an expert for a consultation about your patient. A three-party matrix is created connecting patient, therapist, and expert consultant. This triangular relationship is present in all consultation activities as is the notion that services will be provided to the client/patient directly by the treating psychologist and indirectly by the consultant.

In the world of business, consultation means organizational consultation. The client is the organization itself or some subset of the organization. Organizational consultation is the topic of this chapter. Organizational consultation can be carried out by individuals from a range of backgrounds and training sets. In this chapter, I will discuss psychologists in the role of organizational consultants. I will make the case that psychologists with their exhaustive clinical training are well suited to acquire the competencies required to be consultants to organizations. In addition, psychologists must practice and provide services in accordance with APA ethical and multicultural guidelines, whereas consultants from other backgrounds and disciplines may have no such guidelines regulating their work.

20.2 Personal Journey

I was trained and received my Ph.D. in Counseling Psychology. Within my doctoral program, I was able to complete a minor in organizational development (OD) and small group studies. I entered the field with a strong interest in working with individuals, groups, and organizations.

In my first post-Ph.D. job, I held a position in a university counseling center. Within 2 years, I was promoted to the director's role. My supervisor became aware of my knack for understanding organizational dynamics, and began to ask for my input and opinion about some of the complex political pressures she was experiencing as the only woman in an executive "cabinet" of all white men. I was flattered by this attention and recognition of some of my incipient skills. I found myself in a type of executive coaching relationship, as an internal (not external) consultant, and I was advising my own boss. I tell this story today to my students as an example of a very perilous way to engage in a consulting relationship. Ultimately, my supervisor fell out of political favor with the university president and, because I was closely associated with her, my stock value fell dramatically as well with the powers-to-be.

It was during that same 5-year period, however, that I got my first legitimate consulting job. I was hired by a nonprofit organization in the community to do an employee satisfaction survey. I met with the executive director and the board, interviewed all the employees, and delivered a written and oral report of my findings. This consultation project went very well and the organization made a number of changes which improved employee satisfaction and retention.

Twenty-five years later, I reflect on a career in which I have been able to have a steady stream of organizational clients representing businesses (small and large) and nonprofit, educational, and government organizations. Organizational consulting has never been a full-time endeavor. Rather, I have integrated my consulting work with clinical private practice, teaching, training, and writing. I am privileged to be able to teach consultation to students in both a Master's and PsyD program and be the director of an organizational track in a PsyD program. Identification of competencies in organizational consulting and how to teach them is still in its

infancy in the field of psychology. In the "Basic" and "Expert" competency sections of this chapter, I will outline what is known and the work ahead of us.

20.3   Selected History

Earlier I pointed out the differences between organizational consultation and clinical consultation. Another clarification is also necessary. Within the field of psychology, there are clinical psychologists, industrial/organizational (I/O) psychologists, and consulting psychologists. None of these designators is a pure type because there are clinical psychologists who engage in consultation activities and I/O psychologists who might do clinical work. Lowman (1998) differentiates these three types of psychologists based on emphasis. The clinical psychologist works primarily with individuals, wherein the I/O psychologist sees the organization as the client, while the consulting psychologist "plays no favorites" and sees the individual and the organization as the client.

Consulting psychology has a division (13) in APA, has been around in various iterations since 1915, and is a place that psychologists who engage in organizational consultation can call home. O'Roark (2007) stated that the attempt to identify competencies can be dated to 1920, when the APA's Standing Committee on Certification of Consulting Psychologists was charged with identifying core consulting competencies. Unfortunately, that initiative was severely derailed when the Consulting Psychology division was stricken from APA bylaws from 1926–1945. In 1946, after World War II, APA reorganized and the Division of Consulting Psychology, now known as the Society of Consulting Psychology, was reestablished.

Other streams have fed the river of organizational consultation in the past 60 years. In 1999, the Society of Consulting Psychology (SCP) launched a "Best of the Century" survey to determine who had the most influence on consulting psychology during the past century. Surveys were mailed to 23 past presidents of Division 13 and 300 general members, with a response rate of 70% from the past presidents and 8% from the general membership or 39 usable surveys (as reported by O'Roark, 2007).

Kurt Lewin was named as the most influential figure in the past century in the field of consulting psychology. Lewin, who died in 1947, was a social psychologist and is best known for his writings in field theory (Lewin, 1951) and as one of the founders of the National Training Laboratory in Bethel, Maine. Lewin is also known as the originator of "action research," although an earlier version of a very similar approach to OD was outlined by Collier (1945). Lewin's contributions were manifold and his belief in the democratic/collaborative process (having fled Nazi Germany in the late 1930s) in organizations is notable. The consultant's role after collecting data is to feed that data back into the system and to the individuals who provided it and to facilitate a process, whereby the members of the organization derive meaning and action steps from that data. This is a practice which has lost favor with many contemporary consultants who interpret the data they collect and present it only to the sponsors who have commissioned the assessment.

Another frequently cited individual in that survey was Caplan, whose *Theory and Practice of Mental Health Consultation* (1970) was an important work in a surge of contributions to the consulting literature which took place in the 1970s. Caplan outlined four types of consultations that could occur in mental health organizations including "program-centered" and "consultee-centered administrative." Both of these types of consultation

were departures from the more traditional client-centered (supervision) awtee-centered (clinical consultation) approaches, and opened the door for organizational consulting and coaching in mental health settings. Other prominent names in the survey included Levinson, whose *Organizational Diagnoses* (1972) was named most often as the most influential writing, and Schein who was cited for his works *Process Consultation* (1969) and *Organizational Culture and Leadership* (1985).

The field of OD is closely related to consulting psychology and organizational consultation. OD consultants concern themselves primarily with assisting their clients to undertake planned (typically long-term) organizational change processes. Efforts to identify and define OD competencies have been ongoing since the 1970s (e.g., Warrick & Donovan [1979] and Sullivan [1974]). More recently, Worley, Rothwell, and Sullivan (2005) surveyed 365 early, mid, and late career OD practitioners using a list of 141 competencies generated originally by Sullivan (1974) and which have been updated annually since 1992. The survey task was for respondents to rate how important the competencies were in successful OD practice. The authors were able to reduce the number of critical competencies from a cumbersome 141 to a more workable 20–24. Perhaps the most intriguing finding was that "self-mastery" is the most important competency an OD practitioner can have. "Viewed not as an intervention in the system, but a characteristic of the person doing the work, self-mastery allows the practitioner to access and apply theories and models in a customized rather than a 'canned' fashion" (p. 158).

20.4 Competencies Revisited

I mentioned earlier that the quest to identify and define the basic competencies involved in organizational consulting can be dated back to 1920. More recently, the Education and Training Committee of Division 13 published the Principles for Education and Training at the Doctoral and Postdoctoral Level in Consulting Psychology/Organizational (2007). In that document, competencies were divided into three domains: individual level, group level, and organizational/systemic level with the proviso that many competencies (e.g., assessment) are required in more than one domain. In that same document, ten general competencies were added: (1) self-awareness and self-management; (2) relationship development; (3) assessment; (4) process consultation/action research; (5) interventions; (6) knowledge of theory, case studies, empirical research, applications, evaluation methods; (7) multicultural and international awareness, knowledge of sociopolitical backgrounds and cultural values and patterns; (8) research methods and statistics; (9) business operations, legal, industry regulations, technological advances; and (10) professional ethics and standards.

The Society for Consulting Psychology has taken the lead for the overall field of organizational consultation in defining the basic and more advanced competencies necessary to provide consultation services. O'Roark (2007) summarizes the task of consulting psychologists very clearly.

▶ Consulting psychologists are practitioners of applied psychology. Interventions and educational programs require knowledge of relevant information, drawn from credible sources with verifiable data supporting effectiveness of consultation practices, approaches, and strategies for problem solving. Services are tailored to respond to requests from specific client populations with particular cultural contexts. To provide competent services, practitioners review and evaluate the best available research evidence (O'Roark, 2007, p. 189).

She also points out, citing APA's policy on evidence-based practice, that interventions that have not been studied in controlled trials (virtually impossible to do in organizational consulting) can still be effective. "Consulting practitioners work as scientist-practitioners, methodically planning future interventions based on what has been beneficial in the past for clients in comparable circumstances" (O'Roark, 2007, p. 189).

20.5   Challenges Ahead

In a recent article, Cooper, Monarch, Serviss, Gordick, and Leonard (2007) outline some of the significant challenges which lie ahead for consulting psychologists and psychologists in training or practice who seek to provide consultation services. On one hand, more psychologists are becoming full-time and part-time consulting psychologists either earlier in their career or as a first career choice. Thus, there is a need for comprehensive standards of competence, educational opportunities, and training experiences. On the other hand,

▶ academic barriers and scattered resources limit education and training opportunities for four distinct groups of CP practitioners: beginning (0–3 years/first career choice), entry (0–3 years/experience in another psychological specialization), mid-level (4–7 years experience) and senior consulting psychologists (those with 8 + years of experience in the field). (p. 3)

The authors discuss external barriers, including a dearth of graduate training programs in consulting psychology, predoctoral and postdoctoral training sites and supervised work experiences. Another external obstacle is the unwillingness of many state licensing boards to "count" hours that are not devoted to direct clinical service.

In terms of internal barriers, Cooper et al. (2007) state that although the development and publication of competencies for consulting psychology is an excellent start,

▶ continued development of companion documents for CP/mental health, CP/schools, CP/forensic, and other major types of psychological consulting practice is imperative. Even with a prototype statement of graduate and postdoctoral curricula, the quality of current education and training opportunities is difficult to assess without continued identification of characteristics and competencies that can serve as benchmarks and aspirational guideposts. (p. 3)

I would contest the first point made and absolutely concur with the second. I am not sure that it is "imperative" to develop companion documents which highlight consulting competencies according to a specific setting. My own consulting work has crossed most types of organizations, and I have found the skills necessary to translate well across settings. I do agree, however, that there is a great deal of work ahead regarding the task of identifying the most critical core competencies for consultation, determining the best way to teach them, and evaluating the degree to which the competencies have been learned.

20.6   Definition, Characteristics, and Stages

For the purposes of this chapter, consultation will be defined using the definition established by Division 13 of the American Psychological Association, SCP Bylaws (2008):

▶ Consulting psychology shall be defined as the function of applying and extending the special knowledge of a psychologist, through the process of consultation, to problems involving human behavior in various areas. A consulting psychologist shall be defined as a psychologist who provides specialized technical assistance to individuals or organizations in regard to psychological aspects of their work. Such assistance is advisory in nature and the consultant has no direct responsibility for its acceptance. Consulting psychologists may have as clients, individuals, institutions, corporations, or other kinds of organizations.

There are some shared characteristics which are present in most types of consultation. Consultation is triadic and involves a consultant, a consultee, and a client system. Consultation services are indirect and voluntary in nature. Consultation is provided by an individual(s) external to the client system. Consultation services can be related to content (what the organization does) or process (how the individuals in the organization work together [or not] as they carry out the tasks of the organization).

Finally, organizational consultation takes place over time and through a series of stages. These stages have been defined somewhat differently by the various authors and practitioners who have described them. These stages are key because each involves specific consultation skills. For the purposes of this chapter, I will use the stage model that I teach in my consultation classes. It closely adheres to most of the stage models described in the literature:

- Initial contact and screening
- Entry and preliminary assessment
- Contracting
- Assessment
- Feedback and identification of issues of concern
- Goal setting
- Intervention(s)
- Evaluation
- Termination

In the following two sections, basic and expert competencies will be discussed and illustrated through case studies. Some of the competencies pertain to particular stages in the consultation process. Most are required through all the stages.

20.7 Gaining Competence

The development and publication of the Principles for Education and Training at the Doctoral and Postdoctoral Level in Consulting Psychology/Organizations by members of Division 13 was a major step forward. Questions such as "What are the basic competencies to consult to organizations?", "How are they acquired?", and "How do we measure the attainment of competency?" were addressed at least to some extent.

Fuque and Newman (2002) were asked to review these principles and competencies from an academic perspective and commented as follows:

▶ We found the task of reacting to the principles to be much more difficult than we expected, due in part to the multiplicity and complexity of issues raised by such comprehensive training

principles. … Everyone involved in this process realizes that the publication of these proposed principles is only another step in the long process of trying to improve the services we provide to our clients. (pp. 223–224)

Fuque and Newman also point out that since the principles are organized around core competencies or end states, they can be obtained in a variety of ways not just through coursework.

Clearly the standardization and verification of the efficacy of consultation competencies is a work in progress. Moreover, how and where organizational consultants receive their training is varied and uneven. Cooper et al. (2007) summarize my last statement well:

▶ Largely, those who engage in the practice of consulting psychology have managed to accumulate sufficient training and expertise to function well in the role and have done so despite the historical absence of formal training programs and curricula. Consulting psychologists have followed diverse pathways to achieve and maintain competence. However, professional training and education venues have not yet been adequately defined or developed preparing consulting psychologists to address the growing interest in our services. (p. 2)

In the remainder of this chapter, I will address two core issues that have been brought to light primarily by the excellent work of the members of the SCP. The first is a need to define the basic (and expert) competencies in more practical, teachable terms. The second is how clinical psychology students who are interested in working as organizational consultants can be trained and prepared to offer these services.

20.7.1 What Are the Basic Competencies?

The SCP has published a list of core competencies. They are organized by levels: individual, group, and organizational/systemic. Competencies listed in these three domains may carry over to other levels as well. Example competencies are individual level (executive and individual coaching), group level (assessment and development of teams), and organizational level (organizational-level interventions). However, there is a problem with the language of these competencies. Executive coaching, team development, and organizational intervention are all activities that require training and skills, but the competencies involved in these activities are not clearly stated. More details are provided later in the SCP principles, but generally there is more focus on what the consultants do rather than the specific competency required to do it well.

From the world of OD, we have the competencies listed most recently by Worley et al. (2005). Again the language is problematic for the academic who is charged with training future consultants. For example, "self-mastery" was the most frequently endorsed competency in that survey but what does it mean and how do you teach it? A third group, NCSPP, has also been actively involved in developing lists of competencies for psychologists in training and practice. The result of their most recent effort is the DALs (2007). Unfortunately in that document, the consultation competency is combined with the "education" competency, and the knowledge and skills required to be a consultant and an educator are discussed together. Specific consultation competencies are not well articulated or defined.

20.7.2 How to Train Organizational Consultants

As mentioned earlier, those practitioners who identify themselves as organizational consultants come from a wide variety of backgrounds and have received their training in a variety of ways. We have an opportunity in the field of clinical psychology to develop specific programs and curricula and create standards and accountability in training psychologists to provide consultation services to organizations. Despite the advent of a few consulting psychology doctoral programs' consulting tracks, the formalization of training processes is in its infancy. Training must also occur beyond the classroom through workshops, training programs, supervised field work, and mentoring by seasoned consultants.

20.8 Basic Competencies

Clinical psychologists who want to prepare themselves to provide consultation services to organizations respond favorably to training anchored by three models or frameworks: The NCSPP basic competencies, process consultation and stages of consultation.

The NCSPP basic competencies of relationship, assessment, intervention, and evaluation translate fluidly from clinical work to organizational work as does the diversity competency. Schein's (1988) "process consultation" is a model of consultation which is compatible with the developmental level of psychologists in training to become consultants. Schein defines his model as "a set of activities on the part of the consultant that help the client to perceive, understand and act upon the process events that occur in the client's environment in order to improve the situation as defined by the client" (p. 11). Adopting process consultation as a model improves the skill set of psychologists, because it allows them to focus on the relationship issues within organizations and avoid being perceived as the expert on the content or product of that organization. Finally, learning how to consult to organizations involves understanding the competencies required for each stage of the consulting process. Therefore, a stage model is extremely useful.

No two consulting projects are exactly the same, but the generic consulting process typically has these stages:

Stages of consultation	Clinical counterpart
Initial contact	Screening
Entry and preliminary assessment	Intake
Contracting	Informed consent
Assessment	Assessment
Feedback, diagnosis, goal setting	Treatment planning
Intervention	Intervention
Evaluation	Measuring progress
Termination	Termination

I have listed the clinical counterparts to the right of the stages of consultation. The similarity in the stages of clinical work and consulting to organizations accelerates the learning curve of the clinical psychologists or the clinical psychology students who seek training in consultation.

Before identifying and discussing the basic competencies, I will provide a brief case example of a consultation project I completed several years ago. I have altered a number of the details of this project to protect my client's identity and enhance this example as a teaching case.

20.8.1 Case Example #1

I was contacted by Peter who was an architect at a relatively large architecture firm. Peter knew of me as he attended a class I taught in a local MBA program. We spoke by phone about the possibility of me doing some work for his firm (*initial contact*). After some initial screening to make sure that I had the skills and experience to address the issues Peter laid out, we agreed to have a meeting with Peter, his boss Larry, who was a project manager, Craig, the president of and a partner in the firm, and Lisa, who was the chief financial officer. The meeting took place several days later at the architecture firm. During that meeting, I asked the four of them to tell me what they saw as the issues of concern and the focus of a consulting process (*entry and preliminary assessment*).

In this exploratory meeting, there was a consensus that Larry's project group had some significant interpersonal conflict and communication issues. The group had just completed a project which involved the design of a university classroom building but problems within the group resulted in the final product coming in over budget and several weeks behind schedule. Another project (a state government office building design) was about to be launched, and Craig and Lisa were reluctant to assign the project to this team. Peter and Larry, on the other hand, believed that it made more sense to try to improve this project group's performance rather than dismantle this group to form another. I proposed a further assessment process in which I would have contact with every member of the project team (*contracting*). In the next week, I conducted individual interviews with each group member and sat in on a project group meeting led by Larry (*assessment*).

I then reviewed and summarized the data I had collected and developed a written and oral report that focused on key themes, concerns, and strengths which emerged from the input of group members. I had a follow-up meeting with Peter, Larry, Craig, and Lisa. During that meeting, I presented feedback from the assessment phase and facilitated a discussion in which they were able to identify the key problems and the changes they viewed as necessary for this group to function together at a higher level on the next project (*feedback*, *diagnosis and goal setting*). I then proposed several initiatives that would potentially support the changes they were seeking as well as a method by which change could be measured. The initiatives proposed involved several psychoeducational trainings (which focused on communication, conflict resolution, and team building), "coaching" with Larry to enhance his leadership skills, and a modification to the present compensation system in which individuals would receive bonuses and firm-wide recognition at different stages of the project, if the project group as a whole either met (or exceeded) a series of deadlines or budgetary goals. This final initiative was a response to a culture of competitiveness which existed in the group whereby newer members of the firm would

try to stand out to the firm's partners as up and coming "stars" by looking better than their peers (*intervention*).

Efficacy of the consulting work was evaluated by measuring the degree to which previously determined benchmarks (related to meeting deadlines and staying within budget) were met (*evaluation*). I left the project several months after my initial meeting with Peter, Larry, Craig, and Lisa before the project was completed, but after determining that the group was functioning at a much higher level based on the evaluation method just mentioned (*termination*).

I will use this case study to identify and briefly discuss basic consultation competencies.

20.8.1.1 Initial Contact

In this phase, three basic competencies are required: *Relationship* skills including the ability to listen and put the caller at ease are critical. *Interviewing* skills are also necessary so that the information necessary for the consultant to decide whether to move forward is obtained quickly and efficiently. Finally, *knowledge of the consulting process* is required so that the consultant can begin to orient the caller on how the process will work, the next steps, and who should be present during the next phase.

20.8.1.2 Entry and Preliminary Assessment

Again *relationship* skills are critical in this phase. The consultant is now meeting with individuals from the client system on their "turf." To *interviewing* skills I would add *knowledge of group dynamics*, *group leadership skills*, and *observation skills*. Most consulting projects begin (or end) with an exploratory meeting with key players of the organization. In my meeting with Peter, Larry, Craig, and Lisa, I wanted to demonstrate that I had solid interpersonal skills, could facilitate a small-group process, could inspire all parties to speak up and respond to "smart" questions and probes. Smart questions are developed through the initial contact by doing your "homework" about the organization before the first meeting on site and by using *listening* and *observational skills* during the meeting to formulate further questions or to propose preliminary statements of issues of concern. Sometimes *conflict mediation skills* are useful in this type of meeting to redirect and reframe heated differences into useful "multiple perspectives." Finally, *diversity* skills come into play in this phase. For example, in this case example, I noticed that Lisa's comments were either ignored or minimized by two of the men in the meeting, so I intentionally highlighted several of her comments in my summary statements near the end of the meeting.

20.8.1.3 Contracting

Contracting is another critical phase of any consultation project. It occurs at both the informal and formal level (Schein, 1988). On the informal level, the consultant must work toward a mutual understanding with the client regarding each party's expectations about the nature and the amount of work to be done. Formally, the consultant must have the skill to *construct and*

negotiate a written contract which details the terms of the consulting relationship. A crucial aspect of all consultation work is the *determination of "who is the client?"* This is a competency in and of itself because in consultation, unlike clinical work, there can be several types of client. Schein refers to contact clients or the individual who makes the first call to the consultant (Peter), intermediate clients or those who are involved in early meetings (Peter, Larry, Craig, Lisa), primary clients on the "unit" targeted for the assessment and intervention (the whole project group), and ultimate clients, anyone directly or indirectly impacted because of the consultation (pp. 117–118).

20.8.1.4 Assessment

NCSPP has designated "assessment" as a primary competency across most of the roles and activities of clinical psychologists. In organizational consultation, assessment is both an ongoing process beginning with the initial contact stage and an activity specific to particular phases of a consulting process. There are a number of competencies involved in the assessment stage of consultation. In my work with the architecture firm, I conducted interviews and observed a project group meeting. Assessment through individual interviewing requires competency in *developing the interview questions* and *interviewing* itself. Assessment through observation of groups requires competency in *observing communication processes* and *knowledge of group dynamics* (e.g., leadership styles, decision-making models, phases of group development, etc.). Assessment in organizations is also carried out using surveys or focus groups. *Developing questionnaires* (assuming that a nonstandardized one is necessary) and *administering questionnaires* are additional competencies often required in the assessment phase. *Facilitating focus groups* is another specific competency. Focus groups can be utilized alone but are more frequently combined with other assessment methods like interviews and surveys.

20.8.1.5 Feedback, Diagnosis, and Goal Setting

Before the consultant can give feedback, the data collected during the assessment phase must be organized, reviewed, and shaped into a format that will be most useful to the client. I will name this competency *organizing and formatting assessment data*. The task can be challenging if the consultant has collected information from many (what are the central themes and concerns) or from few (how to protect the anonymity of individuals). The next competency required is *giving feedback*. Assessment data are usually presented both orally and in writing. *Report writing* is a skill specific to the feedback phase of consultation. So is *conducting a feedback session*. From a process consultation perspective, one of the goals of the feedback session is to encourage the clients to "own" their data. In other words, the consultant does not tell the clients what their problem is and what they need to do about it. Rather, the consultant uses *group leadership skills* to facilitate a dialogue in which problems are identified (diagnosis) and goals for change are proposed. I worked in this capacity with Peter, Larry, Craig, and Lisa, and they determined that the project group's poor performance could be mediated by a shift in culture from rewarding individual achievement to more collaboration.

20.8.1.6 Intervention

The term "intervention" favored by NCSPP and utilized broadly throughout the consultation literature is again too broad and too general to capture specific competencies. I will return to the topic of intervention in the next section of this chapter on expert competencies because specific types of organizational interventions typically require more training and experience to execute. The interventions I used with the architecture firm could all be seen as competencies: *preparing and delivering trainings*, *team building*, *executive coaching* and *compensation system analysis*. These interventions represent the individual, group, and organizational/systemic levels of competencies proposed in the Division 13 principles.

20.8.1.7 Evaluation

Organizational consultants must also evaluate the results of their efforts. The competencies involved are *identifying consulting goals* (always in conjunction with the client) and specifying how to *measure progress toward consulting goals*. Unfortunately, this is the phase of consultation most commonly overlooked by consultants. The evaluation of consultation typically takes place during and after the intervention stage. The questions are "what are the changes the client system wants (short- and long-term) and how can the interventions recommended and carried out by the consultant to create those changes be measured to see if they have actually worked?" Evaluation can be both formative as well as summative so that interventions can be modified along the way. In the case of my work with the project team, there were time deadlines and budget goals that served as ways to measure group performance (compared to the previous project) and the success of my interventions.

20.8.1.8 Termination

Although there is no particular competency associated with this stage, organizational consultants need to know when to leave and complete a consulting project. As in clinical work, the key is not to abandon prematurely or engender dependency.

20.8.2 Summary of Competencies

In ❯ Table 20.1, the competencies identified in the previous section are listed. Several of the competencies (e.g., relationship, interviewing skills) were cited more than once over the stage of consultation. The checkmarks highlight the competencies that are required across most or all of the stages of a consulting process.

Two of the competencies, relationship and diversity, are critical to all phases and aspects of a consulting project. Each of these general terms can be reduced into more specific competencies. For example being competent in the area of relationship requires interpersonal skills, empathy, listening skills, etc. Likewise, the diversity competency is sometimes referred to as "multicultural competence" and involves knowledge and skills in terms of self-awareness, awareness of others, and utilization of contextually relevant interventions.

◼ **Table 20.1**
Competencies from case example #1

	Most phases	All phases	Level
Relationship		✓	BE
Listening skills			B
Conflict mediation skills			BE
Interviewing skills			BE
Knowledge of consulting process	✓		B
Knowledge of group dynamics			BE
Group leadership skills			BE
Observation skills	✓		BE
Observe communication patterns			BE
Diversity		✓	BE
Construct and negotiate contract			B
Determine who is the client	✓		B
Developing interview questions			B
Develop and administer surveys			B
Organize and format assessment data			BE
Giving feedback			BE
Report writing			BE
Conducting feedback meeting			BE
Prepare and deliver trainings			BE
Team building			E
Executive coaching			E
Compensation system analysis			E
Identify consulting goals (measurable)			B
Measure progress of consulting goals			B

Organizational consultants both new to the field and experienced will possess some level of interpersonal and basic relationship skills. Diversity skills, however, are not given. SCP recently conducted an informal survey of its members and found that "the majority have very limited education, training or supervised practice in dealing with the cultural, racial, and ethnic issues that impinge on the delivery of effective organizational consulting psychology" (Cooper & Leong, 2008, p. 135).

The other competencies listed in ❯ Table 20.1, which are crucial over many phases of consulting, are knowledge of the consulting process, observational skills, and determining who is the client. Knowledge of the consulting process is important for the consultant to stay grounded in any particular stage while also seeing the larger picture. This knowledge is also imparted to the clients throughout the project to demystify the process and encourage collaboration. Whenever the consultant is physically with the client, the ability to assess and gather information through observation is vital to the success of any project. Finally, the concept of "client" in

consultation is more slippery than in clinical work. To practice effectively and ethically, the consultant must be able to keep track of the various types of clients being served and impacted at each stage of the consultation.

20.8.3 Basic or Expert?

To provide the reader a comprehensive sense of the many competencies required to engage in consultation, I listed all the competencies that were involved in my project with the architecture firm in ❯ Table 20.1. The division of basic and expert competencies in consultation is more art than science. Like the psychotherapy competency, most consulting practitioners take the "long view" that becoming truly proficient as a consultant is a lifelong effort. Of the 24 competencies listed, only eight (knowledge of consulting process, listening skills, contracting, knowing who is the client, developing assessment questions, survey construction and administration, identifying consulting goals, and measuring progress) could be defined at the basic level. Thirteen others (e.g., interviewing skills, observational skills) are learned at a basic level and enhanced with consultation experience. Indeed an argument could be made that all the competencies in ❯ Table 20.1 exist at the basic and expert level. Finally, team building, executive coaching, and compensation system analysis are types of consulting interventions that require more training and experience. The topic of expert competencies in consultation will be taken up in the next major section of this chapter.

20.8.4 Acquisition of Basic Competencies

Just as there is a lack of consensus about how to identify and define the basic competencies, there is no agreement or solid research about how to prepare clinical psychologists in training for the role of organizational consultant. I have had considerable success over the past 10 years teaching the basic competencies and will briefly outline the methods I have used.

Acquisition of the basic competencies starts in the classroom. Students are introduced to the practice of consultation through a combination of reading and in-class simulations. It is beyond the scope of this chapter to detail the readings available that help prepare psychologists in training to become competent in consultation. I adopt Schein's (1969, 1988) process consultation model and utilize a variety of other source materials from publications associated with APA Division 13 to works by other scholars and practitioners who write about consultation.

The key to learning the basic competencies is for the students to practice, practice, and practice. I create consulting scenarios and divide my classes into organizational clients and consultants. The clients are briefed about their roles and the primary issues of concern in their fictional organization. The student consultants work in teams and I coach them through the various phases of the consulting process. Usually, I will demonstrate the primary consulting competencies in each phase before beginning the simulation.

For example, the first meeting (sometimes called the exploratory meeting) between the consultant(s) and the members of an organization is a critical point in any consultation project. During this meeting, relationships are formed; a preliminary assessment and diagnosis takes place; the consultant decides to pursue the project or not and contracting begins. Many of the competencies listed in ❯ Table 20.1 come into play. In my class, I will lead an exploratory

meeting (with students as organization members) to demonstrate the basics required to have a successful outcome. Then, I allow the designated student consultants to lead such a meeting using a scenario I bring to class, often from my own consulting practice. Consultants are encouraged to call "time outs" and ask for supervision in the process, if they get stuck or I might intervene if I see course corrections that are necessary.

I have found that all the early stages of consultation can be practiced through this simulation method. One organizational scenario will usually require several 3 hour class periods to complete. I either rotate the consultant and client roles so that all the students have the chance to practice consulting competencies or, if time allows, retain the same consultants throughout and then run subsequent simulations in which other students have the opportunity to practice their skills. The phase of consulting which does not lend itself to this model is intervention. Students will work through the initial contact, entry, contracting, assessment (usually conducting interviews with organization members), feedback and diagnosis, and goals for change. They might make recommendations for types of interventions in their feedback to the client. As mentioned earlier, there are many types of consultation intervention, most of which require more advanced competencies.

In these simulations, if students have the chance to practice the competencies associated with each phase of consulting more than once, a dramatic increase in their confidence and skill level is evident.

The final component of my teaching approach involves a field project or placement. After the students have demonstrated a basic level of competency through classroom work, they form consulting "teams" and partner with a community organization to conduct a "live" consultation project. Nonprofit organizations are particularly eager for such partnerships. Competency levels improve rapidly when students are engaged in "real work." I supervise the teams typically from the classroom, not at the site itself. Through these field projects, key basic competencies such as interviewing skills, contracting, observation, and relationship skills and providing feedback are refined and enhanced.

20.9   Expert Competencies

There is no finite list of expert competencies in consultation. I will begin this section with another case study from my practice in which several are demonstrated. Like case example #1, aspects of the project will be modified for the sake of confidentiality and to add value to teaching.

20.9.1 Case Example #2

I was contacted by Paula, who owned several hotels and a variety of other businesses. She was referred to me by a mutual acquaintance. Paula suggested that we meet at my office and I agreed. In the meeting, she outlined a complex and sensitive situation at one of her hotel properties. The general manager, James, was having significant problems in his relationships with his managers and employees. Paula explained that she had hired James 6 months earlier because of his proven record of improving profitability of hotels that were having financial difficulties. The previous general manager was well liked and respected by the employees, had a collaborative (laid-back) management style, but after the events of 9–11 was unable to bring the hotel back to a positive revenue picture. Paula described a very "emotional" meeting in

which she met with all the employees and announced the change she was going to make bringing James in and the reasons why. She was complimentary of the outgoing general manager, but told the employees she was faced with the difficult choice of installing new leadership or selling the property.

When Paula and I spoke, James had been on the job for 6 months, and she reported that he had already made significant progress on the financial side of the business. Unfortunately his management style was diametrically opposite to the former general manager. She described James as intense, confrontational, and frequently critical of his managers and employees. Turnover and absenteeism were up 25% since his arrival. He was working 60–70 hour weeks (often sleeping at the hotel) and expected his managers to do the same. He had difficulty delegating and was inclined to micromanage employees who resented not being allowed to carry out their duties with autonomy. Finally, Paula had heard complaints that James favored white males and treated them with more respect than women and employees of color.

I asked Paula about the sources of her information. She told me she usually spent 1 day a week at that property and had an "open door" policy. She encouraged employees to drop in and talk to her. She said she wanted to continue to promote a "family" atmosphere and open communication even with the change in leadership. I asked Paula about her own supervision style with James and if she had confronted him with the feedback she was receiving. She replied that she tended to be a "hands off" boss. She had spoken to James several times but he either dismissed or minimized the complaints. He would remind her that she hired him because he had a different management style, that there are always growing pains when a new leader takes over, that the employees who were quitting would have been let go anyway due to poor performance, and that the hotel was making money again.

Paula had never hired a consultant before. She was not exactly sure what I could do or what she wanted to occur. Her desire to meet at my office and not the property was strategic. At this point, she did not want James or any hotel employees to know she was considering hiring an external consultant. As we sorted through the complex situation she presented, she was able to specify the initial goals. She wanted to retain James. She wanted to reduce turnover, absenteeism, and job dissatisfaction. She wanted to maintain some semblance of the family culture that had been a hallmark of this organization, since this hotel opened 8 years earlier. She wanted to make sure that the employees were treated fairly regardless of race or gender.

We spent the remainder of that first meeting discussing the next steps, the consulting process in general and negotiating the outline of a contract (which would be formalized at a later date). I was mindful of the nuances of this consultation project, which would require several more advanced and expert competencies:

- I was hearing only one perspective about the situation and would need to do further assessment.
- To address Paula's goals, I would want to spend considerable time with James which posed the question, "who is my client?"
- The owner was ambivalent about the desired organizational climate, wanting to keep the family atmosphere among her employees, while recognizing that James was making changes which were necessary to make the hotel profitable.
- Paula's open-door policy effectively created a triangle in communication in which James was usually bypassed.

- Would James be open to a consultation process?
- There were accusations of possible sexism and discrimination.

Altering the format used in case example #1, I will first outline the stages of consultation and then append a section on expert competencies.

The *initial contact* was made by Paula. In the meeting with Paula at my office, a *preliminary assessment* was carried out. *Contracting* began but would be finalized later in the process. I proposed to Paula that another assessment meeting occur on site which would include James. The primary function of this meeting would be to shut down yet another communication triangle, one that I was now part of with James and Paula. Other purposes of this next meeting would be to elicit James' perception of the matters at hand and to assess his level of "buy-in" to a consulting process in which he would be a key player. The meeting was set for the following week in Paula's office at the hotel.

I did meet with Paula and James the following week (*entry*, *preliminary assessment*, *contracting*). Paula and I began by telling James we had met once before and what we had discussed. I am promoting, in this step, transparency and no hidden agendas on Paula's part. I specifically asked Paula to repeat her concerns and then asked James to respond. At that point, I was assessing James' level of openness, defensiveness, and capacity to objectively assess his own strengths and weaknesses. I was generally encouraged in what I heard, as James admitted to making some mistakes with employees, and "welcomed" some outside intervention to assist him in examining his management style. He denied any awareness of treating particular groups of employees differently. The three of us drew up the first stage of a contract. I would have three 90 minute meetings with James in my office. The primary purpose of these meetings would be further *assessment* and relationship and trust building with James. After my meetings with James, a follow-up meeting with Paula would be scheduled to plan the next steps and sharpen the goals of consultation. I would provide no information to Paula until that time.

Before that meeting ended, I made a deliberate *intervention* with Paula. Although intervention can be seen as a discrete phase of a consultation project, in fact, the consultant is intervening at every stage. I suggested to Paula that during the next 2 weeks when I was meeting with James that she should not meet with the employees to hear their concerns. Instead, I encouraged her to counsel the employees to take their concerns directly to James (it is interesting that despite the size of this organization there was no formal HR director or position – an artifact of we are a family not a formal business culture).

James and I held our meetings. Near the end of the second meeting, he acknowledged that he had hoped to go through the motions with me to pacify his boss and that he neither saw any reason nor had the time to meet me. He thought he was doing exactly the job Paula hired him to do and did not appreciate her lack of support or open-door policy which allowed his "problem employees" to go over his head to "mommy." I saw that meeting as a breakthrough and absolutely vital, if the consultation process was going to move forward. James was being more honest about his attitudes and feelings. In our third meeting, he softened slightly and admitted that he was struggling in the relationship area with many of his employees. In his previous positions, his management style worked more effectively. He reluctantly agreed that perhaps he could make some slight modifications.

James, Paula, and I met again as planned. I provided *feedback* from all of the meetings to date. James spoke about his willingness to examine his management and interpersonal style, given the number of complaints and the increase in turnover and absenteeism. He also agreed to reevaluate whether his expectations of his employees and managers were realistic. I came to

that meeting with several intervention strategies which I was prepared to present contingent on the *goals to be set* and changes to be pursued.

The *interventions* that I carried out were:

- Ongoing weekly executive coaching with James, including "role plays" in which James practiced different styles of confrontation and communication with me playing the role of the employee.
- Homework assignments – again geared toward James trying out new behavior with employees.
- Two 360° feedback evaluations of James. One was carried out at the beginning of my work with James and another 16 weeks later to measure any changes that were occurring in his style and performance rating.
- Meetings with James and Paula, so we could all be present as James and I discussed the progress of our sessions.
- Meetings with James and Paula to discuss "cultural" issues and structural changes, including the formation of an executive committee to advise James and the creation of an HR position to shift that function from Paula.
- A referral of James to cultural competency training for managers.
- Facilitation of initial meetings of the executive committee to assist them to define their functions and areas of responsibility.

My work with this organization spanned 2 years. James remained as general manager. The hotel continued on a path of financial health. Turnover continued to be an issue for several months and then settled to industry-wide average levels. James was able to make some changes in his style, reluctantly at first, but more sincerely when he saw the results of a more positive work atmosphere. The culture of the organization did shift to a more formal business operation with a clearer hierarchy (Paula's door only opened if other steps had been taken first). I heard, however, that the yearly Christmas party at Paula's house continued to be a successful and family-like affair. Allegation of unfair or discriminatory behavior by James diminished markedly and was handled by the HR director (*evaluation and termination*).

20.9.2 Summary of Expert Competencies

I will begin by reiterating that there is no clear line which demarcates basic and expert consultation competencies. Rather, the vast majority of consultations can be conceptualized as existing on a continuum and becoming a master or an expert consultant is a lifetime process.

My work with Paula, James, and their organization did require that I perform at an expert level utilizing many advanced skills and competencies. In this section, I will attempt to name these competencies using the context of case study #2. In the early part of my involvement with this organization, I relied primarily on my basic assessment and relationship building skills. I asked a lot of questions, listened carefully, and advised Paula about the consulting process and on the initial steps to get us started. Once James entered the process, more advanced skills were called for.

I would call the first expert competency demonstrated in this case as *boundary management*. It was evident from the very first contact I had with Paula that individuals in the organization favored indirect communication to direct communication. James, in particular,

was frequently triangulated. Boundary management means that I attempted to clarify and support direct lines of communication while eliminating the "end run" method of expressing concerns and information. Another expert competency was the ongoing need to *manage multiple layers of organizational clients*. Paula was my sponsor (she was paying me) and a client. James was my primary client. Over the 2 years, I had contact with the majority of the hotel employees. For James to trust me and be open to my change initiatives, it was essential that the "rules" of what I would say about our meetings and to whom be absolutely clear. I would say to James, "Paula pays me. For this consulting project to succeed she must be aware of many of the things we discuss. I will only have those conversations, however, when you are in the room." If Paula would call me and ask how the coaching with James was going, I would politely tell her to ask James about that or to wait until our next scheduled meeting with the three of us. Boundary management and managing multiple layer of organizational clients are closely related competencies and functions.

The success of this project pivoted on developing an alliance with James. He was a reluctant client who was going through the motions of cooperating with my interventions while resenting his supervisor for calling me in and for doubting and questioning his management style. The expert competency required to form an alliance with James was *acknowledging*, *validating*, *and working with resistance*. In my early meetings with James, I was empathetic and sympathetic to the difficult position he was in, being required to meet with me and not being fully supported by Paula. At first, he denied any discomfort or resentment, but over the course of our three initial meetings, he admitted that he did not see that he needed any help or coaching.

Before meeting with James and Paula to provide feedback and facilitate a process in which goals could be set, I had a phone conversation with Paula. I did some *executive coaching* in this call with Paula. I advised her to use a portion of our meeting to point out to James his strengths and accomplishments to date. I knew that James would be much more responsive to a change initiative and more likely to admit to some problems in his management style, if the discussion among the three of us was balanced and included acknowledgement of his strengths.

Moving into the formal intervention phase of this project several more expert competencies were required.

- In my ongoing executive coaching with James, I used *directed role plays*. We would construct typical interpersonal situations he encountered at work, in which by his admission his approach failed or his goals were not met. First, I would play the employee. James would approach me in the way that was unsuccessful. Then, we would reverse roles and I would approach James (now in the role of the employee) with a different interpersonal style (e.g., more complimentary). James then had the opportunity to see how it felt to be approached in another manner. Then, James would try to adopt my approach and we would reenact the employee encounter one more time. In this last round, James was trying on a different management style to see how it fit. Sometimes, we would make modifications so that my proposed style could be better integrated into his existing style. Finally, I would assign homework and require that James try out the new approach at least once with an employee before our next coaching session.
