Older adults – particularly those of advanced aged – commonly have multiple problems. A common client is an older adult who exhibits three medical conditions, takes six medications, evidences a depressive syndrome with concurrent anxiety as well as mild cognitive impairment. The older adult may receive health services from five providers: an internist, two specialists, a psychologist, and a psychiatrist. Psychosocial stressors include a decreasing social network (owing to death or infirmity of friends), with concurrent reduction in social involvements, and financial difficulties. Particularly for older people, optimal care is integrative care in which members of the health care team work collaboratively to establish a health care plan, implement it, and make revisions of the plan as necessary (APA Presidential Task Force on Integrated Health Care for an Aging Population, 2008). However, most health care services are fragmented and not well-integrated. The psychologist must at least be knowledgeable about the client's physical and mental health and associated treatments, and life circumstances, and make a substantive effort to coordinate care with other providers. Problems need to be prioritized and the interaction among them recognized, monitored, and addressed (e.g., increasing depression leads to lessened adherence to medical regimens with subsequent decline in health).

Understanding what is normative about the lives of older adults informs psychological work with them. Knight's "contextual, cohort-based, maturity, specific-challenge model" (Knight, 2004) draws upon the substantive gerontology literature to guide clinical practice with this age group. This model asks the clinician to appreciate and understand the environments and institutions that are relevant to the lives of older adults, the generational experiences that have sculpted the way each generation looks at the world, maturational changes (both positive and negative), and common age-associated problems. This broad understanding of what is normative for older people is, of course, shaped by race/ethnicity, socioeconomic status, sexual orientation, gender, and the individual's unique life experiences.

The therapist makes efforts to enhance the therapeutic encounter. In view of the increasing prevalence of physical, sensory, and cognitive change in older adults, the clinician makes adaptations to optimize therapeutic services. Given the varied places where services are provided to older adults (e.g., community, outpatient, inpatient, long-term care settings), the location needs to be accessible to people with mobility problems. The clinician is alert to vision or hearing difficulties and makes needed adjustments to optimize communication (e.g., inquiring about hearing or sight difficulties, speaking clearly to the client, adjusting lighting to avoid unnecessary glare). For example, among people aged 65 years and older, two-fifths have trouble hearing and almost one-fifth have trouble seeing (Federal Interagency Forum on Aging Related Statistics, 2008). It may be particularly challenging to find a quiet, confidential setting for clients in institutional settings (e.g., inpatient hospital, nursing home). The current generation of older adults is more likely to consider the utilization of mental health services as stigmatizing than subsequent generations. Providing basic information about the nature and purpose of mental health services will often help to build rapport with the older client. With the consent of the client, gathering information from family members and other persons close to the client may be very helpful in understanding current problems and monitoring the progress of treatment. Family or other close relationship involvement is critical if the client has cognitive impairments.

The clinician is proficient in the use of therapeutic approaches which are more commonly used with older adults than with other age groups (Duffy, 1999). In view of the increasing medical problems of late life, clinicians are familiar with therapeutic interventions associated with end-of-life care and treatment of complicated bereavement (Ott, Lueger, Kelber, & Prigerson, 2007). Life review techniques developed for older adults may be useful in clinical practice. One major stressor of late life is care for an infirm relative. There is a large professional and lay literature on family caregiving, with a number of evidence-based treatments shown to reduce distress and improve functioning in caregivers. Several recent books provide good overviews of psychotherapy with older adults (Gallagher-Thompson, Steffen, & Thompson, 2008; Hinrichsen & Clougherty, 2005; Karel et al., 2002; Qualls & Knight, 2006).

17.5.2 Evidence on the Efficacy of Psychological Interventions for Older Adults

Evidence on the efficacy of psychotherapeutic interventions for older adults and their families has accumulated over the last 25 years. With some adaptation, most interventions developed for younger adults are useful and have similar effect sizes for older adults (Pinquart & Sorensen, 2001; Scogin & McElreath, 1994). In the subsequent discussion, we will review the evidence of

the utility of psychological interventions in the treatment of depression, anxiety, distress in family caregivers of infirm older adults, behavioral problems among older adults with dementia, sleep problems, and substance abuse. We will highlight reviews that identified Evidence Based Treatments (EBT) for older adults that used a manual developed by the Committee on Science and Practice of the Society of Clinical Psychology (Yon & Scogin, 2007). It is worth noting that, as a basis for practice, EBTs have been criticized on a number of grounds, including neglect of important practitioner-related factors that are tied to good treatment outcomes. EBT reviews have also set a high methodological standard for study results to be considered efficacious. Therefore, the following reviews are conservative in estimating the psychological interventions that are useful for older adults.

Depression. A wide variety of interventions for depression are effective in treating older adults. Scogin and colleagues (Scogin, Welsh, Hanson, Stump, & Coates, 2005) found that behavioral therapy, cognitive behavioral therapy, cognitive bibliotherapy, problem-solving therapy, brief psychodynamic therapy, and reminiscence therapy are effective in treating older people. Other psychotherapies for depression were identified to be promising (e.g., interpersonal psychotherapy, Hinrichsen & Clougherty, 2005), but lacked a sufficient corpus of acute treatment studies to be included in the analysis. For example, despite interpersonal psychotherapy's well-demonstrated efficacy in the acute and longer-term treatment of depression in adolescents and adults (Weissman, Markowitz, Klerman, 2000), further evidence is needed to establish its efficacy in older people. Observations of Scogin et al. generally support earlier reviews of the literature on the efficacy of psychotherapy in the treatment of late-life depression (Arean & Cook, 2002; Gatz et al., 1998; Karel & Hinrichsen, 2000).

Anxiety. Despite estimates that up to 10% of older adults have anxiety disorders (Flint, 1994), the number of treatment studies of anxiety disorders is much more limited than those of late-life depression. In their review of evidence-based treatments, Ayers and colleagues (2007) concluded that "psychosocial interventions are moderately efficacious" (Ayers, Sorrell, Thorp, & Wetherell, p. 12) in treating anxiety disorders in older people. Treatments with evidence to support their efficacy include cognitive behavioral therapy, relaxation training and, to a limited extent, supportive therapy. There are limited data on the treatment of anxiety disorders other than those for generalized anxiety disorder (e.g., phobias, panic disorder, and obsessive-compulsive disorder).

Distressed Family Caregivers of Older Adults. As noted earlier, family members providing care to older adults with health problems and dementia are at risk for adverse mental health outcomes (Schulz & Matire, 2004). Numerous psychosocial interventions have been developed to reduce distress and improve mental health outcomes in this group. Gallagher-Thompson and Coon (2007) reviewed the evidence for the utility of psychologically informed, evidence-based treatments in reducing distress and improving the well-being of family members providing care to older adults with health problems and dementia. They found that psychoeducational skill-building interventions (e.g., increasing knowledge, enhancing coping and behavioral skills), psychotherapy-counseling (including behavior therapy, cognitive therapy, and cognitive-behavioral therapy), and multicomponent interventions (e.g., combinations of support group, respite, family counseling) are all effective in reducing caregivers distress. Cognitive behavioral approaches are especially useful and demonstrate robust effect sizes.

Behavioral Interventions for Problematic Behaviors in Older Adults with Dementia. Mental health and behavioral problems are common among people with dementia, and are especially taxing for family members and staff in institutional settings who must manage them. Logsdon,

McCurry, and Teri (2007) reviewed the evidence for the efficacy of psychologically informed interventions for persons with dementia who had a variety of behavioral problems. The research data support efficacy of two approaches. First, the progressively lowered stress threshold (PLST; Gerdner, Hall, & Buckwalter, 1996) is an educational intervention designed to improve family caregivers' ability to understand and manage behavioral problems in a relative with dementia. Second, the Seattle protocol (Teri, Logsdon, & McCurry, 2005) teaches behavioral skills to family caregivers to improve well-being and functioning, as well as decrease behavioral problems in relatives with dementia. Both approaches share problem-solving and behavioral-activation elements. Other non-psychologically informed interventions to improve behavioral problems in persons with dementia were not the focus of their review.

Treatment of Sleep Problems. Sleep problems are common among older adults and are associated with increased risk for a number of mental health problems and symptoms (Lichstein, Stone, Nau, McCrae, & Payne, 2006). McCurry and associates (McCurry, Logsdon, Teri, & Vitiello, 2007) reviewed evidence on the efficacy of sleep treatments that were based on psychological principles. Two treatments were identified as efficacious. These include sleep restriction–sleep compression (i.e., reducing the duration of time spent in bed to correspond to the actual time spent sleeping) and multi-component cognitive-behavioral therapy (CBT). Multicomponent CBT includes education about sleep, relaxation training, sleep restriction, and stimulus control (i.e., strengthening association of bed with sleep and not other activities).

Alcohol Abuse. Older adults have been shown to benefit from a range of treatments for alcohol abuse, including brief counseling interventions in primary care settings, cognitive-behavioral approaches, and motivational counseling (Sorocco & Ferrell, 2006). In general, older adults appear to respond better to treatment approaches that incorporate age-appropriate components, including non-confrontational approaches, attending to negative emotions, slowing pace and content of treatment, recognizing age-specific psychological, social, and health issues, and linking to aging services as needed (Gurnnack, Atkinson, & Osgood, 2002; SAMSHA, 1998; Sorocco & Ferrell, 2006).

Study Limitations. While a solid body of evidence on the efficacy of psychological interventions for older adults now exists, there are a number of limitations with most of these studies. Most studies do not include the "oldest old" (i.e., individuals 85 years of age and older), who often have multiple medical problems and whose mental disorders may be more difficult to treat than those in younger older adults. There are a limited number of studies on older adults residing in long-term care settings. Studies often do not include individuals with multiple mental disorders who are likely to be more difficult to treat than those with single mental disorders. There is also limited research on the treatment of minority older adults. Finally, most studies evaluated the efficacy of acute (i.e., short-term treatments) and not long-term treatment.

17.6   Consultation Competencies

Consultation is integral to providing clinical services to older adults, and is interwoven with the work of a geropsychologist. Geropsychologists work in concert with families and other members of the older person's social network, health care and non-health care professionals, and agencies. Gathering and sharing information with members of this network, with the older client's consent, optimizes care.

Many older adults seek mental health services at the behest of someone else – primary care physician, family member, friend, neighbor, or agency. Often, these individuals are interested in understanding the problems with which the older adult is contending, the plan of care, and the client's progress as mental health services are provided. We want to reemphasize that consultation is provided with the consent of the client. Some older adults feel that they become invisible when a family member accompanies them to a medical or mental health appointment. One client who was being evaluated by one of the authors pointedly reminded him of this fact after an initial interview and prior to having her daughter join us to provide additional information. "When my daughter is here, remember that I am the patient, not her. And don't forget to continue to make eye contact with me when she's in the room." Consultation is provided to family members in a manner that is clear, frank, supportive, and hopeful. Family members often wonder what they can do to be helpful, and practical recommendations and, if needed, referral to other resources for themselves can be made (e.g., psychotherapist, support group, bibliographic resources).

Similarly, other professionals and agencies may request a status report on client progress and recommendations on how they might best deal with mental health issues that affect their ability to deliver effective services to their clients. For example, the primary care physician may be concerned when the seriously depressed older adult does not adhere to dietary and medication recommendations, and may seek guidance regarding how to best address these issues with the client in medical appointments.

Psychologists have increasingly played an important role in the delivery of mental health services to older adults in long-term care residential facilities (Rosowsky, Casciani, & Arnold, et al., 2008). A very high prevalence of dementia and other mental disorders exists in these settings. Many clients have concurrent mental health and physical health problems within settings that have complex institutional, interprofessional, and interpersonal dynamics. In addition to providing individual care to clients, geropsychologists are often asked to provide guidance on how to address a wide range of problems: The resident is constantly in conflict with the staff and other residents. The resident is frequently agitated for reasons that are not clear. The resident assaults a nursing aide. The resident refuses to join other residents in communal activities or be bathed. Consultation on these and other issues requires not only an understanding about the individual client, but also the interpersonal, institutional, and environmental factors that may contribute to the identified problem and, if modified, may reduce the problematic behavior. Client "problems" may be a predictable response to a problematic environment that needs to be changed rather than the client (Burgio et al., 2002; Stevens & Hochhalter, 2006).

A general consensus exists that the U.S. system of health care is fragmented and poorly integrated. Such a system is too often ill-suited to the needs of older adults, many of whom have chronic health problems and multiple providers. Fragmented care can be especially problematic for chronically ill older adults with mental health problems (Bartels, 2003; Wenger et al., 2003). While the U.S. health care system is fragmented, there is also general consensus that integrated care is better care. Integrated care is a holistic approach to providing care and is characterized by sharing of information and professional expertise, setting goals, and addressing patients' problems within teams of professionals. Psychologists have a set of assessment, treatment, and consultation competencies that can make a substantive contribution to integrated care. Integrated care exists in some health care sectors, notably in the Department of Veterans Affairs health care system, which serves a large population of older adults. A recent

report by the APA, *Blueprint for Change: Achieving Integrated Health Care for an Aging Population* (APA Presidential Task Force on Integrated Health Care for an Aging Population, 2008), outlined the role that psychologists can play in providing integrated care. Although many geropsychologists provide services in poorly or partially integrated care settings, they are encouraged to weave integrative care principles into their work and strive to refashion existing health delivery systems.

Geropsychologists have a long history of researching and reshaping the environments in which older people reside or receive care (Lawton, 1990), and in how the care is organized and delivered (Zeiss, 2003). Geropsychologists may provide consultation to groups, organizations, and government. Increasingly, geropsychologists have played a role in advising and developing public policy initiatives to improve care delivery to older Americans (Elmore, 2006). Given widespread misinformation about older adults, geropsychologists can educate the general public and other professionals about what is normative about the aged as well as the unique problems and resources possessed by older people (APA Working Group on the Older Adult, 1998).

17.7   Settings of Care for Geropsychology Practice

The Pikes Peak competencies explicitly address the fact that geropsychologists work with older adults across a wide range of care settings, including but not restricted to: outpatient mental health services, outpatient primary care/medical settings, inpatient medical settings, inpatient psychiatric settings, long-term care settings including nursing homes, assisted living facilities and day programs, rehabilitation settings, hospice care, community-based programs, forensic settings, home-delivered psychological services, and research settings (Knight et al., 2009). While most psychologists who work with older adults may not have the interest, training, or competence to serve older adults in all these settings, it is recommended that geropsychologists work competently in at least two of these care settings.

Several of these settings deserve special mention. Most practicing psychologists are familiar with outpatient mental health treatment settings, including community mental health and private practice settings. Currently, psychological services for older adults are growing in primary care, long-term care, and end-of-life care settings. As these settings may be less familiar to readers, we provide additional information on these select settings.

Primary Care. The current generation of older adults rarely self-refers for psychological services. Instead, most of the older adults who get connected to mental health care do so through their primary care providers, or through concerned family members. Most older adults seek regular medical care and, thus, the doctor's office truly offers the best opportunity for screening, evaluation, and intervention for mental and behavioral health problems. Several large, multi-site studies over the past decade have demonstrated the effectiveness of various models of assessing and treating geriatric depression, suicidal thoughts, anxiety, and substance abuse in the primary care setting (Bartels et al., 2004; Bruce et al., 2004; Hunkeler et al., 2006). These models are consistent with the growth of integrated care more broadly, and primary care psychology, more specifically (e.g., Frank, McDaniel, Bray, & Heldring, 2003).

Psychologists who work in primary care are likely to have older adult clients, and can work to identify areas for further training in geropsychology based on self-evaluation of their competencies described in this chapter. Furthermore, psychologists who wish to expand their

practices with older adults can consider co-locating or collaborating closely with primary care practices (Hartman-Stein, 2006). Primary care psychology has its own knowledge and skill base, and hence, psychologists who wish to treat older adults in primary care should also develop competencies for primary care practice (Frank et al., 2003). Recommendations about geriatric depression screening, evaluation, and treatment in primary care settings have been provided by Arean and Ayalon (2005). Problem-solving therapy, interpersonal therapy, and cognitive-behavioral therapy have been successfully adapted to help depressed older adults in primary care settings (Arean & Ayalon, 2005).

Long-Term Care. Long-term care for older adults occurs in settings as diverse as skilled nursing facilities (or nursing homes), assisted living facilities, community day-care programming, and at home. Nursing homes, in particular, have become a growing setting for psychological practice since 1989, when psychologists could be reimbursed as independent Medicare providers. In fact, many psychologists began to work in long-term care settings, often without adequate training. Recognizing the need for standards of care, a professional group, Psychologists in Long-Term Care (PLTC; http://www.wvu.edu/~pltc/), published the Standards for Psychological Services in Long-Term Care Facilities (Lichtenberg et al., 1998). The standards are recommendations for appropriate referral for psychological services in long-term care settings, assessment, treatment, and related ethical issues.

An increasing number of resources are available to psychologists who want to develop the knowledge and skills to practice in long-term care settings. Good practice in long-term care includes an understanding of the medical, neurological, psychiatric, and psychosocial co-morbidities common in older adults who need assistance or skilled nursing care; working ethically and effectively with an interdisciplinary team, including supporting staff in environmental and behavioral interventions; and knowing and applying evidence-based practices for psychological assessment and intervention with physically and/or cognitively disabled older adults. Multiple books, review articles, and chapters on these issues have been published in the past decade (Frazer, 2006; Hyer & Intrieri, 2006; Molinari, 2000; Norris, Molinari, & Ogland-Hand, 2002; Powers, 2008a). PLTC has published a training manual that psychologists can use to help train others (Rosowsky et al., 2008). The research base supporting psychological practice in long-term care is developing (Powers, 2008b), along with opportunities for continuing education.

End-of-Life Care. Until recently, few psychologists were involved in clinical practice, research, or training regarding care of patients at the end of life. While terminal illness can strike people of all ages, older adults represent the majority of dying individuals. Likewise, psychologists who work with older adults will undoubtedly confront issues of death and dying more frequently than those who work with other age groups. Geropsychologists benefit from knowledge regarding the experience of advanced illness and the dying process; ethnic, cultural, and spiritual influences relevant to illness and end-of-life care; models of hospice and palliative care; the impact on family members providing care at the end of life; and bereavement and grief. Psychologists can make important contributions in helping patients and families with: advance care planning, coping with life-threatening illness, the dying process, and bereavement care (Haley, Larson, Kasl-Godley, Neimeyer, & Kwilosz, 2003; Werth & Blevins, 2006). There are growing opportunities for psychology continuing education about end-of-life care, including APA-sponsored workshops, books, and an online series of ten interactive training modules including audio and video vignettes (see http://www.apa.org/ce/).

17.8   Basic versus Expert Geropsychology Competencies

Basic competence in geropsychology is important for any psychologist who comes across older adults in practice. Expert-level competence is reserved for those whose practice is devoted to a wide range of diverse, complex older-adult clients, practicing across multiple care settings, as well as for those who provide training and supervision to psychologists learning to develop geropsychology competence.

Development of professional competence occurs gradually over the course of one's training and professional career. A useful competency development framework is described by Hatcher and Lassiter (2007). The framework considers five stages of development: novice, intermediate, advanced, proficient, and expert. A novice has very little experience, is unable to recognize patterns or themes, and needs intensive supervision. At the other end of the spectrum, an expert has developed almost an intuitive sense of clinical situations based on tremendous experience, and serves as a consultant or teacher to others. With ongoing training and development, the professional is able to function with increasing autonomy and decreasing need for supervision or consultation.

In defining basic versus expert geropsychology competence, it is not so much which Pikes Peak competencies are relevant or not at the basic level; all the competencies are relevant and important. Rather, it is important to determine at what level of processing and independent functioning the psychologist can address each competency that distinguishes basic versus expert competence in the field. Our working model is that a psychologist with basic geropsychology competence can work with older adults at the intermediate or advanced level (typical of an advanced practicum or internship student), while a geropsychology expert works with older adults at the proficient and, in some domains, expert levels.

17.8.1 Depth and Breadth of Practice

Depth and breadth of geropsychology practice have implications for training and development of basic (intermediate or advanced) versus expert (proficient or expert) competencies. At a basic level of geropsychology competence, a psychologist must be aware of the common issues that affect older adults and their families, know what questions to ask, and have enough knowledge and skill to at least do appropriate screening and referral for further assessment, consultation, or treatment as needed. Psychologists with basic geropsychology competence should know enough about the landscape of geropsychology practice to inform their own "metacompetence" – to have an accurate sense of what they know and do not know in working with a particular older adult, with a particular diagnostic picture, in a particular care setting. A psychologist with basic competence may not be able to continue assessment or treatment in depth, but knows enough to consult or refer out. An expert may be able to not only recognize the possible issues contributing to an older adults' presentation, but independently complete a full evaluation (often with multiple sources of information, informants, perhaps standardized testing) as well as devise and implement a treatment plan (which also may have multiple elements such as individual therapy, family consultation, interprofessional collaboration, community care coordination).

Breadth of practice is important as well. A psychologist with basic geropsychology competence may provide assessment and treatment of older adults which is limited to a particular

setting or population of older adults. For example, a psychologist who works with severely mentally ill adults in inpatient settings may learn about special issues in psychopathology and risk assessment in late life, but perhaps not gain fuller breadth of competence to work with older adults in community-based settings. On the other hand, a psychologist who specializes in couples and family therapy may develop basic competence to work with older couples who are essentially cognitively intact and wishing to work on late-life marital and family stresses (and be able to note "red flags" for issues that may require further evaluation or consultation), but perhaps not gain competence to provide psychological consultation in nursing home settings. However, a geropsychology expert has greater breadth of competence in being able to meet the mental health needs of a wide range of older adult clients across a wider range of care systems. Certainly, no single professional can be an expert at everything, and a geropsychology expert should know the limits of his or her competence and know when to refer to or consult with colleagues who have expertise in the areas in which he or she does not.

17.8.2 Defining Basic Versus Expert Geropsychology Competencies

Within the field of geropsychology, there has been some effort to define basic versus more advanced practice in the field. The APA Interdivisional Task Force on Qualifications for Practice in Clinical and Applied Geropsychology, whose work led to the publication of the APA *Guidelines for Psychological Practice with Older Adults* (2004), defined three levels of geropsychology training: (1) general exposure to aging; (2) training compatible with proficiency in geropsychology practice, and (3) training compatible with geropsychology specialty expertise (Molinari et al., 2003). A Department of Veterans Affairs working group (the VA Technical Advisory Group in Geropsychology) took on a project that resulted in "Recommendations about the knowledge and skills required of psychologists working with older adults" (Molinari et al., 2003). The project was initiated to address the need for VA psychologists, in particular, to develop competencies to work with the aging veteran population, but resulted in recommendations pertinent to any psychologist working with older adults. These recommendations address two levels of practice: Level 1 refers to the knowledge and skills that all psychologists should have to work competently with older adults in general practice, and Level 2 refers to the knowledge and skills required for practice and training by specialized experts in the field. Recommendations for Level 1 and Level 2 functioning were made for seven broad competency areas.

The Pikes Peak geropsychology competencies were aimed somewhere between Level 1 and Level 2, as defined by Molinari et al. They were geared towards newly licensed professional psychologists who have completed a year of geropsychology postdoctoral training – not yet experts, but having developed more than basic competence. Based on the Pikes Peak competencies and the work by Molinari et al., we have attempted to outline what we believe are essential (basic) competencies for work with older adults, knowing that this issue remains open in this field and that other geropsychologists may have different opinions. We argue that geropsychology expertise entails having the full complement of knowledge and skills outlined in this chapter. A geropsychology expert had achieved significant breadth and depth of experience in applying the Pikes Peak competencies to work with diverse older adults with a wide range of diagnostic and life problems, across various care settings.

17.8.2.1 Foundational Attitude, Knowledge, and Skill Competencies

The foundational geropsychology competencies, as described earlier, are all critical for basic geropsychology competence. Within these foundational skill competencies (e.g., self-reflection, appreciation of diversity, ethical practice), the core attitudes that must inform competent practice with older adults are embedded. The Pikes Peak Model acknowledges the importance of these core attitudes, including recognition of one's scope of competence, self-awareness of attitudes and beliefs about aging and older adults, appreciation of diversity among older adults, and commitment to continuing education. Likewise, basic knowledge about adult development and aging must inform clinical practice with older adults; that is, not all older adults are the same, aging encompasses both growth and decline across domains of functioning, and older adults are generally experts at optimizing their strengths and compensating for losses. Here, we highlight the competencies that we believe are critical to basic professional competence in working with older adults.

Perhaps the most important aspect of professional psychology functioning in general is self-awareness and self-reflection – regarding one's own potential biases, discomforts, and professional competencies (Falender & Shafranske, 2007). Basic competence in professional geropsychology requires enough self-awareness and knowledge to be able to counter aging stereotypes, to question one's assumptions about what is "normal" for an older person in terms of health, mood, memory, everyday functioning, and relationships (e.g., is it "normal" for an older person to be depressed, forgetful, and lonely?). Possibly biased assumptions can lead to unfortunate missed opportunities for helping older adults whose suffering can be alleviated. Thus, basic geropsychology competence does require basic knowledge about normal versus pathological aging (APA, 2004; APA Working Group on the Older Adult, 1998).

Similarly, basic competence for geropsychology practice requires a respectful, collaborative, and genuine relationship stance with older adults. For a variety of cultural and individual reasons, we often observe health care professionals communicate with older adults as if they were children or ignore them if other family members are in the room. On the other hand, some may grow impatient with an older adult's stories or, perhaps, slowness to respond to questions. It is important for psychologists to feel comfortable being with older adults and be aware of the possible disrespect or exaggerated respect that can get in the way of collecting important clinical information. Our students often have difficulty interrupting older adults, not wanting to be disrespectful, and must learn how to interrupt and guide an interview in a respectful and constructive manner.

The importance of appreciating diversity among older adults is related to the relationship with and respect for older adults. Respect for diversity includes challenging our own biases or stereotypes about aging in general, as well as about particular subgroups of older adults. Each older person would have accumulated 60–100+ years of unique individual experiences in their own cultural and environmental context, which may make it difficult to carry out age-based generalizations. It is incumbent upon psychologists working with older adults to work to learn about the individual's life experience and related values, beliefs, goals, and strategies for coping.

A critical and basic competency in working with older adults is to know where to go for more information or resources. While it is not realistic to ever know all there is to know about working with older adults, it is important to have a good sense of where to go for help. Such resources include community information and referral services for older adults and families (e.g., local aging services office), geriatric medical, psychiatric, neurology providers in one's

community; local residential, social, and day-care services for older adults; websites with information about aging-related conditions; and professional geropsychology organizations that facilitate sharing of information and resources. Knowing where to find information is a critical and basic competency in any field.

Finally, another basic foundational competency is to practice the business of geropsychology ethically and legally. Geropsychologists, particularly those working in private or fee-for-service practice settings, must be aware of evolving Medicare and Medicaid policy and know how to bill appropriately for the services rendered.

17.8.2.2 Assessment

Basic geropsychology assessment competence entails being able to appreciate the potential complexity of differential diagnosis in this population, screen for a range of possible contributing problems (as well as strengths), and consult, collaborate, or refer to other providers if needed to help clarify a case conceptualization. Again, it is the capacity to have the sense that "maybe I'm in over my head here," being able to ask good questions, and knowing where to seek assistance which are important. Many older adults present with fairly straightforward concerns that can be addressed by one's general professional psychology competence. When the situation appears more complex, psychologists with basic geropsychology competence should seek help if needed.

Recognizing potential risk is a basic competency for working with older adults. "Risk assessment" with older adults may differ significantly than that with younger adults. Psychologists need to be aware of signs of poor self-care, elder abuse or neglect, substance abuse, as well as signs of risk of harm to self or others. Risk management in older adults is ethically and clinically challenging. On one hand, a novice might miss important signs of risk and not take steps necessary to help protect an older adult's safety. On the other hand, a psychologist with limited experience with older adults may take an overprotective stance and threaten an older adult's autonomy unnecessarily. Large "gray areas" characterize risk assessment with older adults, and the responses by professionals are not only influenced by professional knowledge and skill, but also by our own cultural and individual beliefs and ability to tolerate risk (e.g., should a frail older woman who has had several falls continue to live alone?). Good supervision and consultation are important to help develop skill in this area.

17.8.2.3 Intervention

As discussed earlier, older adults generally benefit from psychotherapy interventions for a range of psychological problems. Psychologists who have developed proficiency or expertise in providing particular psychological interventions (e.g., CBT for depression) should have little difficulty adapting their knowledge base and skills to help older adults. Basic geropsychology competence entails being able to adapt psychological interventions to developmental, cohort, or contextual circumstances of older adults (e.g., adjust to sensory deficits, be aware of possible contributions of medical or medication factors, be aware of possible stigma associated with being a mental health patient, determine how best – ethically and clinically – to address the fact that the patient's daughter wants to know what's going on).

In addition, basic competence entails being able to evaluate if a particular psychological intervention appears appropriate for a particular older adult (e.g., an extreme example is that

one would not begin a course of CBT with an older adult who is clearly confused and possibly needs a medical evaluation). When the problems of the older adult become more complex – at the individual, family, and/or broader systemic levels – the psychologist with basic geropsychology competence may need to consult or refer to a geropsychology expert.

17.8.2.4 Consultation

Basic respect for and ability to collaborate with other professionals is foundational to geropsychology practice. Similarly, the ability to interface ethically and appropriately with family members and other care providers of an identified older adult patient is a basic geropsychology competency. As discussed earlier, sometimes a "problem" with an older adult is more a problem with the system that can be remedied by working with the family, health care provider, or changing the environment. Basic geropsychology competence entails being able to consult with various stakeholders in the system, communicate clear biopsychosocial conceptualizations of a problem, and elicit a team or systemic response if needed.

Certainly, these inter-professional and systemic issues can become quite complex and ethically difficult if the older adult does not have the capacity to provide informed consent for sharing information with family or other team members. Geropsychology experts are able to negotiate complex ethical and clinical terrain in their consultation activities. Further, geropsychology experts are more likely to provide formal education and training to others (e.g., nursing staff), and help teams devise behavioral or environmental interventions, as well as develop and evaluate new geriatric care programs. Finally, as stated earlier, geropsychology experts may serve as consultants to a range of organizations and as policy advocates at local, national, and international levels.

17.9   Transition from Basic to Expert Competencies

The Pikes Peak Model of geropsychology training acknowledges that pathways to geropsychology competence will vary greatly from one psychologist to an other. Relatively few new graduate students in psychology choose to specialize in aging early in their careers. Those who discover this interest early often follow a path from graduate school, internship, and postdoctoral training, all of which provide geropsychology didactic and experiential training. These individuals will develop geropsychology expertise in many domains by the time they finish postdoctoral training. Most trainees will discover their interest in aging later on, during an internship rotation and, for most psychologists, after completing formal training in the field. Many psychologists find themselves working with older adults "on the job," or discover a growing interest as they, or family members and friends, start to grapple with the challenges faced by aging individuals and families.

Therefore, the Pikes Peak Model does not endorse a particular training plan, but recommends core components of training that could be sought at any time during one's training career. These core training experiences are recommended to inform basic geropsychology competence. We recognize that these training recommendations are aspirational ones, and it is more difficult to access them the farther one is in one's career from formal training settings. It is incumbent upon the field of geropsychology, as well as upon resourceful psychologist learners, to develop and access opportunities for geropsychology training, particularly supervised experiential training (Karel et al., in press).

Key elements of a professional geropsychology training program include: (1) learning about normal aging to understand abnormal aging experiences (e.g., through the equivalent of a one-semester course on psychology of aging, and can be accessed through continuing education); (2) learning about core clinical issues for older adults, such as psychopathology in late life (e.g., through the equivalent of a one-semester course on clinical geropsychology, and can be accessed through continuing education); (3) gaining direct clinical experience with diverse older adults across different care settings (e.g., to gain exposure to relatively healthy as well as frail older adults); (4) facilitated experiences to gain self-awareness about one's responses to aging that may vary with respect to cultural and individual identities, disability status, and diverse cohort experiences; (5) supervision by competent geropsychologists, using observational methods at some point; (6) inter-professional team training – learning about the knowledge base, scope of practice, and distinct professional work styles of other disciplines; and (7) learning about the distinct ethical and legal issues and practice standards that underlie practice with older adults (Knight et al., 2009).

Ideally, developing geropsychology competence entails some opportunity for supervised clinical practice with older adults, with opportunities for observation of one's work – through direct observation, audio- or video-taping, or co-therapy. A psychologist who is new to working with older adults may simply not have the awareness of biases or "blind spots" brought into the consultation room, and may, therefore, not be able to tell a supervisor or consultant about those problems. For example, learning to recognize signs of mild cognitive impairment may take practice and experience; a novice psychologist will benefit from working closely with a supervisor who can point out behavioral signs of possible cognitive problems. Likewise, the opportunity to function as a psychologist on an interdisciplinary geriatric care setting is important for developing geropsychology competence. Certainly, for psychology interns and fellows in training, learning to "find one's voice" as a psychologist in a medically-oriented team environment is a very important part of professional development as a geropsychologist.

Developing expert competencies in geropsychology requires greater depth and breadth of training and, subsequently, ongoing professional experience and continuing education. There are growing opportunities for formal postdoctoral training in geropsychology (Hinrichsen et al., in press), which is certainly the most efficient way to get a "jump start" on becoming an expert geropsychologist. Others develop geropsychology expertise by applying their training in related fields, such as health, rehabilitation, or neuropsychology, to work with older populations. These psychologists subsequently learn more about aging issues through on-the-job training, self-directed reading, continuing education workshops, and consultation or supervision with colleagues. We know several geropsychology colleagues who have developed expertise in the field through post-licensure training, by taking several graduate classes and arranging for supervised experience with geropsychologists and/or geriatric neuropsychologists in settings serving older adults.

Another important part of developing, and maintaining, geropsychology expertise is keeping up-to-date with advances in research, policy, and clinical program development. The field of geropsychology has advanced to the point where there are many resources to help psychologists learn and keep up with the field. Leading journals in the field include *Psychology and Aging*, *Journals of Gerontology*, *The Gerontologist*, *Clinical Gerontologist*, *American Journal of Geriatric Psychiatry*, *Journal of Geriatric Psychiatry and Neurology*, as well as many journals devoted to the related fields of geriatrics, dementias, palliative care, and so forth. Additionally, geropsychology research is widely published in general clinical psychology journals.

Professional organizations including APA's Society of Clinical Geropsychology (Division 12, Section II, at http://www.geropsych.org/), APA's Division on Adult Development and Aging (Division 20, at http://apadiv20.phhp.ufl.edu/), and PLTC (http://www.wvu.edu/~pltc/) provide informative websites and list-serves, including active discussions about policy updates with respect to the psychologists' ability to provide care for older adults under Medicare. The APA Office on Aging has an excellent website with links to many resources to inform clinical practice with older adults (http://www.apa.org/pi/aging/). Likewise, the newly formed Council of Professional Geropsychology Training Programs (CoPGTP) has a website that can serve, among other things, as a resource for identifying training opportunities in the field, at all levels l of training including post-licensure continuing education (http://www.uccs.edu/~cpgtp/).

17.10 Summary

Professional geropsychology is a growing area of practice within professional psychology. Given the reality of demographics, most psychologists will need to develop basic competence to work with older adults, while growing numbers of psychologists will need to develop expertise to serve as teachers, supervisors, and consultants. Psychological practice with older adults, their families, and related care systems is intellectually and personally challenging and rewarding. As the population (including psychologists) continues to grow older and with increasing opportunities for geropsychology practice and training, we anticipate that increasing numbers of psychologists will seek to develop competence to work with older adults.

The Pikes Peak Model for geropsychology training defined attitude, knowledge, and skill competencies for professional geropsychology practice. In this chapter, we have provided a "bird's eye" view of these competencies: the knowledge base in adult development and aging, foundational skill competencies for geropsychology practice, and functional competencies in the domains of assessment, intervention, and consultation. We have highlighted several settings of care for geropsychology practice, and have provided a framework for considering the development of basic through expert competencies in the field. Furthermore, we have made recommendations for the essential components of basic geropsychology competence, and have reviewed the core components of a training program to develop basic geropsychology competencies. While this chapter necessarily provides a broad overview, we hope to have inspired interested readers to pursue further information through our referenced works and, perhaps, further training in this exciting and meaningful area of professional psychology practice.

18 Pharmacological Adjuncts

William J. Burns · Jose Rey · Kayreen A. Burns

Abstract: There is a broadly accepted list of basic competencies that are expected of a licensed clinical psychologist. In the case of a clinical psychologist with advanced training in Clinical Psychopharmacology (CPP), who is engaged in prescribing or consulting about medications, there is also a list of acceptable basic competencies. In order that psychologists may achieve basic competency in psychopharmacology, they need to begin with a solid core of academic learning and clinical practicum in psychopharmacology that will motivate them to continue to progress in competency as they engage in this specialized field of patient care. To progress from basic to expert competency, most clinicians trained in CPP will need years of experience. The route to expert competency is made more complex by the added burden of combining two disciplines effectively. Since there is no national board exam for diplomate status in CPP, the competencies of an expert need to be defined informally by colleagues in the field. There is no doubt that experts are appearing among the small group of men and women who were first to enter this career. The knowledge and experience that drive the transition from basic to expert competence reaches beyond an academic program. It must be nurtured by the experiences that these professionals encounter in their practice and especially by the input of other competent practioners who provide professional models for this new generation of prescribing and consulting psychopharmacologists.

18.1 Overview

The field of psychology has made significant progress over the past decades in the understanding of psychopathology and the development of effective methods of psychological treatment for mental disorders. During the same period of time, the fields of pharmacology and medicine have been making similar progress in the understanding of the underlying chemical mechanisms of psychopathology and the development of effective methods of psychopharmacological treatments for these disorders. During the past decade, an exciting progress has taken place within the field of psychology to combine these two endeavors in one practitioner, the prescribing psychologist (Burns, Rey & Burns, 2007). Some members of both psychology and medical communities have stepped forward to express their doubts about the efficacy and safety of such a synergistic treatment modality. However, following the practice of prescribing psychologists in the military for a decade and more recently following the successful and safe practice of the combined area of health service in New Mexico and Louisiana, these doubts began to disappear. How did these prescribing psychologists become competent in such a complex combination of tasks? How can we be sure that they will, not only maintain their competency, but progress to expert competency? It is the objective of this chapter to answer some of these questions and describe the route by which competency is attained by a prescribing or consulting psychologist who has postdoctoral training in clinical psychopharmacology.

The editors of this volume have given this chapter a title that uses the word "adjuncts" to describe the relationship of pharmacology with psychology. Psychologists have been trained to view medications as a supplementary type of intervention for patients with mental disorders. And, indeed, licensed psychologists, who have sought advanced training in clinical psychopharmacology, have done so after they have completed their doctoral degree, internship, residency, and licensing exam. The administrative council of the American Psychological Association has voted to make such a sequence of study mandatory, because they want to make sure that psychologists view themselves first and foremost as psychologists, and only secondarily as prescribers of psychopharmacological medications. Regardless of the order of education, a prescribing or consulting psychologist must attain basic competence in both disciplines to treat patients competently.

18.1.1 Critical Competencies Needed

There is a broadly accepted list of basic competencies that are expected of a licensed psychologist. It is agreed that they must know how to evaluate and conceptualize the cases they have received. They must use evidence-based interventions, as well as understand the maintaining factors and mechanisms operative in their patients. They must be able to digest and use both the research and program evaluation literature. They must show basic competence as they engage in supervision, management, and consultation. They must appreciate the impact of diversity and cross-cultural values in the patients to whom they extend their service. They must show basic competence in their ethical behavior.

In the case of a clinical psychologist with advanced training in Clinical Psychopharmacology (CPP), who is engaged in prescribing or consulting about medications, there is also a list of accepted basic competencies. These cross-discipline professionals must know how to evaluate and conceptualize cases of patients with physical disease. They must have basic competence in evidence-based medicine, especially in psychopharmacological medications. They must be knowledgeable in maintaining factors and underlying mechanisms in disease and medical treatment. They need basic competence in psychopharmacological supervision, management, and consultation. They must appreciate the impact of diversity and cross-cultural factors in diseases. They must show basic competence in their ethical behavior as they treat their medical patients. They must know when to refer to medical specialists and how to combine their clinical psychology competence with their competence in medicine.

18.1.2 Expert Competency

Because the list of competencies is very long and difficult to accomplish for clinical psychologists who have advanced training in CPP, not many psychologists will step forward to enter this new cross-discipline. And only some of those who seek this training will progress beyond the consultation level to become actual prescribers. The route to expert competency is made more complex by the addition of extra competencies and by the added burden of combining the two disciplines effectively. Since there is no national board exam for diplomate status in CPP, the role of expert needs to be defined informally by colleagues in the field. There is no doubt that experts are appearing among the small group of men and women

who are first to enter this career. They are the CPP psychologists who were first trained in the military, or who were successful in obtaining legislation for prescription privileges in the states of New Mexico and Louisiana. They are currently serving as officers in Division 55 and administering programs in postdoctoral education in CPP. They have written books and chapter, articles, and manuals. They have presented at conferences and have given testimony to congress and state legislatures for their expertise in this new discipline. They have been acknowledged as experts, and have expert competencies in many of the skills listed above. They progressed to expert competency in the hard way, through persistent effort to learn the knowledge base of their cross-discipline, through many hours of clinical practicum, clerkship, and supervision at their own expense, and through consistent effort to keep up with the research in their field.

18.1.3 Chapter Outline

This chapter is dedicated to the men and women who are pioneers in the effort of making clinical psychopharmacology, as practiced by clinical psychologists, a permanent aspect of the health service system in the United States. The chapter begins with a discussion regarding the basic competencies that these professionals must have in the assessment and the recog-nition of symptoms in their patients. The expertise required in the understanding of maintaining factors of the disorders is discussed next. Evidence-based practice in psychology and medicine is discussed in detail along with some of the underlying mechanisms that are operative in these validated treatment methods. A section on basic competencies and one on expert competencies follows. And, finally, a section describes the transition from basic to expert competency. Since the number of separate competencies that are expected of a medical psychologist are multitude, only primary aspects of these competencies could be discussed. In the years to come as the field of CPP expands and becomes more widely accepted, the competencies expected of its professionals will also grow in number, and priorities among these competencies will be established.

18.2 Recognition of Symptoms and Their Assessment

18.2.1 Diagnostic Competency

The process of diagnosis is often conceptualized as a "best estimate" or educated decision made on the basis of evidence (both subjective and objective), which is used to label a problem or a dysfunctional behavior, to offer advice about intervention methods. Symptoms or complaints are described by the patients and signs of psychopathology are observed by the clinician. If these signs and symptoms meet the criterion for a specific category of pathology listed in diagnostic classification manuals such as the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV) or the International Classification of Disease (ICD-9), a clinician feels justified in applying that diagnostic label to the patient's problem.

However, there is a risk that such a "best estimate" may be given in error. Groopman (2007) cites a report in which 15% of all diagnoses made by physicians were in error. The impact of such diagnostic error may be long-lasting, because diagnoses are kept in medical records, and

used by future diagnosticians and insurance companies affecting how that person is perceived and treated the rest of his/her life.

Since the impact of diagnostic error may be a threat to a patient's future health, some authors have suggested that diagnosis is an ethical process (Brown & Freyd, 2008). It is of utmost importance that clinicians are trained to be competent in their diagnostic ability. And, it must be with great care and utmost caution that they apply their diagnostic labels.

18.2.2 Diagnostic Competency of a Medical Psychologist

For each type of mental disorder that a clinical psychologist encounters in the practice setting, there are both psychological and medical characteristics of that disorder that need assessment. For example, a patient with a complaint of depression needs to be assessed for the psychological symptoms of their depression (e.g., psychomotor retardation, insomnia, etc.), which may be assessed by interview or self-report scales. In addition to this psychological approach, a patient with depressive complaints needs to be assessed for those medical disorders that may be the cause of the depressive complaints (e.g., thyroid disorder, dementia, chronic pain, renal failure, etc.), which may be evaluated using laboratory tests and medical exams. Competency in both of these forms of assessment is part of the skill requirements for efficacious and safe clinical care.

18.2.3 Psychological Diagnostic Competency

Of all health professionals, it is the clinical psychologists who are trained to the highest level and who have the broadest range of competence in psychological diagnostics. Clinical psychology doctoral students take academic coursework in both structured and unstructured interviewing methods and receive practicum and internship supervision in the quality of their interviewing skills. Coursework in adult, adolescent, and child psychopathology gives them a basis for making diagnoses. Coursework in case conceptualization offers them guidance in treatment planning using evidence-based treatment research, evidence-based practice methods and clinical decision-making using a variety of theoretical orientations. Academic coursework, practice residency, and licensed experience prepare a clinical psychologist to make accurate diagnoses of their patient's psychopathologies using the diagnostic categories of DSM-IV (Diagnostic and Statistical Manual – 4th edition revised, 2000). In addition to the DSM-IV method of identifying the signs and symptoms of psychopathology, clinical psychologists have academic coursework and practice residency training in the use of psychometric assessment measures. They study the administration and interpretation of IQ tests, personality tests, and rating scales, which are used to gather detailed information about their patient's psychopathologies. Some clinical psychologists obtain specialized training in neuropsychological assessment, forensic assessment, assessment for addictions and pain, and other aspects of health psychology. These measurement tools assist them in making accurate and detailed analysis of patient psychological problems. The level of skill that they are able to demonstrate using these instruments and applying DSM-IV diagnoses is the basis for the national board exams in clinical psychology called the American Board of Professional Psychology (ABPP). Obtaining this ABPP diplomate in clinical psychology is an evidence-based method for demonstrating

the expert competency of a clinical psychologist in the area of psychological diagnostics and ethics. Basic competency of a clinical psychologist and diagnostician is certified by state licensing boards.

18.2.4 Medical Diagnostic Competency

On the other hand, clinical psychologists are not typically trained or licensed to diagnose medical problems. In fact, there has been a trend in clinical psychology programs to move away from biopsychology issues and fill the gap with courses on psychological topics. Only those specialized concentrations in neuropsychology and health psychology have continued to focus somewhat on coursework such as anatomy and physiology, neuroanatomy, neurophysiology, neuropathology, pathophysiology and psychopharmacology at the predoctoral level and residencies in these specializations at the internship and postdoctoral levels. Since these specializations do not include licensing to diagnose medical problems, most of these neuropsychologists and health psychologists refer to physicians for such diagnostic work.

The licensing of medical psychologists in New Mexico and Louisiana and the practice of medical psychology in the military has added a new demand that some psychologists be trained to recognize the symptoms of medical disease. To attain such a competency, training programs designed to educate medical psychologists have structured their academic curriculum and clinical practice to include coursework and clinical experiences in medical diagnostic work.

Master of Science programs in Clinical Psychopharmacology have been established at five universities in the United States: Nova Southeastern University, New Mexico State University, Fairleigh Dickenson University, Massachusetts School of Professional Psychology, and Alliant University. These programs offer a similar diagnostic curriculum in pathophysiology, laboratory testing, and physical assessment designed to prepare a medical psychologist for practicum training and licensing as a medical psychologist. Some of these programs do not require all course work to be done in the classroom and some do not require a practicum for graduation, but all offer similar academic curriculum.

As an example of the curriculum offered by most of these programs, the list of required diagnostic courses and credits for Nova Southeastern University are as follows:

- Review of Organic Chemistry and Biochemistry
- Anatomy and Physiology
- Neuroanatomy and Neuropathology
- Neurophysiology and Neurochemistry
- Pathophysiology
- Laboratory Testing
- Physical Assessment
- Practicum I

This curriculum provides clinical psychologists with an academic curriculum and clinical experience that prepares them to become competent in symptom recognition of medical problems. Nova Southeastern University requires a clinical practicum at the end of the academic coursework to acquire modeling and supervision in the application of their knowledge of psychopharmacology. Passing a capstone exam at the completion of academic course work

provides evidence of basic competency. Passing the PEP exam and being licensed in the state of New Mexico or Louisiana, or becoming a military medical psychologist provides the pathway to expert competency, which develops with practical experience as a medical psychologist. Graduates of advanced training in psychopharmacology who do not become prescribing psychologists, may, however, become expert consultants in psychopharmacology.

18.3 Maintenance Factors of the Disorder or Problem

18.3.1 Competency Related to Maintaining Factors

In addition to their expertise in diagnostic assessment, clinical psychologists and medical psychologists need to be competent in the estimation of maintaining factors in the psychopathology of their patients. Just as above it was shown that medical psychologists who prescribe and clinical psychologists who consult regarding psychopharmacological medications need to be competent in the twofold set of knowledge bases (psychological and medical) in the area of diagnostic assessment, so also these clinicians need to understand the combination of psychological and medical maintaining factors involved in the psychopathology of the patients to whom they prescribe psychopharmacological medications.

18.3.2 Competency in Psychological Maintaining Factors

Clinical psychologists need to be knowledgeable regarding the factors, which might tend to maintain the psychopathology of their patients, despite the accurate application of a treatment of choice. The rationale for this need is that psychological maintaining factors represent mechanisms that have been found to complicate and attenuate traditional intervention strategies (Rapee & Barlow, 2001). These researchers have offered a thorough description of the maintaining factors in generalized anxiety disorders, panic disorders, and phobias. Other authors have more recently presented research findings regarding maintaining factors in other disorders. For example, Voncken and Bogels (2006) found that interpretation and judgmental biases concerning negative evaluation maintained social phobia. Schmidt and Treasure (2006) found that perfectionism, avoidance, and pro-anorectic beliefs maintained anorexia nervosa. Appraisal of intrusions has been found to maintain OCD (O'Connor et al., 2005). Positive belief about eating and negative belief about weight and shape have been found to maintain bulimia nervosa (Cooper, Wells & Todd, 2004). Therefore, competent clinical and medical psychologists must take such maintaining factors into consideration when carrying out assessment, case conceptualization, treatment planning, intervention, and post-intervention follow-up. Research findings have indicated that these maintaining factors need to be the basis for modifications in the treatment plan and treatment process, to enhance the potential for therapeutic success (Hoffman, 2006).

18.3.3 Competency in Medical Maintaining Factors of Psychopathology

Mental disorders and the treatment of these disorders both occur within the context of psychological adjustment and bodily integrity. Brain and body integrity supports psychological

integrity. Diseases and injury to brain and body can be a cause or a maintaining factor of psychopathology. In their review of the characteristics of anxiety and panic and phobic disorders, Rapee and Barlow (2001) described the genetic, familial, neurological, and other biological factors that play an etiological or maintenance role in these disorders. Moras (2006) notes that neural networks are hypothesized to be the primary neurological maintaining factors of psychopathology. Pineles, Street and Koenen (2006) found that guilt and shame proneness were associated with somatization symptoms. A competent clinical or medical psychologist needs to be aware of this research literature on biological maintaining factors of psychopathology.

Depression is a good example of psychopathology that is often found to be secondary to neurological, medical, and surgical diseases, and medications. It is known that depression frequently accompanies degenerative diseases, such as Parkinson's, Huntington's, and Alzheimer disease, as well as focal brain diseases, such as stroke, brain tumor, brain trauma, and multiple sclerosis. Depression has been found to occur with corticosteroid excess or deficiency, hypothyroidism, Cushing's syndrome, Addison disease, hyperparathyroidism, Pernicious anemia, renal failure, myocardial infarction, open-heart surgery, brucellosis, viral hepatitis, infectious mononucleosis, cancer, and parturition. Medications such as analgesics, anti-inflammatories, amphetamines, antibiotics, anti-hypertensives, cardiac drugs, corticosteroids, disulfiram, L-Dopa, methysergide, oral contraceptives, and alcohol are all known to be associated with depression (Victor & Ropper, 2001). Clinical and medical psychologists, who serve patients with complaints of depression, need to be aware of these potential biological maintaining factors in these patients. These clinicians, also, need to know the potential biological maintaining factors that are associated with psychosis, anxiety, bipolar disorder, obsessive-compulsive disorder, and other mental disorders.

However, especially in medical settings, clinical and medical psychologists will be asked to consult regarding the psychological status of a patient with a given medical condition. In this case, where the medical disease is the presenting information for a referral, a competent clinician needs to be aware of the psychopathologies that have been found to most frequently occur when there is disease in a specific bodily system. Many of the diseases found in bodily systems are known to be accompanied by psychopathology and these diseases become the maintaining factors during the treatment process. In a study of the relationship between chronic somatic diseases and mental disorders, Härter et al. (2007) found prevalence rates of greater than 40% mental disorders in patients diagnosed with cancer, musculoskeletal, cardiovascular, and respiratory disorders.

Diseases of the Nervous System. Neurological disorders, especially those that are difficult to identify early, such as brain tumors, often have as their first sign or symptom a personality change. A slow-growing meningioma of the frontal lobes may only produce classic headache signs later in the disease process, whereas friends and relatives may notice deterioration in personality early in the disease process. Brain trauma, especially focalized lesion, is frequently the cause of personality change. In the classic case of Phineas Gage, the tamping rod is known to have damaged the orbital frontal lobe and changed the individual from a responsible crew manager into an individual with an irresponsible and impulsive personality. Temporal lobe seizures can be associated with a broad range of psychopathology including aggression, hallucinations, and delusions. Because one of the major symptoms of degenerative diseases such as Alzheimer Disease is memory loss, behaviors that reflect this memory loss may resemble psychotic hallucinations and delusions. Although, neuropsychologists may have the highest competency in

assessing such examples of brain–behavior relationships, every clinical psychologist who engages in diagnostic assessment must be aware of the possibility that the psychopathology, which they identify, may have a neurological etiology. Masters programs in clinical psychopharmacology are well designed to provide medical psychologists with adequate academic and practical experience in the identification of neurological causes of psychopathology.

The Endocrine System. Growth hormone deficiency may cause pathologies in both intelligence and personality. Dysfunction of adrenocorticotropic hormone may be related to under or over activity and the inability to handle stress. Diabetic hypoglycemia and hyperglycemia may be related to personality disorders. Laboratory tests of hormonal sufficiency must be a part of the initial intake of patients who complain about depression, anxiety, and suicidal behavior. Competence in identifying this link between hormonal dysfunction and psychopathology must be a part of the education of a medical psychologist.

With regard to the immune system, asthma is known to cause considerable stress in patients, and the stress in turn can aggravate asthma (Berger, 2000). Schmidt and Lerew (1998) in a prospective study of military personnel under stress found that premorbid factors such as anxiety and sensitivity were predictive of the development of physical disorders such as cardiovascular disease. Skeletal, muscular, integumentary, nervous, endocrine, cardiovascular, lymphatic, respiratory, digestive, urinary, and reproductive systems of the body have all been found to be associated with mental disorders or mental symptoms of physical disease.

Medical psychologists who practice as prescribers of medication, especially, need to be thoroughly familiar with all of these physical systems, the impact of medications on patients as well as the literature that reports their relationships to mental disorders. Masters programs in clinical psychopharmacology offer courses in anatomy, physiology, and pathophysiology that are designed to address these issues. Clinical psychologists, also, need to be aware of the possibility that these biological maintaining factors are operative in their patients with mental disorders.

18.4   Evidence-Based Treatment Approaches

A prescribing psychologist, who uses evidence-based practice (EBP), would consider diagnostic assessment and maintaining factors to be the first two components in a three part sequence leading to competent treatment planning. Evidence-based treatment (EBT) approaches are typically chosen from the research literature to fit the needs of the patient as delineated through assessment and estimation of maintaining factors. Therefore, competent treatment planning requires an expertise in assessment, maintaining factors, and EBT, as well as the sophistication in case conceptualization that will lead to the effective combination of these three components of treatment planning. Clinical psychology doctoral programs offer thorough training in the psychological treatment aspect of these steps, but may not offer in-depth training in the psychopharmacological treatment aspect. It is for this reason the postdoctoral masters programs in clinical psychopharmacology have recently been added to some clinical psychology programs.

18.4.1 Evidence-Based Psychological Treatment

Early efforts to provide informal guidelines for the application of EBT by clinical psychologists (Hersen & Ammerman, 1994; Nathan & Gorman, 1998) offered a treatment-of-choice or

prescriptive model, which presented disorder–treatment matches for the clinician to use in practice. In 1994, APA Division 12 began publishing the EBT articles in their new *Journal of Clinical Psychology*. In 2007, Stuart and Lilienfeld in a letter to the editor of the *American Psychologist* could state that "psychologists bear an *ethical obligation* to offer evidence-informed services" (p. 616) (italics added). Such rapid progress from early informal guidelines to ethical responsibility reflects, also, a growing burden of knowledge-base required for competency. Most recently specialized groups within psychology, such as biofeedback clinicians (Yucha & Montgomery, 2008), have chosen to provide relief for this burden by publishing a suggested set of procedures to help members of their societies to choose the most efficacious match between biofeedback procedures and disorders. Such a provision of EBT guidelines will become a part of most specialties in clinical psychology in the future. Medical psychologists are primarily clinical psychologists and benefit from the guidelines that are sensitive to the balance between their psychological functioning and their medical expertise.

18.4.2 Evidence-Based Medical Treatment

Medical Guidelines. As the medical model of the 1980s has given way to the biosocial model of the 1990s in the field of medicine, evidence-based medicine (EBM) has begun to conceptualize psychological treatment as an integral part of healthcare (Bruns, 2008). Such a small percentage of medical procedures have been proven to be effective, according to Bruns, that EBM has become the way to fill the void. Medical specialties have initiated the use of evidence-based guidelines (EBG), as EBM is yet to dominate medical practice. EBG are produced by a panel of experts who review the available treatments and make recommendations about their use. Much of the advice that is given in EBG is based not on research evidence but on the traditions of clinical experience that have been adopted from leaders in the field. A good example of EBG that is relevant to the patient population served by a clinical psychologist is the *American Psychiatric Association Practice Guidelines* (2004), which provide recommendations for assessment and treatment of the following disorders: Acute stress disorder and Post Traumatic Stress Disorder (PTSD), Alzheimer's Disease and other dementias, bipolar disorder, delirium, eating disorders, HIV/AIDS, major depressive disorder, obsessive-compulsive disorder, panic, schizophrenia, substance abuse, and suicidal behavior. American Psychiatric Association Practice Guidelines included the methodology and recommendations for the formulation of a treatment plan, specific clinical features that influence the treatment plan, epidemiology and natural history of each disorder, and a summary of the literature on evidence-based treatment studies, which provide a rationale for treatment of choice in both the areas of psychotherapy and psychopharmacology.

In order that they demonstrate basic competency, prescribing psychologists and clinical psychologists who offer consultation regarding psychopharmacology would need to be capable of evidence-based practice that is similar to the method proposed by these guidelines. In other words, a competent prescribing or consulting psychologist must have a working knowledge of the current evidence-based treatment research that would provide support for the psychological and medical assessment and treatment methodologies that are to be used to treat each new patient with a specific disorder. Competency of an evidence-based practitioner requires both a thorough knowledge of the research and thorough training in decision-making regarding the clinical characteristics of each new patient. In addition to the American Psychiatric Association

Practice Guidelines mentioned above, other guidelines may be found in the literature, which propose similar clinical recommendations based on evidence-based treatment research. Other examples of such guidelines are those published by the British Association of Psychopharmacology (Anderson et al., 2008).

Maintaining a Balance Between Psychological and Medical. Prescribing psychologists in clinical practice such as the military psychologists (Moore, 2008) have emphasized how important it is for them to use a balance of psychological treatment and psychotropic medications for their patients. Especially in the cases of PTSD, depression, and sleeping problems, they see their medical colleagues too quickly using only medications as a first line treatment. In addition, military psychologists have emphasized how important it is for them not to assume that unusual behaviors have a psychological etiology (Younger, 2007), especially in emergency room cases. A prescribing psychologist must be aware of the medical disorders that can precipitate behaviors that at first appear to be psychological in origin. Therefore, Masters of Science programs in clinical psychopharmacology offer instruction in pathophysiology and its relationship to psychological symptomatology.

Recent efforts to produce balanced protocols that combine psychotherapy and psychopharmacology (LeVine & Mantell, 2007; Sammons & Schmidt, 2001) have offered prescribing psychologists a method for maintaining equilibrium between the biological and psychological aspects of their service. Prescribing psychologists benefit from access to the research results of both evidence-based treatment for their psychotherapy and evidence-based medicine for their psychopharmacological treatment. However, there is an ever increasing volume of literature covering both of these research endeavors. Evidence-based practice using both sources of information, therefore, offers a challenge to those seeking to become competent providers. It is understandable that one of the frequent objections of the prescribing psychologist group is that psychologists have too much to learn already (Brown, 2003). In a review and analysis of the research on the combination of psychotherapy and pharmacotherapy for mood and anxiety disorders, Otto, Smits and Reese (2006) concluded that combined treatment should not be the first-line choice for the treatment of mood and anxiety disorders, except for bipolar disorder. Thus, a thorough knowledge of the literature may very well incline a prescribing psychologist to use only one treatment modality or none. After all, the authority to prescribe includes the authority to unprescribe and not to prescribe at all (Dunivin, 2003).

18.5 Mechanisms of Change Underlying the Interventions

18.5.1 What Are Mechanisms of Change?

Kazdin (2008) has aptly addressed the concerns of researchers and clinicians regarding the applicability of findings from psychotherapy research in the practice of clinical psychological treatment. He points out that the findings of evidence-based treatment studies may not easily be generalized to the treatment of individual patients. He recommends that researchers put more effort into the study of the mechanisms of change. He appropriately defines mechanisms as "processes that explain why therapy works or how it produces change" (p. 151). Although, as Kazdin points out, an EBT study may have verified that the specific treatment procedures were the overall causal agents in the change, certain aspects of the treatment may be more basic

change producers or more basic contributors to the change. And these underlying change producers or contributors to change are the mechanisms of change that further research must investigate. As research findings concerning the mechanisms of change appear in the literature, a competent prescribing psychologist must be an avid user of this literature, an understanding user of the concepts conveyed in that literature, and an expert clinician who is ready to modify therapeutic procedures to fit this research.

18.5.2 Psychological Mechanisms

Rather than the traditional nonspecific factors that are common to various types of treatment, Kazdin (2005) notes that the genuine mechanisms of change are those that are specific to a single psychological treatment outcome. Kazdin further points out that such factors need to show how the therapeutic process unfolds to affect the outcome of the treatment. Demonstrating such a process may take several waves of research per mechanism, as sequential studies approximate the steps in the process. For instance, in a randomized controlled trial in patients with schizophrenia it was found that cognitive behavioral therapy provided significant reductions in suicidal ideations. The next step in this line of research would be to further unveil the mechanisms through which this reduction was obtained (Bateman, Hansen, Turkington & Kingdon, 2007).

A recent example of research on the identification of mechanisms of change is found in the study by Forman, Herbert, Moitra, Yeomans and Geller (2007) who compared cognitive therapy (CT) and acceptance and commitment therapy (ACT) in a randomized controlled trial and found differences in the mechanisms of action for the two types of treatment procedures. In the CT group, the outcome was mediated by changes in observations and descriptions of self-behavior, whereas in the ACT group, avoidance, awareness, and acceptance were found to be mediators of change. Another example is a study by Hogarty, Greenwald and Eack (2006) who randomly assigned patients with schizophrenia to either cognitive enhancement therapy (CET) or enriched supportive therapy (EST) and found stress regulating effects of treatment to be the underlying mechanism that led to a positive outcome. These authors also noted that an improvement in processing speed appeared to be involved. For a clinical psychologist to be competent in the awareness of and the use of such underlying psychological mechanisms, a regular effort would need to be made to study current research findings in the literature.

18.5.3 Medical Mechanisms

Two types of change mechanisms dominate the literature with regard to the way in which medical interventions are applied: surgical and pharmaceutical. Each of these has a substantial literature to provide guidance for the manner in which the methods are to be applied and evidence for the effectiveness of the methods. It is assumed that a boarded surgeon has extensive training in the first method, and that boarded internists in endocrinology, cardiology, hematology, oncology, pulmonology, and other internal medicine specialties have extensive training in their specialties. Medical psychologists are not offered such surgical or internal medicine training, and, therefore, must be trained to refer to such specialists when they encounter diseases that require such specialized training.

18.5.4 Psychopharmacological Mechanisms

Psychopharmacology is a subspecialty of pharmacology. The mechanisms underlying the treatment modalities of psychopharmacology are chemical in their composition, but neurological in their internal effects and psychological in their intended final impact. Psychopharmacological medications are designed to modify the brain mechanisms that lead to abnormal behavior and abnormal emotion. In other words, they have the same purpose as does psychotherapy and behavior therapy. It is assumed that both modalities of treatment (psychological and psychopharmacological) share some of the same underlying brain mechanisms (Etkin, Pittenger, Polan and Kandel, 2005). Some studies have found that psychological treatment methods can be used to improve neurological disorders. For example, Lundgren, Dahl and Hayes (2008) found that psychological treatment reduced the frequency of epileptic seizures compared with placebo controls.

18.5.5 Neurological Mechanisms

A new era of understanding of the mechanisms underlying the combination of psychotherapy and psychopharmacology began with the study of the NMDA receptor in the context of psychological treatment (Barlow, 2008; Kazdin, 2008). Barlow considers the discovery of these mechanisms to be one of the three most significant advances in the field of psychology that proclaim "a new era of competency and quality in professional psychology" (Barlow, p. 8). Mechanisms of change using a combination of psychological treatment and psychopharmacological treatment have been demonstrated for three disorders: social anxiety disorder (Hoffman et al., 2006), acrophobia (Ressler et al., 2004), and obsessive-compulsive disorder (Rothbaum, 2008; Wilhelm et al., 2008). In all the three disorders, the mechanism of change identified has been the glutamatergic NMDA receptor, which is stimulated by behavior therapy and enhanced by doses of D-cycloserine (Cycloserine, seromycin), which is a glutamate antagonist that had been previously marketed as an antibiotic owing to its competition with the amino acid D-alanine. The reason for excitement about these discoveries is that they have not only uncovered the basic chemical–neurological mechanisms underlying psychotherapy and psychopharmacology interventions, but that these discoveries offer knowledge to psychology and medical practitioners that will be beneficial to their patients. These discoveries make it obvious where the future field of clinical psychology is headed, and what challenges are there for the competent clinician.

In addition to these findings of mechanisms at the molecular level, research also continues to advance using radiology to identify neurological mechanisms at the level of anatomical and body tissue. In a study of the brain mechanisms underlying the effects of psychotherapy, Schienle, Schafer, Hermann, Rohrmann and Vaitl (2007) used fMRI to investigate changes in brain activation during cognitive behavior therapy for spider phobia. Principle brain activation changes were found in the orbital frontal gyrus, which is known to be a center for emotional regulation. The long-term benefit of this mechanism might be its use as an outcome measure in future research and practice. In a comparative study of the neurotransmitter mechanisms underlying the use of electro convulsive therapy (ECT), sleep deprivation (SD), and fluoxetine (FL), Conti et al. (2007) found that ECT and SD elicited fast-onset, short-lived responses in the catecholaminergic system of the locus coeruleus and hippocampus and FL elicited slow-onset

responses in the serotonergic system of the raphe and hypothalamus. Practitioners may be aided in the selection of therapy based on these findings.

18.6   Basic Competence of the Clinician

18.6.1 Professional Competency

Clinical competency of a prescribing or consulting licensed psychologist who has advanced training in clinical psychopharmacology refers to the extent and depth of knowledge and skills possessed by that professional. It is the extent of knowledge and skills which qualify a prescribing psychologist to accept patient referrals who have a broad range of psychopathologies, to diagnose their problems accurately, and to prescribe appropriate psychological or pharmacological treatment for these problems. Competency is an attribute that is most often conceptualized as a general trait possessed by those professionals who are well respected for their clinical knowledge and skills. However, competencies can be operationalized into specific subtypes of knowledge and skills. It is these operationalized competencies that allow us to judge who is competent at what, and to formulate methods by which competency may be attained.

18.6.2 Training to Be a Competent Clinical Psychologist

Psychologists who are licensed to prescribe psychopharmacological medication or who are trained to consult in clinical psychopharmacology are primarily clinical psychologists. Traditionally, they have academic training at the undergraduate level in experimental psychology, academic training at the graduate school level in an APA approved doctoral program in clinical psychology that includes four semesters of clinical practicum supervision and 1 year of an APA approved internship in clinical psychology practice, and a postdoctoral residency in clinical psychology practice. Their licensing examination administered by a state licensing board assures basic competence to practice clinical psychology. Some specialties in clinical psychology require a second year of postdoctoral residency, such as clinical neuropsychology. Therefore, depending on the level of credentialing, a prescribing or consulting clinical psychologist may be assumed to have at least basic competence (or higher for diplomats) in clinical psychology.

18.6.3 Specific Skills of Basic Competence in Clinical Psychology

Research. The first and most basic skill acquired in doctoral programs in professional psychology is the ability to design and carry out research in the social sciences to appropriately do a master's thesis and doctoral dissertation. Some psychologists will use this knowledge to go on as a researcher or professor, and others to use it to properly become a wise consumer of research as a practitioner, health, or forensic psychologist. Every clinical psychologist will learn to search the literature for the latest advances in evidence-based assessment and treatment, maintaining factors in treatment, and mechanisms of outcome to appropriately engage in clinical practice, consultation, supervision, and program evaluation. Competency in written composition, which fits the special mode of scientific writing, is a skill that is learned by researchers.

Assessment. A skill that is needed for competency as a licensed psychologist is that of psychological assessment and interviewing. After academic courses in test construction and psychometric theory, psychologists learn to administer, interpret, and write reports regarding specific tests of intelligence, personality, behavior, attitudes, career preferences, and therapy outcome evaluation techniques. Some psychologists will seek special assessment training in neuropsychology, forensic work or health psychology. Most psychologists are trained to engage in evidence-based assessment through the use and construction of reliable and valid measurement instruments. They take coursework in case conceptualization that is frequently based on their assessment and interviewing skills. They are trained to recognize the signs and symptoms of psychopathology and their maintaining factors to prepare them for accurate treatment planning. Competence in written composition is focused on the ability to report the interpretation of assessment findings in such a way that they can be understood and digested by other professionals such as physicians, lawyers, teachers, judges, and nurses.

Treatment. A third area of expertise that is part of the learning of a clinical psychologist is that of treatment of psychological disorders. After initial coursework in the research literature regarding evidence-based psychological treatment, and in regard to the various available treatment procedures, psychologists learn how to apply case conceptualization to treatment planning. Traditionally, doctoral students are supervised by experienced clinicians for 2 or more years of clinical practicum. These supervisors guide doctoral students through their first assessments and treatment casework to prepare them for their predoctoral year of supervised clinical internship. This intensive clinical supervision of casework is designed to help students to learn to conceptualize their cases properly, to engage in careful treatment planning, to be vigilant of the underlying mechanisms of their evidence-based practice procedures, and to consistently evaluate the progress and outcome of their treatment. The goal of this training is to reach competency as a therapist in the conceptualization, planning, execution, and evaluation of their treatment and management of cases.

Consultation and Supervision. A fourth area of knowledge and skill that some psychologists are offered in graduate school is consultation and supervision with other professionals such as physicians, lawyers, legislators, social workers, nurses, police, and teachers. They are taught how to refer to other professionals for consultation and how to give consultation and supervision when requested by other professionals. Some psychologists will pursue a double career, such as a psycholigist–lawyer to become an expert consultant in legal aspects of psychology. Other psychologists may become competent in several specialties in psychology sequentially as they move from being practitioners, to then become teachers, then supervisors, consultants, and managers. Competency at one type of professional skill may build on the competency obtained at another, in such a way that the professional is practicing several of these specialties in a combined fashion. For instance, many health psychologists involve their students in apprenticeship type of supervision as they make bedside rounds with their patients in the hospital or have students engaged as co-therapists in group therapy sessions with their patients.

Ethics, Diversity, and Cross-Cultural Sensitivity. A fifth area of competence expected of a professional psychologist is the ability to apply ethical standards of conduct to clinical practice and to appreciate the diversity and cross-cultural values of their patients. It is expected that professionals will not only behave in an ethical manner, but adapt their behavior to fit the needs of the specific cultural values of their patients. A competent clinician will be aware of the cultural background of each patient and make special effort to use only assessments normed in that culture. A competent clinician will either learn the special cultural needs of their patients

for intervention, or will find a therapist who is more capable of providing such service. Ethnic and cultural backgrounds of both the client and the psychologist not only impact the choice of psychotherapy, but may also guide the medical psychologist in pharmacotherapeutic treatment selection, taking into account the genetic variations of the client and the culturally-influenced perceptions of medication taking for mental illness, just as they would consider specific psychotherapeutic treatment modalities that have been established as efficacious (Rey, 2006a).

It is assumed that a prescribing or consulting psychologist with advanced training in clinical psychopharmacology will have all five of these basic competencies to carry out the complex task of combining the practice of clinical psychopharmacology with that of clinical psychology.

18.6.4 Competence as a Psychopharmacologist

What a Competent Psychologist Brings to Psychopharmacology. Prescribing or consulting medical psychologists who have been thoroughly trained in a program specializing in clinical psychopharmacology will have been previously trained to basic competency in clinical psychology as described above. They bring with them knowledge of psychopathology and the recognition of symptoms and signs of mental illness that will help them to make choices of medications. They bring with them research skills that will help them to become consumers of the research findings in evidence-based medicine. They bring with them knowledge of evidence-based treatment findings that will help them to combine medication and psychotherapy properly. They bring with them an understanding of the psychological needs of mental patients that will keep them from writing prescriptions too hastily, before psychological needs are met or at least assessed.

What Psychopharmacology Training Adds. Most psychologists have taken coursework in chemistry and neuroscience, but are in need of update and review of organic and biochemistry, neuroanatomy, neuropathology, neurophysiology and neurochemistry, anatomy, and physiology before they begin to study general pharmacology, pathophysiology, and clinical psychopharmacology. Training in administration and interpretation of a physical exam and laboratory tests are needed before beginning practicum training and supervision in clinical psychopharmacology. This supplemental training in the practice of psychopharmacology adds another dimension of competence to the training in clinical psychology. On graduation from a master's program in clinical psychopharmacology (or equivalent program), a clinical psychologist is ready to take the Psychopharmacology Exam for Psychologists (PEP), a national exam, and seek licensing in New Mexico or Louisiana, or to practice in the military as a prescribing or consulting psychologist. Such is the route to basic competency in clinical psychopharmacology. There is an opinion that a year of supervised residency should precede independent practice, and currently that is the policy of the United States military branches for prescribing psychologists.

Specific Competencies. The seven primary skills expected of a clinical psychologist who has basic competency in clinical psychopharmacology and who will be examined for these competencies on the PEP exam are the following: (see Appendix for details).

1. *Neuroscience*. For clinicians to understand the brain tissues in which psychopharmacological medications have their effects, they need to have a thorough knowledge of neuroanatomical structures and functions.

2. *Neuropathology*. For them to understand the interaction between neuropathology and psychopathology, clinicians need to have a thorough knowledge of neurological disorders.
3. *Pharmacology*. For them to understand the interaction between medications for other diseases and those for mental disorders, clinicians need to have a thorough knowledge of general pharmacology principles and medications.
4. *Psychopharmacology*. For them to be capable of properly selecting and prescribing appropriate medications for their patients, clinicians need to have a thorough knowledge of psychopharmacology principles and medications.
5. *Anatomy, Physiology, Pathophysiology*. For the clinicians to understand the anatomical basis for disease and understand the relationship between disease and mental disorder, they need to have knowledge of normal anatomy, physiology, and pathophysiology.
6. *Physical Assessment, Laboratory Exams and Differential Diagnosis*. Clinicians also need to be trained in how to assess pathophysiology through the use of a physical exam, how to interpret the results of laboratory tests, and how to arrive at a differential diagnosis of disease.
7. *Special Issues in Pharmacotherapeutics.* Clinicians must know psychotherapy–pharmacotherpy interaction, computer-based practice aids, pharmacoepidemiology, and professional, ethical, legal, and interprofessional issues.

18.6.5 Psychopharmacology Examination for Psychologists

The PEP exam was framed by the American Psychological Association (APA) to provide state licensing boards with a measure of basic competency as prescribing psychologists. It was designed to set credentialing standards for psychologists who had completed a postdoctoral degree in psychopharmacology. If an examinee passes this exam, there is some assurance that the individual has sufficient knowledge-based competence to prescribe psychotropic medications (Bricklin & Ciuccio, 2003, p. 180). The exam contains questions in ten knowledge-based areas: neuroscience; neuropathology; anatomy–physiology and pathophysiology; pharmacology; clinical psychopharmacology; research; differential diagnosis; professional, legal, ethical, and interprofessional issues; biopsychosocial and pharmacologic assessment and monitoring; and integrating clinical psychopharmacology with the practice of psychology.

The PEP exam is a computer-based instrument that has security built into the system. The requirements that have been established for admission to the PEP are the following: (Bricklin & Ciuccio, 2003, p. 186).

- A psychology doctoral degree.
- A provider of health service in psychology.
- A license to practice psychology on an independent basis that is currently in good standing.
- A postdoctoral program of education in psychopharmacology successfully completed. This postdoctoral program must be organized as intensive didactic instruction, offered by a regionally accredited institution of higher learning, an APA approved sponsor of continuing education, or a setting approved to provide continuing education by a state or provincial psychology licensing board.

A psychologist who has passed the PEP exam is ready to apply to a state licensing board, such as those in New Mexico or Louisiana, to be credentialed for prescribing medication. In addition to an academic program in clinical psychopharmacology and the passing of the PEP exam,

licensing boards also require supervised practicum in clinical psychopharmacology before certifying the basic competence to prescribe. Once such a supervised practicum, clerkship, or residency has been completed, basic competence may be certified for independent practice as a prescribing clinical psychologist.

18.6.6 Measures of Competency

For a licensed psychologist, the currently accepted measures of basic competence are a doctoral degree in professional psychology, a clinical psychology internship, a postdoctoral residency, and a passing score on the state licensing exam leading to the awarding of a state license to practice clinical psychology. For a prescribing psychologist, the criteria are a state license to practice clinical psychology, a postdoctoral masters degree (or equivalent) in clinical psychopharmacology, an intensive practicum or externship in the practice of clinical psychopharmacology, a passing score on the PEP exam, and a state license to practice psychopharmacology (or certification within the military or Guam). The complexity of these multiple criteria which combine certifications in both clinical psychology and clinical psychopharmacology make it somewhat difficult to define the competency of a prescribing psychologist. In a sense, however, it is somewhat analogous to the long and arduous route taken by a student in a highly specialized medical specialty such as endocrinology.

18.7 Expert Competencies of the Clinician

18.7.1 Expert Competency for Psychologists

Basic competency is typically certified at the beginning of one's career by a licensing board after a licensed clinical psychologist has obtained a Masters of Science in clinical psychopharmacology (or its equivalent) and has passed a national exam (such as the PEP exam). A clinical, counseling, cognitive-behavioral, family, forensic, group, school, rehabilitation, child and adolescent, health, psychoanalytic, or organizational psychologist as well as a clinical neuropsychologist has the opportunity to apply for specialty certification by the American Board of Professional Psychology by passing a board exam, and being awarded diplomate status. The ABPP exam can be taken only after training and postdoctoral experience in clinical practice. The ABPP diplomate affords psychologists the opportunity to proceed to a higher level of credentialing than the basic competence credentialing of the state licensing board. Those who have passed this boarding and received a diplomate (ABPP) have a level of competence that some consider qualifying them to have expert competence in their specialty. However, the field of clinical psychopharmacology is so new, that there has been no opportunity, thus far, to create such a national board. Therefore, other criteria need to be used to define expert competency in this new discipline within professional psychology.

The expert level of competency for a psychologist with postdoctoral training in clinical psychopharmacology is typically an advanced stage of progress in the career of such a professional. Experts have typically spent a number of years in successful private or institutional clinical practice, or teaching in a graduate program in clinical psychopharmacology, or experience mentoring and supervising the training of new candidates for a career in medical

psychology. Often experts have been recognized by their professional colleagues and societies by election to office, invitations to present workshops, and the presentation of awards for excellence. In other words, expert competency is something that is publicly acknowledged by ones colleagues, students, employers or fellow professionals. Although such recognition is not usually given in the form of certificates or diplomas, it can often be documented in the form of published manuscripts, presentations, workshops, elected offices held, letters of recommendation, or years of clinical practice, teaching, supervision, and consultation.

18.7.2 Specific Competencies of an Expert

Although expert competency may be somewhat difficult to define as a general trait, specific competencies of an expert are more easily defined, because they are measureable. The following are some of the specific competencies one would expect to find in an expert prescribing psychologist or one consulting in psychopharmacological medications:

1. *Expert Literacy*. Literary experts have a familiarity with published research and opinion, so comprehensive, that they are well versed and understand the limitations and insufficiencies of that literature better than their colleagues. An expert knows not only what has been well verified by research findings, but what has not yet been researched well, what is not yet known and what are the limitations about the research findings that have been published. To have expert competency in the current literature, an expert stays informed about what has been accomplished in the past, what is currently being researched, and what yet needs to be done in the future. Such a historical perspective on the literature in a specific science allows the expert to be comfortable answering any question or issue that might be brought up in public forum. Such a grasp of the literature would give a prescribing psychologist specific expert competency as a consultant, teacher, and practitioner. For a prescribing psychologist such expert competency will in the future be measurable in an oral board exam.

2. *Expert Ability in Diagnostics*. An expert is not bound by any diagnostic theoretical orientation, but is familiar with and is able to combine and use behavioral, dynamic, humanistic, and medical approaches to diagnostics equally well and in combination with each other. Such an eclectic orientation allows the expert to be more sensitive to the personal needs of patients and less concerned about fitting diagnostic impressions into theoretical categories. An expert is sensitive to the signs and symptoms of psychopathology in a way that allows conceptualization of the case to be built gradually from the most objective aspects of information. Although an expert begins to formulate diagnostic hypotheses with each complaint and observed behavior, no conclusions are reached until the confirmation and disconfirmation process is completed, because the expert is flexible and open to consider many possible solutions to a problem. For a prescribing psychologist, expertise involves a combination of skills in pathophysiology and psychopathology, to discriminate and integrate problems that bridge the medical and psychological areas, especially in health psychology.

3. *Expert Therapist*. As an expert in both evidence-based psychological treatment and evidence-based medicine, the prescribing psychologist would demonstrate expert competency in the application of evidence-based practice by appropriately combining psychotherapy and pharmacotherapy in treatment planning. Patients who depend on the expert

prescribing psychologist for clinical care could expect efficient, effective interventions that would lead to successful outcome of their problems. They could expect that their clinician would not only use treatments of choice that had the best research support, but that there would be modifications of their treatment that would fit their problems on a day-to-day basis. They could anticipate help with relapse prevention and long-term monitoring in years of follow-up evaluations.

4. *Expert Researcher*. Prescribing psychologists with expert competency would contribute to the knowledge in their field through their own data collection, analysis, interpretation, and written manuscripts. An example of such research by a practicing clinician is described in an article (Schwartz, 2008) regarding a military prescribing psychologist who, during a tour of duty both treated thousands of service members and Iraqi citizens and collected data on 6,000 active duty troops on the topics of Post Traumatic Stress Disorder and traumatic brain injury.

5. *Expert Consultant*. A prescribing or consulting psychologist, who has a reputation as an expert consultant, is one who is frequently sought out by clinicians and researchers to give advice about clinical problems. Not only do fellow psychologists seek to consult with experts, but also, physicians, lawyers, judges, nurses, physician's assistants, social workers, police, parole officers, teachers, coaches, and government leaders seek advice from them.

6. *Expert Supervisor*. Students seek out expert supervisors on the basis of their reputation as someone whose clinical direction leads neophytes to successful outcomes. Experts provide ideal models for students who are searching for someone to imitate, someone who will be a role model for them to follow, and someone who may be a long-term mentor for them. A prescribing psychologist with expert competency as a supervisor has a wealth of clinical experience to pass on to the next generation of psychologists and enjoys the role of counselor and guide.

7. *Expert Teacher*. Doctoral and postdoctoral schools in clinical psychopharmacology search for experts who will be able to provide educational leadership in their training and teaching programs. Prescribing psychologists who have expert competency as a teacher, typically, combine many of the expert competencies listed above, expert literacy, expert diagnostician, expert therapist, expert researcher, consultant, and supervisor. By the time they have been employed as expert teachers they have already spent many years in practice and consultation as well as advancing their own individual competency. Therefore, prescribing psychologists with expert competency as teachers come to the classroom with a depth of real-life experience that is appreciated by their students. They are more interesting as lecturers, more engaging as story-tellers, more vivid in their examples, and more believable as teachers of facts, than are teachers who have acquired knowledge only through book-reading.

18.7.3 Measures of Competency

Although the following criteria do not have the support of research, they are often used as informal measures of competency. They provide a method of rating the level of competency expressed in the performance of professional behavior. When deficiencies are found in these ratings of competency, the fault may be due to inadequate education and training at the academic level, inadequate mentoring at the practicum and residency level, inadequate maintenance of that training at the continuing education level, or inadequate motivation to

provide an optimal level of service to patients. If a measure of competency indicates that competency is lacking, remedial steps may then be taken to rehabilitate or enhance the knowledge and skills of the professional to regain or attain competency.

Efficacy as a Measure of Competency. Competent professionals use the most efficacious methods of treatment, and efficacious treatments are the ones most often chosen by competent professionals. The relationship between competence of the professional and efficacy of the treatments that they use may be employed as one way to measure the level of competency. How knowledgeable is the professional about the efficacy of the choices of treatments available? A prescribing psychologist who is learning how to choose efficacious treatments may be basically competent, whereas another prescribing psychologist who keeps apace with the research literature regarding this efficacy well enough to consistently choose efficacious treatments may be of expert competency. Therefore, the frequency with which a professional uses the treatment of choice that is currently available could be used to rate that person's basic versus expert competency. Such a frequency of use of treatment of choice would most likely be related to the professional's own success rate with patient cases (another measure of competency).

Credentialing as a Measure of Competency. Competence to practice is often discussed in the context of past educational or training experiences that may be used to verify a basic level of knowledge or professional activity. Such experiences are certified by professionals who function as clinical supervisors, professors, training directors, and program administrators. Credentialing certificates, transcripts, letters of recommendation, and other methods of verification are sought by licensing boards, hospitals, clinics, and practice settings where professionals seek employment or the right to practice (Rozensky, 2007). Credentialing usually includes evidence of competency to perform specific techniques (e.g., orthopedic surgery, radiology, neuropsychological assessment, clinical psychopharmacology, family therapy, etc.), and may also include the competency to serve specialized populations of patients (e.g., pediatrics, geriatrics, etc.) and specialized disorders (e.g., cancer, heart disease, psychosis, PTSD, etc.).

The rationale for credentialing on the part of institutions is that professionals who practice outside their scope of competency place the institution at considerable risk for malpractice litigation. Professionals who are insufficiently trained in specific techniques, populations, and disorders risk potential harm to patients and to the reputation of the institution, when they inappropriately expand their scope of practice. For instance, psychologists who have inadequate training in clinical psychopharmacology should avoid the role of consultation with medical professionals regarding prescription medications for psychological disorders. And physicians who have inadequate training in clinical psychology should avoid the role of prescribing psychopharmacological medications to patients with psychological disorders.

Credentialing for prescribing psychologists has currently developed as a sequence of three steps to certification:

1. The doctoral degree in psychology and licensure to provide mental health services
2. A postdoctoral master's degree in clinical psychopharmacology or an equivalent educational certification and an externship in supervised clinical practice in clinical psychopharmacology
3. A passing score on the PEP exam leading to state licensure in New Mexico or Louisiana, or military certification to practice clinical psychopharmacology

Informal credentialing as a consultative clinical psychopharmacologist has developed around the completion of the first two steps above, although no credentialing body has as yet attempted

to delineate formal credentialing requirements for consultation by psychologists who have had special training in clinical psychopharmacology.

Safety of Patients as a Measure of Competency. For a prescribing psychologist, safety refers to the lack of medical error in the clinical practice of a professional. In the states of New Mexico and Louisiana, where psychologists may apply for licensing as an independent practitioner, medical psychologists trained in clinical psychopharmacology have been approved to prescribe medication for patients with psychopathology. Their competence has been verified by thousands of prescriptions that they have written without a single negative event. Such a high level of performance by these medical psychologists has provided good evidence for the safety and effectiveness of their prescribing. The combination of basic competence and a clean safety record makes a prescribing psychologist a very desirable service provider. The frequency of medical errors may be used as a measure of competency. Experts most often function without any of the types of error that would be harmful to patients.

Networking as a Measure of Competency. Experts tend to maintain large networks of communication with their colleagues. They attend and give workshops, attend and present at conferences, serve on national committees, and serve other leadership roles in the national societies of their colleagues. Consequently, they maintain regular communication with their colleagues to plan and organize committee work and programs, but also to stay abreast of the latest research findings and techniques developed by these colleagues. For a prescribing or consulting psychologist who has advanced training in clinical psychopharmacology, the volume of this networking is traditionally documented in a curriculum vita. Such a summary of this networking can be used as a measure of expert competency.

A combination of these measures may be used to judge the level of competency of a prescribing and consultative psychologist. Those with expert competency are usually more efficacious and credentialed, are safe in their practices, and do more networking than their colleagues. Therefore, a prescribing psychologist with expert competency would tend to have an excellent record on all of these informal measures.

18.7.4 Ethical and Cultural Competence

Competency in one aspect of clinical practice does not make a clinician competent to treat or assess other disorders or patients from other cultures. A good example of the necessity for a therapist to be competent to treat a specific individual is the case of a patient from another culture who is diagnosed with PTSD. Zayfert (2008) observes that the re-experiencing and arousal symptoms of PTSD are most likely a response to trauma that is common across various cultures. However, the expressions of that response may be quite specific to different cultures. Therefore, a therapist of a culture different from that of a patient would not be competent to assess or treat that individual, if that therapist was not familiar with the specific expressions of a PTSD response found in that patient's culture. The therapist might use the correct evidence-based treatment procedures in a competent manner but yet be incompetent to treat this specific case owing to the lack of understanding the specific type of expressions of PTSD expected from this patient. For a prescribing psychologist, the competency issue might be even more complex, since the specific cultural response to a treatment medication would also need to be known.

18.8 Transition from Basic Competence to Expert

18.8.1 Forces That Drive the Transition

The goal of the transition from basic to expert competence is to convert knowledge and skills that qualify as basic competence to knowledge and skills that qualify as expert competence. For example, the basic competence of the psychopharmacologist in the assessment and recognition of symptoms must be converted to expert sensitivity to signs and symptoms of disorders and superior discrimination of diagnostic categories of pathology. The steep developmental trajectory of such a transition requires a significant effort to excel, a great deal of experience from which to learn, and exceptionally high-quality educational input to drive the transition. A professional with basic competence would need the beneficial input of a broad range of patient pathologies from which experience is gained, a broad range of assessment techniques from which normative and abnormal types of behavior are learned, astute teachers, supervisors, and consultants from whom the steps to excellence are learned, and personal reading habits that cover the literature on assessment are developed.

Basic competence is gradually transformed into expert competence by enhancing experiences and enriched learning. Licensed psychologists who have completed postdoctoral training in clinical psychopharmacology (CPP) have reported that they are aware that their own clinical practice skills have improved, that the number of patient referrals have increased, and that they have more requests for clinical consultation. Such an outcome suggests that they have made personal progress in clinical competency. The intensive study of CPP by a clinical psychologist represents an increased focus or concentration in one's career that leads to enhancement of knowledge and skills. This enhancement in competency is most likely driven by the similarity in goals and outcome of the two clinical disciplines, which make them complementary to each other. For a clinical psychologist, the addition of CPP skills in the recognition of medical signs and symptoms of disease is complementary to the psychologists own skills in the recognition of symptoms of psychopathology. And the resulting enhancement in both psychological and medical skills improves a psychologist's ability to distinguish between medical and psychological disorders. Such an expansion of knowledge and skills impels the transition from basic to expert competency. A similar transition occurs with regard to the mechanisms underlying the treatment of mental disorders as Barlow (2008) has indicated. A clinical psychologist who does postdoctoral training in CPP studies the chemical mechanisms underlying the use of psychotropic medication and learns the theoretical bases for the efficacy of psychopharmacological treatment. The study of these scientific advances in evidence-based medicine enhance a psychologists own professional knowledge of evidence-based psychological treatment and, therefore, also, enhance the opportunity for progress toward expert competency. The study of medical maintaining factors of psychopathology by a psychologist in advance training in CPP is yet another avenue of competency enhancement.

Basic competence in treatment is often converted to expert competence, when, after many years of successful treatment experience, a practitioner becomes a teacher and supervisor of graduate students in clinical psychopharmacology who are learning to be treatment providers. This type of driving force for the transition from basic to expert competence is especially powerful when the professor and supervisor continues simultaneously to be a practitioner and uses the patient contacts as an occasion for apprenticeship for students. Often, a highly motivated and alert teacher and supervisor learn from the students as the students are learning from the supervisor.

The driving forces of the transition from basic to expert competence are, therefore, both personal and social, both learned and taught, dependent on both motivation and effort, and driven by both environmental contingencies and vicarious reinforcement. Those in the midst of the transition are personalities who are satisfied with gradual successive approximation to the goal of expert competency. By exposing themselves to the shaping forces of education, modeling, rewarding experiences, and social enjoyment of collegiality with fellow professionals, a psychopharmacologist may make rapid progress toward expert competence.

18.8.2 Form of the Transition

The transition from basic to expert competency as a prescribing or consultative psychologist may involve many years of experience or may be accomplished rather rapidly with some individuals. The transition may not be an all-or-none phenomenon. Transitions may occur in individual subtypes of competencies at different times in the individual's career. An experimental psychologist, for example, may spend many years obtaining expert experience as a researcher, grant writer, and teacher. At some point in such a career, the experimental psychologist may decide to return to school to take academic coursework in clinical psychology and become certified as a practitioner with basic competence as a clinical psychologist. With time such a person might progress to expert competencies in both experimental and clinical psychology. Currently, this type of transition, almost always occurs with professional psychologists, who wish to obtain basic competence in clinical psychopharmacology. In fact, the administrative council of the American Psychological Association has voted to require that psychologists obtain basic competence first as licensed psychologists before they are even allowed to begin their study to obtain basic competence in clinical psychopharmacology. However, most transitions from basic to expert competence or from one subtype of competency to another are not legislated, but rather occur as a result of personal effort to learn or a special talent in a focused area of knowledge or skill.

18.8.3 Identifying Competent Psychologists

Although each professional who actually reaches the expert level of competence may differ, some common behaviors of these individuals can be described:

1. *Experts Seize the Opportunity to Learn*. Prescribing psychologists with expert competency regard the structured education that they have obtained as a step toward learning on their own. They develop an awareness of their capacity to learn without the structure of the classroom and curriculum of graduate school. Through the development of successful study habits, they gain a sense of their own learning ability. They feel capable of self-learning and capable of teaching themselves. Although they seek out learning experiences in workshops and classes taught by others, they view themselves more as active learners who do not wait for learning to appear, but who continue to seek out the information that is needed to take the next step in moving toward expert competency.
2. *Experts Cultivate a Dynamic Style of Learning*. Instead of viewing the content of learned facts as material written in stone, these individuals begin to realize how fluid human

knowledge really is. Through the shifts of historical knowledge of the paradigm that have occurred in science, they begin to understand that knowledge is an ever growing phenomenon. They memorize facts, but still realize that they are open to change. Gradually, they understand that learning itself is the prized possession that they have acquired in graduate school and not the content of the facts that they have memorized. Competency is no longer viewed as the storage of a body of facts, but rather it is the capacity to keep learning and stay abreast with science.

3. *Experts Adopt a Competitive-Sharing Attitude*. Instead of working in isolation from colleagues, the learners who are on their way to expert competence are willing to share thoughts, ideas, plans, writings, and new insights with colleagues and students, while at the same time, maintaining a healthy, competitive stance. These professionals on their way to expert competency enjoy the collegiality of working with other professionals, and are aware that they themselves make more rapid progress in their own learning when they collaborate with others. They build their own personal skills through behaviors such as co-therapy, co-authorship, team-teaching, interdisciplinary discussions, and collaborative grant writing. They enjoy passing on their own knowledge and skills to the next generation of students, and develop a reputation for friendliness, congeniality, and cooperation. They also enjoy competing for grant funding, competing for awards, and competing for journal space for their manuscripts. This combination of a competitive-sharing relationship with their colleagues earns them respect and admiration as competent experts.

4. *Experts Are Persistent in the Development of Their Expertise*. The transition from basic to expert competence has been documented frequently in the lives of famous psychologists such as B.F. Skinner, Albert Ellis, Albert Bandura, Ralph Reitan, and David Barlow, who have become known for their expert competence as psychologists. A common factor in the pathway to expert competence of each of these famous psychologists was the highly focused specialization of knowledge and skills that was pursued by each of them. Each of them carved out a narrow and highly concentrated area of work in the field of psychology, to which they tenaciously devoted all of their time and efforts. Such a lifelong devotion to a single purpose is clearly a successful method to progress toward expert competency. Underlying such a focused career was the personal trait of perseverance that appears to be part of the personality of a successful expert. Steadfast persistence was needed to make a single focus on the heart and core of a life career. These famous psychologists did not become famous overnight. But they were willing to push forward even when the tasks became difficult and frustrating. Therefore, one of the principal factors in the transition from basic to expert competence is the persistence effort to maintain a focused career.

5. *Experts Choose an Area of Specialization*. Psychologists with expert competency do not try to know and do everything that is possible within their profession. Instead they choose an area of specialization that blends the highest priority as set by their profession and their own personal goals. Because they have deliberately prioritized their focus of learning and competence, they are very aware of their areas of expertise and their limitations. They admit to patients and colleagues those areas of knowledge and skill that they do not have. They readily refer to their colleagues and to other professionals. An example of such prioritizing is a child clinical psychologist, who has advanced training in clinical psychopharmacology and decides to focus his or her practice on children with brain disorders. Such a priority could lead to highly focused expertise in the use of a combination of psychological assessment and treatment combined with psychotropic medication for children who have

brain injuries. This choice would limit the practitioner to the treatment of children with brain disorders who were in need of a combination of psychology and psychopharmacology. Not all of those professionals who are on route to expert competency need to prioritize to such a limited population, but many experts do so.

6. *Experts Are Proficient Communicators of Their Area of Expertise.* Some experts are skillful and productive writers, who publish books, articles, manuals, and newsletters that contribute significantly to the literature in their area of expertise. Other experts are proficient speakers who give workshops and conference presentations, who are talented teachers and consultants and who aid others to learn about their area of expertise. Prescribing psychologists who have exceptional ability in writing or speaking often become professors or clinical consultants.

18.8.4 Current Trends in Competency in the Field of Psychology

How do we know who is a competent psychologist? What are the indicators of competency within the field of psychology? Three trends that have signaled a "new era of competency" (Barlow, 2008, p. 8) in psychology are the following:

1. The first trend is the public recognition that psychological treatment is as effective as psychopharmacological treatment. Barlow warns, however, that one of the important ingredients that underlie this recognition, and that contributes to successful treatment outcome, is the competence of the therapist. Without competency in the therapist, the psychological treatment procedures, as validated as they may be, will not lead to a successful outcome. Psychological treatments will be efficacious if they are competently applied by a skillful therapist. Competent psychologists can be identified as those who use validated treatments and are successful with their treatment cases.

2. The second trend that signals the beginning of a new era of competency is an ever increasing utilization of outcome assessment in evidence-based practice to evaluate treatment success. Outcome assessment can identify the level of competency of an individual therapist as well as identify which treatment setting is applying evidence-based treatment most successfully.

3. A third trend that has signified a new era of competency is the combined use of psychological and psychopharmacological treatments for mental disorders. In the case of psychotic disorders such as schizophrenia, the addition of a psychological treatment to a psychopharmacological treatment doubles the efficacy of the medication. Until recently, such a beneficial effect had not been found with anxiety disorders. Hoffman (2006) showed that D-cycloserine, a partial agonist of the NMDA neurotransmitter enhances the effect of exposure-based psychological treatment for fear and anxiety. Such a finding forecasts the application of similar medication enhancement to other mental disorders. The professional who would be most competent to carry out this combined treatment would be a prescribing psychologist with advanced training in psychopharmacology.

18.9   Summary

This chapter provides a description of competencies needed by a professional psychologist, who have been educated to prescribe or provide consultation in psychopharmacotherapy.

A small number of clinical psychologists in the United States have been certified to prescribe psychotropic medications for their patients. These prescribing psychologists are located in Guam, New Mexico, Louisiana, and the military. These "medical psychologists" need to be competent in both clinical psychology and clinical psychopharmacology. They have been well educated in the use of diagnostic assessment in both psychology and medicine. They know evidence-based psychological treatment and evidence-based medicine. They are basically competent in the understanding of maintaining mechanisms in both psychopathology and pathophysiology. They are basically competent to engage in supervision, management, and consultation in their areas of competence. They have had coursework in both psychological and medical ethics, and appreciation of diversity for both psychological and medical health service. Another larger group of clinical psychologists in the United States has been trained in the same manner as these medical psychologists, but do not live in regions of the country where they may be licensed to prescribe medication, or who do not chose to do so. These clinical psychologists are considered to be basically competent to engage in consultation regarding the same topics. Both of these groups of clinical psychologists who are competent in clinical psychopharmacology tend to progress toward expert competence through continued education, clinical practice, teaching, research, and consultation. They reach the expert level most often through competencies in subtypes of practice.

Appendix

Seven Academic Content Areas of Specific Competency. The primary skills expected of a clinical psychologist who has basic competency in clinical psychopharmacology are the following:

1. *Neurosciences*. For the clinicians to understand the brain tissues in which psychopharmacological medications have their effects, they need to have a thorough knowledge of neuroanatomical structure; neurochemistry and neurophysiological function of neurons; central nervous system and peripheral nervous system neuronal pathways and their functions; vascular supply of the brain, and the blood-brain and placental barriers; cellular and molecular nervous system biology and regulatory processes and second messenger systems; endocrine system and the interface of various hormones and other neurotransmitters; major neurotransmitter and neuromodulator synthesis, storage, release, distribution throughout the brain and the rest of the body; action, reuptake, and degradation of neuropeptides; etiological factors and diagnosis of sleep disorders as related to the nervous system and psychopathology; neurodiagnostic markers of neurobehavioral disorders.

2. *Neuropathology*. For them to understand the interaction between neuropathology and psychopathology, clinicians need to have a thorough knowledge of neurological disorders such as dementia, delirium, pain, Parkinson's, Huntington's, and Tourette's syndromes, mental retardation, fetal alcohol syndrome, pervasive developmental disorders, Fragile-X syndrome, CNS vascular disorders, seizure disorders, traumatic brain injury, multiple sclerosis, infectious diseases, neoplasms, schizophrenia, affective disorders, anxiety, ADHD, and the mechanism of extrapyramidal dysfunction.

3. *Pharmacology*. For them to understand the interaction between medications for other diseases and those for mental disorders, clinicians need to have a thorough knowledge of general pharmacology principles. These would include, but not limited to, drug

classifications and pharmacokinetic principles such as absorption, bioavailability, volume of distribution, protein and tissue binding, metabolism, elimination and clearance, and half-life. Pharmacodynamic principles such as dosing, potency, efficacy, toxicity, types of drugs and other agents interacting with receptors (e.g., agonists, antagonists, and inverse agonists), drug-induced cellular adaptation (e.g., cellular signaling of ion channels, second messenger systems, neurotransmitter release, sensitivity, and supersensitivity), drug effects on genetic expression, mechanisms of action of a range of pharmacotherapeutic agents, the theoretical relationships thought to exist between neurotransmitter systems and psychopathological conditions are also included. In addition, drug–drug, drug–disease and drug–food interactions, drug-induced disease and dysfunction, and adverse reactions, genetic polymorphisms, familial patterns of drug response and toxicity, and pharmacoepidemiology are also considered. Understanding the development of drug tolerance, dependence, and withdrawal syndromes is necessary. Also knowledge of the U. S. Food and Drug Administration (FDA) drug development process and the current status of research regarding specific medications is necessary.

4. *Psychopharmacology*. For them to be capable of properly selecting and prescribing appropriate medications for their patients, clinicians need to have a thorough knowledge of indications, contraindications, and off-label uses of various psychotropic and adjunctive medications, and the rational for psychotropic medication selection, taking into account target symptoms, patient and family history, premorbid personality, demographics, comorbid medical conditions, existing medication regimen and potential for interactions, and differences among medications within classes of drugs. Knowledge of dosing, time course of therapeutic action, and adverse effects; patient factors that influence dose, therapeutic monitoring, augmentation strategies; dose adjustment, route of administration, management of adverse reactions, interactions, relapse prevention, drug effects in special populations; psychological and physiological manifestations of recreational substances and treatment of intoxication or addiction, including strategies for assisted withdrawal, maintenance, and relapse prevention, tolerance, cross tolerance, dependence and withdrawal; sensitization/cross-sensitization with respect to specific medications; and the management strategies used to treat them are necessary. Clinicians also need to be trained in the method of combining psychological treatment with psychopharmacotherapy, especially its adaptation to be used in children and the elderly. They need to learn how to use computer-based practice aids to search the literature for research findings regarding practice and updates on medications and their applications, as well as epidemiological findings about diseases.

5. *Anatomy, Physiology, Pathophysiology*. For clinicians to understand the anatomical basis for disease, and understand the relationship between disease and mental disorder, they need to have knowledge of normal anatomy and physiology and pathophysiology including cardiovascular, pulmonary, renal/genitourinary, hepatic, endocrine, hematological, muscular, skeletal, dermatologic, and immunologic/rheumatology, and reproductive systems, and how each of these systems is affected by psychopharmacological medications. An excellent example of these potential interactions is the issue of how many psychotropics have been associated with an increased risk for hyperglycemia, hyperlipidemia, and weight gain requiring special monitoring and careful consideration in psychotropic drug selection in patients with preexisting diabetes mellitus or hyperlipidemia and the possible changes in treatment selection when these drug–disease interactions or drug-induced adverse reactions occur (ADA, 2004; Rey 2002, 2006b).

6. *Physical Assessment, Laboratory Exams and Differential Diagnosis*. Clinicians also need to be trained in assessing pathophysiology through the use of a physical exam, interpreting the results of laboratory tests and arriving at a differential diagnosis of disease.

7. *Special Issues in Pharmacotherapeutics*. Finally, clinicians must know psychotherapy–pharmacotherpy interaction, computer-based practice aids, pharmacoepidemiology, and professional, ethical, legal, and interprofessional issues.

19 Managing Suicidality

Kelly C. Cukrowicz · Phillip N. Smith · Erin F. Schlegel

Abstract: A high percentage of individuals who die by suicide are in treatment at the time of their death. This speaks to the importance of ensuring adequate training for mental health providers in the assessment and treatment of suicidal behavior. This chapter provides information on areas of competence that are essential for clinicians working with patients at risk for suicide. Specifically, this chapter provides guidelines for assessing suicide risk and ensuring patient safety, as well as data on factors that maintain suicidal behavior. An overview of the literature on empirically-based treatment of suicidal behavior is provided, as well as data on the mechanisms of action for these treatments. Importantly, this chapter provides an overview of the basic competencies of clinicians working with patients at risk for suicide and the steps necessary to move from basic competence to expert competence.

19.1 Overview

The ability to effectively evaluate and treat suicidal behavior and patients with elevated suicide risk is a critical skill in routine clinical practice for psychologists. Suicide is the 11th leading cause of death in the United States with approximately 30,000 deaths by suicide each year (Center for Disease Control, 2007). Previous research has indicated that as many as 50% of individuals who died by suicide were in treatment at the time of their death (Fawcett, 1999). This highlights the importance of adequate training to achieve at least a basic level of competence in offering services to patients who may be at risk for suicide. The purpose of this chapter is to present information that will allow clinicians to ascertain and further develop their current level of competency in managing suicidality.

The term "suicidality" has previously been used to refer to a variety of behaviors associated with suicide, including thoughts of suicide, self-harm, plans and preparations for suicide, suicide attempts, and death by suicide. Lack of specificity is problematic because it makes clear communication between professionals more challenging. To attempt to increase the clarity of terms associated with the suicide risk, Silverman et al. (Silverman, Berman, Sanddal, O'Carroll, & Joiner, 2007) revised the existing nomenclature (O'Carroll et al., 1996) that is used to describe thoughts and behaviors associated with suicide. Within this revised nomenclature, suicide-related ideation includes thoughts of suicide that may vary in intensity and their associated intent to engage in suicidal behavior. Suicide ideation is contrasted with death ideation, which occurs when an individual wishes for death or escape in the absence of thoughts associated with injuring oneself or taking one's own life. A suicide threat is defined as an interpersonal action that can be interpreted as an indication that the individual plans to engage in suicidal behavior in the future. A suicide plan consists of the actions an individual plans to take that will lead to self-injury or death.

This nomenclature also includes careful definitions of behaviors that bring about self-injury to an individual. These terms include self-harm, suicide attempt, and suicide. Silverman

et al. (2007) define self-harm as behaviors that are "self-inflicted, potentially injurious with a nonfatal outcome for which there is evidence that the person did not intend to kill himself/ herself" (Silverman et al., p. 272). A suicide attempt is defined identically with the exception that the behavior involves the intention to die. This intent can range from mild, which involves a great degree of ambivalence, to severe. Self-injurious behavior that is engaged in with the intention for death (with a nonfatal outcome) is classified as a suicide attempt. It is important to note that self-harm and suicide attempts may result in no injury, injury, or death. If death occurs, it is classified as an accidental death in the case of self-harm (i.e., no intent for death) or as death by suicide in the case of a suicide attempt (i.e., intent for death). These terms will be used throughout this chapter to refer to thoughts and behaviors associated with suicide risk. It is our hope that these clear definitions will aid in understanding the content of this chapter.

As previously stated, the goal of this chapter is to aid clinicians in developing skills associated with assessing and treating patients who may be at the risk of suicide. This chapter begins with a discussion on the recognition and assessment of elevated suicide risk. Within this section, we provide an overview of risk factors for suicide, strategies for determining current risk, and assessment tools that can aid in this endeavor. We will then discuss factors that maintain suicide risk and contribute to the desire for death (e.g., hopelessness, emotional pain). Subsequent sections of the chapter will include a review of evidence-based treatment approaches and evidence for the mechanisms of action underlying successful treatment outcomes. The final sections of the chapter will focus on the basic and expert competencies of clinicians, as well as the necessary skills and training tasks associated with the transition from basic to expert competency. Within these sections of the chapter, we will present eight core competencies described by a partner project of the Suicide Prevention Resource Center and the American Association of Suicidology (Suicide Prevention Resource Center, 2006).

19.2 Recognition and Assessment

The collection of accurate information, while highly dependent on establishing a relationship of trust, is also dependent on knowing which questions are important to ask. While it is impossible to gauge with certainty who will and will not attempt and die by suicide, we endorse an approach that emphasizes identification of risk and protective factors in a manner that is empirically supported and theoretically meaningful. This approach focuses on factors that have been demonstrated to be associated with suicide to identify a level of risk: low, moderate, and high (see Joiner, Walker, Rudd, & Jobes, 1999 for a thorough review of risk designation). These factors cover separate domains of suicide or components informing risk: (1) previous attempt status, (2) distal risk factors for suicide, (3) suicide symptom presentation, and (4) warning signs or stressors.

Research has demonstrated that the strongest predictor of future suicide attempts is a history of past attempts (Joiner et al., 2005). As such, a patient's suicide attempt status is one of the most important factors in determining risk. Specifically, a patient who has multiple suicide attempts is at a greater baseline level of risk when compared with never and single suicide attempters (Joiner et al.). It is important to note that many individuals do attempt and die by suicide on their first attempt and that the lack of previous attempts is in no way a guarantee of

safety. Rather, a patient with multiple suicide attempts is more likely to attempt when a number of other risk factors align. In addition to previous attempt status, there are a number of other more distal risk factors for suicide. Demographic risk factors include male gender, age 45 and above, divorced or widowed, solitary living situation, and unemployment (Bryan & Rudd, 2006; Brown, Beck, Steer, & Grisham, 2000). Psychiatric risk factors include a mood disorder (Major Depressive Disorder, Bipolar Disorder), substance use disorder, Schizophrenia or psychotic episode, and personality disorder (particularly Borderline Personality Disorder; Brown et al., 2000; Kessler, Borges, & Walters, 1999). Additional psychiatric issues that increase risk include comorbidity, physical or sexual abuse, mixed anxiety and depression, hopeless depression, insomnia, past psychiatric hospitalization, and a general pattern of impulsivity (Brown et al.; Joiner et al., 1999; Kessler et al., 1999).

Following identification of previous attempt status, collection of information related to these risk factors is important as each provides information that informs the likelihood that an individual is or could be at risk for suicide. Specifically, for multiple suicide attempters, the presence of any additional significant risk factor (e.g., Major Depressive Disorder) denotes at least moderate risk. The presence of multiple additional risk factors (e.g., Major Depressive Disorder with prominent hopelessness, childhood sexual abuse, and substance abuse) would suggest high risk. However, it is also important to organize and integrate these risk factors with information regarding suicide symptoms.

Research exploring suicide symptoms has demonstrated that suicide can effectively be conceptualized in two parts: (1) the presence of suicide ideation and the desire for death, and (2) the presence of resolved plans and preparations for suicide (Joiner, Rudd, & Rajab, 1997). This format of organizing suicide symptoms is particularly useful as each factor is composed of specific pieces of information. Furthermore, a patient's level of risk can be assessed by evaluating his or her suicide symptom presentation (i.e., the degree to which the patient endorses suicide ideation, expresses desire for death, and possesses resolved plans and preparations for suicide) in conjunction with his or her previous attempt status and other risk factors.

The desire for death and presence of suicide ideation includes information related to "reasons for living, the wish to die, frequency of ideation, the wish not to live, passive attempt, desire for attempt, expectancy of attempt, lack of deterrents to attempt, and talk of death and/or suicide" (Joiner et al., 1999, p. 448). Resolved plans and preparations include "a sense of courage to make an attempt, a sense of competence to make an attempt, availability of means to and opportunity for attempt, specificity of plan for attempt, preparations for attempt, duration of suicide ideation, and intensity of suicide ideation" (Joiner et al., p. 448). Consistent with Joiner's (2005) model of suicide, previous attempt status, in addition to serving as a risk factor for suicide, has implications for this resolved plans and preparations factor. Specifically, an individual who has previously attempted suicide on multiple occasions is more likely to be capable of suicide (i.e., to have the courage and competence necessary, a developed plan, and access to that plan). Consistent with this theoretical relationship between attempt status and the resolved plans and preparations factor, these factors have been shown to be differentially related to suicide risk. More specifically, while presence of suicide ideation and the desire for death clearly warrants clinical attention, it is less predictive of suicide attempts and death by suicide than the resolved plans and preparations (Joiner et al., 1997). Therefore, while many patients may voice suicide ideation, this does not automatically suggest high risk for suicide unless additional suicide symptoms and/or risk factors are present. Rather, when an individual desires suicide and also has resolved to act on those thoughts, suicide risk is

increased. When combined with information regarding other risk factors for suicide, details regarding resolved plans and preparations can be an essential element of identifying potential risk of suicide.

Previous writing has distinguished between risk factors and warning signs for suicide (Rudd, Berman et al., 2006). Little research has examined warning signs; however, elevation on warning signs suggest that an individual is at imminent risk for suicide (Bryan & Rudd, 2006; Mandrusiak et al., 2006; Rudd, Mandrusiak et al., 2006; Van Orden, Joiner et al., 2006). Warning signs for suicide include such symptoms as a sense of agitation or perturbation, intoxication, psychotic symptoms, and acute distress (Bryan & Rudd; Rudd, Berman et al.). Additionally, stressors such as loss (e.g., financial, professional, etc.), acute medical conditions and chronic diseases, and interpersonal and family disruptions (e.g., divorce) are frequently related to suicide risk (Joiner, 2005). These warning signs should be considered in the context of other general risk factors and prominent suicide symptoms.

When collecting information related to suicide risk, the mnemonic, IS PATH WARM (Rudd, Berman et al., 2006) can be helpful (Ideation, Substance abuse, Purposelessness, Anxiety, Trapped, Hopelessness, Withdrawal, Anger, Recklessness, Mood changes). This mnemonic attempts to integrate much of the information discussed earlier on risk factors and suicide symptoms with warning signs to guide suicide assessment. For example, an individual experiencing suicide ideation, substance abuse, and who is demonstrating acute mood changes with anxiety or agitation might be considered at least at moderate risk. However, we again stress the importance of previous attempt status as such experiences in the context of a multiple attempt history would suggest high risk.

While we have suggested that the cumulative effect of a number of risk factors is suggestive of greater risk of suicide, it is important to organize these risk factors in a manner that provides meaningful framework for risk designation. Specifically, we argue that the combination of risk factors can effectively designate an individual as low, moderate, and high risk of suicide (Joiner et al., 2005). However, it is also important to consider protective factors against suicide.

Protective factors include "social support, problem-solving skills and demonstrations of coping skills, participation in treatment, hopefulness, the presence of children in the home, pregnancy, religious commitment, life satisfaction, intact reality testing, fear of social disapproval, fear of suicide or death," and writing about suicide in a manner that does not communicate plans or intent (Bryan & Rudd, 2006, p. 189). The presence of these protective factors should not be considered definitive evidence that a suicide attempt is not imminent. Rather risk factors can also be central to assessment of suicidal risk. While the presence of a greater number of protective factors provides evidence that the individual's risk for suicide may be diminished, information about these factors should be considered in conjunction with other information about previous attempt status, risk factors, and suicide symptoms. Furthermore, designation of risk does not perfectly correlate with the actual risk of suicide. Absolute certainty with regard to prediction of suicide risk, as we have stated, is impossible. Therefore, careful clinical judgment is vital in working with high-risk patients.

19.3   Maintenance Factors

Many studies have focused on variables that are associated with the onset or maintenance of suicidal behavior. The most recent theory of suicidal behavior, the Interpersonal-Psychological

Theory of suicide (Joiner, 2005), suggests that suicide can be understood in the context of three dimensions: (1) thwarted belongingness, (2) perceived ineffectiveness and resultant burdensomeness on others, and (3) an acquired capability for suicide. Individuals are at greatest risk for death by suicide when each of these conditions is met.

Thwarted belongingness is associated with feelings that an individual does not have important social connections with others. Such lack of connection may result from the absence of a social network (Stellrecht et al., 2006). Conner, Duberstein, and Conwell (1999) assessed men with alcohol dependence who died by suicide. Among risk factors for completed suicide, living alone and loss of a partner within the last month or two before death were particularly important. Similarly, a comparison of those who died by suicide and those who died by other means revealed that those who died by suicide were more likely to have been recently separated and living alone (Boardman, Grimbaldeston, Handley, Jones, & Willmot, 1999). The significant others of people who had recently attempted suicide pointed to loneliness as an important factor in suicide attempts (Magne-Ingvar & Oejehagen, 1999). Further, situations that foster a sense of belonging or increased connection to others have been associated with reduced risk of suicidal behavior (Joiner, Hollar, & Van Orden, 2006; Van Orden, Merrill, & Joiner, 2005).

Recent studies have begun to examine the relationship between perceived burdensomeness and suicide ideation in a variety of samples of younger adults. Van Orden, Lynam, Hollar, and Joiner (2006) examined the association of perceived burdensomeness to suicide ideation in a clinical sample of adult outpatients. This study indicated that perceived burdensomeness was endorsed by 5.5% of the sample. In addition to a significant correlation with suicide ideation, perceived burdensomeness was predictive of suicide ideation above and beyond the contribution of depressive symptoms and hopelessness (in addition to age, gender, and personality disorder status). Interestingly, there was a significant correlation between age and perceived burdensomeness, with greater perceptions of burdensomeness among those who were older. This suggests that older adults may view themselves as a burden on family and friends, at times of increasing dependence thereby increasing their risk for suicide. Similarly, Van Orden, Witte, Gordon, Bender, and Joiner (2008) found that perceived burdensomeness was predictive of suicide ideation after controlling for age, gender, and depressive symptoms in a sample of college students. A number of additional studies have also demonstrated an important link between perceived burdensomeness and suicidal behavior across age groups, suicide-related outcomes, and ethnicities (Brown, Comtois, & Linehan, 2002; De Catanzaro, 1995; Foster, 2003; Joiner, Pettit, Walker, Voelz, & Cruz, 2002; Motto & Bostrom, 1990; Pettit et al., 2002; Van Orden, Lynam et al., 2006).

Previous suicidal behavior (consistent with Joiner's [2005] construct of acquired capability) also appears to facilitate future suicide behavior. Beck (1996) has argued that suicidal behavior may sensitize individuals, such that suicide ideation and behaviors are more accessible and easily triggered. This is consistent with Rudd, Joiner, and Rajab's (2001) conceptualization of the suicidal mode (i.e., a mode in which cognitive, behavioral, physiological, and affective responses are primed for suicidal behavior). In a 20-year prospective study of risk factors for suicide among psychiatric outpatients, Brown et al. (2000) found that previous psychiatric hospitalization, *previous suicide attempts*, bipolar disorder, recurrent major depressive episode, current suicide ideation, and several demographic variables were associated with the risk for eventual suicide. Joiner and colleagues (e.g., 2005; Rudd, Joiner, & Rajab, 1996) have found that previous suicidal behavior (especially multiple attempt status) is associated with increased risk for engaging in future suicidal behavior. This relation holds even after controlling for a variety of

importance risk factors for suicide, including hopelessness and symptoms of Axis I and II disorders (among others).

Hopelessness is among the most robust risk factors for suicide attempts and death by suicide, and has been the subject of many research studies (e.g., Beck, Steer, Beck, & Newman, 1993; Chance, Kaslow, & Baldwin, 1994; Chapman, Specht, & Cellucci, 2005; McMillan, Gilbdoy, Beresford, & Neilly, 2007). Hopelessness is associated with suicide risk in children and adolescents, as well as adults. Wagner, Rouleau, and Joiner (2000) examined 100 inpatient children and adolescents between the ages of 7 and 17. Fifty percent of the sample experienced suicide ideation at admission to the unit. Those with elevated suicide ideation at admission reported significantly greater hopelessness as well as a negative attributional style.

A variety of studies have also demonstrated that self-harm may be maintained through functions such as affect regulation, self-punishment, relief from dissociation, avoidance of suicide, interpersonal influence, and sensation seeking (among others; Klonsky, 2007; Linehan, 1993). Linehan's biosocial theory of Borderline Personality Disorder (BPD) indicates that symptoms of this disorder (e.g., self-harm, suicide attempts) are associated with difficulty regulating emotions, a biological vulnerability to intense emotions, and a history of invalidation (e.g., childhood sexual abuse). A variety of studies have supported the relation between affect regulation and self-harm (Brown et al., 2002; Gratz & Chapman, 2007; Gratz & Roemer, 2004; Nock & Prinstein, 2005).

19.4 Evidence-Based Treatment Approaches

The primary task for those who provide treatment for suicidal behavior is to decrease suicidal behavior by reducing psychological pain and the symptoms of psychiatric disorders. Fortunately, suicide is a rare phenomenon; however, this leads to difficulty when attempting to evaluate the success of psychosocial interventions. To circumvent this problem, proxy measures are used as an index of reduction in suicide risk. These include suicide attempts, self-harm, and suicide ideation. In addition to problems associated with treatment for a low-base rate occurrence, most randomized clinical trials (RCTs) for disorders associated with elevated suicide risk exclude these individuals. This occurs because of ethical risks associated with the possibility of assignment to a control group; however, this practice has prevented the field from gaining knowledge of the impact of many treatments for reduction of suicide ideation, self-harm, and suicide attempts. Another obstacle to treatment research on suicidal behavior is the reticence of researchers to take on the legal risk, emotional burden, and time commitment associated with conducting treatment research with high-risk patients.

To date, well-designed RCTs have offered empirical support for four therapeutic approaches to the reduction of suicidal behavior: intensive follow-up treatment (Motto & Bostrom, 2001; Vaiva et al., 2006; Welu, 1977), cognitive behavior therapy (Brown et al., 2005; Rudd et al., 2001; Salkovskis, Atha, & Storer, 1990), interpersonal psychotherapy (Guthrie et al., 2001), and dialectical behavior therapy (Linehan, Armstrong, Suarez, Allmon, & Heard, 1991; 2002; Linehan, Comtois, & Korslund, 2004; Linehan et al., 1999, 2002, 2006).

Intensive Follow-Up Treatment. Intensive follow-up treatment approaches typically consist of services offered to an individual following emergency room or inpatient psychiatric services for a suicide attempt. Welu (1977) compared a 4-month intensive outreach program to treatment as usual for 120 suicide attempters randomized to these two conditions. The results of

this study indicated that those assigned to the follow-up outreach program had significantly fewer repeat suicide attempts during this period. Motto and Bostrom (2001) randomized 843 patients who had not sought follow-up treatment during the 30 days following hospitalization for depression or elevated suicide risk to a usual care condition or a contact letter condition. Those in the experimental contact letter condition received a letter from hospital staff expressing concern about how the patient was doing and inviting response. These letters were sent monthly for 4 months, then every 2 months for the subsequent 8 months, and then every 3 months for an additional 4 years. Significant differences were found between the groups, with a greater time interval to suicide for those receiving the caring contact letters. Vaiva et al. (2006) randomized 605 individuals treated in 13 emergency departments who attempted suicide by drug overdose to three conditions: telephone contact to review treatment recommendations at 1 month, telephone contact (same purpose) at 3 months, and no telephone intervention. Significant differences in repeated suicide attempts were found at 1-month for those receiving the follow-up call when compared with those who did not (12% vs. 22%). These effects were maintained over the first 6 months. No impact was apparent for those receiving calls at 3 months following emergency contact.

Cognitive Behavior Therapy. Several treatments for suicide risk have been developed that utilize cognitive and behavioral principles. Salkovskis and colleagues (1990) randomized 20 patients to either a five-session cognitive behavioral problem-solving intervention or treatment as usual. The cognitive behavioral problem-solving intervention targeted identifying problems, generating solutions, obtaining goal outcomes, and greater cognitive flexibility. The results of this study indicated significantly greater change on depression, hopelessness, and suicide ideation following treatment and at 1-year follow-up when compared with the treatment as usual condition. Importantly, repeated self-injury was significantly lower in the cognitive behavioral problem-solving group. Rudd et al. (2001) developed a cognitive behavior therapy (CBT) approach for resolving suicidal behavior. Early sessions focus on resolving suicidal crises and completing a coping card that provides instructions for activities to carry out when urges for suicidal behavior re-emerge. These sessions also focus on reducing problematic psychological symptoms (e.g., insomnia, loneliness, sadness) through behavioral activation, sleep hygiene, and seeking social support (among others). Subsequent sessions focus on examining thought patterns that typically lead to urges for suicidal behavior and developing strategies that can be applied in daily life (e.g., problem-solving, emotion regulation, cognitive restructuring). Rudd, Rajab et al. (1996) evaluated the efficacy of an intensive, short-term group therapy version of this intervention for individuals at risk for suicide as a function of a suicide attempt that precipitated a referral for additional care, mood disorder with concurrent suicide ideation, and alcohol abuse with concurrent suicide ideation. Three hundred and two participants were randomized to the intervention or a treatment as usual control condition. Follow-up assessment of participant improvement indicated that participants in both groups reported improvement in suicide ideation and behavior and associated symptoms (e.g., depression, hopelessness, problem-solving, stress) at 1, 6, 12, and 18 months following treatment.

Brown and colleagues (2005; Brown, Jeglic, Henriques, & Beck, 2006) developed a cognitive therapy (CT) approach that aims to reduce suicidal behavior though 10 brief, focused therapy sessions aimed at decreasing thoughts, images, and core beliefs that occurred in proximity to a prior suicide attempt (e.g., hopelessness, poor problem-solving, impulse control, social isolation, treatment noncompliance). Early sessions are designed to allow for the establishment of

the relationship between the therapist and patient, a commitment to treatment, and the development of a safety plan (including coping strategies, written out safety plan). Subsequent sessions include behavioral strategies aimed at increasing pleasurable activities, social support, and treatment compliance, as well as a focus on developing effective cognitive coping strategies. The final sessions focus on mastery of a relapse prevention task, which includes a visualization exercise that requires the patient to develop more effective strategies to address events, thoughts, and behaviors associated with a previous suicide attempt.

An RCT was carried out to evaluate this intervention (Brown et al., 2005). One hundred and twenty adults who had attempted suicide within 48 hours of an evaluation in the emergency department were randomly assigned to this treatment or to usual care. Follow-up assessments conducted at 1, 3, 12, and 18 months examined repeat suicide attempts (including number of days to attempt), suicide ideation, hopelessness, and depression. During this 18-month period, 24% of the CT participants and 41% of the usual care participants reattempted suicide. Examination of suicide symptoms indicated that CT resulted in greater reductions in depressive symptoms (at 6, 12, 18 months), and hopelessness (at 6 months).

Psychodynamic Interpersonal Psychotherapy. Guthrie et al. (2001) examined a brief psychodynamic interpersonal psychotherapy intervention for individuals being treated for a suicide attempt in an emergency setting. One hundred and nineteen individuals who had attempted suicide through deliberate self-poisoning were assigned to this intervention or treatment as usual. Those in the intervention condition received 4 in-home sessions of treatment. Weekly sessions were delivered by nurse therapists and included assessment of suicide risk, attempts to resolve interpersonal difficulties, and consultation with a treating physician. Six months following treatment, participants randomized to the psychodynamic interpersonal psychotherapy intervention reported significantly greater reductions in suicide ideation (mean Beck Scale for Suicide Ideation 8.0 vs. 1.5) and repeated suicide attempts (9% vs. 28%), compared with the treatment as usual group.

Dialectical Behavior Therapy. Of the intervention strategies used to treat suicidal behavior, dialectical behavior therapy (DBT; Linehan, 1993) has been the treatment utilized in the greatest number of RCTs (Koons et al., 2001; Linehan et al., 1991, 1999, 2002, 2004; Lynch et al., 2007; Turner, 2000; Verheul et al., 2003). This treatment was developed for individuals with Borderline Personality Disorder (BPD). Patients with BPD are at heightened risk for suicide as a function of self-harm, suicide attempts, and chronically elevated suicide ideation. DBT is a flexible treatment in which patients participate in individual therapy and a once-weekly skills group. In addition, therapists participate in a consultation team, and are available for coaching calls from patients between sessions. Individual sessions target life interfering behavior, therapy interfering behaviors, and behaviors that impact the quality of life of the patient. A variety of strategies are used during these therapy sessions including validation, balancing acceptance and change, behavioral chain analysis, contingency management, examining cognitions, and behavioral exposure. Group skills training includes four modules of skills that are necessary for behavioral stability and progress in treatment, including: mindfulness, emotion regulation, interpersonal effectiveness, and distress tolerance. As noted above, a variety of RCTs have evaluated the efficacy of DBT and have found positive results. Across these studies, results have indicated that when compared with control conditions (typically treatment as usual), DBT results in significantly greater reduction in self-harm, suicide attempts, and suicide ideation (e.g., Koons et al.; Linehan et al., 1991, 1999, 2002; Verheul et al.).

19.4.1 Mechanisms

Owing to the recent development of many of the psychological treatments for suicidal behavior, very little research has been conducted that examines possible mechanisms of change for the therapy approaches described above. In fact, a literature review revealed that mechanisms of change have been examined only for DBT. Lynch and colleagues (Lynch, Chapman, Rosenthal, Kuo, & Linehan, 2006) published a review article that examined mechanisms of change underlying the efficacy of this treatment. In this review, mechanisms of change are provided for mindfulness, validation, targeting and chain analysis, opposite action, dialectical strategies, and the client–therapist system.

As indicated by Lynch et al. (2006), mindfulness may result in reductions in symptoms of BPD through the broad focus on acceptance of painful emotional experiences. This willingness to experience aversive emotional and physical states may lead to an individual's ability to learn new behaviors and responses through exposure to unique or feared situations. Lynch et al. also indicated that mindfulness may increase an individual's ability to regulate emotions through attentional control and "automatic response tendencies [that occur] when the patient observes, describes, and participates in emotional experiences without acting on them" (p. 465). These response tendencies may then alter the context of the event and its associated emotional response.

Similar mechanisms are offered for the benefits of opposite action, which includes choosing an opposite action urge and engaging in an associated behavior when an emotion is not warranted. For example, a client may report that she felt guilt when she said that she could not take on another responsibility at work given her already full plate. Opposite action would involve choosing a behavior that is inconsistent with guilt (e.g., making eye contact, keeping her head up). Lynch et al. suggest that opposite action leads to beneficial therapy outcomes caused by exposure and response prevention, broadening of behavioral responses, and altering cognitive and emotional experiences.

Lynch et al. (2006) also provide several hypothesized mechanisms of action for changes associated with the use of validation and dialectical strategies. They suggest that validation may lead to increased stability of self-views (self-image, sense of self) and increased motivation to participate in therapy. Validation may also influence change strategies occurring in session. Specifically, the purposeful use of validation in session (e.g., increased or decreased) may serve as a behavioral contingency (i.e., validation reinforces skillful actions), as well as a tool for teaching the patients to validate themselves (i.e., modeling). Dialectical strategies (e.g., balancing different communication styles, magnifying tensions) often create an environment in which the patient is not sure about what to expect from the therapist, thus facilitating increased attention and learning of new responses in session.

Several mechanisms are also offered for the effectiveness of targeting specific behaviors and conducting chain analyses of problematic behaviors. Lynch et al. (2006) suggest that these change strategies may be effective through the aversive nature of discussions on these behaviors (e.g., self-harm, drug use). In addition, chain analysis also provides an opportunity for the patient to re-experience painful emotions (e.g., shame) while considering more adaptive alternatives than was selected in the situation being examined. Targeting specific behaviors and chain analysis may also be beneficial as a result of enhanced memory of the chain of events leading to previous problematic behaviors and the selection of skillful responses in subsequent times of vulnerability. Lynch et al. also suggest that these strategies are associated with learning

new skillful behaviors through learning occurring in-session and then obtaining coaching outside of session to gain skill in using these skills in daily life.

The final element of DBT that may enhance therapy outcomes is the client–therapist system. Lynch et al. (2006) suggest that the constant striving for a synthesis of opposite ends of a dialectic may serve to reduce polarization or black-and-white thinking commonly experienced by individuals with BPD and/or elevated suicide risk. In addition, the inclusion of a consultation for the therapist enhances client outcomes through increased therapist efficacy and confidence.

19.5   Basic Competencies of the Clinician

The magnitude of this important public problem underscores the critical importance of adequate training for mental health practitioners to care effectively for individuals at risk for suicide. The National Strategy for Suicide Prevention (Satcher, 2001) includes goals associated with the need for adequate knowledge of issues associated with the assessment and treatment of suicidal behavior. For example, one goal is to implement training for recognition of behaviors associated with increased risk, and delivery of effective treatments for these behaviors. To address this need for adequate dissemination of information regarding suicide and related behaviors, the Suicide Prevention Resource Center (SPRC) partnered with the American Association of Suicidology (AAS) to define core areas that mental health practitioners should gain knowledge to be competent in the delivery of services to individuals who may have heightened suicide risk. In this context, eight "core competencies" were identified (SPRC, 2006). The SPRC defines core competencies as "clusters of knowledge, skills, abilities, and attitudes or perceptions required for people to be successful in their work. In this case, core competencies refer to the clinical evaluation, formulation of risk, treatment planning, and management of individuals at risk for suicide to protect their lives and promote their well-being."

The eight core competencies identified include: (1) Working with individuals at risk for suicide: Attitude and approach; (2) Understanding suicide; (3) Collecting accurate assessment information; (4) Formulating risk; (5) Developing a treatment and services plan; (6) Managing care; (7) Documenting; and (8) Understanding legal and regulatory issues related to suicidality.

Working with the Suicidal Patient: Attitudes and Approach. Discussion on suicide can elicit negative reactions from clinicians, including fear, anxiety, hopelessness, frustration, anger, sadness, avoidance, defensiveness, and others (Birtchnell, 1983). Furthermore, patient deaths by suicide have been associated with therapist reactions of shock, anger, a sense of guilt, anxiety, doubts about competence, grief, fear of blame, shame, and betrayal (Hendin, Lipschitz, Maltzberger, Haas, & Wynecoop, 2000; Mennenger, 1991). While a general sense of anxiety may promote a sense of urgency, many of these reactions can serve to inhibit an effective clinical interaction.

For example, during the second author's (P. N. S.) first intake interview for a department outpatient psychology clinic, he was experiencing some anxiety given that this was his first interview. However, that anxiety spiked to shear panic when the patient said, "I've been feeling really down. In fact, last night I decided that next week [Valentine's Day], I am going to kill myself." At that moment, the second author found himself fearful about not knowing the "right"

thing to do to complete an assessment and reduce the patient's suicide risk. While he had been trained in the appropriate questions to ask, he found the experience very different. The author found himself less concerned with the patient as an individual in pain and more concerned with carrying out procedures. Fortunately, he was receiving good supervision at the time and was able to consult about his feelings and the best way to proceed to ensure the patient's safety.

Clinicians frequently worry about the legal and professional ramifications of patient suicide, which may prompt rigid adherence to a procedure at the expense of a genuine human interaction. Fearful avoidance is also a common reaction that may result in statements such as "Yeah, you think things would be easier, but you'd never do anything like that right?" Strong principles against suicide might even result in admonishment of the patient with statements like, "But how could you do that when you've got children and a family to care for?" Such statements are neither good clinical practice, nor are they helpful for the patient. To *effectively* work with the suicidal patient, it is important that we be aware of our attitudes, fears, and understanding of suicide.

It is important that clinical service providers be consistent in how they interact with patients who describe thoughts of suicide. Extreme changes in a clinical service provider's demeanor can alter a developed alliance, make the patient even more uncomfortable, and possibly influence the patient to keep silent in times when he or she need to be the most vocal about experiences. It is also critical to be clear with patients that you are working toward the same goal (i.e., to end suffering). The patient may view suicide as a solution to psychological, emotional, and/or physical pain (cf., Shneidman, 1996). While it is your goal to ensure the safety of the patient by preventing suicide, it is critical to communicate that you plan to do this by reducing emotional pain. This bridges the goals of the patient and the clinician and helps one to avoid arriving at an impasse of conflicting goals.

Understanding Suicide. A number of theoretical models of suicide have been offered (cf., Baumeister, 1990; Beck, Brown, & Steer, 1989; Durkheim, 1951; Joiner, 2005; Linehan, 1993; Rudd, 2000; Shneidman, 1996). While a full review of these models is beyond the scope of this chapter, having knowledge of these conceptualizations allows a more effective understanding of patients. For example, in the example provided above, it would be most effective to communicate to the patient a goal of reducing the current emotional pain by focusing on those experiences that are functionally implicated in the patient's suicide symptoms (according to theories mentioned earlier). In this case, the patient's depression could be linked to unfulfilled needs for affiliation and the lack of romantic relationship; hence, the implication for the chosen day for his planned suicide. This level of understanding could have led to a discussion on how the patient's difficulties in these areas may have been related to his distress and to begin to discuss how things could be done to remedy those problems. A collaborative discussion of this nature allows the suicidal client the opportunity to describe his or her concerns in a manner that may instill hope.

The understanding of suicidal behavior is also facilitated through the conceptualization of the behaviors included in various treatment approaches (e.g., Linehan, 1993; Rudd et al., 2001). Within DBT, self-harm and other suicidal behaviors are partly conceptualized as emotional regulation strategies. The use of various skills, such as distress tolerance, may diminish the emotional pain that lead to a desire to engage in self-harm. Rudd et al. provide four interactive processes (cognitive, behavioral, physiological, effective) that are associated with suicidal behavior. Thus, a clinician's clear understanding of this suicidal mode for a given client may facilitate recognition of changes in risk.

Collecting Accurate Assessment Information. As managed care becomes an increasingly important element of psychological service provision, clinical service providers are increasingly required to limit the amount of time they spend with patients (Hayes, Barlow, & Nelson-Gray, 1999). This requires providers to prioritize the issues discussed, often leaving off many things patients would like to cover. Despite these increasing limitations and the avoidance behaviors evoked by the anxiety associated with suicide, ensuring that a clinical service provider makes an inquiry regarding suicide risk is of paramount importance. When determining how and when to incorporate questions about suicide symptoms, a number of approaches are available. These approaches can be viewed as more or less appropriate in light of considerations such as the setting, the therapeutic alliance, and the immediacy of risk.

The first approach is most appropriate for patients in ongoing individual or group therapy. This therapeutic context allows for the incorporation of ongoing assessment, be it objective testing, weekly check-ins, or other forms of monitoring. For example, a patient being treated for Major Depression might complete the Beck Depression Inventory-II each week prior to the session. This instrument includes an item inquiring about suicide symptoms that can be readily scanned before the session begins. DBT for BPD incorporates diary cards that explicitly include monitoring of suicide and self-harm symptoms (Linehan, 1993). These cards are typically used early in individual sessions, as suicide and self-harm are treated as the highest priority in this treatment.

Encounters that do not lend themselves to such brief initial assessment of symptoms on an ongoing basis should also include attention to suicide symptoms early in the interview. For example, intake screening interviews, consultation interviews, and other brief, focused encounters may not allow for formal testing or include an established therapeutic relationship; making it difficult to address suicide symptoms directly and early. However, that does not absolve the clinical service provider from assessing suicide symptoms.

In such situations, we have found it helpful to offer a comment aimed at initiating rapport. For example, statements like, "I know it can be difficult to talk about these problems and experiences with someone you've just met. I really appreciate you taking the time to talk to me and I really want to work with you to do whatever we can to help you out." Such a statement will serve to validate any discomfort the patient is experiencing, demonstrate that you are on their side, and begin to facilitate a collaborative, non-adversarial relationship.

Following such an initiation at developing rapport within brief encounters, we have also found it helpful to present a number of questions as standard questions that may or may not apply to them. Such questions can include items addressing attention, memory, and orientation to the situation, psychotic symptoms, identifying information, living arrangement, occupation, and suicide symptoms. Presenting questions about suicidal symptoms in a standardized manner may help one to remove the discomfort experienced by the patient and the interviewer in situations in which rapport has not yet been fully established. However, it is important to note that such questions should be offered in a way that normalizes and reduces the stigma patients often associate with their suicide symptoms.

Inquiring about suicide symptoms early in an interview can be vital to identifying potential risk early and allowing for ample time for thorough assessment and safety management. However, directly addressing suicide symptoms early in a manner that elicits truthful responding may not always be possible. For patients who are defensive, interpersonally distant, or overtly anxious, the interviewer may be required to work up to directly addressing suicide. By beginning with less threatening material and actively working to demonstrate empathy and

establish a collaborative alliance, the encounter can move toward a more safe and open interaction in which the patient is more likely to report suicide symptoms accurately.

Regardless of which approach is most appropriate, inquiring about suicide symptoms is essential. Many patients may not offer information on their suicide symptoms without prompting and some health service providers do not inquire about suicide. The importance of this is highlighted by statistics that suggest that many older adults who go on to die by suicide often have contact with medical service providers within the month prior to suicide (Conwell, 1994). Additionally, when asking questions about suicide, it is important to be direct and thorough (Goldberg, 1987). Asking questions in a manner that is vague and evasive can cause confusion and further discomfort. Questions about suicide should be explicit and direct and should not stop with an initial denial of current suicide ideation. For example, a patient who reports that they are not thinking about suicide should be asked about past suicide attempts and ideation. Such a direct, thorough addressing of suicide symptoms early in an encounter in a manner that is empathic and promoting of rapport will serve to elicit more accurate information that can be used to determine appropriate safety and treatment plans.

Formulating Risk. The information we have discussed thus far describes important symptoms, risk factors, and warning signs for suicide. While we have suggested that the cumulative effect of a number of risk factors is suggestive of greater risk of suicide, a more structured manner of risk designation is warranted. Specifically, we argue that the combination of these risk factors can effectively designate an individual's level of suicide risk as low, moderate, or high. Note that this system emphasizes risk factors as opposed to warning signs (Bryan & Rudd, 2006). Furthermore, the designation of risk does not perfectly correlate with actual risk of suicide. Such prediction, as we have stated, is impossible.

A number of studies have demonstrated that the single strongest predictor of future suicide attempts is past attempts (Joiner et al., 2005). As a consequence, the formulation of risk we have adopted begins with the designation of attempt status. For those patients with a multiple suicide attempt history, the presence of any other significant risk factor confers at least a moderate risk (see Joiner et al., 1999 for a thorough description of risk designation). For multiple attempters who evidence a number of risk factors and prominent suicide symptoms associated with resolved plans and preparations, a designation of high risk is warranted. Individuals with a single or no suicide attempt history will be designated as at least moderate risk if they also evidence symptoms of resolved plans and preparations and an additional risk factor. Single and non-attempters would be designated as high risk if they also experience multiple additional risk factors. Lastly, individuals with a single or no suicide attempt history who do not evidence resolved plans and preparations would only be designated to be at least moderate risk if they also report suicide ideation and the desire for death in combination with two or more additional risk factors. Individual exhibiting no risk factors or suicide symptoms can be designated as low suicide risk.

Guidelines for intervention based on the risk designation have been offered (Cukrowicz, Wingate, Driscoll, & Joiner, 2004; Joiner et al., 1999; Rudd et al., 2001). Patients who at low risk should be given the phone number and locations of emergency facilities they can contact in the event that any crisis occurs. Patients who are at moderate risk should be monitored closely and treatment should be continued outside of the emergency setting. At this point, it is critical to consider increasing the frequency of therapy sessions and contact with the client to ensure ongoing awareness of changes in suicide risk. The patient should also be encouraged to seek out additional supportive individuals and communicate his or her feelings (i.e., only in safe,

supportive relationships). Patients should also be provided with information regarding steps to take in the event of increased thoughts of suicide or urges for suicidal behavior, as well as locations and phone numbers for crisis services (e.g., 1–800–273-TALK, 911, emergency room).

Finally, for patients at high risk, it is necessary to ensure safety through immediate evaluation for inpatient or emergency care. It is imperative that patients understand safety concerns and the reasons for requiring this evaluation and likely inpatient hospitalization. Following explanation of these concerns, the patient should be encouraged to voluntarily go to the emergency facility. In the event that the patient is driving or being transported by a friend, family member, or significant other, it is wise to let them know that you will call the facility to ensure they arrived safely. In the unlikely event that the person does not go as expected, you will then need to contact emergency services (e.g., the police) to pick up the individual and transport them. Similarly, if the patient refuses to go to the emergency facility for evaluation, you must contact an appropriate agency (e.g., the police) to transport your patient "involuntarily." Regardless of the level of risk and associated actions, it is critical that you continue to assess suicide risk regularly and document all actions taken to ensure the patient's safety.

Developing a Treatment and Services Plan. After the suicidal client has received a detailed psychiatric evaluation, it is imperative that a safety plan be developed in collaboration with the client. Bridge, Goldstein, and Brent (2006) indicate that the development of a safety plan often consists of the creation of a list of behaviors that the client can use to facilitate emotion regulation during future crises. A discussion of the events that preceded the most recent suicidal crisis may also help the client identify the feelings that preceded his or her urge to self-harm. A safety plan should also include specific strategies to eliminate the suicidal client's access to potentially lethal instruments (Bridge et al., 2006; Huey et al., 2004) including knives, firearms, large doses of medication, sheets, and rope. Eliminating access may often require that the clinician ensures that appropriate precautions have been taken; for example, Simon (2007) asserts that plans to remove a suicidal individual's access to guns should involve careful (and collaborative) follow-up with the person who has been designated to remove or secure the guns.

The development of a safety plan is complimented by the formation of a written plan for the suicidal client's utilization of mental health services. The format and content of this plan should be tailored to the suicidal individual's level of risk. Individuals who experience suicide ideation of limited duration that is not currently intense may be best suited to a plan that involves the provision of telephone numbers for emergency facilities that the client can call if they experience a crisis (Cukrowicz et al., 2004) and, if the client is not already seeking mental health services, the arrangement of an appointment with an outpatient provider (Roberts, 2002).

The treatment and services plan devised for individuals who are experiencing more intense and frequent thoughts of suicide but do not have an immediate plan to act on these thoughts may consist of a few additional elements distinct from the basic plan. This plan may describe a need for longer or more numerous therapy sessions and detail the specific efforts that will be employed to stay in frequent contact with clients who are struggling to stop thinking about suicide (e.g., telephone monitoring, weekly updates from close family members). For clients with this level of ideation, the written treatment plan might also specify that there will be ongoing monitoring of the client's level of risk and request that the client will contact their mental health provider if he or she begins to feel compelled to act on suicidal thoughts (Cukrowicz et al., 2004). Clients with thoughts of suicide may also benefit from having a detailed action plan to follow in the event that their desire to engage in suicidal or self-injurious behavior intensifies. The steps associated with the action plan are often provided on a "crisis card" that the client and the

therapist develop together. According to Joiner (2005), strategies provided on the crisis card help the client to identify non-suicidal activities that can be used to relieve feelings of distress (e.g., engaging in stress-reducing activities that have allowed the client to feel better in the past). If the client's suicidal impulses are not sufficiently diminished by trying the earliest strategies suggested on the crisis card, subsequent steps instruct the individual to call an emergency contact person or go to the emergency room.

Managing Care. Managing the care of a suicidal client requires that providers promote compliance to treatment and make efforts to ensure that patients continue to receive psychiatric services (Appleby et al., 1999). With respect to the first of these elements, treatment compliance, therapists should make efforts to foster an open and supportive atmosphere in which patients can address any obstacles that they encounter during the course of therapy. Jacobs et al. (2003) cite a number of different reasons that clients do not adhere to their mental health treatment, including financial limitations, difficulty in finding transportation, scheduling conflicts, confusion regarding the requirements of the treatment (e.g. uncertainty about a therapeutic homework assignment), and disagreement with the mental health provider over the recommended course of treatment.

Nevertheless, there is some evidence to suggest that consistent and thorough tracking procedures may enhance treatment compliance. In one study of adolescent suicide attempters (Piacentini et al., 1995), initial therapy appointments were scheduled within 1 week of the time that the clients were evaluated at the emergency room. Therapists kept weekly records of all therapy appointments that had been scheduled and attended or missed by each individual. Therapists called clients who missed appointments within 24 hours to arrange a time for another session. The use of this intensive follow-up approach made it considerably more likely that the adolescent attempters would participate in the early stages of treatment. Another study (Spirito, Boergers, Donaldson, Bishop, & Lewander, 2002) suggests that introducing a pre-treatment discussion on what a client can expect when receiving outpatient care and reviewing the factors that may make it less likely that the client will attend treatment improves treatment adherence among suicidal adolescents when the influence of barriers to treatment (e.g., problems with insurance coverage) are controlled.

Managing an individual's psychiatric care also involves careful attention to the manner in which treatment-related services are coordinated. Deliberate and comprehensive management of an individual's mental health services is important because loss of contact with a mental health service provider has been described as an event that commonly occurs prior to death by suicide (Appleby et al., 1999). In addition, research suggests that adult (Van Heeringen et al., 1995) and adolescent (Granboulan, Roudot-Thoraval, Lemerle, & Alvin, 2001; Piacentini et al., 1995) suicide attempters who are hospitalized frequently do not seek follow-up outpatient services. By one estimate, nearly half of all adolescents who visit the emergency room on account of suicidal behavior do not seek subsequent mental health care (Spirito, Brown, Overholser, & Fritz, 1989).

Fortunately, some evidence suggests that providing some degree of continuity among mental health services can make it more likely that suicidal individuals will remain in treatment. Granboulan et al. (2001) discovered that the adolescent suicide attempters who were more likely to seek psychotherapeutic services following their discharge were given specific instructions to seek treatment (as evidenced by the discharge plan). They also noted that individuals who received a greater number of psychotherapy sessions while being hospitalized were more likely to seek subsequent outpatient care. Jacobs et al. (2003) suggest that the coordination of mental health services can be further facilitated by regular communication between mental

health service providers, the provision of telephone numbers to call if problems or questions arise, and periodic check-ins with family members to ensure that the treatment and safety plans are being implemented.

Documentation. Comprehensive treatment of suicidal clients necessitates the use of thorough documentation procedures. For each client, a specific treatment plan, diagnostic information, psychosocial history, and information associated with any assessments should be described in detail (Callahan, 1996). Comprehensive progress notes should also be written to depict the nature of psychotherapeutic efforts and to afford a record of the information obtained through clinical interviewing (Cukrowicz et al., 2004). Another particularly important element of record keeping for suicidal clients is assessment of suicide risk. According to Jacobs and Brewer (2004), the ongoing assessments of suicide risk should provide evidence to illustrate why a patient is currently experiencing the determined level of risk. In addition, suicide risk assessments should contain a description of any alterations made to the treatment plan and the reasons for these changes.

Documentation should also occur whenever there is communication between the healthcare provider and the patient's family. Further, any discussion with family members about specific plans to eliminate a suicidal client's access to firearms or other lethal materials should be described in the patient's record (Jacobs et al., 2003). The need for documentation extends to the health professional's interactions with colleagues. Documentation should reflect any circumstances under which the healthcare professional sought group or peer consultation (Cukrowicz et al., 2004).

When documenting risk assessment and resultant clinical decisions, it is important to not only identify what pertinent information was collected and what specific clinical interventions were enacted, but to provide a rationale supporting those decisions using clear and consistent terminology (Bryan & Rudd, 2006). For example, the following documentation would quite likely be insufficient: "During individual therapy session with patient, he indicated that he was having thoughts of suicide. On discussion of these thoughts with the patient, he was deemed to be at low risk for suicide." Such a note lacks specific information that is required to justify action or inaction in such cases.

A second example is more consistent with complete documentation including a description of the pertinent information, a designation of risk, a description of the intervention, and rationale for that intervention: "During an individual therapy session, the patient reported that he was experiencing thoughts of suicide. Specifically, he reported that he had thoughts like 'Things would be better off if I were not around and I may as well just get it over with.' On questioning, the patient denied having developed a specific plan or experiencing any urges to act on these thoughts. Furthermore, the patient denied having any previous suicide attempts and identified a number of protective factors including finishing school, obtaining a job, and his current romantic relationship. The patient has also demonstrated positive use of coping skills and distress tolerance skills during treatment. However, as the patient experiences suicide ideation and a number of risk factors for suicide (i.e., Major Depressive Disorder, alcohol abuse, and a general pattern of impulsivity), he was designated to be at moderate risk for suicide. Therefore, a crisis management plan was adopted. The patient identified specific distress tolerance skills he would use during increases in suicide ideation. The patient also indicated three significant individuals he could contact in the event distress persisted. Lastly, the patient was given phone numbers for a national crisis hotline and the local emergency department. The patient has also been instructed that additional therapy sessions are available if suicide

symptoms persist. This case was further discussed with the treatment team and consensus reached on the identified plan."

The latter note contains essential elements that suggest that a thorough assessment was conducted, an appropriate plan was enacted, and that this plan had a rationale. Furthermore, it is often a good practice to receive supervision or to consult with other experienced colleagues. Such consultation further affirms that the identified assessment and plan was adequate and justifiable.

Understanding Legal and Regulatory Issues Related to Suicidality. A variety of legal issues are relevant to the care of individuals at risk for suicide. Awareness of the laws regarding mandatory evaluation or hospitalization for the protection of clients who may engage in suicidal behavior is important because these statutes vary from state to state. It is also important for practitioners to be aware of these laws so that they may strive to ensure adequate compliance. As noted above, clinicians should practice thorough documentation to ensure that the rationale for specific decisions and interventions can be understood by others examining the records. Incomplete documentation may result in greater vulnerability to lawsuits in the event of a patient suicide attempt or death by suicide. Documentation should make it clear that the therapist is engaging in services that meet the standard of care, defined as "degree of care that a reasonable person should exercise" (Black, 1996, p. 589). According to Packman, O'Connor Pennuto, Bongar, and Orthwein (2004), several allegations occur commonly in malpractice complaints following a patient suicide: "failure to predict or diagnose the suicide, failure to control, supervise, or restrain, failure to take proper tests and evaluations of the patient to establish suicidal intent, failure to medicate properly, failure to observe the patient continuously (24 hours) or on a frequent enough basis (e.g., every 15 min), failure to take an adequate history, inadequate supervision and failure to remove dangerous objects, such as a patient's belt, failure to place the patient in a secure room" (p. 700).

The two primary legal issues associated with suicide are forseeability and reasonable care. Forseeability refers to the actions required for a therapist to thoroughly evaluate known risk factors and current thoughts and behaviors to arrive at a decision regarding the patient's risk for suicidal behavior (Jobes & Berman, 1993). Following this risk determination, the therapist is expected to establish and follow through with a treatment plan based on this risk level (i.e., reasonable care; Jobes & Berman). Again, documentation is critical to ensuring clear communication with other professionals regarding these actions. This documentation and all client records are protected through the Health Insurance Portability and Accountability Act of 1996 (effective April 15, 2003). It is important that clinicians are familiar with this Act and compliance with these privacy and confidentiality policies.

19.6 Transition from Basic to Expert Competence

Within the field of suicidology, there are no defined and agreed upon criteria that mark the transition from basic to expert competence. Rather, it is the accumulation of knowledge over a period of time spent engaged in research or clinical activity within this field that marks this "expert" status. Drawing from the expert performance literature in cognitive psychology, Ericsson, Krampe, and Tesch-Romer (1993) indicate that deliberate practice is critical to establishing expertise in a particular area. Ericsson and colleagues (2007) indicate that deliberate practice is "a very special form of activity that differs from experience and mindless drill" (p. 18). They go on to explain that deliberate practice involves engagement in practice activities

that change and refine elements of performance required to move to the next level of skill through the acquisition of more complex cognitive mechanisms.

Considering this conceptualization, expert competence in suicidology would require an individual to devote a significant amount of time (i.e., years) to gaining and mastering knowledge of suicidal behavior across the domains described above (basic competencies). An expert would emerge as the individual progressed for a more basic level of knowledge to an advanced and complex understanding of this field. The expert suicidologist would gain this skill through a variety of mechanisms, including review and mastery of the literature; expression of knowledge through writing of case conceptualizations, reports, manuscripts, or books; providing services to patients; supervising trainees in attaining basic competence; and application of these areas of knowledge to advancing the science of suicidology.

It is common for the generation of this level of expertise to develop during periods of time with intensive exposure to clinical populations presenting with elevated suicide risk. The day-to-day practice of psychotherapy with patients at risk for suicide requires application of the basic competencies described above, as well as refinement of these skills. For example, a basic level of competence may be present in a clinician who occasionally treats patients with slightly elevated suicide risk (e.g., suicide ideation in the absence of plans or preparations for suicide). This individual has knowledge of many of the risk factors for suicide, methods for assessment, and guidelines for determining level of suicide risk. In contrast, expert competence is gained by a clinician who works primarily or exclusively with individuals presenting for treatment of suicidal behavior, perhaps as a function of recurrent or chronic depression or BPD. The latter clinician quickly becomes intimately familiar with models of suicide (e.g., Joiner et al., 2005; Linehan, 1993) and their implications for conceptualizing and treating these high-risk patients. This daily exposure to patients who think about suicide and have attempted suicide requires "finger tip" knowledge of theories of suicide that can be used to understand and explain painful emotions and urges for self-harm and suicide to patients. Further, expertise is gained through training and implementation of treatments designed for suicidal patients (e.g., CT, CBT, DBT).

To more clearly articulate an example of expert competence, we will provide examples of performance abilities across the basic competencies described above. The first of these competencies includes the attitude and approach to working with individuals at risk for suicide. Through acquisition of a high level of skills, the expert suicidologist is keenly aware of their emotions, thoughts, and opinions regarding their patient and the possibility of suicidal behavior. In addition, the expert may continue to feel some anxiety from time to time during crisis and high-risk situations; however, this does not impede performance as it might for an individual with a basic level of competence. Further, greater understanding of suicide allows the expert to discuss common goals with a patient (i.e., eliminating psychological pain) with a level of skill that prevents the patient from feeling that he or she has "given in" to the therapist by letting go of suicide as an option. This skillful discussion of the patient's experiences and goals evolves into a collaborative treatment plan. Finally, experts have a clear understanding of the time and resources required to treat individuals at risk for suicide and maintain clear boundaries with regard to the number of patients they will treat at any given time. Further, experts have knowledge of their limitations and needs for consultation and support and are able to seek this out from colleagues when needed.

The second basic competence is understanding suicide. This area of competence involves mastery of terms, statistics, risk factors, and models of suicide. The primary difference between an individual with basic competence and expert competence is the breadth of this knowledge.

The expert suicidologist typically is aware of more information (e.g., genetic risk factors, differences in risk factors for individuals of differing ethnic, age, and racial groups, studies finding patterns of differing results, etc.) and typically possesses an area of specialty. For example, many clinicians are trained intensively to deliver DBT for individuals with BPD. This level of training provides a breadth of knowledge that goes beyond basic competence. Researchers often gain specialized training in a particular theoretical approach, age or ethnic group, study design, or type of research that investigates specific risk factors for suicidal behavior. Regardless of the content area of specialized training, an individual's depth of understanding of suicidal behavior in that specialty area typically far surpasses that of others.

Experts also possess greater knowledge and skills in collecting accurate assessment information and formulating suicide risk. Through years of practice, an expert will have learned a broad range of assessment tools that can be used for assessment of specific risk factors that they have identified during early interactions. For example, while interviewing a patient during the intake session, the patient indicates that her emotions feel "out of control" sometimes and she has difficulty turning her attention away from urges to cut herself as a method of regulating these intense emotions. The suicide expert might ask the patient to complete the Affect Intensity Measure (Larsen, 1984) as well as asking her to indicate the number of times she has attempted suicide and engaged in self-harm. Such information as to her attempt history and the functions of self-harm are integrated with other assessment information (e.g., diagnostic status, hopelessness, plans for suicide) to allow the clinician to formulate risk with greater specificity than a clinician with basic competence. For example, the collection of information as described above would allow an expert clinician trained in the Rudd et al. (2001) CBT approach to define the suicidal mode of the client, including details about cognitive, behavioral, physiological, and affective experiences associated with heightened suicide risk states.

Development of a treatment and services plan and management of care most likely differs in content for a clinician with a greater depth of expertise in the treatment of suicidal behavior. For example, a clinician with basic competence may have no formal training in treatments designed for suicidal behavior, and would require supervision or consultation in their implementation. An expert is very likely to have gained an advanced level of training and had opportunities to use these treatments with patients presenting with a variety of presenting problems (e.g., severe depression, personality disorder, schizophrenia, eating disorder). Further, through consistent use of these treatments, experts have gained skill in the development of safety plans, crisis intervention and skills coaching, and enhancing client motivation to engage in these activities during times of crisis. Further, experts are able to engage clients in role-play and other exercises aimed at increasing knowledge of skillful behaviors and modification of crisis-oriented cognitive states. Expert clinicians also make significant efforts to reach out to other practitioners (e.g., psychiatrists, psychiatric nurses, homecare providers) to share assessment information and work together to ensure collaborative treatment plans and implementation.

Expert clinicians have gained years of practice in their work with clients and keep careful record of informed consent, information that was collected from a biopsychosocial perspective, the formulation of risk and rationale, a well-described treatment plan, the follow through with treatment plan, and consultation with professional colleagues (Rudd, Cukrowicz, & Bryan, 2008). Finally, expert clinicians possess a greater depth of understanding of legal and regulatory issues related to suicidality. For example, experts gain legal knowledge beyond that required for practice when testifying in cases of patient suicide attempt or death. In addition,

experts often consult with colleagues in states that have different policies and procedures with regard to state laws and statutes, as well as licensing regulations.

The transition from basic competence to expert competence occurs over a period of years, typically while one is in training. The form of training required to acquire expert competence in suicidology is flexible and may include pre-doctoral internship, post-doctoral or fellowship training, or intensive trainings sought after one has achieved an independent position (e.g., solo practitioner, assistant professor). This training must be provided by an individual who has achieved an expert level of competence to move the trainee to this level. This level of skill is not typically associated with graduate students; however, it is conceivable that a graduate student trained by an expert and provided with near constant ability to work with suicidal patients may gain a level of expertise that is similar to most experts.

The transition from basic competence to expert competence is often a time during which the individual reserves a significant amount of time to devote to self-awareness, content mastery, and skill acquisition. As indicated in the previous section, this development transition will occur most naturally during times of delivery of clinical services to a large number of patients with elevated suicide risk. As with any other skill, it is nearly impossible to gain this level of expertise without consistent access to individuals with the risk factors, psychological disorders, suicide history, and unique characteristics that are seen in individuals at risk for suicide. The cognitions, behaviors, histories, and psychological profiles of suicidal patients are never the same, thus, as with any other skill, expertise comes through learned to effective enact all areas of competence regardless of patient differences.

19.7 Summary

The goal of this chapter was to aid clinicians in developing skills associated with assessing and treating patients at risk for suicide. This chapter has presented an overview of risk factors for suicide, as well as important information regarding the assessment of and determination of suicide risk. Two prominent theories of suicidal behavior were discussed that include psychological experiences that may maintain suicidal behavior. This section also included a number of robust cognitive, emotional, and behavioral experiences that are associated with continued self-harm and suicide attempts. An overview and data supporting several empirically based treatment approaches were presented, including intensive follow-up treatment, CT, CBT, psychodynamic interpersonal psychotherapy, and DBT. The mechanisms underlying one of these treatments (DBT) were then discussed to provide additional information on key treatment ingredients that are associated with reduction in symptoms associated with suicidal behavior. The eight basic competencies developed by AAS and the SPRC were described, including working with individuals at risk for suicide: attitude and approach; understanding suicide; collecting accurate assessment information; formulating risk; developing a treatment and services plan; managing care; documenting; and understanding legal and regulatory issues related to suicidality. The subsequent section of the chapter described the required knowledge and skills of expert competency in suicidology, as well as examples of expert performance in the areas of competence described here. The final section of the chapter included learning and developmental experiences that occur during the transition from basic competence to expert competence. This section also included an example providing an overview of training experiences that fostered this transition.

20 Managing Pain*

Robert J. Gatchel · Nancy D. Kishino

Abstract: The prevalence and cost of chronic pain is a major mental and physical health care problem in the United States. As a result, this has fueled a great deal of clinical research on the assessment and treatment of chronic pain. Such clinical research has led to the development of the biopsychosocial model of chronic pain, which has been shown to be the most widely accepted and most heuristic perspective in the assessment and treatment of chronic pain. This model uses physiologic, biologic, cognitive, emotional, behavioral and social factors (as well as their interplay) when explaining a patient's report of pain. In fact, in order to comprehensively assess chronic pain, one must be certain to account for such potential interactions before prescribing the best treatment regimen, which must also be individually tailored for a particular patient. The present chapter will review this biopsychosocial model, and also discuss how the model has led to the development of comprehensive interdisciplinary pain-management programs. These interdisciplinary programs have been demonstrated to be more treatment- and cost-effective than traditional medical programs that focus only presumed pathophysiology. A review of the core ingredients of these pain-management programs will be provided, as well as the basic mechanisms of change underlying such intervention and the basic competencies of health care providers involved in such interdisciplinary pain management.

20.1 Overview

As noted by Gatchel, Peng, Peters, Fuchs, and Turk (2007), the prevalence and cost of chronic pain is a major physical and mental health-care problem in the United States. For example, epidemiological research has revealed that chronic pain (which can loosely be defined as prolonged or persistent pain of at least 3 months in duration) and chronic recurrent pain (i.e., recurrent episodes of pain interspersed with pain-free periods extending over months or years) affect about 10–20% of adults in the general population (Gureje, Von Korff, Simon, & Gater, 1998). Indeed, in a large-scale epidemiological study, Von Korff et al. (2005) estimated a 19% prevalence for chronic spinal pain (neck and back) in the United States in the previous year, as well as a 29% lifetime rate. It should also be noted that individuals aged 50 years and older are twice likely to have been diagnosed with chronic pain (Gatchel, 2004, 2005). Presently, there are approximately 35 million Americans aged 65 years or older, accounting for 12.4% of the total population. Added to that, the fact that the proportion of the population aged 65 and older is expected to increase by 57% by the year 2030, with Americans now having an average life expectancy of 77 years (Social Security Administration, 2005), has strikingly increased future health-care issues of older Americans, including chronic pain problems. Finally, as summarized by Gatchel (2004, 2005), pain is a pervasive

medical problem that affects over 50 million Americans and costs more than $70 billion annually in health-care costs and lost productivity. It also accounts for more than 80% of all physician visits and is often associated with major comorbid psychiatric disorders and emotional suffering.

The above strikingly high statistics have, fortunately, fueled a great deal of clinical research on the assessment and treatment of chronic pain. The purpose of the chapter is to provide a review of the most noteworthy advances in the area of the management of chronic pain. As will be initially discussed, the *biopsychosocial* model has been shown to be the most widely accepted and most heuristic perspective to understanding and treating chronic pain. Emanating from this biopsychosocial model, interdisciplinary pain management programs have been developed and shown to be both treatment- and cost-effective. In stark contrast to the biopsychosocial model and interdisciplinary pain management programs that have been developed in recent years is the traditional and outdated approach that embraced a dualistic viewpoint that conceptualized the mind and body as functioning separately and independently. The repeated demonstration of the inadequacy of this dualistic model contributed to a growing recognition that psychosocial factors, such as emotional stress, could affect the reporting of symptoms, medical disorders, and response to treatment (Gatchel, 2004). In fact, George Engel (1977) is credited as one of the first clinicians to call for the need of a new approach to replace the outdated and overly simplistic biomedical reductionist philosophy that dominated the field of medicine since the Renaissance. This subsequently led to the growth of the field of health psychology and behavioral medicine (Gatchel & Baum, 1983), which, in turn, stimulated the development and evolution of the biopsychosocial model. As noted above, this model has been especially influential in the development of more effective interdisciplinary chronic pain management approaches.

20.2 Recognition of Symptoms and Their Assessment

As succinctly summarized in numerous recent publications (Gatchel, 2004, 2005; Gatchel et al., 2007), the biopsychosocial model conceptualizes pain as a complex and dynamic interaction among physiological, psychological, and social factors, which often results in, or at least maintains, pain. Chronic pain cannot be broken down into distinct, independent psychosocial, or physical components. Each individual also experiences pain uniquely. The complexity of pain is especially evident when it persists over time, as the range of psychological, social, and economic factors can interact with physical pathology to modulate each patient's report of pain and subsequent disability. The biopsychosocial model uses physiologic, biologic, cognitive, emotional, behavioral, and social factors, as well as their interplay, when explaining a patient's report of pain. Thus, in order to comprehensively assess chronic pain, one must be certain to account for such potential interactions before prescribing the best treatment regimen, which must be individualized for a particular patient. Gatchel (2004) offers an example of how such factors must be considered in the biopsychosocial assessment of chronic pain:

► [A] patient may present with chronic pain resulting from an earlier accident, which produced a severe musculoskeletal injury, such as bone fractures and ligament tears that have not completely healed. Besides these physical injuries and resulting pain, the accident may have led to the

inability to work again. The patient might also have self-esteem problems because he or she is viewed as being disabled and is stigmatized by it. This may have also resulted in economic problems and stressors because of the sudden decrease in income. There are debts to be paid, causing family stress, turmoil, and guilt. If this patient comes from a "macho" culture in which work and activity are highly valued, there may be even more psychosocial distress. Thus, as one can see, there are potentially multiple levels of psychosocial issues that all need to be assessed before one can develop a comprehensive pain management program for a patient such as this…One may need to assess the patient individually, as well as in the context of the family, workplace and other social situations. This is not an example of an atypical chronic-pain patient; it is more the norm than the exception. (p. 24)

There are now a number of assessment techniques that have been developed for chronic pain patients (e.g., Gatchel, 2004; Turk & Melzack, 2001). It should also be noted that several important organizations in the United States have developed new standards for the evaluation of pain. For example, the Joint Commission on Accreditation of Healthcare Organizations (JCAHO, 2000) now requires that physicians consider pain to be the *fifth vital sign* (added to pulse, blood pressure, core temperature, and respiration) when evaluating patients. The JCAHO guidelines require that pain severity be documented, using a pain scale. In addition, the following assessments also need to be made:

- The patient's own words describing his or her pain
- Pain location, duration, and aggravating and alleviating factors
- Present pain management regimen and its effectiveness
- Effects of pain
- The patient's pain goal
- Physical examination

All of these factors need to be documented on initial assessment, along with a more thorough biopsychosocial evaluation when the pain is chronic in nature. This is important because, if not assessed and not treated, many of these biopsychosocial factors can serve as maintenance variables of the chronic pain condition, to be discussed in the following section.

20.3 Maintenance Factors of Chronic Pain

In keeping with the biopsychosocial conceptualization of pain, there are many individual differences in how people respond in the face of nociception and differences in the methods used to understand and interpret the painful stimuli. Thus, as emphasized by Turk and Monarch (2002), this makes the experience of pain dependent upon *cognitive-evaluative processes* and on *affective-motivational processes*. In terms of the *cognitive-evaluative processes*, individuals evaluate pain in terms of the perception of the consequences of the pain, the importance of the pain, and their perceived ability to quote with the pain. These various factors are delineated in ⊙ Table 20.1. These are all important factors that need to be carefully evaluated in order to determine whether they need to be addressed in the treatment.

In terms of the *affective-motivational processes*, cognitive appraisal of pain can lead to a variety of affective responses that, in turn, can affect a patient's motivation to seek and/or continue treatment. For example, patients who perceive their pain as "out of control" or as a threat

◘ **Table 20.1**

The cognitive-evaluative processes associated with pain (Turk and Monarch, 2002)

Beliefs about pain
Certain beliefs about pain (e.g., the pain signifies ongoing tissue damage; the pain is likely to persist; the pain is indicative of some underlying disease; the pain will increase if one engages in exercise behaviors or simple activities) will result in maladaptive coping, feelings of helplessness, and exacerbation of pain, increased suffering, and greater disability
Beliefs about controllability
Beliefs that one's pain cannot be controlled can lead to negative effects: subsequent nociceptive input perceived as more intense than it actually is (i.e., overreaction); decreased activity level in the hope of minimizing the pain; inappropriate medication use; psychological sequelae such as demoralization, learned helplessness/depression, and poor psychosocial functioning
Self-efficacy
Self-efficacy refers to one's belief or conviction that he or she can successfully perform certain required behaviors in a particular situation to provide a desired outcome. This construct has been shown to be an important mediator of therapeutic change. It has been demonstrated that a patient's report of low self-efficacy regarding pain control is associated with low pain tolerance, poor psychosocial functioning, greater impairment and disability, and poor behavioral treatment outcome
Cognitive errors
Cognitive errors, such as *catastrophizing* (thoughts or images anticipating negative outcomes of aversive aspects of an experience), *overgeneralization* (assuming that the outcome of one event will apply to the outcome of all future or similar events), and *selective abstraction* (paying attention only to the negative aspects of an experience, while ignoring positive aspects), can greatly influence the experience of pain and disability, as well as the concomitant depression
Coping
A number of overt and covert coping strategies can help individuals deal with pain, adjust to pain, or minimize the distress caused by pain. Overt behavioral coping strategies include simple rest, the use of relaxation methods, or the use of medication. Covert coping strategies include methods such as distracting oneself from pain, seeking information from various sources, and problem solving

are more prone to emotional distress. This affective-state-associated pain spans the spectrum, from vague unpleasantness to more discrete emotions such as fear, anger, and depression. This relation between affect and pain is both dynamic and complex. Fernandez (2002) for example, has described this as a six-factor relationship:

- When there is a maladaptive personality trait or a prior trauma, affect can be a predisposing factor in how pain is experienced and presented during evaluation.
- The affect or emotion of anxiety can often trigger pain. For example, we know that as anxiety increases, pain threshold decreases.
- Relatedly, pain and affect can be correlational in nature, necessitating the careful evaluation of their interrelationship.
- Pain may be exacerbated by affective state, such as in the case of anger creating tension that can aggravate the already existing pain (e.g., as in the case of muscle tension headache).
- Affect is often a consequence of pain, which is then referred to as "distress."

- Affect can also perpetuate pain. If a patient receives a great deal of secondary gain (such as increased nuturance and attention received from others), then he or she may use pain to get these needs continually met.

Thus, as can be seen, there is often a dynamic relationship between affect and pain. Affect can be both a consequence and an exacerbating factor in pain. It can be explained as pain causing stress, which causes more pain, more stress, and so on. Finally, the motivational aspects of this affective-motivational part of pain perception refer to an individual's willingness to perform certain behaviors. Because pain is a subjective, private, and unpleasant experience, a number of negative emotions are usually associated with it that can maintain it. Affect often leads to action, such as approach and avoidance (which are the simplest forms of action). Again, Turk and Monarch (2002) have delineated the common affective factors associated with pain: depression/learned helplessness, anxiety/pain-related fear, and anger/frustration.

Finally, there is often a significant comorbidity of chronic pain and psychiatric disorders (Dersh, Polatin, & Gatchel, 2002; Gatchel, 2004). The *big three* forms of psychopathology often associated with chronic pain conditions are major depression, anxiety disorder, and substance abuse disorders. If left untreated, these psychiatric disorders can significantly exacerbate and maintain the chronic pain problem. This is not to say that these psychiatric disorders need to be "cured," but only that they be appropriately managed in a chronic pain treatment program so that they do not interfere with the treatment process. This can be accomplished by the judicious use of pharmacotherapy, as well as the more widespread use of cognitive-behavioral treatment techniques.

20.4   Evidence-Based Treatment Approaches

There can now be no doubt that the most cost- and treatment-effective approach to the treatment of chronic pain is interdisciplinary pain management programs (Gatchel & Okifuji, 2006). In their comprehensive review of the evidence-based scientific data evaluating the treatment- and cost-effectiveness of comprehensive pain programs for chronic non-malignant pain, relative to other traditional treatment approaches (such as pharmacotherapy, surgery, traditional psychotherapy, etc.), it was clearly shown that these interdisciplinary pain management programs offer the most efficacious and cost-effective, evidence-based treatment for persons with chronic, non-malignant pain. The evidence for making this conclusion was based upon a large host of studies conducted both in the United States as well as in centers across the World. As noted by these authors, "These results are particularly impressive, given that many patients have undergone other treatments without achieving satisfactory outcomes and have come to CPPs as the last resort. If those patients could be referred early or undergo preventive programs, the clinical effectiveness and cost-effectiveness of CPPs probably would yield more improvement." (p. 790). In an independent review of the literature by Turk and Swanson (2007), the same conclusion was made that chronic comprehensive pain programs offer the most vital clinical option for persons with chronic, disabling pain problems.

Finally, it should be emphasized that the core ingredient of these interdisciplinary or comprehensive pain management programs is the simultaneous and coordinated involvement of multiple disciplines in the treatment process (i.e., physician, nurse, psychologist/ psychiatrist, physical therapist, and occupational therapist). For example, the critical elements

of an interdisciplinary pain management program, such as functional restoration, involve the following components:

- Formal, repeated assessment of quantified physical deficits, as well as psychosocial and socioeconomic variables, in order to guide, individualize, and monitor pain/disability behavior-oriented interventions and outcomes
- Multimodal disability management programs using cognitive-behavioral approaches
- When needed, psychopharmacological interventions for detoxification and psychological management
- Interdisciplinary, medically-directed team approach with formal staffings and frequent team conferences
- Ongoing outcome assessment using standardized objective outcome criteria in order to document clinical improvement

20.5 Mechanisms of Change Underlying the Intervention

As noted earlier, the biopsychosocial model of chronic pain was responsible for stimulating the development of comprehensive interdisciplinary pain management programs that were capable of dealing with the often complex interrelationships among physiological, psychological, and social factors that are involved in the development and maintenance of chronic pain. Indeed, patients suffering with chronic pain are at increased risk for emotional disorders (e.g., anxiety, anger, and depression) as well as maladaptive cognitions (e.g., catastrophizing and poor coping skills). In addition, there are often functional deficits and physical deconditioning (due to decreased physical activity and fear of injury) as well as basic nociceptive dysregulation. All of these variables, in turn, are often interdependent on one another so that one cannot simply treat one to the exclusion of the others. Therefore, the interdisciplinary pain management approach embraces the fact that comprehensive assessment-treatment of all these dimensions is essential in order to be effective. This is in keeping with the fact that there often is not a documentable, isomorphic relationship between a specific nociceptive event and pain (Gatchel et al., 2007). Instead, multiple other dimensions involving emotion, cognition, and behavioral and brain processing (i.e., total biopsychosocial functioning) must be carefully considered in order to maximize the probability of treatment success. We should also keep in mind that future breakthroughs in the understanding of such biopsychosocial mechanisms will hopefully lead to even greater understanding in the areas of etiology, assessment, treatment, and prevention of chronic pain. Moreover, the potential role of genetic factors in the development of chronic pain is also a promising new area of research that should provide even greater insights into the etiological mechanisms of pain that may actually account for individual differences in the pain experience and response to treatment.

20.6 Basic Competencies of the Clinician

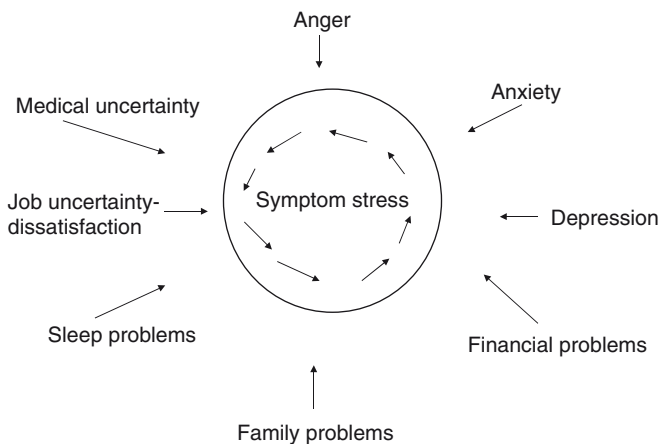
There are some basic concepts of which a competent pain management clinician needs to be aware. The first is the fact that one needs to distinguish pain as a neurological event from pain perception. The neurological event is called *nociception*, which originates in pain receptors/

regions and then passes through nerve fibers and pathways to the central nervous system. *Pain perception* is the actual interpretation of the pain sensation by the patient. This is often a two-way pathway. That is to say, the perception of the nociceptive event can significantly influence one's emotional and behavioral response to it. The stress associated with the meaning of pain, in turn, can then have a significant effect on the original nociception by decreasing the pain threshold (as indicated earlier, increased anxiety can decrease pain threshold). Indeed, various pain syndromes can often lead to stressors and changes of lifestyle that most people find unpleasant at the very least.

Indeed, unplanned and unwanted lifestyle changes due to the onset and presence of pain can lead to significant stress, so patients may begin to feel even worse than they had anticipated, and the stress actually can interfere with physical recovery. As Gatchel and Oordt (2003) have noted, this can be explained in terms of a cycle in which pain and the changes that it brings lead to stress, which leads to increased pain, increased stress, and so on. In fact, many investigations have demonstrated that stress and anxiety significantly influence pain perception, with higher levels of stress or anxiety associated with higher levels of pain intensity (Cornwal & Doncleri, 1988). In addition, stress may activate biologic responses of the autonomic and musculoskeletal systems. Thus, for example, muscle spasms may occur along with anxiety accompanying tension headaches which can, in turn, produce even more pain and muscle tension, and so on. This *pain-stress cycle* can often be important to point out to patients (see ❯ Fig. 20.1).

As further delineated by Gatchel and Oordt (2003), approximately 80% of primary care visits are prompted by patients reporting pain symptoms. Gatchel (1996) had also earlier delineated the most common types of pain seen at primary care settings, which have also been the focus of epidemiological studies.

🔲 **Fig. 20.1**

The pain-stress cycle, emphasizing the interaction of stress-related issues and the actual pain problem. It is helpful to draw patients' attention to this cycle (From *Personality Characteristics of Patients with Pain* (p. 17) by R.J. Gatchel and J.N. Weisberg, 2000, Washington, DC: American Psychological Association. Copyright 2000 by American Psychological Association. Reprinted with permission from the author)


- *Abdominal pain* is most prevalent in women, and it decreases with age. Even though the rates are the lowest among the elderly population, elderly individuals make up the greatest percentage of people seeking care for abdominal pain.
- *Back pain* prevalence tends to rise in men up to age 50, and there do not appear to be any gender differences.
- *Headache* pain from migraine appears to have its higher prevalence among both men and women, ages 35 to 45. Moreover, the prevalence for women with migraine is higher at all ages, and the female-to-male ratio tends to increase with age from menarche to about 42 years, and then declines thereafter.
- *Joint pain* is usually age-specific, reflecting the degenerative changes that occur with aging. A high rate of age-related joint pain appears to occur in women, who experience a greater degree of degenerative changes than do men.
- *Chest pain* is a very common symptom associated with many disorders and diseases, including heart, lung, esophageal and panic disorders, to name just a few. Males and females appear to share rates for chest pain that change little with age.
- *Facial pain* is approximately twice as high in women, relative to men. It rises with age among women through their mid-40s, and then drops after age 65.
- *Fibromyalgia* is a diagnosis often made in patients with unexplained widespread pain. The main physical finding in making this diagnosis is the presence of "tender points" (i.e., tenderness at the bony insertions of certain tendons and muscles). Most patients also frequently complain of associated fatigue and sleep disturbances. This widespread pain appears to peak between the ages of 50 and 60, and it appears to be more prevalent in women than in men.

Finally, it should be understood that pain is usually broadly defined as *acute, chronic, or recurrent*, depending on the time course. This rather broad classification of pain duration is often used to better understand the biopsychosocial aspects that may be important when conducting assessment and treatment. For example, chronic pain is frequently the result of unresolved acute pain episodes, resulting in accumulative biopsychosocial effects such as prolonged physical deconditioning, stress, and depression. Obviously, this type of information can be extremely helpful in directing specific treatment approaches to the type of pain that is being evaluated.

20.7 Expert Competencies of the Clinician

Charlton, Gourlay, and Butler (2005), in coordination with the International Association for the Study of Pain, have delineated the important basic competencies that should be taught to pain assessment and management specialists (❯ Table 20.2). Further elucidation of these competencies can be found in Gatchel (2004).

20.8 Transition from Basic Competence to Expert

As repeatedly emphasized throughout this chapter, the interdisciplinary pain management program, based upon the biopsychosocial model of chronic pain, is the most treatment- and cost-effective approach for a clinician to use. Therefore, it is of utmost importance for a clinician's expert competency to thoroughly understand this basic approach. Fortunately, there are

■ **Table 20.2**

Important competencies that should be taught to pain assessment and management specialists

• Understand the distinction and interrelationship among chronic pain, impairment, disability, and incapacity for work
• Understand the different epidemiology of chronic pain, health-care usage, and associated disability and incapacity for work
• Understand the musculoskeletal, soft tissue, and neurophysiologic bases of chronic pain and the methods and limitations of assessing them clinically in the individual patient
• Understand the possible influence of workers' compensation and litigation on the clinical presentation, evaluation, and management outcomes of chronic pain
• Understand occupational health issues in chronic pain, disability, and (in)capacity for work. Understand the concepts, methods, and limitations of yellow flags, barriers to recovery, rehabilitation, and return-to-work interventions
• Understand the different disability systems and the different approaches to disability evaluation. Understand the need for a systematic approach to the assessment of disability and (in)capacity, the application of test results, and the preparation of a report directed to the particular referral question
• Understand the role and limitations of medical and psychological/psychiatric evidence in the workers' compensation, social security, and litigation systems
• Understand the concepts, methods, and limitations of assessing chronic pain clinically in the individual patient, including the American Medical Association Guides, 5th edition
• Understand the concepts, methods, and limitations of independent medical examinations
• Understand the concepts, methods, and limitations of functional capacity evaluations
• Understand the concepts, methods, and limitations of assessment of malingering, exaggeration, and credibility (including *Diagnostic and Statistical Manual of Mental Disorders* [1994] and World Health Organization definitions [1990])

now a number of resources that can be used to educate and orient clinicians to this approach. For example, Gatchel and Mayer (2008) have provided a thorough review of the basic functional restoration approach to chronic low back pain management, which can be generalized to chronic pain in general. In addition, there are a host of other publications that can be accessed (e.g., Deschner & Polatin, 2000; Feuerstein & Zostowny, 1996; Gatchel, 2004; Gatchel & Turk, 1999; Mayer & Gatchel, 1988; Mayer & Polatin, 2000; Robbins et al., 2003; Sanders, Harden, & Vicente, 2005). Of course, it is essential that, once one develops a working understanding of the basic components and workings of interdisciplinary pain management, then actual clinical experience in the area is required under appropriate supervision. Only tying the education with the clinical experience will yield an expert in the field of chronic pain management.

It should also be pointed out that cognitive-behavioral therapy (CBT) is often an important psychosocial component of interdisciplinary pain management programs, and, therefore, one should also develop competence in this widely used psychological treatment method. As recently noted by Gatchel and Rollings (2008), the major goal of CBT is to replace maladaptive patient coping skills, cognitions, emotions, and behaviors with more adaptive ones. However, from a biopsychosocial perspective, CBT alone does not address all the important variable potentially contributing to chronic pain (e.g., biological factors), but may improve care for patients with psychosocial comorbidities. Also, it should be pointed out that use of the term CBT can vary

widely, and may be used to note self-instructions (e.g., distraction, imagery, motivational self-talk), relaxation and/or biofeedback, development of adaptive coping skills (e.g., minimizing negative or self-defeating thoughts), changing maladaptive beliefs about pain and goal setting. Patients who are referred for CBT may be exposed to varying selections of these strategies, specifically tailored to their needs. There are a number of resources available that describe the fundamentals of CBT. One good resource, which takes the reader through a session-by-session of CBT for pain management, has been published by Gatchel and Robinson (2003). Again, though, one must remember that after learning the basic skills of CBT, supervised clinical training is essential for the most efficacious application of this treatment modality.

20.9 Summary

We have noted the high prevalence and cost of chronic pain, and the fact that it is a major physical and mental health-care problem in the United States. As a consequence, there is a great need for appropriately trained clinicians, both to assess and manage this large population. Fortunately, the biopsychosocial model of chronic pain has been shown to be the most widely accepted and heuristic perspective to understanding and treating chronic pain. Moreover, emanating from this biopsychosocial model, interdisciplinary pain management programs have been developed and shown to be both treatment- and cost-effective. This biopsychosocial model was reviewed as an essential underpinning of better recognizing symptoms of chronic pain, as well as their assessment. This biopsychosocial model uses physiologic, biologic, cognitive, emotional, behavioral, and social factors (as well as their interplay) when explaining a patient's report of pain. Indeed, in order to comprehensively assess chronic pain, one must be certain to account for such potential interactions before prescribing the best treatment regimen, which must also be individually tailored for a particular patient. Indeed, there are many individual differences in how people respond in the face of nociception, and variation in the methods used to understand and interpret the painful stimuli. As noted, this makes the experience of pain dependent on *cognitive-evaluative processes* and on *affective-motivational processes*. Both these processes were comprehensively reviewed. Finally, we also highlighted the fact that there is often significant comorbidity of chronic pain and psychiatric disorders. Therefore, psychiatric disorders must be managed, along with the chronic pain symptomatology.

We again highlighted the fact that there can be no doubt that the most cost- and treatment-effective approach to the treatment of chronic pain is interdisciplinary pain management programs. This conclusion is based on a great deal of evidence-based scientific data published in the scientific literature. A review of the core ingredients of these interdisciplinary/comprehensive pain management programs was provided. Moreover, because the biopsychosocial model of chronic pain was responsible for stimulating the development of comprehensive interdisciplinary pain management programs, the underlying mechanisms of dealing with the often complex interrelationships among physiological, psychological, and social factors that are involved in the development and maintenance of chronic pain were reviewed. Finally, the following important areas were discussed: the basic concepts of which a competent pain management clinician needs to be aware; the important concepts that need to be taught in order for the clinician to develop expert competency in the area; and the transition process with which clinicians must be involved in developing basic competency to becoming expert in the area.

It was repeatedly emphasized that these clinicians must not only learn the basic core components of this biopsychosocial model and the interdisciplinary pain management programs, but also must receive appropriate clinical training and supervision by other experts in the field before becoming accomplished independent clinicians in their own right.

Volume III
Intervention and Treatment for Children and Adolescents

1 Major Depression

John F. Curry · Mark A. Reinecke

Abstract: Major Depressive Disorder (MDD) is one of the more frequent disorders of adolescence and also occurs among children. In addition to the character and fitness necessary for any clinical work, clinicians who work with depressed adolescents must be competent in the areas of knowledge, assessment and treatment for this disorder. We describe basic and advanced competencies across these domains. Currently there are two evidence-based psychological interventions for adolescent depression, Interpersonal Psychotherapy and Cognitive Behavior Therapy. Basic competencies include knowledge of these interventions, of their evidence-base, and of their limitations. Associated basic assessment competencies include the skills required to conduct assessments to determine accurate diagnosis, to take into account possible co-occurring disorders, and to formulate an effective treatment plan. As clinicians move from more basic to more advanced competencies, they develop knowledge of more severe forms and possible developmental outcomes of mood disorders, including psychotic and bipolar disorders, of the diagnosis and treatment of frequent comorbid combinations, such as depression and substance abuse, and of more intensive or complex treatments, such as combined psychotherapy and medication and of inpatient care for suicidal adolescents. Within evidence-based psychotherapies, there is also a continuum of competencies, as more advanced clinicians develop a deeper understanding of and application of the treatment model, and conduct sessions that indicate an integration of the treatment model, the needs of the adolescent and the ongoing therapeutic alliance.

1.1 Overview

For many years, depression was considered a condition that affected only adults. Over the past 30 years, however, there has been a recognition that the major affective disorders occur during childhood and adolescence, are persistent, and are associated with a wide range of negative outcomes. Experiencing a major depressive episode (MDE) during childhood or adolescence places an individual at risk of depression as an adult (Kessler & Walters, 1998). Developmental continuities or trajectories appear to exist in those individuals who experience an episode of major depression as a child and are more likely to experience further episodes as an adolescent (Kovacs & Gatsonis, 1994). Clinically depressed adolescents, in turn, are more likely to experience depressive episodes as an adult (Fombonne, Wostear, Cooper, Harrington, & Rutter, 2001). Major depression among youth can have a severe impact on social relationships and academic functioning, and can place youth at risk of other psychiatric conditions, alcohol and substance abuse, and suicide (Angold, Costello, & Erkanli, 1999; Brent, 1995). Major depression among youth, then, is a significant clinical and public health concern, and it is important for clinical psychologists who work with adolescents to develop the necessary competencies to provide high quality care.

1.2　Recognition of Symptoms and Their Assessment

Major Depressive Disorder (MDD) is marked by one or more MDEs in the absence of manic or hypomanic episodes. MDEs during childhood and adolescence are phenomenologically similar to those experienced by adults. DSM-IV-TR criteria for major depression during childhood and adolescence are very similar to those for adults (American Psychiatric Association, 2000), with the few exceptions noted below in italics. To meet criteria for MDE, a child or adolescent must manifest five or more of the following symptoms for most of the day, nearly every day, for at least a 2-week period: (1) depressed *or irritable* mood, (2) markedly diminished interest or pleasure in activities, (3) significant weight loss or gain, or a change in appetite *or failure to make expected weight gains*, (4) sleep disturbance, (5) psychomotor agitation or retardation, (6) fatigue or loss of energy, (7) feelings of guilt or worthlessness, (8) indecisiveness or inability to concentrate, or (9) recurrent thoughts of death or suicide, or a suicide attempt. Either the depressed or irritable mood, or anhedonia, must be present. Moreover, these symptoms must cause significant impairment in academic or psychosocial functioning and cannot be due to the direct effects of substance abuse or a general medical condition. As with adults, then, major depression during childhood is characterized by affective, cognitive, and somatic changes.

Epidemiological research indicates that the first onset of MDD frequently occurs during adolescence, and that the condition is not uncommon among prepubertal youth. Across a number of studies, approximately 5–8% of adolescents (Essau & Dobson, 1999; Kessler, Avenevoli, & Merikangas, 2001) meet diagnostic criteria for MDD. A recent meta-analysis generated estimated point prevalence rates of 2.8% for childhood MDD, and 5.9% for girls and 4.6% for boys for adolescent MDD (Costello, Erkanli, & Angold, 2006).

Major depression frequently co-occurs with other psychiatric illnesses (Angold et al., 1999), which can complicate diagnosis, case formulation, and treatment planning. Both internalizing and externalizing behavior problems can co-occur with depression among youth. Of these, anxiety disorders are the most common, with over 50% of clinically depressed adolescents reporting a *current or past* history of anxiety (Pine, Cohen, Gurley, Brook, & Ma, 1998). In the Treatment for Adolescents with Depression Study, 27% of the participants also met DSM-IV-TR criteria for a current anxiety disorder (TADS Team, 2005). Twenty-four percent of the sample met diagnostic criteria for a current externalizing disorder. Given these complexities, a principal competency of the clinician is that of accurate diagnosis, including differential diagnosis and comprehensive assessment of comorbid disorders.

As noted, rates of MDD among prebubertal youth are relatively low. Childhood MDD tends to occur equally in boys and girls. Rates of depression among males and females diverge during adolescence, with females meeting the criteria for major depression about twice as frequently as males. Depression among youth has a highly variable course (Lewinsohn, Clarke, Seeley, & Rohde, 1994), but both chronicity and recurrence are frequent (Reinecke & Curry, 2008). In Lewinsohn's study of a high school sample, duration of MDE ranged from 2 to 520 weeks! Clinical samples, not surprisingly, demonstrate considerable duration. The median duration of depressive episodes among youth entering the Treatment for Adolescents with Depression Study (TADS) was 40 weeks, and the mean was 71 weeks (TADS Team, 2005). Depression among adolescents also tends to be recurrent.

Rao et al. (1995) reported a 7-year recurrence rate (i.e., emergence of depressive symptoms after a period of sustained recovery from a depressive episode) of approximately 70% in their clinical sample of depressed youth.

1.3 Maintenance Factors of the Disorder

MDD among adolescents, like other psychiatric disorders, appears to be multiply determined. A range of biological, social, environmental, developmental, and cognitive factors appear to interact in placing individuals at risk (Gotlib & Hammen, 1992; Kendler, Gardner, & Prescott, 2002). Contemporary models of psychopathology, including interpersonal and cognitive behavioral models discussed below, typically take the form of diathesis-stress formulations in which vulnerabilities interact with the occurrence of social or environmental stressors in contributing to the onset of a depressive episode. From this perspective, it is unlikely that any single factor (biological, social, etc.) will account for a very large portion of the variance in predicting the onset of MDD. Rather, these factors appear to influence one another in a transactional manner over the course of development in placing youth at risk. These models are consistent, as well, with recent models of gene–environment interaction in developmental psychopathology (Moffitt, Caspi, & Rutter, 2006).

Some vulnerability factors, such as biological vulnerability and past developmental history, are beyond the scope of psychotherapeutic intervention, i.e., they cannot be changed by psychotherapeutic treatment. Others, however, can be identified as targets of treatment. Those vulnerability factors that are currently serving to maintain a depressive episode, and that are modifiable by psychological intervention serve as targets for evidence-based psychotherapies.

In the psychotherapeutic treatment of adolescent depression, clinicians must recognize that both individual and family factors might contribute to or maintain the disorder. The specific focus of treatment will be driven both by the clinician's theoretical orientation (e.g., cognitive behavioral or interpersonal) and the salient maintaining factors in a given case. Psychological maintenance factors can be categorized as cognitive, behavioral, and interpersonal/family factors, any of which can interfere with the adolescent's ability to cope effectively with stress, and thus maintain the depressive condition.

Cognitive Factors. A variety of cognitive correlates of adolescent depression has been identified in psychopathology research guided by social cognitive learning theory or cognitive processing theory. In the classic cognitive theory of depression (Beck, Rush, Shaw, & Emery, 1979), cognitive processes at different levels of awareness are proposed as contributing to depression. At the most superficial level of cognition, *automatic thoughts* are proposed as rapid ideas, reactions, or images triggered by certain situations. For example, an adolescent boy who fails a math test may experience the thought "I am dumb." Automatic thoughts are related to underlying *dysfunctional attitudes* or conditional beliefs, such as "Unless I am an excellent student, I am incompetent." At the most fundamental level of cognition are the adolescent's *core beliefs*, such as "I am worthless." Negative beliefs may pertain to the self, the world, or the future (Kaslow, Stark, Printz, Livingston, & Tsai, 1992). Cognitive therapy proceeds from the identification of automatic thoughts to that of their underlying attitudes and core beliefs, with the therapist assisting the patient to restructure cognitions at each level.

As treatment proceeds along this path, the adolescent's typically used *cognitive distortions* will be identified, such as failure to process positive feedback, dichotomous (all/none, good/bad) thinking, or overgeneralization. By collaboratively identifying and challenging these information processing distortions, the therapist and adolescent increase the adolescent's openness to information that serves to disconfirm depressive beliefs, thus alleviating depression.

Additional cognitive maintenance factors have been identified by other models of depression, and shown to be associated with depression. For example, Abramson, Seligman, and Teasdale (1978) demonstrated that depressed individuals attribute negative outcomes to internal, stable, global causes ("It is my fault that we lost"; "I will never be any good at this game"; "I am not good at anything."), a feature that is characterized as a depressive *explanatory style*. On the other hand, they tend to attribute positive outcomes to external, unstable, and specific causes ("I aced the test because it was easy"; "I had a good day"; "I can do long division, but not other math."). Whereas attributions pertain to judgments about events that have already occurred, expectancies pertain to future events. Studies have demonstrated that *hopelessness*, or negative expectancies about the future, characterize depressed adolescents (e.g., Garber, Weiss, & Shanley, 1993).

A recent review article summarized the evidence in support of the association of these cognitive variables and youth depression (Ingram, Nelson, Steidtmann, & Bistricky, 2007). Measures exist for the assessment of each variable, facilitating the clinician's ability to target relevant processes in specific cases.

Behavioral Factors. Research based on operant or multifactorial models of depression has emphasized the importance of social withdrawal or general inactivity to the maintenance of depression (Clarke, DeBar, & Lewinsohn, 2003). By avoiding potentially gratifying mastery activities and social interaction, depressed adolescents deprive themselves of pleasure, or positive reinforcement that can counter depressed mood or anhedonia. In addition, depressed adolescents tend to engage in more unpleasant activities than do nondepressed adolescents (Carey, Kelley, Buss, & Scott, 1986).

Interpersonal and Family Factors. Interpersonal problem-solving deficits have been identified in some studies of depressed adolescents, particularly suicidal depressed adolescents (Speckens & Hawton, 2005). Such deficits can prevent resolution of interpersonal conflicts that are, themselves, quite normal for adolescents. Interpersonal loss can be another factor contributing to or maintaining adolescent depression. Bereavement following parental death has been found to be associated with increased psychiatric symptomatology in the first 2 years following death, with complex bereavement (parental death and additional stressors) more likely to be associated with depression (Cerel, Fristad, Verducci, Weller, & Weller, 2006). Loss of relatives or close friends has been associated with elevated depressive symptoms (Harrington & Harrington, 2001). Adolescents can experience traumatic grief reactions to the death of a peer by suicide, which in turn predicts subsequent depression (Melhem et al., 2004).

Additional family factors that can maintain adolescent depression include excessively high parental expectations of the adolescent, coupled with low levels of praise or positive reinforcement (Cole & Rehm, 1986), poor family problem-solving, negative parent–adolescent affect, or high parent–adolescent conflict and mutual criticism (Asarnow, Tompson, Hamilton, Goldstein, & Guthrie, 1994; Ge, Best, Conger, & Simons, 1996; Sheeber, Davis, Leve, Hops, & Tildesley, 2007).

1.4 Evidence-Based Treatment Approaches

Several approaches have been piloted as treatments for adolescent depression (e.g., attachment-based family therapy; Diamond, Reis, Diamond, Siqueland, & Isaacs, 2002). To date, two approaches to the psychotherapeutic treatment of adolescent depression have garnered a substantial evidence base: cognitive behavior therapy (CBT) and interpersonal psychotherapy (IPT). The evidence base in support of CBT is more extensive than that in support of IPT, and CBT is the only psychotherapy that has been tested in multisite adolescent depression trials. We review IPT first, and then CBT.

Mufson and her colleagues adapted IPT for depressed adolescents and completed the initial efficacy trial of this treatment with 48 mostly Hispanic female subjects (Mufson, Weissman, Moreau, & Garfinkel, 1999). Compared to a clinical monitoring condition, 12 weeks of IPT led to greater reductions in interviewer-rated depression, self-reported depression, and remission from the episode of MDD. A larger school-based study was subsequently completed (Mufson et al., 2004), in which IPT was compared to usual treatment in school-based clinics. Sixty-three adolescents with MDD, or other depressive diagnoses, across five schools, were randomized to one of the two conditions. IPT surpassed usual treatment on interview-based and self-reported depression, and on global functioning at outcome.

Rossello and Bernal (1999) applied a somewhat different version of IPT with 71 Puerto Rican adolescents with MDD. Adolescents were randomized to IPT, CBT, or a Wait List (WL). After 12 weeks of treatment, those receiving either IPT or CBT reported significantly less depression than those in the WL condition. IPT, but not CBT, surpassed WL on measures of self-esteem and social adaptation.

In summary, IPT has been demonstrated to be more effective acutely for adolescent depression than WL, clinical monitoring, or standard school-based counseling. It has not yet been compared to pill placebo, or compared to, or combined with, medication in controlled trials.

Based on Beck's cognitive processing model of depression, Brent et al. (1997) at the University of Pittsburgh conducted a single-site comparison of CBT, nondirective supportive therapy (NST), and systems behavioral family therapy (SBFT) for adolescents with MDD(Brent et al.). All treatments included psychoeducation for parents regarding the nature of depression and available treatments. CBT was adapted for adolescents by increasing the emphasis on interpersonal problem-solving and social skills training, and including a component to enhance adolescent affect regulation. Treatment sessions were held weekly for 12–16 weeks across conditions. Positive response to treatment was defined as absence of significant MDD symptoms on a diagnostic interview along with at least 3 consecutive weeks of normal scores on self-reported depression. CBT was more effective than either of the comparison conditions, led to faster time to response, and was rated as a more credible intervention by parents.

During treatment, CBT had a significantly greater impact on reducing cognitive distortions than did either of the other psychotherapies, a finding maintained at the 2-year follow-up. SBFT had more impact on the measure of family functioning. By contrast, there was no difference among treatments in their impact on hopelessness (Kolko, Brent, Baugher, Bridge, & Birmaher, 2000). At the 2-year follow-up, the great majority of adolescents (80%) had responded and there were no longer differences in outcome across treatment groups (Birmaher et al., 2000). This finding is likely related to the nature of depression as an episodic disorder, and suggests that the advantage of CBT lies in its facilitation of a more rapid response than is attained by less

depression-specific psychotherapies. Conversely, 30% experienced a recurrence of MDD during the 2-year period, pointing to the importance of relapse prevention as a treatment target.

A second approach to CBT for adolescent depression has been based upon Lewinsohn's multifactorial model of MDD, which identifies multiple biological, cognitive, and behavioral factors contributing to MDD (Clarke, Lewinsohn, & Hops, 1990). In this model, the same priority is not accorded to cognition as in the Beck model. Instead, the underlying assumption is that cognition, behavior, and emotion are mutually influencing factors, so that change in either behavior or cognition can lead to modifications in emotion and reduction in depression. Treatment stemming from this model is psychoeducational in nature, administered in highly structured groups, and focused on the learning of a wide variety of skills. These include mood monitoring, goal-setting, problem-solving, relaxation, increasing involvement in pleasant activities, and cognitive restructuring. The intervention is presented as a course, with sessions usually held in nonclinic sites, and the program is entitled the Adolescent Coping with Depression Course (CWD-A).

Two randomized trials have assessed the effectiveness of CWD-A, the second of which was a two-site study. In each study, three conditions were contrasted. One third of adolescents were randomized to CWD-A alone; one third to CWD-A plus a parallel psychoeducation group for their parents; and one third to a WL. Treatment response was defined as no longer meeting the criteria for a depression diagnosis. In both studies, response was greater in the two CBT conditions than in the WL group. Of note is the fact that the absolute response rates varied greatly between studies. In the initial study of 59 subjects (Lewinsohn, Clarke, Hops, & Andrews, 1990), response to CWD-A was 43% without concurrent parent group and 48% with concurrent parent group, as opposed to only 5% in the WL condition. Parallel rates in the second study (Clarke, Rohde, Lewinsohn, Hops, & Seeley, 1999), with 123 subjects, were 65%, 69%, and 48%. Follow-up of the initial study cohort showed that 82% had responded by 6 months, indicating, as in Brent et al.'s (1997) study that improvement continues following acute treatment. Also, similar to Brent's findings, after the second CWD-A study, follow-up indicated a 25% recurrence rate over a 2-year period.

A recent application of the CWD-A compared it to a life skill (LS) condition for adolescents with comorbid MDD and conduct disorder (Rohde, Clarke, Mace, Jorgensen, & Seeley, 2004). Adolescents treated with CWD-A had higher recovery rates than those treated with LS (39% versus 19%), but, as would be expected with this significant comorbid condition, absolute response rates were lower than in the initial CWD-A studies.

Two major multisite studies of CBT for adolescent MDD have now been conducted in the USA. In the 13-site TADS, 439 adolescents with moderate to severe MDD were randomized to receive CBT, fluoxetine, their combination, or clinical management with pill placebo for 12 weeks of acute treatment. After week 12, the placebo arm was discontinued and placebo nonresponders received their treatment of choice. Partial or full responders to the active treatments continued to receive treatment for 6 weeks in continuation and then 18 weeks of maintenance therapy in their assigned arms. CBT in TADS combined elements of the Brent and Lewinsohn/Clark models: Behavioral and cognitive skills training was embedded within the individual therapy sessions (Curry et al., 2000; Wells & Curry, 2000). Parents were included in some treatment sessions. Core elements of the CBT included mood monitoring, goal-setting, behavioral activation, problem-solving, and cognitive restructuring. The TADS CBT model has been described extensively in a special issue of *Cognitive & Behavioral Practice* (Vol. 12, No. 2, 2005). The primary hypotheses of the TADS study were that the

combination of CBT and fluoxetine would be more effective than either monotherapy, and that each of the latter would surpass placebo acutely.

Acute treatment results supported combined CBT + fluoxetine as the most effective intervention, as measured by the rate of change (slope) of scores on a standardized interview-based rating scale completed by Independent Evaluators uninformed of treatment assignment (TADS Team, 2004). Combined treatment surpassed placebo, CBT alone, and fluoxetine alone on this primary measure. Response rates at week 12 were 71% for combined treatment, 61% for fluoxetine, 43% for CBT, and 34% for placebo. Fluoxetine, but not CBT, was superior to PBO at the end of 12 weeks of treatment. By week 18, response rates for CBT and placebo were equivalent (69% and 65%, respectively), and at the week 36 treatment endpoint, all three active treatments converged with rates of 86%, 81%, and 81% for combination, fluoxetine, and CBT, respectively (TADS Team, 2007).

In the six-site Treatment of Resistant Depression in Adolescents (TORDIA) study, 334 adolescents who had not responded to an adequate trial of a selective serotonin reuptake inhibitor (SSRI; antidepressant medication) were randomized to one of four conditions. They were switched either to another SSRI or venlafaxine, with or without concurrent CBT. CBT with a medication switch proved more effective than a medication switch alone, with 55% responding in the CBT-containing conditions versus 40% without CBT (Brent et al., 2008). In summary, CBT has been shown to be more effective acutely than WL, and alternative psychotherapies, but not to pill placebo acutely. The combination of CBT and fluoxetine has attained a higher absolute response rate than either of these single interventions for acute treatment of MDD, and surpassed medication alone as a second stage treatment following nonresponse to initial medication. However, a British study found that CBT did not add to the efficacy of antidepressant medication for adolescents not responding to initial psychosocial intervention (Goodyer et al., 2007).

1.5   Mechanisms of Change Underlying the Interventions

Only a limited amount of empirical evidence exists regarding the mechanisms of change associated with the efficacy of CBT or IPT for adolescent depression. We review that evidence below, following a discussion of theoretically proposed mechanisms of change. IPT is based on the assumptions that clinical depression is a psychiatric disorder manifested in specific symptoms, and that it may be either a cause or an effect of disturbances in current interpersonal relationships (Klerman, Weissman, Rounsaville, & Chevron, 1984). Treatment proceeds in three phases. Initially the therapist reviews the patient's symptoms, identifies the depressive syndrome as a disorder, explains the interpersonal model of depression and treatment, and assesses the need for antidepressant medication. An inventory of past and current interpersonal relationships is conducted, and the current depression is linked to a major interpersonal problem area. Patient and therapist work together to formulate goals, with a focus of work primarily on one interpersonal problem area.

The second phase of treatment constitutes the majority of sessions. One of the four possible major problem areas is the focus of these sessions: grief, interpersonal disputes, role transitions, or interpersonal deficits. The final phase of treatment is termination, which is discussed openly and viewed as a type of grieving, in itself. During IPT sessions, the therapist encourages the patient to explore and express emotions, especially in the context of the problem area that

is the focus of treatment. There are emphases on clarification of communication and the IPT therapist may also incorporate social skills or interpersonal problem-solving skills into sessions. To this extent, there is a clear overlap between IPT and CBT. In the course of the treatment, the patient is assisted to resolve the key interpersonal problem that appears to be most clearly associated with the onset and/or maintenance of the current depressive episode.

For example, an adolescent girl may experience the onset of depression following the death of her father. This would clearly determine the focus of IPT on the major problem area of grief. During the initial treatment phase, the onset of depressive disorder would be linked to the loss of the adolescent's father. In the middle phase sessions, the girl would be assisted to review her relationship with her father, both in its positive and negative aspects, exploring all associated emotions. As the mourning process proceeds, the adolescent is encouraged to become interested in other relationships and activities or social interactions that can, to some extent, substitute for the loss of the parent.

A different example would be that of an adolescent who experiences the onset of depression after making a transition from middle to high school. This is an instance or "role transition." It is analogous to a grief reaction, however, in that the focus of treatment would be on mourning the loss of the old role, partly by reviewing both its positive and negative aspects, and then moving toward adoption of a new role. Inherent in the latter may be the need to develop more advanced social or academic skills required for mastery in the new situation.

These examples illustrate the centrality of the interpersonal context of depression that characterizes IPT. It appears that the proposed core mechanism of change underlying IPT is the resolution of the most salient interpersonal problem associated with the onset or maintenance of the current depressive episode. IPT is a short-term treatment and does not seek to restructure personality or rework relationships from the past as these may be internalized in object relations or schemas.

As noted above, American CBT for adolescent depression has stemmed from two different schools of thought: the cognitive model of psychopathology and the multifactorial model. As such, there are some differences in proposed mechanisms of change. The cognitive model hypothesizes that depression is a cognitive disorder (Beck et al., 1979). Negative life events trigger underlying cognitive diatheses or vulnerabilities that may stem from early life experiences, such as a core belief that the self is unlovable or helpless. Cognitive therapy for adolescent depression, like IPT, begins with an assessment of symptoms and the description of the depressive syndrome as a disorder (Brent & Poling, 1997). The adolescent and family receive psychoeducation about depression and about the treatment. In the early phase of treatment, the adolescent is asked to attend to events or situations that affect his or her mood (mood monitoring), and may be helped to engage in an increased level of activities, not only to counter depressive passivity, but also to create more opportunities to monitor mood and associated cognitions. Within sessions, here-and-now focusing on subtle shifts in mood is facilitated by the therapist, to help the adolescent identify what thoughts or images are going through his or her mind as mood shifts occur. In general, cognitive therapy proceeds from identification of automatic thoughts associated with depressive affect to the identification of underlying conditional beliefs (dysfunctional attitudes) and to that of depressive core beliefs. Themes in the automatic thoughts tend to disclose the nature of the relevant underlying attitudes and beliefs.

For example, an adolescent boy may become depressed after breaking up with his girlfriend. Associated automatic thoughts may be: "She thinks I am unattractive"; or "She likes my best friend better than me." By rigidly focusing on the breakup, the boy may be demonstrating

an underlying dysfunctional attitude such as, "Unless every girl finds me attractive, I am a loser." The associated core belief may be, "I am unlovable." To maintain such a belief, the adolescent relies on cognitive distortions, such as ignoring the fact that another girl seems to like him, or overgeneralizing from this one negative experience to form an expectation that all romantic relationships will end in painful separation. The proposed key mechanism of change in cognitive therapy is modification of depressive automatic thoughts, dysfunctional attitudes, and core beliefs, and ultimately the latter. Thus, cognitive restructuring is the major therapeutic mechanism of change.

Multifactorial CBT (Clarke et al., 2003) is less linear in its assumptions and uses a reciprocal influence model of depression, according to which deficits in behaviors, cognitions, or emotional coping responses can be associated with the onset and maintenance of depression in any given case. Treatment proceeds, therefore, by presenting to adolescents an array of skills to learn for coping with stress. Since treatment is psychoeducational and often done in a group format, the assumption appears to be that some skills will be relevant for a given adolescent, while other skills will be relevant for another adolescent. There is a greater emphasis in multifactorial CBT on behavioral activation as an end in itself, and not only as a means to generate depressive cognitions for subsequent restructuring. Thus, the CWD-A program puts considerable emphasis on monitoring mood while increasing weekly pleasant activities, in order to show the link between pleasant activities of a social or achievement nature with elevations in mood.

To our knowledge, there have not been any empirical studies of the mechanisms of change associated with effective IPT for adolescents. There have been only a few relevant studies of CBT. In a small study of 22 adolescents with depressive symptoms (not diagnosed MDD), Ackerson, Scogin, McKendra-Smith, & Lyman (1998) found that reductions in dysfunctional attitudes mediated response to a bibliotherapeutic intervention based on cognitive theory. Kaufman, Rhode, Seeley, Clarke, & Stice (2005) conducted a mediation analysis of the sample included in Rohde et al.'s (2004) study of CBT or life skills training for depressed, conduct-disordered adolescents. They found that changes in negative automatic thoughts mediated the outcome of CBT on depression. Thus, there is some evidence that a key mechanism of change in CBT for adolescent depression is the restructuring of depressive cognitions.

1.6   Basic Competencies of the Clinician

Clinical psychologists who propose to work with depressed adolescents must have relevant competencies in knowledge, assessment, and treatment. A framework for conceptualizing these professional psychology competencies, in general and not with specific reference to adolescent depression, was generated by a large conference work group in 2002, and we will rely to some extent on that framework in the discussion of this topic (Collins, Kaslow, & Illfelder-Kaye, 2004). In addition, the most fundamental competencies for psychological practice with children, adolescents, or adults involve aspects of personal character and psychological fitness that are essential for clinical effectiveness (Johnson & Campbell, 2004).

Johnson and Campbell (2004) argue that character and fitness are necessary but not sufficient personal characteristics for competence in professional psychology. Under the rubric of character, they include honesty and integrity in one's dealings with other persons. More specifically, clinicians must have the personal qualities of integrity (honesty and consistency across contexts), prudence (capacity for planning and good judgment), and caring (concern for the

welfare and needs of others) (p. 406). Under psychological fitness, they refer to emotional stability, absence of serious psychological disorder, benign personality adjustment, and absence of substance abuse. In a survey of the Directors of Clinical/Counseling Training (DCT's), they found that such character and fitness markers were ranked as quite important, both for admission to graduate school, and even more so for graduation from doctoral training.

How do these character and fitness requirements pertain to clinical work with depressed adolescents? First, honesty and consistency across contexts are necessary in order to establish good working alliances both with the adolescent and with the parent(s). Research by Hawley and Weisz (2005) has shown that a positive therapeutic alliance with the adolescent or child is associated with better treatment outcome, and that a positive alliance with the parent is associated with retention in treatment and regular attendance at sessions. In adolescent depression work, it is critical that the adolescent and parents be aware of the parameters of treatment, including confidentiality limits, child abuse reporting requirements, and steps that will be taken in the event of worsening suicidal ideation or a suicide attempt. There is a risk of the therapist identifying either with the adolescent or the parents, instead of forming a clear working alliance with both. Identification with the adolescent can lead therapists to offer excessive guarantees of confidentiality, which then serve to trap them when dangerous information is disclosed by the adolescent. Identification with the parents can lead therapists to transform treatment into socialization, by trying to obtain the outcome parents wish for, rather than the outcome most appropriate for the adolescent. For example, depression may be associated with excessive parental expectations for academic achievement. Therapists who identify with parents will be inhibited from confronting this parental pressure, a step essential to the recovery of the adolescent.

Honesty and consistency across contexts require that the therapist begins treatment with a clear contract about whether and when parents will be expected to attend sessions or parts of the sessions, how parents will be informed of the adolescent's progress, or lack thereof, what level of detail from adolescent sessions will be shared by the therapist with the parents, and how out-of-session contacts (e.g., phone calls or e-mails) from the parents will be shared with the adolescent. Limits of confidentiality must be clarified at the outset of treatment. In general, the adolescent needs to know that increased suicidal risk, any homicidal ideation or threats, incidents of possible physical or sexual abuse, and medical emergencies will be disclosed to relevant authorities and/or parents. As for adolescent substance use, it is important for the therapist to have a clear position on disclosure to parents that is consistent with state law and acceptable both to the adolescent and the parents. The key principle in all of these matters is that the therapist must be clear and consistent with all parties so that trust is created and maintained.

Prudence, or capacity for planning and good judgment, will inevitably be required in working with depressed adolescents. One element of prudence is the capacity to develop, monitor, and modify the initial treatment plan, about which more will be said, below. Prior to the start of treatment, the clinician must use prudence to address these key questions:

1. Is this adolescent a suitable candidate for outpatient psychotherapy? Adolescents who are either experiencing merely a normal mood variation of mild severity or brief duration might benefit more from reassurance and "watchful waiting" than from the immediate implementation of a course of treatment. On the other hand, those with severe and/or persistent depression need to be evaluated for possible medication treatment. Those with

complex comorbid conditions, such as substance abuse or serious conduct disorder, will likely need more than simply weekly outpatient psychotherapy.

2. Is this adolescent's family likely to be able to support outpatient psychotherapy for the adolescent? "Family" here is broadly construed to mean the adolescent's immediate support system, including the adolescent's living situation, and is not restricted to nuclear or biological family. Some adolescents living in group homes, for example, will be fully supported in the practical matters of attending psychotherapy sessions, whereas others in chaotic, disorganized nuclear families or those who are homeless may lack such support. Given that evidence-based forms of psychotherapy for adolescent depression are intended to last for 3–4 months, an adolescent who is unlikely to be able to attend even a significant proportion of the sessions may not be suitable for such intervention. Alternative interventions, such as as-needed crisis management, school-based counseling, or involvement in other school-based activities may be of more benefit to such adolescents.

3. If the adolescent does appear to be a reasonable candidate for outpatient psychotherapy, which psychotherapy should be initiated? To date there are two forms of psychotherapy with empirical support in the treatment of adolescent depression: IPT and CBT. The choice of which to implement will depend primarily on the expertise of the therapist.

Caring, or concern for the well-being of the other, is clearly essential for working with depressed adolescents. The therapist must be willing to tolerate the pessimism and even hopelessness that some depressed adolescents express without becoming immobilized by them. Beck et al. (1979) wrote eloquently of the risk that the therapist will "buy into" the depressed patient's negative views of self, world, or future by abandoning the role of a scientific observer and the task of collaborative empiricism (p. 59). Again, this points to the difference between caring for the well-being of the depressed patient and identifying with the patient's depressive world view. Some depressed adolescents have experienced exceptionally negative life experiences or are currently living in extremely negative situations. For example, one of us worked with a boy who had lost both parents to AIDS and was now living with a rejecting stepmother. In the face of such adversity, the therapist needs to maintain a caring and hopeful stance, seeking to apply the treatment model, augmented if necessary by environmental modifications, to help the adolescent reduce depression and establish sources of hope.

Therapists who work with depressed adolescents must also be emotionally healthy, themselves. If the therapist is in significant distress due to current life circumstances, longer-standing personality disturbances, psychopathology or substance abuse, such work is seriously contraindicated. As is the case in all types of psychotherapy, the therapist needs to have his or her own emotional needs met elsewhere, and not seek to meet them through the treatment.

1.6.1 Basic Knowledge Competencies

Clinical psychology is grounded in psychological science, and the "scientifically minded" practitioner is an intended outcome of all accredited doctoral training programs, whatever the specific training model of the program might be (scientist-practitioner, practitioner-scientist, clinical scientist, local clinical scientist) (Belar & Perry, 1992; Bieschke, Fouad, Collins, & Halonen, 2004). Bieschke et al. delineated five components of scientifically minded practice in professional psychology, the first of which is the ability to access and apply current scientific

knowledge habitually and appropriately. What does this competence imply with regard to clinical work with depressed adolescents?

First, a basic knowledge competence is to be cognizant of the contemporary theories and their evidence regarding the psychopathology of depression in adolescents. This includes the kind of material that would be included in the doctoral-level courses in psychopathology, especially developmental psychopathology. Familiarity with biological, cognitive, behavioral, social learning, and interpersonal (including family) models of depressive psychopathology would constitute required knowledge.

Second, a basic knowledge competence includes awareness of current evidence-based interventions for adolescent MDD, as reviewed above. It is incumbent on psychologists to know the essential outcome of major treatment studies, the limitations of those studies, and also to be aware of the lack of evidence supporting nonscience-based interventions.

Third, a basic knowledge competence is facility in the process of reviewing emerging knowledge on adolescent depression. It is extremely unlikely that the practitioner's graduate school knowledge will remain current after more than 5 or 7 years. As new knowledge develops, the practitioner needs to have the skills to locate and obtain updated sources of knowledge. Bieschke et al. (2004) argue that clinicians need to adopt an evidence-based practice approach and make use of systematic review papers, meta-analyses of treatment outcome studies, and reviews of randomized controlled trials, as sources of continuing education. Training in the requisite computer and data searching skills should be obtained during graduate school, although these, too, will need to be revised as methods of data reporting, collection, and dissemination are modified over time.

1.6.2 Basic Assessment Competencies

As Mash and Hunsley (2005, p. 362) noted, "[i]t would be difficult to imagine providing any form of psychological services to children and families without using some type of informal or formal assessment." Assessment is central to our work as clinicians – it guides the selection of problems to be addressed, provides a foundation for case formulations and treatment planning, and allows us to determine if what we are doing is doing any good. In a very real sense, the development and application of tests and measures is central to the identity of clinical psychology. It is a defining characteristic of the profession. With this in mind, care must be taken to insure the utility and integrity of our assessments, and to demonstrate that they contribute to improved care and enhanced outcomes. There are number of essential tasks which must be accomplished when working with depressed adolescents. These include: (1) making the right diagnosis, (2) attending to comorbid psychiatric and medical illnesses, (3) assessing symptom severity and monitoring treatment gains, (4) understanding the home and school environments in which the teen is functioning, and the ways these may be exacerbating or maintaining their distress, and (5) monitoring suicidal risk. Each of these tasks requires a specific set of skills, and can be facilitated by the use of psychometrically strong assessment instruments. At a minimum, the clinician must have competencies in the administration of clinical interviews, semi-structured diagnostic interviews, and self-report rating scales.

The clinical interview (Beutler & Groth-Marnat, 2005) is necessary in order to establish rapport, obtain a broad picture of the adolescent's interests, functioning, and problems, and to gain information about the home and school environments. The clinical interview can lead

directly into a semi-structured diagnostic inquiry, and in fact the latter should not be attempted without at least some less structured interview time.

Determining whether an adolescent manifests a MDD, and ruling out alternative diagnoses and conditions, can be a challenging endeavor. One impetus for the development of criterion-based psychiatric diagnosis was the unreliability of diagnoses based on unstructured clinical interviews. With this in mind, it is important for clinicians to receive training in the administration of semi-structured diagnostic instruments, such as the K-SADS-PL (Schedule for Affective Disorders and Schizophrenia for School-Age Children) (Kaufman et al., 1997), and to use them in a systematic manner. The K-SADS-PL addresses both current and past episodes of each psychiatric disorder. The instrument includes a screening interview incorporating key symptoms from each diagnostic domain to determine if further, more detailed, assessment is necessary. In addition to each of the affective disorders, the K-SADS-PL allows for the assessment of the full range of anxiety, disruptive behavior, and substance use disorders. The clinician interviews the adolescents and their parents separately, insuring that both behavioral observations and the adolescent's subjective emotional state are taken into account. The clinician integrates information from each of the respondents in making the diagnosis. As might be expected, differences between parents and teenagers about the occurrence of specific symptoms, their severity, and their meaning often occur. As a consequence, clinical judgment and sensitivity play an important role in the diagnostic process. It is usually too time-consuming and not necessary to administer an entire semi-structured diagnostic interview in clinical practice. However, practicing clinicians should administer those components of an interview that are indicated by the referral question and/or screening question responses.

When treating depressed youth, it is very helpful to assess the severity and the key concomitants of depression, especially hopelessness and suicidal ideation, and monitor these regularly over the course of the therapy. Objective self-report scales, such as the Beck Depression Inventory-II (BDI-II; Beck, Steer, & Brown, 1996), the Suicide Ideation Questionnaire-Junior High School Version (Reynolds, 1987), and the Beck Hopelessness Scale (BHS; Beck, Weissman, Lester, & Trexler, 1974), can be very helpful in this regard. These scales are quick, efficient, and psychometrically sound. Responses on these measures can be used as a stimulus for discussing the teen's concerns, and complement a clinical discussion of their recent feelings and experiences. Some adolescents are more comfortable acknowledging their feelings on a rating scale, rather than in an interview. With this in mind, the "numbers" of an objective rating scale may or may not mesh with what a teenager (or his or her parent) reports in the session. The art of clinical practice, then, is in integrating information garnered through objective assessment with the subjective reports of the adolescent.

1.6.3 Basic Treatment Competencies

Psychologists who treat depressed adolescents must have the basic competencies required for any psychotherapy, as well as competencies in evidence-based interventions for this particular disorder. We first delineate the basic competencies required for any psychotherapy, relying significantly on the work of the competencies conference (Spruill et al., 2004). Subsequently, we outline basic competencies required to conduct CBT or IPT.

Dovetailing with scientific knowledge competence is the basic treatment competence of knowledge about current evidence-based interventions for the problem of adolescent

depression. This can be expected to constitute a moving target over the course of a psychologist's career, but at present the evidence-based treatments in the psychotherapeutic domain are cognitive behavior therapy and interpersonal psychotherapy. Knowledge of these treatments entails knowledge of the relevant model (theory) of depression and the model of treatment. Such knowledge implies that the psychologist can explain to the adolescent and parents how depression develops or is maintained, and how the treatment at hand proposes to alleviate it. Moreover, the psychologist needs to conduct such psychoeducation in a manner that is accessible to the adolescent and parents, so that the proposed treatment "makes sense" to them and their motivation to engage in psychotherapy is increased.

Basic competence also entails knowledge of the alternative treatments, specifically antidepressant medication. It is beyond basic psychological competence to have detailed knowledge of the pharmacotherapy literature, but at a basic level, the psychologist should be aware of the evidence in support of medication, as this is reflected in review papers and psychiatry practice guidelines (e.g., Hughes et al., 2007). Finally, the psychologist should be aware of the major studies that have compared evidence-based psychotherapy, medication, and their combination, as interventions for adolescent depression (Brent et al., 2008; Goodyer et al., 2007; TADS Team, 2004, 2007). Such knowledge enables the psychologist to have a dialogue with the adolescent and parents in which consideration is given to the selection of an initial single or combined treatment.

Another domain of knowledge required for competent practice is the relevant state laws, and the psychologists' ethical principles and code of conduct. In work related to depressed adolescents, psychologists need to be aware of state laws pertaining to age of legal consent, voluntary and involuntary commitment for inpatient care, confidentiality, and privileged communication. Regarding adolescents of divorced parents, the psychologist must know the custody arrangement, which parent(s) may seek professional care for the adolescent, and what are the rights of the noncustodial parent to be involved in treatment and have access to records. Psychologists who work with adolescents must have the requisite training and supervision for such work and practice within the bounds of their competence. Any professional working with young people must know the requirements for reporting suspected physical or sexual abuse or neglect.

Beyond knowledge, the psychologist needs to demonstrate competence in the establishment of a therapeutic alliance with the adolescent and parents. Spruill et al. (2004) consider here three relevant sets of more specific competencies: relationship skills, communication skills, and sensitivity to individual and cultural differences. Included under relationship skills are the essential components of warmth, genuineness, and empathy (Rogers, 1992). Explanations of evidence-based treatments sometimes tend to omit discussion of these fundamental skills, instead focusing on intervention techniques, but in fact all evidenced-based psychotherapies require fundamental relationship skills. Beginning therapists sometimes err in the direction of emphasizing change techniques too rapidly, such as introducing cognitive restructuring too early in the process of CBT, before allowing the adolescent time to develop trust and feel that her or his concerns have been heard and understood (Wilkes & Rush, 1988). Other beginning therapists rely too rigidly on treatment manuals, almost "reading" the treatment to the adolescent. This is a distortion of evidence-based treatment that actively precludes establishing a therapeutic alliance. Indeed, it is incumbent on therapists who used manual-based interventions to learn how to "breathe life into the manual" (Kendall, Chu, Gifford, Hayes, & Nauta, 1998).

Communication skills are the second elementary competence upon which an alliance depends (Spruill et al., 2004). Verbal communication with adolescents must be honest, open, and clear. The therapist needs to listen to what the adolescent expresses and check to be sure that understanding is accurate. Listening also involves attending to omissions, distortions, repetitions, emphases, and the other markers of the personal salience of interview material that have been identified by Alexander (1990). Nonverbal communication conveys respect for the adolescent and parents, and includes the therapist's dress, posture, eye contact, and time management. Therapists should begin sessions at the scheduled time, alert patients when the end of a session is approaching, and stop the session on time. If urgent matters appear to require additional time, the therapist should renegotiate the end point of the session or schedule an additional meeting within a short period of time.

Sue and Sue (1999) noted relevance of understanding the patient's culture for establishing a therapeutic alliance. If we consider culture to refer primarily to national, ethnic, or racial heritage, it becomes part of a broader context required for understanding the diversity represented by the given patient. Such a context would also include religion, gender, sexual orientation, family composition, geographic location, and socioeconomic status among other possible sources of diversity. Certainly therapists need to understand frequent commonalities in the cultural groups that come to their attention at given clinical sites, always with the caveat that individual differences can override frequent commonalities. This points again to the need to listen attentively to the adolescent's and the parent's narrative at the outset of treatment, so as to avoid erroneous overgeneralizations based on frequent cultural features.

Given requirements for establishing a working therapeutic alliance, the psychologist treating depressed adolescents needs to be able to use information gathered in the assessment to develop a provisional case formulation and treatment plan (Spruill et al., 2004). The case formulation goes beyond diagnosis to include the factors proposed as contributing to the presenting problem (in this case, depression) and the factors representing personal assets upon which treatment can be based. As an example of a case formulation, recent loss of a friend may have precipitated a depression in a young female with a primarily introverted, conscientious personality, and a family history of mood disorders. The impact of loss may be mediated through maladaptive cognitions such as: "I will never again have a good friend like Sarah, who moved away." This depressed young woman may be noted to have supportive parents, good verbal skills, and the capacity for self-reflection, all of which will facilitate psychotherapy. Stemming from the case formulation, the therapist develops a treatment plan. If opting to use IPT, the therapist will help the adolescent to see the link between the loss of her friend and her own depression, and will then focus on moving through the associated grief reaction. If opting to use CBT, the therapist may focus more on the maladaptive thinking that has changed normal sadness into a hopeless kind of depressive reaction. In either case, it is likely that the therapist will want to engage one or both parents in initial psychoeducation about depression and treatment, and perhaps in auxiliary sessions to support the adolescent over the course of treatment.

1.6.4 Basic Competencies in Delivery of IPT or CBT

Evidence-based treatments have by definition been used in clinical trials. As an element of these trials, it is incumbent on investigators to assess and monitor the extent to which therapists

adhere to and competently enact the type of psychotherapy that is being tested in the trial. Thus, a number of scales have been developed for this purpose. In addition, several instruments have been developed to measure psychotherapeutic processes across treatment models. Ablon and Jones (2002) used a rating method to develop prototypes of ideal sessions of IPT and ideal sessions of CBT so that these ideal models could then be applied in a study of actual sessions from the NIMH Treatment of Depression Collaborative Study (Elkin et al., 1989). In Ablon and Jones' study, a panel of ten experts in CBT and a panel of 11 experts in IPT rated each of the 100 items of the psychotherapy process measure on the extent to which the item was characteristic of an ideally conducted session of CBT or IPT, respectively, using a 1–9 rating of each item. Based on their findings about the 20 highest-rated items in each treatment model, we propose that the most basic competencies of the IPT and the CBT therapist, respectively, enact the following characteristics.

In the IPT sessions, the therapist focuses on the patient's interpersonal relationships, puts an emphasis on the patient's emotions, makes interpretations that refer to actual people in the patient's current life, and adopts a supportive stance. Feelings of love, being close to someone, or romantic relationships are a topic of discussion. Attention is drawn to the patient's nonverbal behavior or to the changes in the patient's mood or affect. The therapist facilitates the patient's expression, and clarifies or rephrases the patient's communications. The structure of the session is such that the current or recent life situations, rather than past situations, are the focus of attention, dialogue is focused, and the patient's goals are discussed, as are practical issues such as termination or scheduling.

In the CBT sessions, the discussion centers on cognitive themes, such as ideas or beliefs. There is a focus on activities or tasks for the patient to complete before the next session. The therapist encourages the patient to try out new behaviors, and presents to the patient a different perspective for interpretation of an experience or event. Therapists explain the rationale behind any technique introduced into the session, and tend to be active in structuring the session. CBT therapists may be didactic in manner and give explicit advice or guidance. As in IPT, the patient's goals are discussed, the focus is on the patient's current or recent life situation, and the therapist adopts a supportive stance.

In short, the IPT therapist has the competence to facilitate the patient's emotional expression, to focus on emotions and interpersonal relationships, in the service of resolving one of the four foci of IPT (grief, role transitions, role conflict, interpersonal skill deficits). The CBT therapist has the competence to identify and target relevant cognitions, explain and introduce therapeutic techniques, encourage exploration of new behavior and new perspectives, and assign between-session tasks. Both the IPT and the CBT therapist are competent in providing support, focusing on the present, rather than the past, structuring the session, and structuring the treatment sequence.

1.6.5 Basic Competence with Families

As noted above, basic competence in the treatment of adolescent depression includes formulating a treatment plan that designates how parents will be involved in treatment. Unfortunately, there is very little empirical evidence to guide clinicians in making this decision. As a general rule, the therapist must establish a working treatment alliance with the parents, and must provide parents with at least psychoeducation about depression and about the treatment to be

delivered. Parents should be involved in developing a safety plan in the event that a depressed adolescent experiences worsening suicidal ideation or urges, and most certainly, if there has ever been a suicide attempt. Parents should be kept informed about the progress of the adolescent and about the types of skills that the adolescent is learning in treatment. The therapist must rely on clinical judgment on the question of whether and when to include conjoint parent–adolescent sessions in the course of treatment.

The therapist will, in some cases, note that the parent also has a psychiatric or substance use disorder. In such cases, the related competence is the ability to make a treatment referral at a time and in such a way as to increase likelihood that the referral will be followed.

1.6.6 Advanced Knowledge Competencies

Along with advanced competencies in assessment and intervention considered below, there are advanced competencies in knowledge, case formulation, and case management. We consider these together because they are likely to be relevant to cases marked by greater severity or complexity. Psychologists with advanced competence in the treatment of adolescent depression will be knowledgeable regarding the following aspects of adolescent mood disorders:

1. Psychotic depression: its symptom pattern, and how to differentiate this from schizophrenic disorders, substance-induced psychosis, and bipolar disorder with psychosis
2. Bipolar disorder: prevalence of bipolar outcome in the early-onset mood disorders; its symptoms; and how to differentiate this from nonbipolar depression, schizophrenic disorders, and substance-induced disorders
3. Anxiety disorders: comorbidity of anxiety and depressive disorders; prevalence and patterns of the relative first onset of anxiety and depression in young people; establishing a primary diagnosis for initial treatment
4. Disruptive behavior disorders: comorbidity of disruptive behavior and depressive disorders; prevalence and patterns of the relative first onset of disruptive behavior and depressive disorders in young people; establishing a primary diagnosis for initial treatment
5. Substance use disorders: comorbidity of substance use and depressive disorders; establishing an integrated treatment plan to address both disorders in comorbid cases
6. Medication guidelines: the array of first-line and second-line medications and evidence supporting these; augmenting medications; and principles to follow in the process of medication modification (Hughes et al., 2007)
7. More intensive, lengthy, or invasive treatments for refractory cases: extended IPT or CBT; continuation and maintenance phases of outpatient treatment; hospitalization for suicidal risk; aftercare following inpatient care; evidence pertaining to consideration of electroconvulsive therapy in rare or extremely refractory cases

1.6.7 Advanced Expert Competencies of the Clinician

As noted, adolescent depression is multiply determined. The ways in which biological, social, environmental, and cognitive variables interact in contributing to the development of depression, however, is not well understood. Basic competence requires the ability to construct a case

formulation, but this skill should advance as the clinician's knowledge base advances in concert with scientific advances in the field. By targeting factors implicated in risk for depression, we may be able to offer treatments that yield a positive outcome. This task requires an understanding of research on moderators and predictors of treatment response, and of mediators of depression among youth, as well as competence in their assessment.

Studies indicate that a number of factors predict and moderate response to treatment among depressed adolescents (Brent et al., 1998; Curry et al., 2006). These include: age, family income, verbal IQ, duration and severity of the depressive episode, number of comorbid diagnoses, level of anxiety, hopelessness, parental depression, cognitive distortions, parent–child conflict, and treatment expectancies. Systematically assessing factors that predict outcome can be helpful in selecting the most effective program of treatment, addressing factors that may impede progress, and assisting adolescents and parents to set realistic expectations for rate of progress and likely duration of treatment. Findings from the TADS project indicate, for example, that treatment with a combination of CBT and medication management with fluoxetine may be more helpful for depressed adolescents who manifest high levels of cognitive distortions than treatment with medication alone (Curry et al., 2006). In the same study, adolescents from affluent families (family income over $70,000) were found to respond well to CBT alone. Treatment strategies may be tailored, then, based upon the specific needs and strengths of the patient and an understanding of moderators of outcome. In a similar manner, parental depression, parent–child conflict, and parent and teen expectations about the effectiveness of treatment all have been found to predict treatment response. All can be assessed during an initial diagnostic evaluation and addressed clinically, if appropriate.

Given new developments in research on cognitive factors in depression and the importance of these factors in contemporary cognitive theories of depression (Jacobs, Reinecke, Gollan, & Kane, 2008; Spence & Reinecke, 2003), they can serve as targets of clinical intervention. Assessment that directly addresses a number of recently identified cognitive factors can thus be used to provide a more advanced case assessment.

In addition to the classic cognitive targets of negative automatic thoughts, dysfunctional attitudes and core beliefs, and depressive explanatory style, recent research has identified depressive schemata (including perfectionistic standards), deficient problem-solving motivation, and rumination as potentially relevant cognitive factors maintaining depression. Rating scales have been developed to use in the assessment of each of these variables, and adolescents can be asked to complete them as part of an initial assessment. Both cognitive vulnerabilities and cognitive strengths or abilities can be identified and harnessed. CBT, from this perspective, employs both deficit and competency-based strategies. A teenager may, for example, manifest deficits in problem-solving motivation (they may approach day-to-day problems in an impulsive or careless manner, or attempt to avoid them altogether) and strongly believe that others will reject or abandon him or her, if they get to know him or her. Once identified, these difficulties could be addressed through problem-solving training, social activity scheduling, and schema-focused CBT strategies. Another teenager, in contrast, may demonstrate relatively strong problem-solving skills, yet be troubled by rigid, perfectionistic standards. For her, it would make little sense to introduce problem-solving training. Rather, traditional CBT techniques, such as rational responding and behavioral experiments, might be used to address her perfectionistic beliefs. The use of evidence-based assessment strategies facilitates the development of individually tailored treatment programs, and so can accelerate clinical improvement. These approaches can also be used to identify cognitive factors that are hindering progress.

A promising new area of research with clear treatment implications centers on rumination. Rumination, the tendency to focus repetitively on problems or symptoms of emotional distress, and on their meanings, causes, and consequences, has been found to predict recurrent depression among adults (Papageorgiou & Wells, 2004). Moreover, recent studies suggest that relations also may exist between ruminative style and depression among children and adolescents (e.g., Burwell & Shirk, 2007), and that females tend to ruminate more than males. Interestingly, cognitive behavioral treatments for depression typically begin by teaching patients to monitor and reflect upon their negative moods and their accompanying thoughts. It has long been recognized that the introduction of mood monitoring techniques may be accompanied by an initial increase in depressive symptoms. Cognitive therapists, in essence, may be *encouraging* some patients to ruminate about their concerns. Our clinical impression is that it is not rumination per se that places youth at risk for depression, but "unproductive thought" or "nonsolution-focused thinking." With this in mind, we frequently ask adolescents to reflect briefly (5–10 min) upon their feelings of sadness, the causes and consequences of their distress, and the meanings attached to their experiences. At the end of this period, they are asked to answer a simple question: "And the solution to this is …?" Solution-focused thinking – the ability to identify and evaluate possible solutions – is often accompanied by a rapid decrease in feelings of sadness. This is followed by a discussion of how the teen learned to ruminate (i.e., "Where did you pick this up?"), and the ways in which it is adaptive or maladaptive for him or her.

1.6.8   Advanced Competencies of the Treating Psychologist

We propose that advanced competencies in the conduct of psychotherapy sessions can be observed, rated, and improved through supervision and case consultation. Because both of us practice CBT and have more familiarity with rating levels of competence within that treatment model, we will restrict the focus in this section to advanced competencies in CBT. It seems likely that advanced competencies in IPT would be similar, albeit within a different framework.

When considering advanced competencies in the conduct of CBT sessions, we find it helpful to rely on rating scales used by CBT supervisors in training or research contexts. In particular, we rely on the Cognitive Therapy Rating Scale (CTRS; Young & Beck, 1980) and on the Treatment for Adolescents with Depression CBT Quality Assurance Scale (CBT-QA; Curry, 2000). The former is a frequently used measure that assesses adherence to and competence in cognitive therapy; the latter has been used in only one study, but focuses on CBT treatment of adolescents.

Considering first the 11 items rated on the CTRS and the CTRS manual, advanced competencies in the conduct of treatment sessions include the following dimensions. First, CBT is based on an intervention model of collaboration between therapist and patient. Both work together to experiment with new behaviors and test the accuracy of key cognitions. Beck referred to this fundamental aspect of CBT as "collaborative empiricism" (Beck et al., 1979). At an advanced level, collaboration requires transparency on the part of the therapist as well as therapist skill in facilitating session-related disclosure by the patient. Therapist transparency here refers not to self-disclosure about the therapist's life or subjective experiences, but to the therapist's ability to make clear to the patient the rationale for therapist directions,

guidance or decisions, the rationale for any skill training introduced by the therapist, and the reason for any shifts in session focus that are introduced by the therapist. Simply put, the therapist should never "mystify" or puzzle the patient during sessions. Conversely, the therapist elicits from the patient relevant disclosures about treatment. Thus, the therapist elicits from the patient summaries of main points during and at the end of the sessions, assures that the patient understands how the therapist is formulating the treatment, and encourages the patient to voice any concerns or negative reactions to the therapist or the session. As transparency and disclosure are enhanced, the therapist listens carefully, demonstrates an accurate understanding of the patient's internal experience, and communicates this empathic understanding to the patient.

In addition to transparency and the facilitation of session-related patient disclosure, collaboration requires that the therapist socialize the patient into a progressively more active role over the course of CBT. The therapist makes it clear that therapist and patient constitute a team, encourages the patient to bring into sessions those current concerns and problems that the patient wants to resolve, and works with the patient to formulate "homework" assignments for practice between sessions. With adolescents, this aspect of CBT may be quite puzzling initially. Having been socialized primarily in the role of student, adolescents may enter therapy expecting to be taught in a primarily didactic model. It is helpful for child and adolescent therapists to use the role of "coach" (Kendall, 2006) as an understandable analogy. Like a coach, the CBT therapist will work with the adolescent to develop the adolescent's skills, will engage in dialogue with the adolescent, and will work together to shape "practice" assignments. Collaboration is expected to have a temporal dimension, in that the patient should become progressively more self-directed and active over a typical 8–20-week course of CBT.

A second major advanced competency in the conduct of CBT sessions is the ability to structure sessions so as to provide a reliable yet flexible context in which the patient can compete the necessary work of treatment. In contrast to the specific problem focus or the specific skill training that will change across the course of treatment, session structure should remain relatively consistent throughout treatment. In the TADS CBT-QA procedure, we considered the following elements to be critical to session structure: monitoring the adolescent's mood, setting a session agenda, reviewing any homework from the previous session, introducing or reviewing *and* practicing a particular skill, completing part or all of the agenda, and formulating a new homework. Advanced competence in conducting sessions is reflected in particular qualities associated with each of these elements.

Mood monitoring with adolescents can be completed with a brief questionnaire or in the context of the session. A key feature of mood monitoring with adolescents is to conduct this structural element without demand characteristics, i.e., in a manner that emphasizes openness and honesty and decreases social desirability. A cursory approach diminishes the importance of mood monitoring in the eyes of the adolescent. An approach that directly or indirectly reinforces the reporting of improved or positive mood or discourages the reporting of negative mood increases social desirability demand and precludes useful integration of mood monitoring with understanding and skill training.

Agenda setting is critical to the overall problem-solving model inherent in CBT. Adolescents must often be encouraged to bring in items for the session agenda, since this element of CBT differs rather dramatically from their experience as students in school and also from any experience they may have had with other more nondirective forms of psychotherapy. Advanced competency in agenda setting involves allowing some time for the adolescent to name problems

or concerns that he or she wishes to work on or talk about in the session. It also involves having the therapist designate any item that he or she wants to include in the session, including training in a particular skill. The link from agenda setting to skill training is of particular importance. As the therapist helps the adolescent to learn the skills that are theorized as key to overcoming depression (e.g., behavioral activation, problem-solving, cognitive restructuring), advanced competence is demonstrated by the therapist's ability to link skill training to items on the adolescent's agenda. Finally, advanced competence is demonstrated by good therapeutic judgment: the therapist helps the adolescent to identify the most important agenda items and address these first, with the recognition that not all items may be covered during a particular session. For example, an increase in suicidal ideation represents an urgent problem that must be addressed before any less urgent issues.

Homework review is essential if the therapist is to convey to the adolescent the importance of between-session skill practice. A well-conducted review will allot time to exploration of what the adolescent did or did not complete in the previous assignment, what practical restrictions, negative cognitions, or deficits in prerequisite skills interfered with task completion. Based on such a review, subsequent in-session skill training and between-session homework assignments can be adapted to maximize the likelihood of success for the depressed adolescent. The CBT therapist needs to avoid making the same kind of judgments about incomplete homework that the adolescent has likely experienced as a student. Instead, advanced competence is demonstrated by using whatever has happened with regard to the homework as an opportunity to learn and adjust the treatment plan.

Skill training, which is inherent in the multifactorial model of CBT and perhaps more indirect in cognitive therapy, was used in the TADS CBT. Advanced competence in skill training is reflected first by its integration with the overall treatment plan and with the rest of the current session. Thus, the therapist introduces skill training with a clear rationale that ties it to the therapist's and patient's mutual understanding of the adolescent's depression, explains how the particular skill will be helpful in overcoming depression, and ideally, how it will serve to address one or more items that the adolescent has placed on the session agenda. Second, advanced competence in skill training is reflected in bringing the skill to life. Training should not be passive or overly didactic. The therapist needs to use the full range of CBT's "educational technology" to convey the skill: rationale explanation (why to learn the skill), didactic instruction (how to perform the skill), demonstration (therapist performs or models the skill), and role-playing (adolescent and therapist together practice or enact the skill). If the therapist is using a treatment manual, the therapist must have an understanding of the relevant skill and be able to convey it beyond simply presenting material from the manual. Instead the therapist should be able to modify manual material to fit the developmental level and individual needs of the adolescent, and generate more than one way to "teach" the skill.

Completion of the session agenda and formulation of a new homework should also be integrated with skill training. Advanced competence is demonstrated when the therapist can help the adolescent to see the connections between the new skill and how to solve problems on the agenda. An ideal homework assignment is one that applies the newly learned skill to a manageable, not excessively challenging, problem that the adolescent has identified. The advanced therapist can bring the treatment model to bear on the adolescent's agenda items by showing the adolescent how treatment-based skills can help to resolve problems that are contributing to depression. In this way, the overall advanced in-session competence of the practitioner is what might be termed treatment integration: all elements of a session are interrelated

in a meaningful way that makes sense to the adolescent and that actively and directly addresses the problems she or he has brought into the session.

1.7 Transition from Basic to Expert Competence

We propose that there are a number of pathways from basic to advanced competence in clinical work with depressed adolescents. The key foundation for this process is an attitude of lifelong learning, which is one of the objectives of doctoral training in psychology. First, a clinician should maintain an adequate (but not excessive) caseload of adolescent cases so as to gain exposure to some range of depressed adolescents, their differential diagnosis and common comorbid conditions, and their patterns of response to treatment. Second, clinicians benefit from supervision or case consultation with more advanced colleagues. This can be facilitated in some work settings or projects, such as clinical trials or specialty clinics, but may require active pursuit of supervision opportunities in the local community.

Third, training workshops and continuing education opportunities offered in conjunction with state licensure requirements are of some value in learning evidence-based intervention practices and new assessment methods, but consolidated learning will very likely require follow-up supervision. Fourth, specialty training certification programs, such as that offered by the Beck Institute, involve comprehensive didactic, experiential, and supervised practice components leading to certification. Fifth, involvement in professional or scientific societies often leads to additional training and professional development options. For example, the Association for Behavioral and Cognitive Therapies and the Academy of Cognitive Therapy facilitate continued growth in clinical expertise based on science. In psychology, board certification by the American Board of Professional Psychology (ABPP) requires a process that is intended to lead to improved knowledge of the scientific basis of practice, ethical issues in practice, and evidence-based assessment and intervention practice. In particular, the ABPP Child and Adolescent Psychology Board emphasizes integration of science and practice. Advanced competence can be pursued by following one or several of these paths.

1.8 Summary

MDD was once thought to be restricted to adults, but has been demonstrated to be one of the more frequently occurring diagnoses among adolescents, and also to occur in a substantial number of children. Over the past 30 years, as the diagnostic criteria for MDD have been applied to young people, an expanding body of knowledge has accumulated concerning its prevalence across genders and age groups, its variable course, and its status as a risk factor for subsequent mood disorders in adulthood. The clinical psychologist who works with depressed youth needs to have not only those personal characteristics essential for clinical service delivery, but also those competencies in the areas of knowledge, assessment, and psychotherapy that are associated with addressing this disorder. The clinician's scope of knowledge includes theories of depressive psychopathology, the evidence base associated with these theories, and knowledge of effective treatments. Currently, evidence-based psychological treatments for adolescent MDD include CBT and IPT. In this chapter, we have reviewed supportive evidence for these interventions as well as their proposed targets, the maintaining factors associated

with depression in young people. In general, these can be categorized as cognitive, behavioral, and familial/interpersonal factors.

Basic competencies are those required for entry into practice, whereas advanced competencies imply a highly integrative approach to assessment and intervention based not only on experience but also on supervision, consultation, continuing education, and markers of advancement in the profession, such as board certification. Advanced competency also implies the ability to construct a comprehensive treatment plan and the awareness of how best to involve other professionals in that plan.

2 Anxiety Disorders

Thomas H. Ollendick · Laura D. Hovey

Abstract: In the first part of this chapter, we describe the anxiety disorders of childhood and the factors that maintain them (e.g., avoidance and safety behaviors, cognitive errors and biases), as well as evidence-based interventions that have been developed for their efficacious treatment. We also speculate on the mechanisms of change that underlie these effective interventions and how these mechanisms address the core psychopathology of these disorders. In the second part of the chapter, we explore issues of competency including both basic and expert competencies. We submit that the competent treatment of the anxiety disorders in childhood requires attention to relational, developmental, and contextual issues as well as the implementation of specific intervention strategies based on specific models of developmental psychopathology. Moreover, we indicate that expert competency is achieved only when one can implement these basic assessment and intervention strategies in a way that addresses such important issues as comorbidity and difficult-to-treat children and their families. We conclude by indicating that attainment of these competencies is a life-long process that is both fluid and dynamic. It is not at all static. We conclude that although much has been learned about the anxiety disorders in childhood and the competencies that underlie their effective treatment, much remains to be accomplished. The journey to understanding, assessing, and developing these competencies is in its own early stage of development.

2.1 Overview

Manifestation of anxiety disorders in youth can range from the relatively circumscribed anxiety of a specific phobia to the more pervasive symptoms of generalized anxiety disorder. According to the *Diagnostic and Statistical Manual of Mental Disorders, 4th Edition* (DSM-IV)-TR (American Psychiatric Association, 2000), children and adolescents can be diagnosed with any of the 13 different anxiety disorders. Like adults, they can be diagnosed with panic disorder with or without agoraphobia (PD), agoraphobia without a history of panic disorder (AG), specific phobias (SP), social phobia (SOP), obsessive-compulsive disorder (OCD), post-traumatic stress disorder (PTSD), acute stress disorder, generalized anxiety disorder (GAD), anxiety disorder due to a medical condition, substance-induced anxiety disorder, and an anxiety disorder not otherwise specified. In addition, children and adolescents may be diagnosed with separation anxiety disorder (SAD), which is specific to childhood, in that onset must be prior to 18 years of age. In previous versions of the DSM (American Psychiatric Association, 1987), two additional anxiety disorders specific to childhood were included, namely avoidant disorder (AD) and overanxious disorder (OAD). However, in the DSM-IV and its revision, AD is subsumed under SOP and OAD is subsumed under GAD; nevertheless, research prior to DSM-IV, including several of the early, large, randomized controled treatment trials typically included youth diagnosed with AD and OAD.

    As with adults, anxiety disorders are the most commonly occurring class of diagnoses in childhood. According to the results from the National Comorbidity Survey Replication,

approximately 30% of the individuals in the USA will manifest an anxiety disorder by the time they reach young adulthood (Kessler, Berglund, Demler, Jin, & Walters, 2005). Moreover, anxiety disorders in youth are commonly seen in clinical practice.

Of note, while certain fears are developmentally appropriate and transient in childhood, anxiety disorders engender significant distress and, if left untreated, would lead to difficulties in social and academic functioning (Ialongo, Edelsohn, Werthamer-Larsson, Crockett, & Kellam, 1994; Strauss, 1988; Strauss, Forehand, Smith, & Frame, 1986; Strauss, Frame, & Forehand, 1987). Moreover, anxiety disorders in youth leave them at risk for development of subsequent internalizing and externalizing disorders, with the former more common for girls and the latter more common for boys (McGee, Feehan, Williams, & Anderson, 1992; Ollendick & King, 1994). In fact, Feehan, McGee, and Williams (1993) found that anxiety comorbid with depression at age 15 was associated with one of the highest rates of the latter disorder (72.7%).

2.2 Recognition of Symptoms and Their Assessment

Recent years have seen much progress in the assessment of anxiety disorders in youth, resulting from both the development of new instruments and more detailed investigations of the older "tried and true" measures. However, the multifaceted nature of the anxiety construct, the number of anxiety disorders, and the high rate of comorbidity can make assessment of anxiety in children and adolescents a complex and time-consuming enterprise. Additionally, self-reports of children presenting for treatment of anxiety disorders may be incomplete due to their hesitancy to admit the socially undesirable symptoms; parent and teacher reports may also be incomplete because many of the symptoms of anxiety disorders may not be directly observable and the degree to which directly observable symptoms are present tends not to be commensurate with physiological or subjective measures of anxiety (Joiner, Schmidt, & Schmidt, 1996; Pina, Silverman, Saavedrea, & Weems, 2001; Silverman & Ollendick, 2005).

As such, the ideal assessment approach utilizes a multimethod, multi-informant approach that can fulfill the goals of (1) discriminating amongst the anxiety disorders, (2) determining if symptoms are clinically significant, (3) differentiating between symptoms of anxiety and overlapping disorders, (4) determining which, if any, comorbid conditions exist, and (5) monitoring treatment progress (Silverman & Ollendick, 2008). Fortunately, a wide array of psychometrically sound instruments, including diagnostic interviews, child reports, parent-and-teacher reports, behavioral observations, and behavioral avoidance tests, has been developed. Although space prohibits a thorough review, we highlight some of the most widely used instruments below.

2.2.1 Diagnostic Interviews

The Anxiety Disorders Interview Schedule for DSM-IV Parent and Child versions (ADIS-IV; Silverman & Albano, 1996) is the most widely used diagnostic interview designed specifically for assessment of youth with suspected anxiety disorders. The ADIS-IV/C + P is a semi-structured interview designed to be administered by trained clinicians. Modules provide for assessment of all the major anxiety disorders as well as other common disorders in youth

(e.g., depression, externalizing disorders). In addition, screening questions for other disorders (e.g., developmental disorders, learning disabilities) are included. The psychometrics of the ADIS-IV/C + P are good (Silverman & Albano, 1996); however, as is the case of diagnostic interviews in this area, parent–child agreement tends to be low (Grills & Ollendick, 2003). Therefore, it is recommended that both the parent and the child interviews be administered, and composite diagnoses, derived from combining both sources of information, be used.

Although, not specifically designed for anxiety disorders, a variety of other diagnostic interviews such as the Schedule for Affective Disorders and Schizophrenia for School-Age Children (K-SADS; Kaufman et al., 1997) and the National Institute of Mental Health Diagnostic Interview Schedule for Children Version IV (NIMH DISC-IV; Shaffer, Fisher, Lucas, Dulcan, & Schwab-Stone, 2000) provides a thorough assessment of the anxiety disorders and those disorders commonly associated with anxiety. In addition, some of these interviews are highly structured and can be used by interviewers with minimal training.

Although structured and semi-structured interviews are available for use with children and adolescents between the ages of 6 and 18 years and these interviews show good reliability (Silverman & Ollendick, 2005), their use is largely limited to research settings. This seems most likely to be related to the costs associated with using these interviews (i.e., training and purchase of materials) and the amount of time needed to complete them. On this last point, it should be noted that a thorough diagnostic assessment that includes interviews with both the youth and the primary caregiver can take more than 3 h. Despite these real limitations, we suggest that the use of structured and semi-structured diagnostic interviews be routinely integrated into clinical practice for several reasons. First, research shows that clinicians fail to fully evaluate diagnostic criteria when using unstructured interviews (Miller, 2002). This results in unreliable and inaccurate diagnosis, failure to identify comorbid diagnoses, and identification of less-specific diagnoses (i.e., not otherwise specified diagnoses) when compared to structured clinical interviews (Miller, 2001; Miller, Dasher, Collins, Griffiths, & Brown, 2001). Moreover, inaccuracies associated with unstructured interviews have been shown to be related to compromised treatment decisions and greater treatment costs (Miller, 2001, 2002).

2.2.2 Self, Parent, and Teacher Reports of Anxiety in Youth

Numerous psychometrically sound questionnaires exist to assess anxiety in youth. Among the most widely used are the Revised Children's Manifest Anxiety Scale (RCMAS; Reynolds & Richmond, 1985), the Children's State Trait Anxiety Scale (STAIC; Spielberger, 1973), and the Child Behavior Checklist (CBCL; Achenbach & Rescorla, 2001). Additionally, the Revised Fear Survey Schedule for Children (Ollendick, 1983) can be used to assess for specific fears, including social fears in youth. The RCMAS and STAIC are completed by the child and are intended for children (starting around age 7) and adolescents. The CBCL is completed by parents, and versions are available for youth ranging in age from 1 year and 6 months to 18 years; a parallel teacher version and self-report, the Teacher Report Form (TRF; Achenbach & Rescorla), and the Youth Self Report (YSR; Achenbach & Rescorla), are also available. The RCMAS, STAIC, and the CBCL have been shown to discriminate between youth with anxiety disorders and healthy children as well as between youth with an anxiety disorder and an externalizing disorder; these measures are less useful however in discriminating between anxiety and depression in youth (Seligman, Ollendick, Langley, & Bechtoldt Baldacci, 2004).

Several more recent self-report instruments, such as the Spence Child Anxiety Scale (SCAS; Spence, 1998), the Multidimensional Anxiety Scale (MASC; March, Parker, Sullivan, Stallings, & Conners, 1997), and the Screen for Child Anxiety-Related Emotional Disorders (SCARED; Birmaher et al., 1997), have been developed to assess anxiety in youth. These questionnaires have the advantage of items that map directly onto the symptoms of the DSM-IV anxiety disorders; therefore, although they cannot substitute for a formal diagnostic interview, they can aid in the diagnostic process and monitoring of treatment progress.

2.3   Maintenance Factors of the Disorder or Problem

There are two broad factors that appear to relate to maintenance of anxiety symptoms in youth once they have developed. The first is avoidance and safety behaviors. The second broad category is cognitive errors and biases.

2.3.1   Avoidance and Safety Behaviors

Research suggests that children and adolescents with clinically significant anxiety tend to choose avoidant coping strategies when dealing with anxiety-provoking situations (e.g., Chorpita, Albano, & Barlow, 1996). For example, youth with SAD may refuse invitations from friends for sleepover parties or even after-school playdates. Similarly, youth with SOP may avoid asking questions in class or participating in extracurricular activities, such as joining a sports team or trying out for a school play, which give rise to fears of negative evaluation. Children and adolescents with PD often engage in two types of avoidance – avoidance of interoceptive cues of panic symptoms and exteroceptive cues that might trigger panic symptoms (i.e., agoraphobic avoidance). Examples of the former include avoiding exercise or any strenuous activity that might cause tachycardia, while examples of the latter might include avoidance of shopping malls, riding/driving in a car, or any situation that has become associated with a panic attack (Ollendick, 1998). In some especially difficult cases, children with various types of anxiety disorders (e.g., SAD, SOP, PD, SPs) will refuse to attend school and avoid all that school attendance entails.

Alternatively, children and adolescents with anxiety disorders may choose to approach an anxiety-provoking situation by using or enlisting a variety of safety behaviors. This may be especially true in situations that are difficult for a child to avoid. For example, a child with SOP may not be able to avoid being called upon by the teacher in class but could instead engage in a safety behavior by speaking too softly for anyone to hear. Similarly, a child with SAD may not be able to attend school unless the parents and school have arranged for a favored peer or a "safe person" to be in the child's class. Likewise, a child with SP of dogs might report liking to play indoor games rather than to play outdoors where dogs might be present. Other safety behaviors may include keeping a good luck charm or a favorite toy within reach or making sure to have access to anxiolytic medication when approaching an anxiety-provoking situation.

The problem with avoidant and safety behaviors is that although they provide temporary relief, they preclude opportunities for habituation and more adaptive learning in the long term. The socially anxious child who refuses to go to school or responds to questions in an inaudible voice because she or he does not want to have to speak in front of peers never has the

opportunity to learn that this situation is not in fact as dangerous as she or he assumes and that his or her anxiety would dissipate with prolonged exposure. As such, avoidance and safety behaviors beget continued anxiety and avoidance.

Interestingly some studies suggest that parents of children with anxiety disorders, unaware of the undesirable consequences, encourage such behavior. For example, some studies show that children choose increasingly avoidant strategies for dealing with anxiety-provoking situations after being given the opportunity to discuss the situations with their parents (Chorpita et al., 1996). It may be that in an effort to help their child avoid painful situations the parent becomes overprotective and directly instructs the child in avoidant coping strategies. This may in part be because parents of anxious children are more likely to have problems with anxiety themselves (e.g., Beidel & Turner, 1997).

2.3.2 Cognitive Errors and Biases

It has been demonstrated that children with anxiety disorders, than the children with healthy controls, are more likely to interpret ambiguous situations as threatening (Chorpita et al., 1996; Gifford, Reynolds, Bell, & Wilson, 2008); they also demonstrate an attentional bias for threatening information (Roy et al., 2008), and are more likely to remember threatening information (Watts & Weems, 2006). In addition, children with anxiety disorders are likely to overestimate the probability of undesirable outcomes. For example, a boy with SOP giving a speech may see two audience members whispering among themselves and believe that they must be making fun of him. Similarly, a child with a specific phobia of dogs may be more likely to both notice and remember instances of dogs behaving aggressively. A child with GAD may hear that her father had a fight with a co-worker and she might come to believe that the father will soon lose his job and that this means that the family will become homeless.

Such errors and biases help to perpetuate the child's view of the world as threatening and inhospitable and in this way help to maintain the symptoms of anxiety. Interestingly, as with avoidance behaviors, there seems to be emerging evidence that children can learn these cognitive errors and biases, at least in part, from their parents. For example, Perez-Olivas, Stevenson, and Hadwin (2008) found that high maternal overinvolvement, often linked to anxiety symptoms in youth, was related an attentional bias toward threatening stimuli in children evidencing symptoms of separation anxiety. Further, the relationship between maternal overinvolvement and separation anxiety symptoms was partially mediated by the children's attentional bias, suggesting that parental characteristics often linked with anxiety (e.g., overinvolvement and control) may exert their influence through the pathways implicated in a cognitive model of anxiety.

2.4 Evidence-Based Treatment Approaches

Although there are some notable exceptions (Muratori, Picchi, Bruni, Patarnello, & Romagnoli, 2003), the majority of the treatment outcome research for anxiety disorders in childhood has employed cognitive-behavioral treatment (CBT) strategies and, to date, only CBT interventions have received the degree of support necessary for identification as evidence-based treatments (EBTs) (Ollendick & King, 1998; Ollendick, King, & Chorpita, 2006).

In the first randomized controlled trial of a psychological intervention for childhood anxiety disorders, Kendall (1994) compared a CBT intervention for 9–13-year-old children with a wait-list control condition. Treatment consisted of teaching the children to (1) recognize the physiological, emotional, and cognitive symptoms that accompanied their anxiety, (2) develop coping strategies including replacing anxiety-provoking cognitions with coping cognitions, and (3) use self-reinforcement, relaxation training, and both imaginal and in vivo exposure. Treatment was delivered individually in an average of 17 sessions over 16 weeks. Both parents and children reported significant improvement in the children's symptomatology. Moreover, changes were both statistically and clinically significant. For example, while 64% of youth in the CBT condition no longer evidenced an anxiety disorder diagnosis at posttreatment, only 5% of the children in the wait-list condition were diagnosis-free at the end of the wait-list period. Moreover, in a larger trial of the same treatment with similar-aged children, Kendall et al. again demonstrated the efficacy of their treatment (Kendall et al., 1997), with approximately 53% of the treated participants no longer meeting criteria for their primary anxiety disorder at posttreatment as compared to 6% of the participants in the wait-list condition. Further, Dadds, Heard, and Rapee (1992) and Barrett, Dadds, and Rapee (1996) have shown that a similar but somewhat shorter (i.e., 12 session) CBT program could be delivered with comparable outcomes.

All told, over 51 randomized controlled trials and small *n* designs have supported the effectiveness of CBT for the treatment of anxiety disorders in youth (Ollendick, Jarrett, Grills-Taquechel, Seligman, & Wolff, 2008). In general, these studies suggest that approximately two thirds of the youth recover (i.e., no longer meet criteria for the anxiety disorder that was the focus of treatment) at the end of treatment. Moreover, long-term outcome studies suggest that these gains are maintained over time and, in at least some instances, continued improvement is seen (Barrett, Duffy, Dadds, & Rapee, 2001; Kendall & Southam-Gerow, 1996).

Importantly, these and other studies suggest that CBT may be efficacious for a wide variety of youth. Studies have included youth with a variety of anxiety disorder diagnoses and comorbid conditions, and results suggest that children with comorbid conditions, the rule rather than the exception in the anxiety disorders, achieve results similar to those of youth not evidencing comorbidity (Kendall & Southam-Gerow, 1996; Ollendick et al., 2008; Rapee, 2003). Furthermore, evidence across studies suggests that CBT treatment can be successful for primarily Caucasian youth from the USA (Kendall, 1994; Kendall et al., 1997), African-American youth in the USA (Ginsburg & Drake, 2002), Australian children (Barrett et al., 1996, 2001; Shortt, Barrett, & Fox, 2001), Canadian and French Canadian children (Léger, Ladouceur, Dugas, & Freeston, 2003; Manassis et al., 2002; Mendlowitz et al., 1999), and Israeli children (Toren et al., 2000).

While both randomized controlled trials and single-case design studies have demonstrated efficacy of CBT treatments, treatment as usual (i.e., treatment as it is commonly practiced in clinical, rather than research, settings) has been shown to have virtually no positive effects for childhood problems, including the anxiety disorders (Weiss, Catron, Harris, & Phung, 1999; Weisz & Weiss, 1989; Weisz, Weiss, & Donenberg, 1992). There is some evidence that these conclusions apply to children seen for treatment in both clinical as well as research settings. In fact, direct comparisons of EBTs and usual care support the superiority of EBTs in clinical practice (Weisz, Jensen-Doss, & Hawley, 2006). Additionally, benchmarking studies with adults diagnosed SOP suggest that outcomes for CBT in research and private practice are comparable (Gaston, Abbott, Rapee, & Neary, 2006). However, although these findings suggest that CBT

may be an effective as well as an efficacious treatment for youth with anxiety disorders, additional research is needed to bolster these conclusions.

2.4.1   Parent Treatment

Given findings relating parental anxiety (Beidel & Turner, 1997) and parenting behaviors, such as parental overinvolvement and control (Hudson & Rapee, 2001, 2005) to anxiety in youth, it is not surprising that several trials have investigated the effects of adding parent treatment to conventional CBT packages. What is surprising is the varied results. For example, Dadds et al. (1992) and Barrett et al. (1996) investigated the effects of parent treatment plus CBT treatment for children with anxiety disorders. Treatment for parents consisted primarily of education on reinforcement and communication and problem-solving techniques aimed at increasing parents' ability to work together and decreasing parental conflict concerning child-rearing. While a preliminary investigation involving 14 children with diagnoses of SAD OAD found that CBT + parent treatment was superior to a wait-list control (Dadds et al.), a more extensive investigation that allowed for the comparison of CBT + parent treatment to CBT for the child alone (Barrett et al.) resulted in mixed findings. In terms of diagnosis at posttreatment, significantly more children in the CBT + parent treatment group than the CBT alone treatment showed improvement. However, child self-reports did not support the superiority of one method of treatment over the other, while conclusions based on parent reports were mixed. Further, when the superiority of CBT + parent treatment was supported, it was moderated by child sex and age. Girls and younger children had better outcomes with the CBT plus parent treatment as compared to the CBT treatment for the child alone. However, for boys and the older children the treatments seemed to be comparable.

Similarly, another study by Barrett (1998) found modest benefit when a family management treatment was added to group CBT for children between the ages of 7 and 14 years diagnosed with SAD, OAD, or SOP. However, the superiority of parent treatment over CBT for the child alone was not supported in a trial for children and adolescents with posttraumatic stress symptoms resulting from sexual abuse (King et al., 2000) nor for youth with SOP (Spence, Donovan, & Brechman-Toussaint, 2000).

Of note, however, is a study which matched treatment to parental psychopathology. In a trial of 67 youth between the ages of 7 and 14 with diagnoses of SAD, SOP, OAD, SPs, or GAD (Cobham, Dadds, & Spence, 1998), parental anxiety was assessed and some families were given CBT for the child alone, while others received CBT for the child plus parent treatment. While the addition of parent treatment was not significantly better in the absence of parental anxiety, it did significantly improve outcomes for the group with parental anxiety.

Taken together, these studies suggest that in some cases addition of parent treatment may improve outcomes for youth with anxiety disorders but that more research is needed to determine when this is true. To date it appears that parent treatment may be significantly better only for younger girls and in families where one or both parents also experience significant anxiety. However, these results await replication. In addition, research is emerging on the mechanisms that result in parental transmission of anxiety to children (see section on maintenance factors for some examples) which may help clinicians to more specifically tailor the types of treatment that parents of anxious children receive.

2.5 Mechanisms of Change Underlying the Intervention

Several mechanisms of change underlying the efficacy of both cognitive and behavioral therapies of the anxiety disorders have been put forth. Early theories suggested that habituation or counterconditioning accounted for the effects associated with exposure in the behavior therapies (Wilson & Davison, 1971), while corrections in cognitive distortions and maladaptive beliefs were thought to account for the changes associated with cognitive interventions (e.g., Ellis, 1962). However, newer theories have either altered or expanded upon these basic explanations.

For example, Foa and McNally (1996) hypothesized that exposure therapies work because they create new adaptive fear networks that compete with existing maladaptive fear networks which underlie pathological anxiety. Essentially, Foa and McNally suggested that maladaptive fear networks consist of erroneous stimulus–stimulus and stimulus–response associations as well as exaggerated estimations of negative consequences associated with the fear. For example, a child with SOP might associate talking with peers with negative stimuli such as critical comments and rejection from classmates. The child might also associate talking with peers with increased physiological arousal and behavioral avoidance. Moreover, the child might also believe that saying something inappropriate during a conversation with a peer would result in lifelong ostracism from all peers. According to Foa and McNally's theory, exposure therapy creates a competing fear network that does not contain these maladaptive connections but instead includes more adaptive associations such as conversation with peer – pleasure. Although the pathological network would continue to exist, the more adaptive network would also be available and would be activated in most situations. On the other hand, other theories suggest a more cognitive explanation for the efficacy of exposure and the behavior therapies. These theories suggest that exposure without the typically ensuring response of avoidance increases self-efficacy for coping with the feared situation and that increased self-efficacy in turn results in decreased anxiety (Williams, 1996).

Current explanations for cognitive therapies still include changes in maladaptive cognitions (e.g., negative self-talk, overgeneralization, overestimation), but given the current state of research in cognitive processes in anxiety (see previous section on maintenance factors), newer theories also focus on changes to attentional, memory, and interpretive biases as well.

Unfortunately, while theory development has progressed as effective treatments have been established, adequate tests of these theories are notably lacking, particularly in child and adolescent samples. For example, in a relatively recent review of the youth psychotherapy literature, Weersing and Weisz (2002) found that while 22% of the trials examined learning-based therapies and 60% of the cognitive-behavioral trials assessed possible mediators of treatment outcome, few studies formally tested for mediation. Furthermore, when mediation was assessed, interpretation of findings was complicated by methodological problems including the fact that changes in symptoms and candidate mediators were assessed at the same point in time (i.e., posttreatment) and that self-report methods were used to assess both treatment outcome and potential mediators, introducing the confound of monomethod variance (Prins & Ollendick, 2003). With these caveats in mind, two studies have found that changes in anxiety in CBT treatment for anxious youth are related to changes in negative self-talk (Kendall & Treadwell, 2007; Treadwell & Kendall, 1996). In addition, decreases in physiological arousal (i.e., habituation) have been found to change after successful learning-based treatment of anxiety in youth (Weersing & Weisz, 2002). Other possible mediators have not been assessed; thus, this remains an important area for future investigations.

2.6   Basic Competencies of the Clinician

As is evident, CBT interventions have been found to be effective in the treatment of children and adolescents with diverse anxiety disorders. Overall, significant reductions in symptoms or diagnoses have been observed in about 60–70% of the treated youth, compared with about 5–20% of the youth in wait-list comparison groups and 15–30% of the youth in placebo and alternate treatment conditions (Ollendick & King, 2004; Silverman, Pina, & Viswesvaran, 2008). However, given the variety of anxiety disorders that have been treated in these studies (e.g., GAD, SAD, SOP, SP, OCD, PTSD) as well as the format in which the treatments have been delivered (e.g., individual/group, child/family), it is somewhat difficult to specify the exact competencies involved in successful treatment. Still, most of the studies have shown similarly good outcomes regardless of the format of treatment or the specific anxiety disorders treated, and, in as much as the mechanisms of change underlying the interventions are similar, some basic and expert competencies can be identified.

We begin our treatment of competencies by indicating that basic competencies for the treatment of any set of childhood disorders, including the anxiety disorders, are embedded in the core competencies that all professional psychologists share and are expected to evidence: (1) application of scientific knowledge to clinical practice, (2) use of psychometrically sound, evidence-based assessment instruments, (3) implementation of theory-driven, evidence-based interventions, (4) competence in consultation and interprofessional collaboration, (5) development of supervisory skills, (6) attention to professional development and ongoing continuing education, (7) competencies in ethical and legal issues, and (8) awareness of individual and cultural diversity (see Kaslow, 2004; Kaslow et al., 2004; Roth & Pilling, 2008; Sharpless & Barber, 2008). Hupp, Jewell, and Reitman described these basic competencies and others in more detail in ▸ Chapter 1, Volume 1 of this Handbook and they will not be elaborated upon here. Of course, each of these competencies needs to be brought to life in the treatment of any one set of disorders. For example, use of evidence-based assessment instruments requires the clinician to be aware of, master, and use assessment instruments that possess a strong evidence base for a given set of disorders. As noted, such tools include diagnostic interviews, rating instruments, and behavioral observation procedures. Recently, in describing evidence-based assessment tools for the child anxiety disorders, Silverman and Ollendick (2005, 2008) presented the evidence base for different instruments in reference to three distinct assessment purposes: diagnosis, case conceptualization and treatment planning, and treatment monitoring and treatment outcome evaluations. Suffice it to indicate here that many frequently used assessment tools did *not* possess sufficient evidentiary support and were not recommended for ongoing clinical or research use. Still, several evidence-based instruments were identified and recommended for use in best clinical practices. Tools such as the Anxiety Disorders Interview Schedule for Children and Parents (Silverman & Albano, 1996), the MASC (March et al., 1997), the FSSC-R (Ollendick, 1983), and the behavioral approach tasks (BATs) met exacting criteria and were recommended for ongoing use. Basic competencies to administer, interpret, and score these instruments are required (see earlier chapters in this volume). Thus, the use of these evidence-based instruments requires the clinician to apply basic or core competencies (e.g., evidence-based assessment tools) to specific problems and disorders (e.g., anxiety disorders in children).

Similarly, the use of evidence-based interventions requires the clinician to be aware of, master, and use interventions that possess strong empirical support for their use *with specific*

disorders. Ollendick and King (2004) and Silverman et al. (2008) reviewed such interventions for children with phobic and anxiety disorders and provided critical commentary on them. A reasonable inference from these reviews is that clinical outcomes will be improved when clinicians abandon "unproven" or "untested" therapies and adopt evidence-based therapies that have been shown to be effective. Of course, this conclusion also implies that clinicians need to master a reasonably large number of treatment protocols or manuals, or need to specialize in the treatment of a limited set of disorders in order to manage information and skill overload. Thus, while the emergence of evidence-based treatments represents a major advance in the field, the sheer number of effective interventions presents a significant challenge for both therapists-in-training as well as seasoned practitioners. Given the information and skill acquisition demands inherent in mastering different treatments, we propose that what is critical for improvement of child and adolescent therapy in general and with the anxiety disorders in particular may be less about mastery and use of specific treatment manuals and more about understanding and applying core change principles and procedures that are inherent in manuals with known efficacy for any set of disorders. To this end, our attention might be redirected to core principles and procedures that are captured in empirically supported protocols (Ollendick & Shirk, in press). Recently, Woody and Ollendick (2006) summarized the core principles of effective treatments for the anxiety disorders and recommended a common set of procedures in their treatment. In conducting evidence-based treatment for the anxiety disorders, they recommended that clinicians should do the following:

- Challenge misconceptions through discussion and explicitly question the evidence.
- Actively test the validity of erroneous and maladaptive beliefs through behavioral experiments.
- Use repeated exposure to the feared situation to reduce the intensity of the fear response.
- Eliminate avoidance of feared situations.
- Improve skills for handling feared situations.

Of importance, these five procedures are based on scientific knowledge about the anxiety disorders. The first two procedures address cognition and represent methods that describe what is commonly referred to as cognitive restructuring. The third procedure, fear reduction, relates to the affect and the physiological arousal that so frequently accompanies anxiety. The last two procedures explicitly involve behavior, addressing avoidance, and a variety of personal interactive skills. These five procedures do not stand in isolation, however. They each serve to promote the goals of the others, which is one likely reason why evidence-based treatments seldom use strategies based on just one of the procedures and the principles that underlie it. For example, eliminating avoidance of feared situations (behavior domain) not only promotes a return to normal and adaptive functioning, but also promotes exposure to feared situations (affective domain) and serves to challenge and alter maladaptive ideas about bad things that might happen in those situations (cognitive domain). As can be seen, treatment of childhood anxiety disorders requires considerable scientific knowledge about specific disorders and the development of skill levels to implement treatments based on that knowledge.

Of course, these five core procedures for the treatment of the anxiety disorders and the competencies associated with them do not operate or exist in a vacuum; for their effective use, they in turn are likely related to core developmental and contextual issues that require additional basic competencies. Clinicians working with children and adolescents are faced with a challenge rarely shared by their adult therapist counterparts. Between preschool and late

adolescence, children undergo enormous developmental changes in their cognitive, linguistic, emotional, interpersonal, and biological systems. Child clinicians are faced, not only with individual differences, but with developmental differences as well. About 25 years ago, Ollendick and Hersen (1984) suggested that the "same" interventions delivered to children at different ages could produce dramatically different results due to the developmental differences in child capacities. In this respect, our interventions are constrained or facilitated by the developmental processes (Ollendick & Shirk, in press; Shirk, 1988; Silverman & Ollendick, 1999).

For the most part, the search for potential developmental predictors of treatment outcome has focused on child age. Age, of course, represents a proxy for developmental processes, a stand-in for adaptive or maladaptive processes that develop over time and unfold with increasing maturation and experience. Age could be a proxy for processes that either *facilitate* or *impede* treatment efficacy. Most CBT interventions have concentrated on children between the ages of 7 and 14 years, with fewer interventions for younger children or adolescents. Despite this restricted age range, some studies suggest age-related trends in response to CBT treatments for anxiety. For example, Southam-Gerow, Kendall, and Weersing (2001) examined predictors, including child age, of treatment response among children aged 7–14 who received CBT for anxiety disorders. Poor treatment response was defined as the presence of any anxiety disorder diagnosis following a full course of CBT. Analyses revealed a number of predictors of poor response including higher levels of internalizing symptoms at pretreatment, higher maternal depression, and *older* child age. Child age continued to predict poor response even when analyses controlled for the other predictors.

Unlike an early meta-analysis of self-instructional CBT interventions by Durlak, Wells, Cotton, and Johnson (1995), increasing age was not associated with greater treatment benefit among these youth. As such, these results are inconsistent with a developmental facilitation perspective (e.g., increasing age is associated with greater capacity to utilize and benefit from interventions). However, because CBT approaches to anxiety reduction involve both cognitive and behavioral components, it is possible that children at different ages respond to different facets of the intervention (e.g., cognitive restructuring or modifying self-talk, exposure to anxiety-producing situations). Further, as Southam-Gerow et al. (2001) point out, it is not clear if the poorer response of older children is a function of a poor developmental fit between the activities that comprise CBT in these interventions (the activities may be too "childish") or because the anxiety problems were simply present for a longer duration of time (i.e., more entrenched and refractory to change).

In another illustrative study, Barrett et al. (1996) examined age as a potential moderator of treatment outcome in CBT for child anxiety (see above). As will be recalled, findings indicated that younger children responded more favorably (more were anxiety diagnosis-free) to CBT + FAM than older children. A similar pattern was not obtained with individual CBT. That is, both younger and older children responded similarly to the individual approach. Thus, age moderated the association between treatment and outcome. It effect, inclusion of a family component was more useful for younger children than older ones. From a developmental perspective, these results might be attributed to greater role of parent influence over younger children, or possibly to the greater importance of parent-assisted coping strategies for the younger children. Although this pattern of results clearly needs to be replicated, it raises an important developmental question: might greater treatment benefits be expected from the addition of family or parent components in evidence-based treatments for younger compared to older youth?

As illustrated in these two studies, developmental levels may need to be taken into consideration when selecting and implementing CBT interventions with youth of varying ages. If so, basic competencies related to recognition of development and developmental processes will be important. So too, other competencies related to contextual factors such as therapeutic relationship and alliance factors might need to be taken into consideration, and the appropriate competencies enlisted. The importance of the therapeutic relationship has been recognized by child and adolescent clinicians of different theoretical orientations for a long time (Axline, 1947; Freud, 1946; Kendall, 1991; Ollendick & Cerny, 1981; Patterson & Chamberlain, 1994); however, most research over the last 10–15 years has focused on the identification, manualization, evaluation, and dissemination of specific treatment procedures. The search for evidence-based treatments has been based on the assumption that "specific factors," those procedures that distinguish one form of therapy from another, are likely to be associated with greater improvements in outcomes than variations in "nonspecific factors," those features that are common across therapies. Of all the nonspecific factors, the therapeutic relationship has received the most attention in the child and adolescent research literature (Karver, Handelsman, Fields, & Bickman, 2006; Shirk & Karver, 2003). Moreover, a review of treatment manuals, whether for youth or parent-focused interventions, reveals a common focus upon building a collaborative, working relationship (i.e., alliance) with several studies showing these therapeutic variables associated with differential outcomes in different child and adolescent therapies (Karver et al., 2006; Shirk & Karver). Specifically, Shirk and Karver found modest but comparable associations among measures of therapeutic relationship and alliance and outcomes across behavioral and nonbehavioral, manualized and nonmanualized, and adolescent and child therapies.

Two dimensions of alliance – emotional bond and task collaboration – have emerged as core features in child and adolescent therapies (Estrada & Russell, 1999; Shirk & Saiz, 1992). A third dimension found to characterize adult therapies, agreement of treatment goals, has received less attention, perhaps because of the low rate of goal consensus found in child and adolescent therapy (Hawley & Weisz, 2003). In brief, alliance in youth treatment has been viewed as a *collaborative bond* between the child and the therapist (Kazdin, Marciano, & Whitley, 2005). Of course, because youth rarely refer themselves for treatment and typically reside with adult caregivers, treatment typically involves multiple alliances: between therapist and youth as well as between therapist and parent(s). In fact, for some forms of CBT with younger children, the child's problems may be targeted by working directly and solely with the parent. In such cases, the critical alliance, then, is between the therapist and the parent. In other cases, parents can be involved as consultants or co-therapists. The alliance in child treatment, then, is both multidimensional and multi-relational (Ollendick & Shirk, in press). Typically, therapists are faced with establishing and maintaining a collaborative bond with both youth and adult caregivers.

In sum, a number of basic competencies are evident in the assessment and treatment of children and adolescents with anxiety disorders. These competencies require the clinician to move beyond general competencies of professional psychologists, develop the knowledge and skills necessary to use the principles and procedures underlying effective interventions for select disorders, and implement these interventions in a developmentally sensitive manner within a strong therapeutic relationship. In most CBT trials, efforts have been made to articulate and quantify the basic competencies involved in effective interventions. For example, ◉ Tables 2.1 and ◉ 2.2 specify 13 different competencies required for the effective implementation of an intensive, exposure-based intervention for treatment of specific phobias in youth

(Ollendick et al., 2009). Competencies for working with children (❯ Table 2.1) and parents (❯ Table 2.2) are specified. As can be seen, these competencies consist of items that tap the ability of the clinician to create a good and trusting relationship with the child and the parent; provide basic, accurate information about fears and phobias to both the child and the parent; deal with questions the child or parent might have about phobias in a developmentally sensitive manner; inquire about the child's catastrophic beliefs about the phobias and the response of the parents to these beliefs, as well as the child's own beliefs about the phobic objects; use instruction, modeling, and rewards during the sessions and afterwards to teach and reinforce acquisition of skills for interacting with the phobic object; arrange for intensive exposure activities with the phobic object with such activities arranged in a hierarchical fashion; and, finally, handle difficult situation that arise in the treatment session and use time efficiently during the session so that the session progresses at a maximally therapeutic pace. Quite clearly, a host of competencies is involved in the effective treatment of youth with phobic disorders. A similar set of competencies has been articulated for the treatment of other childhood anxiety disorders (Walkup et al., 2008).

2.7 Expert Competencies of the Clinician

It is difficult to differentiate basic from expert competencies. Indeed, some of the competencies listed in ❯ Tables 2.1 and ❯ 2.2 might be viewed by some as "expert" competencies (e.g., the efficient use of time and pacing during the session, handling of difficulties in arranging for, and conducting, exposure procedures during treatment). However, for us, these abilities and skills are all basic ones – without them, the treatment is likely to be ineffective. For us, the distinction between basic and expert competencies resides in what to do when effective treatments – *competently implemented* – do not work with certain children and families for whom they *should* work. Although many possible scenarios exist, we will illustrate expert competencies by addressing two difficult situations: (1) differential diagnosis and the treatment of children with comorbid disorders and (2) dealing with children and families who are seemingly refractory to treatment.

Differential Diagnosis and Comorbidity. Because of overlap in symptoms and underlying psychopathological processes in the different anxiety disorders, differential diagnosis of the anxiety disorders is not always straightforward even when an evidence-based diagnostic interview such as the ADIS-IV/C + P is used (Silverman & Ollendick, 2005, 2008). It is beyond the scope of this brief chapter to provide a complete analysis of the issues involved in the differential diagnosis of each of the anxiety disorders. Instead, for illustrative purposes, we will focus on critical distinctions that need to be made when working with children and adolescents who present with select anxiety disorders: GAD, PD, and SOP.

In terms of GAD, "worry" is a process in which all youth engage at some point in their lives (e.g., Silverman, La Greca, & Wasserstein, 1995); in addition, worry is a pervasive clinical feature of all anxiety disorders (Weems, Silverman, & La Greca, 2000). As a result, it can be quite difficult to distinguish GAD from the other anxiety disorders. The differential diagnosis of GAD requires that the youth's excessive worrying, which must be endorsed as "uncontrollable" and "hard to stop," *cannot* focus solely on areas of worry that would pertain to other anxiety disorders such as social situations (i.e., SOP), specific objects or events (i.e., SP), or separation from attachment figures (i.e., SAD). Moreover, the worries cannot be related solely to a traumatic

▣ Table 2.1

Therapist competency in one-session treatment of specific phobias: Child form (Ollendick et al., 2008)

General scale:

	0	1	2	3	4	5	6
	Not at all	Yes, but poorly	Yes, but inadequate	Satisfactory	Good	Very good	Excellent
1	Created a good and trustful therapeutic relationship with the child						–
2	Provided general instructions before the start of the exposure						–
3	Provided specific instructions during the exposure session						–
4	Gave factual information about the phobic object/situation						–
5	Dealt with questions as they arose in session						–
6	Continued with exposure exercises during the session						–
7	Guided the child in the exposure procedure						–
8	Used modeling during the session						–
9	Used verbal reinforcement during the session						–
10	Elicited and worked with the child's catastrophic beliefs						–
11	Efficient use of time and pacing during the session						–
12	Described how to continue with self-exposure after the session						–
13	Handled difficulties in the exposure procedure						–

Comments:

■ **Table 2.2**

Therapist competency for one-session treatment of specific phobias: Parent form (Ollendick et al., 2009)

General scale:

	0	1	2	3	4	5	6
	Not at all	Yes, but poorly	Yes, but inadequate	Satisfactory	Good	Very good	Excellent
1	Created a good and trusting therapeutic relationship with parent						–
2	Provided general information about fears and phobias						–
3	Applied this information to the child's specific phobia						–
4	Provided information about the causes of phobias						–
5	Dealt with parents' questions about phobias and their causes						–
6	Asked parents about the child's phobic beliefs						–
7	Inquired about the parents' beliefs regarding their child's phobia						–
8	Provided a description and rationale of the treatment to parents						–
9	Informed parents about the purpose of observing child in treatment						–
10	Described the various components of the treatment protocol						–
11	Described how to continue/monitor exposure after the session						–
12	Described the need to reinforce their child for exposure exercises						–
13	Handled difficulties/questions that arose in the treatment session						–

Comments:

event (i.e., PTSD). GAD also needs to be distinguished from excessive worrying about having a panic attack (i.e., PD) as well as worrying in the form of obsessions (i.e., OCD).

Just as worry is a pervasive clinical feature of the anxiety disorders, so too is panic a common clinical feature that can be present in the different anxiety disorders (Ollendick, Mattis, & Birmaher, 2004). In fact, panic attacks can and do occur with each of the disorders. However, the differential diagnosis of PD requires that the panic attacks are not cued by a specific object (i.e., SP), an evaluative situation (i.e., SOP), separation from attachment figures (i.e., SAD), a traumatic event (i.e., PTSD), excessive worrying (i.e., GAD), and thoughts about exposure to the object or situation related to an obsession (i.e., OCD).

Finally, SOP in children and adolescents is frequently confused diagnostically with GAD. Unlike GAD, however, the youth's worry about social situations or academic performance in SOP stems from a fear of negative evaluation by others. In GAD, the worry about social situations and academic tasks stems from a fear of failing to meet some self-imposed standard. The social avoidance associated with SOP also needs to be distinguished from the social avoidance associated with having an unexpected panic attack and not wanting to have this attack in public places (i.e., PD with agoraphobia). Also it is important to distinguish SOP from pervasive developmental disorder (PDD): Youth with SOP have the capacity for, and interest in, social relationships, while youth with PDD have a general lack of interest in social relationships, although this distinction is being challenged these days.

An examination of comorbidity is just as important as differential diagnosis for treatment planning and evaluation, and requires expert competency skills. Comorbidity, the presence of multiple disorders in an individual at the same point in time, tends to occur at high rates among youth with anxiety disorders. Estimated rates of comorbidity among children and adolescents with clinical disorders run as high as 91% in clinic samples (e.g., Angold, Costello, & Krkani, 1999) and up to 71% in community samples (e.g., Woodward & Fergusson, 2001). Although some of the observed rates of comorbidity reflect assessment artifacts (or other artifacts, such as referral bias), there is considerable "fact" to the observed comorbidity (e.g., Beiderman, Faraone, Mick, & Lelon, 1995; Seligman & Ollendick, 1998). This underscores the need to carefully assess for different disorders during the diagnostic interview process and address them in treatment planning and evaluation.

Emerging evidence suggests that anxious youth who are comorbid with another disorder are more severely impaired than youth with either disorder alone. That is, their problems are more likely to persist over time and are more likely to be refractory to treatment (see Seligman & Ollendick, 1998; Saavedra & Silverman, 2002). For example, in a recent study by Franco, Saavedra, and Silverman (2007), children and adolescents and their parents were administered the ADIS-IV/C + P and four diagnostic groups were formed: "Pure" anxiety (i.e., no comorbidity), anxiety + other anxiety disorders, anxiety + externalizing disorders, and anxiety + depressive disorders. The groups were compared along four sets of variables: sociodemographics, clinical phenomenology, psychosocial, and family factors. Findings revealed that *all* the comorbid groups were more severe than the pure anxiety group on clinical phenomenology and psychosocial factors. In addition, the anxiety + depressive disorders group was found to be the most severe on these variables.

From a best practices standpoint, these findings highlight the need to consider carefully the different types of comorbid patterns that accompany an anxiety disorder in youth and the potential for meaningful distinctions with regard to the specific comorbid pattern that is observed. Such comorbidities might also signal the need for differential treatment strategies

(Ollendick, Jarrett, Grills-Taquechel, Seligman, & Wolff, 2008). Although differential outcomes due to comorbidity have not always been found in the treatment of children with anxiety disorders (Beidel, Turner, & Morris, 2000; Kendall, 1994; Kendall et al., 1997; Manassis, Avery, Butalia, & Mendlowitz, 2004; Ollendick et al., 2009; Ost, Svensson, Hellstrom, & Lindwall, 2001; Silverman et al., 1999a, b), two studies have reported significant differences for participants with anxiety and comorbid diagnoses. First, Berman, Weems, Silverman, and Kurtines (2000) created treatment success and failure groups from two previous RCTs conducted by Silverman et al. (Silverman et al., 1999a, b). No differences were found between the success and failure groups with regard to total number of diagnoses, presence/absence of comorbidity overall, or presence of comorbidity with externalizing disorders specifically. However, differences were found for those who evidenced comorbidity with depression, such that those who had comorbid depression diagnoses were significantly more likely to be in the treatment failure group. In a second study, Rapee (2003) grouped anxious youth by comorbidity type: no comorbid diagnoses, comorbid with other anxiety diagnoses, and comorbid with non-anxiety, externalizing diagnoses. Comparisons were made for pretreatment, posttreatment, and follow-up ratings of internalizing and externalizing symptoms by parents and child self-reported anxiety symptoms. A significant group by time interaction from posttreatment to follow-up on maternal ratings of externalizing symptoms (slight increases for those in the comorbid groups versus continued decrease for the non-comorbid group) and a group with comorbid diagnoses that attended significantly fewer therapy sessions were found.

In brief, then, there is limited information that comorbidity *might* affect treatment outcome for youth with anxiety disorders who are provided evidence-based interventions, although the majority of studies clearly fail to show such effects (Ollendick et al., 2008). Nonetheless, these findings suggest that competencies related to differential diagnosis and developing treatment programs for youth with specific comorbid disorders may be important. As such, expert competencies in these areas are required.

2.7.1 Treatment of Youth Who Are Partial Responders or Refractory to Treatment

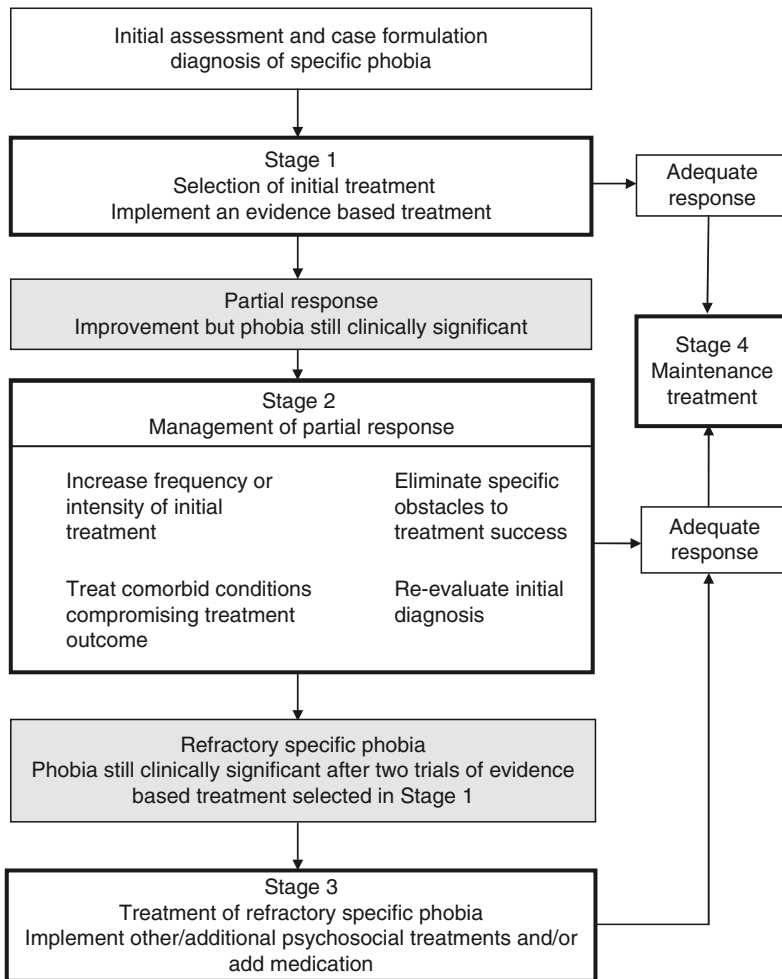
As we have noted, the use of behavioral and cognitive-behavioral procedures for treating specific phobias and the other anxiety disorders in children has led to impressive results, with a clear majority of children and adolescents benefiting from these efficacious procedures. Even so, these evidenced-based treatments do not help a significant minority of children with phobic and anxiety disorders (e.g., up to about 30–40%). In these cases, most of the youth are partial responders but a few are truly "refractory" to change. In these clinical trials, only the selection and evaluation of initial treatment attempts have been examined. That is, an initial treatment was implemented and response to treatment was evaluated, and, no attempt was made to address partial responders or individuals who might have been refractory to change. Ollendick and March (2004) suggest that partial responders are those who improve on a number of outcome measures but still retain their pretreatment diagnoses. For example, clinician severity ratings on the ADIS-IV/C + P might be reduced significantly as a result of treatment, but the child still meets criteria for diagnosis and shows avoidance on a behavioral avoidance task and elevated anxiety on self-report measures. In the published clinical trials, most of the poor responders fit into this category; that is, they showed partial response to some outcome

measures but not all. According to Ollendick and March, these individuals might respond to a greater dose of treatment (i.e., more sessions), a modification in the delivery of the intervention (i.e., inclusion of parents), or "fine-tuning" of the intervention itself (i.e., reexamination of the fear hierarchies). In many instances, adjustments in the exposure activities that are thought to be so critical for change might be necessary for the poor responders (see Bouchard, Mendlowitz, Coles, & Franklin, 2004). For example, it might be the case that the purpose of exposure was not sufficiently explained to the child or the child simply did not understand fully the explanation provided by the therapist or the fear hierarchy itself was not sufficiently graded to address the fears expressed by the child. It might also be the case that the therapist did not adequately or fully address the faulty cognitions associated with the fear or anxiety response. For exposure to work effectively corrective information that is incompatible with the dysfunctional associations stored in memory networks needs to be provided and new and more functional associations need to be made (Foa & McNally, 1996). In other cases, a strong therapeutic alliance may not have been developed with the child and his or her family and the family may not have been engaged fully in therapy activities (see Chu & Kendall, 2004; Ollendick & Shirk, in press). In still other situations, it might be the case that comorbidity or some other factor interfered with treatment progress (Ginsburg & Walkup, 2004; Ollendick et al., 2009). In any event, the primary assumption with the partial responders is that the "problem" does not reside solely in the child or his or her family; rather, the problem resides in the selection and implementation of the intervention itself (Ollendick, Davis, & Sirbu, in press). Based on the componential analysis of the anxiety/fear response (Davis & Ollendick, 2005), it is probable that the selected treatment did not address the "complete" anxiety response and hence the dose of treatment was insufficient to produce more complete and lasting change. For example, Öst et al. (2001) failed to show significant change in the disrupted physiology of the children with specific phobias in their study. It is conceivable that the 15% who did not respond in this trial would have done so had this dimension of fear been addressed and more effectively treated. Unfortunately, these studies do not report additional treatment for these partial responders and so we do not know whether they would have responded or not. Indeed, some of them may have been refractory even to additional psychosocial intervention of the same type.

In contrast, for those individuals refractory to treatment, the assumption is that the treatment itself simply does not work with these children and their families, despite its competent implementation (Ollendick & March, 2004; Ollendick et al., 2009). In these instances, the child and his or her family show minimal to no change following what is thought to be a competent implementation of the treatment. Ollendick et al. suggest that a child should not be viewed as refractory to treatment until any one treatment of adequate dose and duration has been attempted for two to three trials. If the child fails to show an adequate response after two to three trials, then alternate treatments including other psychosocial and pharmacological treatments should be tried. ❯ Figure 45.1 describes a flow chart of a treatment algorithm for specific phobia in children with emphasis on the distinction between partial responders and refractory cases (adapted from Ollendick et al.).

Thus, in our experience, most individuals who do not respond fully to treatment are "partial responders" and they do respond more fully when variations in the delivery, dose, or structure of the treatment are considered. In those cases in which the individual is truly refractory to change, the identified treatment might need to be abandoned and alternate treatments considered. In such instances, we would likely consult with a child psychiatric consultant and

■ **Figure 2.1**

Treatment algorithm for difficult-to-treat children


initiate a trial of selective serotonin reuptake inhibitors. However, we would not have likely selected some other psychosocial treatment such as play therapy or family therapy because there is little evidence for the efficacy of such approaches in the treatment of children with specific phobias or anxiety disorders (Ollendick et al., 2009). Importantly, from our standpoint, we would not consider a child and his or her family who fails to respond to treatment as "resistant" to change; rather, we would view their inadequate response to treatment as a "failure" of a treatment that was properly and competently administered. We would also view it as a failure on our part to conduct an adequate cognitive-behavioral assessment and provide the family with an evidence-based treatment based on that assessment and case conceptualization. Quite obviously, considerable expert competency is needed to make these treatment decisions.

2.8   Transition from Basic Competence to Expert Competency

As noted by several authors, the transition from basic competencies to expert competencies constitutes a developmental process. In a recent paper, Sharpless and Barber (2008) described five stages of evolution for intervention competence: novice, advanced beginner, competent, proficient, and expert stages. They linked these stages to rule-learning and rule-governed delivery of therapy for the first three stages and more fluid/flexible and contextual delivery of therapy for the latter two stages. In the first two stages and through the third stage, the therapist might be exhibiting what we have referred to as basic competencies; namely the mastery and delivery of scientific knowledge and therapeutic skills that take into consideration the clinical disorder being treated and the elements of the specific evidence-based treatment used to treat that disorder. However, we would take issue with Sharpless and Barber and argue that considerable flexibility is required even in the basic stages of competency. As a result, we would include the fourth stage, proficiency, as part of a basic competency. To implement an evidence-based treatment *competently*, one must do so flexibly and fluidly and within different contexts (e.g., development, alliance). Contrary to what some have suggested the competent implementation of an evidence-based treatment is not a "paint by numbers" exercise. We would argue further that the expert stage of competency is realized only when therapists are able to adopt and adapt these basic competencies when difficulties are encountered in treatment (i.e., partial responders and those refractory to change). We would also disagree with Sharpless and Barber's depiction that the expert stage is realized when the therapist responds in therapy "not with rules but with what experience has taught them" (p. 51) and that expert therapists should rely on their "intuitions" – the collection of impulses toward actions derived form what previous experiences in similar situations have taught them. In contrast, we would view the expert therapist as someone who is still bound by scientific knowledge and implements that knowledge in a skillful but fluid way depending on a variety of contextual factors.

We appreciate that such definitions of competency are fraught with difficulty; nonetheless, we suggest that expert skills can be acquired in the same fashion as basic skills: instruction, modeling, role-play, feedback, and reinforcement. Of course such skills would need to be obtained overtime and undoubtedly range from initial forays at the novice level to more extended and complex forays at the expert level. We would also agree that the evolution of competencies is a lifelong venture and requires considerable experience with any one therapy. Continuing education would be desired, especially continuing education that includes attendance at seminars, workshops, and master clinician series. Moreover, ongoing supervision of difficult-to-treat cases over time would be desirable.

Finally, we submit that the process of becoming proficient and achieving "expert" status in the treatment of anxiety disorders in children and adolescents is no different than it is for any other psychiatric disorder. Quite obviously, this process entails the accumulation of scientific knowledge about the disorder, its assessment, and its treatment. It also requires ongoing clinical experience, clinical supervision, and continued education so that the evidence-based practices are mastered, used, and evaluated.

2.9   Summary

In the fist part of this chapter, we described anxiety disorders of childhood and the factors that maintain them as well as the evidence-based interventions that have been developed for their

treatment. We have also speculated on the mechanisms of change that underlie these effective interventions and the principles and procedures of change thought to be effective. In the second part of the chapter, we have explored issues of competency including both basic and expert competencies. We argue that the competent treatment of the anxiety disorders in childhood requires attention to developmental and contextual issues as well as the implementation of specific intervention strategies. Moreover, we indicate that expert competency is achieved when one can implement these basic strategies in a way which addresses such important issues as comorbidity and difficult-to-treat children and their families. We conclude by indicating that attainment of these competencies is a lifelong process and one that is fluid and dynamic and not at all static. Although much has been learned about the anxiety disorders in childhood and the competencies that underlie there effective treatment, much remains to be accomplished. The journey to understanding, assessing, and developing these competencies is in its own early stage of development.

3 Mental Retardation

Jeff Sigafoos · Mark F. O'Reilly · Giulio E. Lancioni

Abstract: Mental retardation is a specialist area of clinical psychology practice that aims to promote improved quality of life for individuals with mental retardation and their families. To promote improved quality of life for children and adolescents with mental retardation and their families, clinical psychologists require a range of basic and expert competencies. This chapter delineates essential areas of basic and expert competencies that will enable psychologists to be more successful in this specialized area of clinical practice. Emphasis is given to the implementation of evidence-based assessments and treatments for children and adolescents with mental retardation. With respect to assessment, the basic competencies include: (a) recognition and assessment of symptoms, (b) familiarity with contemporary definitions and classification systems, (c) intelligence testing, (d) adaptive behavior assessment, and (e) an understanding of how genetic syndromes, learning impairment, operant conditioning, environmental impoverishment, and social barriers influence behavior and development. With respect to treatment, competencies are required with respect to a range of contemporary evidence-based treatment approaches, including: (a) behavioral intervention, (b) cognitive-behavior therapy, (c) family therapy, (d) early intervention, (e) special education, (f) supported employment, and (g) pharmacological treatments. Effective use of these treatment approaches requires skillful implementation and an understanding of the basic mechanisms of change that underlie the approach. Enhancing the quality of life for some children and adolescents with mental retardation and their families will often require additional expert competencies in specialist areas, such as providing culturally-sensitive practices, treating severe problem behavior, and promoting learning in children with profound/multiple impairments. The transition from basic competence to expert clinician requires a planned and systematic approach for gaining relevant new knowledge and clinical skills. By gaining basic and expert competencies, clinicians can greatly enhance the quality of life of children and adolescents with mental retardation and their families.

3.1 Overview

Quality of life is an important outcome measure in clinical psychology (Keith, 2007). Achieving an improved quality of life for clients might thus be seen as one of the clinical psychologist's most important objectives. Progress toward this objective is likely to be particularly important in the field of mental retardation (or intellectual disability), as there is strong evidence that impairments and lifestyle restrictions associated with this condition can negatively influence the overall quality of life (Brown, Parmenter, & Percy, 2007). Clinical psychologists working in the field of mental retardation will need a range of competencies to effectively support children and adolescents with mental retardation in achieving an improved quality of life. To clarify this objective, clinical psychologists would benefit from gaining a general overview of the quality of life concept.

3.1.1 Overview of the Quality of Life Concept

Quality of life includes an objective and subjective component (Cummins, 2005). The objective component covers the number, quality, and nature of one's life circumstances, such as independence and autonomy, academic achievement, community participation, and friendships. The subjective component includes the extent of satisfaction with one's degree of independence, participation, relationships, etc. Both components are important determinants of a person's overall quality of life.

Quality of life for children and adolescents with mental retardation also depends on overall family functioning. Turnbull, Poston, Minnes, and Summers (2007) argued that quality of life should be viewed from the larger perspective of family functioning. In line with this larger family perspective, the emphasis of clinical practice includes provision of support for the child and his/her family. Clinical psychologists working in the field of mental retardation will therefore require skills and competencies related to both individual and family therapy.

In addition to the overall climate of family functioning (Vachha & Adams, 2005), a variety of biological, developmental, psychological, and social variables can influence the functioning and quality of life for individuals with mental retardation (La Malfa, Campigli, Bertelli, Mangiapane, & Cabras, 1997). Along these lines, Dosen (2005) stressed the need for clinicians to consider the extent to which the individual has made "new psychosocial adaptations during each developmental stage" (p. 2). Family values and cultural background should also be acknowledged in clinical practice, as these can exert considerable influence on what is considered successful adaptation and a good quality of life (Xu, Wang, Xiang, & Hu, 2005). Such perceptions are likely to vary from one family and culture to another.

3.1.2 Overview of Clinical Issues in Mental Retardation

Achieving improved quality-of-life outcomes under this multifaceted conceptualization will often require clinicians to simultaneously address several areas of individual and family functioning. Felce (2007) delineated a large number of issues that are likely to be of concern for individuals diagnosed with mental retardation, their families, and the larger community, including "human and legal rights, self-advocacy and empowerment, gender, sexuality, parenting, aging, palliative care, bereavement counseling, health promotion, healthy lifestyles, and quality of life" (p. xix). Many of these issues will become increasingly important during the transition to adulthood. Among children and adolescents, the main clinical issues often center around assessment and intervention to address specific behavioral deficits and excesses.

As should be clear from the above introduction, the decision to work in the field of mental retardation is certainly challenging, but it can also be highly satisfying. A competent clinical psychologist can expect to have a major positive impact on the quality of life of children and adolescents with mental retardation and their families. This chapter aims to delineate the essential areas of knowledge and competences that will enable psychologists to be more successful in this specialized area of clinical practice. In this chapter, we will focus on the clinical competencies related to the assessment and treatment of children and adolescents with mental retardation.

3.1.3 Overview of Chapter Content

In the next section of this chapter, we describe contemporary issues in the recognition and assessment of mental retardation. Thereafter, we identify factors that can maintain behavioral deficits and excesses commonly associated with mental retardation. Our subsequent discussion of evidence-based treatment approaches reveals the need for clinicians to gain a thorough understanding of the change mechanisms that underlie effective intervention. Developing a more evidence-based practice will require a range of competencies. In the final sections of this chapter, we describe those competencies that are most relevant to achieving improved quality of life outcomes for children and adolescents with mental retardation and suggest strategies to facilitate the transition from basic competence to expert clinician.

3.2 Recognition of Symptoms and Their Assessment

Quality of life for children and adolescents with mental retardation and their families can be greatly improved by ensuring timely recognition and assessment of symptoms. Competence in symptom recognition and assessment is required for making accurate diagnoses, counseling parents, consulting with other professionals, and planning intervention. Gaining competence in the recognition and assessment of the symptoms of mental retardation requires familiarity with contemporary definitions and classification systems.

3.2.1 Definitions of Mental Retardation

Definitions of mental retardation have undergone considerable change over the last several decades (Harris, 2006; Scheerenberger, 1983). Contemporary definitions of mental retardation are found in the DSM-IV-TR (American Psychiatric Association, 2000), ICD-10 (World Health Organization, 2001), and Luckasson et al. (2002). Carr and O'Reilly (2007) have provided a thorough comparison of these three systems for defining and classifying mental retardation.

All three of the above referenced systems define mental retardation in terms of two main factors: (a) significantly sub-average intellectual functioning and (b) concurrent deficits in adaptive behavior functioning. These deficits are present, and are usually first identified in the developmental period prior to adulthood (i.e., prior to the age of 18 years).

3.2.1.1 Intellectual Functioning

Significantly sub-average intellectual functioning is typically defined as an IQ score that falls two standard deviations or more below the mean on a standardized and individually administered intelligence test. Because most IQ tests have a mean of 100 and a standard deviation of 15 or 16, the cut-off score for mental retardation is generally considered to be an IQ of 70–75. This 5-point range allows for measurement error and acknowledges that the diagnosis of mental retardation is not based on IQ scores alone, but includes the requirement for concurrent deficits in adaptive behavior functioning.

3.2.1.2 Adaptive Behavior Functioning

The second major symptom of mental retardation is the presence of substantial deficits in adaptive behavior functioning. Adaptive behavior functioning is defined in the DSM-IV-TR as the extent to which the individual copes with the demands of everyday living. According to DSM-IV-TR criteria, a diagnosis of mental retardation requires deficits in adaptive behavior functioning "in at least two of the following skill areas: Communication, self-care, home living, social/interpersonal skills, use of community resources, self-direction, functional academic skills, work, leisure, health and safety" (American Psychiatric Association, 2000, p. 41). Clinical assessment of adaptive behavior functioning must take into account the person's age, sociocultural background, and the environments (e.g., home, school, and community) in which the person is expected to function.

3.2.2 Classification of Mental Retardation

Mental retardation is classified in terms of etiology, severity, and required levels of support (Luckasson et al., 2002). With respect to etiology, mental retardation has a range of causes including environmental toxins, infections, injury, and genetic syndromes (MacLean, Miller, & Bartsch, 2001). Classification in terms of etiology is useful, as many syndromes are associated with unique behavioral phenotypes and specific intervention needs. Classification based on etiology is, however, somewhat limited because the cause of mental retardation often remains unknown. Thus, while an etiology can usually be identified in approximately 75% of cases of moderate to profound mental retardation, only up to 40% of cases of mild mental retardation have a known cause (Harris, 2006). These percentages are likely to improve with advances in genetic and biomedical research.

3.2.2.1 Severity

Clinical psychologists have found it useful to classify mental retardation in terms of severity. Severity in this context generally refers to the degree of general intellectual impairment. Four levels of severity are listed in the DSM-IV-TR: Mild, Moderate, Severe, and Profound. Classification in terms of severity is useful because the presenting profile and needs of individuals with mild mental retardation, for example, are likely to be very different from the needs of individuals with severe and profound mental retardation. However, it must be recognized that there is considerable variability in cognitive and adaptive behavior functioning and learning potential within each of these four categories.

Mild Mental Retardation
Mild mental retardation is associated with IQ scores of 50–55 to approximately 70. Mild mental retardation is often attributed to cultural–familial factors, but etiology may include the full range of known causes (i.e., injury, infection, genetic syndrome, etc.). Cases of mild mental retardation are often not identified until the child enters school and begins to fail academically. However, clinicians should be alert to delays in early developmental milestones (see Carr & O'Reilly, 2007, pp. 4–6), as these may indicate the presence of mild mental retardation that might not be otherwise noticed until the school years.

Moderate Mental Retardation

Moderate mental retardation is associated with IQ scores that range from 34–40 to 50–55. Thus, an individual with an IQ score of 50 or 55 could be classified as having mild or moderate mental retardation depending on the extent of adaptive behavior deficits. Generally, individuals with moderate mental retardation are more likely to have a known etiology than those with mild mental retardation. Because of this and the more obvious developmental delays, moderate mental retardation is usually recognized during early childhood.

Severe and Profound Mental Retardation

Severe and profound mental retardation are associated with IQ scores of 20–25 to 35–40 and below 20 or 25, respectively. Most of these individuals will be identified in infancy owing to known etiology and significant developmental delay. Their learning and behavior deficits are usually so substantial that obtaining a reliable score on an IQ test is difficult. Individuals with severe and profound mental retardation often present with major health-related problems (e.g., epilepsy) and additional sensory and physical impairments, which complicate assessment and intervention.

3.2.2.2 Levels of Support

The American Association on Intellectual and Developmental Disabilities has moved away from the classification in terms of severity, based largely on IQ scores, to one focused on the types and amounts of required supports (Luckasson et al., 2002). Four levels of support are identified: Intermittent, Limited, Extensive, and Pervasive. These categories represent a continuum ranging from brief periods of targeted intervention at specific times, such as teaching interview skills when seeking employment (Intermittent) to more constant, ongoing, and life-sustaining support across all areas of functioning (Pervasive). Levels of support do not necessarily correspond to severity of mental retardation. Instead, level of required support should be based on assessed needs, which are likely to change over time. An adolescent with mild mental retardation might, for example, require extensive supports for a short period of time to address emerging problem behaviors. After this, only intermittent supports might be necessary to maintain treatment gains.

3.3 Maintenance Factors of Mental Retardation

The types of clinical problems that negatively affect independence and quality of life for children and adolescents with mental retardation can be conceptualized in terms of behavioral deficits and excesses (Lovaas, 2003). Deficits are likely to be present in the communication, social, daily living, play and leisure, and fine and gross motor domains (Sparrow, Cicchetti, & Balla, 2005). Behavioral excesses include self-injury, aggression, property destruction, tantrums, hyperactivity, and stereotyped movements. It is important to note that the specific domains affected and the nature and extent of the presenting deficits and excesses will vary considerably from individual to individual. Still, behavioral deficits and excesses tend to be more obvious and significant as the severity of mental retardation increases (Schroeder, Tessel, Loupe, & Stodgell, 1997). Numerous factors interact to maintain the behavioral deficits and excesses of individuals with mental retardation. These factors include genetic syndromes, learning impairment, operant conditioning, environmental impoverishment, and social barriers.

3.3.1 Genetic Syndromes

Mental retardation is associated with a large number of genetic syndromes, such as Down, Fetal Alcohol, Fragile X, and Angelman syndrome (Percy et al., 2007). Many of the known genetic syndromes are associated with a distinct pattern of behavioral deficits or excesses. For example, recognizing that an individual has Fetal Alcohol syndrome indicates a likely pattern of symptom presentation and associated characteristics (e.g., hyperactivity, speech impairment, and sensory impairment) (Burd, Cotsonas-Hassler, Martsolf, & Kerbeshian, 2003). Many syndromes also have a unique behavioral phenotype (e.g., self-biting in Lesch-Nyhan syndrome), prognoses (e.g., regression in Rett syndrome), and intervention requirements (e.g., diet management in Prader-Willi syndrome). Recognition of syndrome-specific behaviors, prognoses, and intervention needs is vital for clinical management (Harris, 1987).

3.3.2 Learning Impairment

Children and adolescents with mental retardation do not learn as easily or as quickly as their typically developing peers (Jensen & Rohwer, 1968). In particular, they seem to have considerable difficultly in gaining knowledge of the world via more symbolic or social learning processes, such as incidental learning, verbal instruction, modeling, and observational learning (Remington, 1996). To some extent, this difficulty stems from attending to irrelevant aspects of the environment and over-reliance on adult cues, phenomena known as stimulus over-selectivity (Wilhelm & Lovaas, 1976) and outer-directedness (Turnure & Zigler, 1964), respectively. Impairments of symbolic learning potentially indicate the need for more direct and systematic instruction to promote learning (Snell & Brown, 2006).

3.3.3 Operant Conditioning

Behaviors, such as aggression, self-injury, and tantrums, are often maintained by specific types of reinforcing consequences such as (a) contingent attention from adults, (b) access to preferred objects and activities, and (c) escape from non-preferred activities (Carr, 1977; Iwata et al., 1994). These behaviors may persist because the individual has difficulty learning appropriate alternatives (Sigafoos, Arthur, & O'Reilly, 2003). Identifying operant contingencies that evoke and maintain behavioral excesses is an important component of clinical practice for individuals who present with severe problem behavior.

3.3.4 Environmental Impoverishment

Numerous studies have implicated impoverished environments in the maintenance and exacerbation of the cognitive impairment and behavioral deficits and excesses associated with mental retardation (Hart & Risely, 1995; Horner, 1980; Skeels & Dye, 1939). The child's environment and experiences can be impoverished both socially and physically. Lack of stimulation, poor health care and nutrition, and unresponsive or abusive parenting are potential maintenance factors in mental retardation. Sensory impairments can also lead to deprivation of experiences

that can maintain and exacerbate learning and behavior problems. By implication, the impact of such factors should be lessened by creating more stimulating, responsive, and nurturing environments and relationships.

3.3.5 Social Barriers

The mental retardation label can be stigmatizing and lead to negative attitudes, lowered expectations, and restricted opportunities (Krajewski & Flaherty, 2000; Rosenthal & Jacobson, 1968). Increasing technological complexity, which demands a high level of cognitive ability, is another potential barrier to participation (Brown, 2007). Clinical efforts to improve attitudes and behaviors may limit the extent to which the person is handicapped by such barriers. For example, a severely retarded child may be unable to talk, but she will be less handicapped if she can be taught manual signs and if others in her environment accept this alternative form of communication. Fortunately, clinical psychologists can draw on a range of evidence-based treatment approaches to lessen the impact of the various bio–psycho–social factors that maintain the behavioral deficits and excesses associated with mental retardation.

3.4 Evidence-Based Treatment Approaches

Evidence-based practice involves the use of treatment approaches that have been validated through scientific research. A number of treatment approaches have been scientifically validated for improving the functioning of individuals with mental retardation. Competence in the clinical application of these approaches is likely to enhance the quality of life for children and adolescents with mental retardation and their families. The range of contemporary evidence-based treatment approaches includes: (a) behavioral intervention, (b) cognitive behavior therapy, (c) family therapy, (d) early intervention, (e) special education, (f) supported employment, and (g) pharmacological treatments.

3.4.1 Behavioral Intervention

Since the 1960s, applied research has repeatedly demonstrated the efficacy of behavioral intervention for improving the functioning of individuals with mental retardation (Thompson, 1977). Behavioral intervention involves application of empirically validated principles of learning to produce changes in socially significant behaviors. Behavioral intervention is associated with the more general paradigm of applied behavior analysis (Baer, Wolf, & Risley, 1987). Applied behavior analysis evolved from operant research into basic learning processes such as shaping, chaining, fading, and differential reinforcement. These and other operant principles have been adapted to create a large number of behavioral procedures, which have in turn been applied to teach a wide range of adaptive skills to individuals with mental retardation, including communication, academic, social, self-care, daily living, play, leisure, community living, and vocational skills (Duker, Didden, & Sigafoos, 2004). Behavioral procedures have also proven highly effective in the treatment of aggression, self-injury, stereotyped movements, and other excess or aberrant behavior (O'Reilly et al., 2007).

Overall, behavioral intervention is a well-established approach for addressing the behavioral deficits and excesses of individuals with mental retardation. This approach has considerable external validity, with demonstrated applicability to infants, children, adolescents, and adults with mild, moderate, severe, and profound mental retardation of varying etiologies. The expertise and support required to effectively implement such treatments will vary depending on the individual client, the skill areas being addressed, and the specific techniques that make up the overall treatment package (e.g., extinction, errorless learning, response shaping). When appropriate intervention targets are identified via careful assessment (Matson & Wilkins, 2007), skillfully implemented behavioral intervention can greatly improve the quality of life for children and adolescents with mental retardation.

3.4.2 Cognitive Behavior Therapy

Cognitive behavior therapy (CBT) has been used with some success in clinical practice for individuals with mental retardation (Dagnan & Lindsey, 2004). The CBT approach is based, in part, on the theory that dysfunctional thoughts, beliefs, self-perceptions, and feelings may underlie some of the problems of adjustment that affect people's lives (Beck, 1976). Typically, as part of CBT, the person might need to learn to identify the dysfunctional cognitions and then learn to adopt alternative thoughts, beliefs, and feelings to deal with problematic situations. By adopting the alternative cognitions, the individual will hopefully show better psychosocial adjustment.

CBT has been used to address a variety of issues that can negatively affect the quality of life for individuals with mental retardation. Examples of areas in which CBT has been successfully applied include anger management, emotional awareness and regulation, and the treatment of depression and anxiety (Lindsey, Neilson, & Lawrenson, 1997). A variety of useful self-management strategies (e.g., identifying the target behavior and its triggers, practicing appropriate responses, and seeking feedback on performance) could also be viewed as being consistent with the CBT approach (Harchick, Sherman, & Sheldon, 1992). Development of self-management skills has enabled many individuals with mental retardation to maintain improved social skills and reach higher levels of academic and vocational performance. Through self-management, some individuals might also learn to control aggressive outbursts (cf. Allen, 2000).

CBT seems to require a high degree of verbal interaction between therapist and client, making the approach perhaps more suitable for individuals with mild mental retardation. Even then, clinicians often need to simplify the therapeutic process to ensure comprehension. For example, children and adolescents with mental retardation will first need to learn how to label and identify emotions before learning how to accurately report and describe their own emotional responses to specific situations (Dagnan, Jahoda, & Stenfert Kroese, 2007). Still, with appropriate adaptations, some children and adolescents with mild mental retardation may be able to benefit from CBT (Willner & Hatton, 2006).

3.4.3 Family Therapy

Parenting a child with mental retardation can be stressful, but does not necessarily lead to inevitable family breakdown (Blacher & Baker, 2002). Indeed, there are a variety of family therapy

approaches that can help reduce stress and prevent family dysfunction (Jackson & Leonetti, 2001). One approach aims to increase knowledge by providing parents with educational information about mental retardation. This type of parent education has been delivered via workshops, lectures, and dissemination of printed information. The effectiveness of parent education seems to depend on the timeliness of information and extent to which the program builds parental confidence (Abidin, 1980). A second approach focuses on developing specific parental skills, such as training parents to manage child behavior problems (Sanders, Mazzucchelli, & Studman, 2004) or respond to emerging child language (Yoder, Warren, McCathren, & Leew, 1998). While competency-based training of specific parent skills can be highly effective for certain families (Kazdin, 1997), not all of the problems that families experience are related to a lack of specific parenting skills. In addition, there has been relatively limited research on sibling issues and diversity, in terms of culture and non-traditional families. Consequently, clinical psychologists may need to consider individualized counseling to support diverse families struggling with issues such as sibling adjustment, parent psychopathology, socioeconomic disadvantage, and limited social supports.

3.4.4 Early Intervention

Developmental delays should be identified as soon as possible so that the child can receive effective early intervention services. Effective early intervention programs typically include a combination of general environmental enrichment, behavioral intervention, family therapy, educational programming, and speech, occupational, and physical therapies. While such services may not necessarily prevent mental retardation (Gilhousen, Allen, Lasater, Farrell, & Reynolds, 1990), there are several evidence-based early intervention programs with demonstrated efficacy for improving child and family functioning (Baker & Feinfield, 2007; Feldman, 2004; Guralnick, 1997; Mahoney, Perales, Wiggers, & Herman, 2006).

One particularly effective approach, known as early intensive behavioral intervention, consists of 25–40 h per week of behavioral intervention with treatment continuing for 2 or more years. Treatment goals generally focus on developing the child's imitation and discrimination abilities and teaching adaptive behaviors (e.g., communication, social, play, and academic skills). Several outcome studies involving children with autism or developmental delay and low initial IQ scores have shown that this form of early intervention can produce clinically significant and long-term improvements in both intellectual and adaptive behavior functioning (Lovaas, 1987; McEachin, Smith, & Lovaas, 1993; Remington et al., 2007; Sallows & Graupner, 2005).

3.4.5 Special Education

In the United States, under the Individuals with Disabilities Education Act of 1997 (IDEA-97), children with mental retardation and other disabilities have the right to a free and appropriate public education in the least restrictive environment. Successful inclusion of children with mental retardation in the least restrictive environment will often require special education to promote academic achievement and develop age-appropriate behavior. Academic achievement among students with mild to moderate mental retardation can often be improved using direct

instructional strategies (Adams & Carnine, 2003). With direct instruction, the teacher presents discrete and repeated opportunities for learning and provides cues and feedback until the child reaches a high level of fluency.

Direct instruction is often combined with ongoing evaluation of the child's performance using valid curriculum-based measures (e.g., percentage of words spelled correctly during brief daily spelling tests). Students with more severe levels of mental retardation will benefit from a functional curriculum that targets improvement of self-care, social, communication, and other adaptive behaviors. These behaviors can be effectively taught using systematic instructional strategies, such as task analysis, response prompting, prompt fading, and reinforcement (Snell & Brown, 2006). In addition to systematic instruction across a range of adaptive behavior domains and academic areas, some children will require more intensive behavioral intervention to promote social interaction, participation, and appropriate behavior (Duker et al., 2004).

3.4.6 Supported Employment

A variety of supported employment approaches have been developed for adolescents and young adults with mental retardation. The intensity of support ranges from initial help in securing employment (e.g., job searching and effective interviewing) to teaching specific job skills (Inge & Moon, 2006). Such services are often provided as part of the child's overall educational program or through funded vocational rehabilitation programs. The same types of behavioral and educational strategies that are used to teach adaptive behaviors (e.g., communication, self-care, and daily living skills) are also effective for teaching a variety of employment-related and specific job skills. While acquisition of employment-related and specific job skills is certainly important, many employment placements fail due to lack of social skills (Wehman, 1996). Thus, social skills training should be included as part of supported employment programs (Matson & Wilkins, 2007).

3.4.7 Pharmacological Treatments

Psychotropic medications are widely used in the treatment of people with mental retardation (Morgan, Campbell, & Jackson, 2003). Various medications, including antidepressants, antipsychotics, and mood stabilizers, have been used to treat comorbid psychiatric disorders and manage severe behavior problems. In a recent review of this literature, Deb et al. (2008) noted that while there is some support for use of psychotropic medications for people with mental retardation, methodological problems make it difficult to fully evaluate the efficacy of such medications when used on individuals with mental retardation. Clinical psychologists working in the area of mental retardation are likely to have individuals on their caseloads receiving these types of medications and can contribute to the evaluation of such treatments by collecting data on relevant target behaviors (e.g., symptoms of depression, and frequency and severity of problem behavior) and monitoring drug side effects. To this end, several assessment scales have been developed to assess the effects and side effects of psychotropic medications in individuals with mental retardation (Aman & Singh, 1994; Matson et al., 1998; Mayville, 2007).

3.5   Mechanisms of Change Underlying the Intervention

Effective use of the evidence-based treatment approaches requires more than skillful implementation of proven techniques or procedures. In addition to competence in the application of a particular treatment approach or specific procedure, effective evidence-based treatment also requires an understanding of the basic mechanisms of change that underlie the approach or procedure. This understanding is necessary for the clinician to effectively modify the intervention plan to suit the unique characteristics of the client and context (Linscheid, 1999). Because mental retardation is not a homogeneous condition, there is often a need to modify and troubleshoot the intervention plan and procedures in light of the person's unique characteristics, circumstances, and response to treatment.

Kazdin (2007) stressed the importance of identifying mechanisms of change that underlie evidence-based psychotherapies. In this context, Kazdin emphasized the need to identify intervening variables, such as genetic syndrome or severity of mental retardation, that can influence or moderate the magnitude of treatment effects. Consideration of intervening variables should enable clinicians to select treatment approaches that are suited to the individual's characteristics. Kazdin also emphasized the need for more research to identify the basic processes that are directly responsible for the therapeutic effect. Knowledge of these processes or mechanisms of change will facilitate the design of new and more effective treatments.

In the treatment of individuals with mental retardation, clinicians should also consider the mechanisms through which the treatment leads to an enhanced quality of life for those individuals and their family. It is important to note that the precise mechanisms of change often remain unclear. Still, for the several major approaches used in the treatment of mental retardation, plausible change mechanisms can be proposed.

3.5.1   Mechanisms of Change Underlying Behavioral Intervention

Behavioral interventions produce change by increasing or decreasing the probability of behavior through operant conditioning. The conditioning process for teaching new adaptive behaviors includes: (a) manipulating establishing operations (e.g., deprivation) to increase motivation, (b) arranging relevant discriminative stimuli to set the occasion for behavior, (c) evoking behavior in the presence of relevant discriminative stimuli, and (d) arranging ongoing reinforcement on some appropriate schedule to strengthen and maintain behavior. Excess behaviors are made less probable by (a) eliminating the contingencies of reinforcement that maintain the behavior (i.e., operant extinction), (b) building response inhibition through punishment contingences, and (c) teaching replacement adaptive skills that are more efficient than excess behavior at gaining reinforcement for the individual. For operant conditioning to produce enduring changes in the person's behavioral repertoire, clinicians need to teach new behaviors that can be generalized to natural environments and that will continue to produce reinforcement once training has ended (Baer, 1999; Esveldt-Dawson & Kazdin, 1998). Acquisition of new adaptive behaviors and replacement of excess behavior through the mechanisms of operant conditioning improves the quality of life by enabling the individual to participate more fully, appropriately, and effectively in a wider range of home, school, vocational, and community environments.

3.5.2   Mechanisms of Change Underlying Cognitive-Behavior Therapy

The mechanisms of change underlying CBT are presumed to stem from changing a person's dysfunctional thoughts, beliefs, and perceptions. By first working to change the person's negative thoughts, beliefs, and perceptions, it may then be easier to change the person's behavior in specific situations. For example, if an adolescent with mild mental retardation has few friends at school and believes that this is because his classmates hate him, then he is perhaps less likely to initiate any interactions with these peers. By changing his perception from one of being hated to one of simply being unfamiliar to his peers, it may be easier to motivate him to initiate positive interactions with peers. However, Kazdin (2007) noted that the causal direction of change in such therapeutic approaches has been difficult to determine. Instead of changed cognitions leading to meaningful changes in behavior; for instance, it could be the case that changes in behavior are responsible for any changes in the person's thoughts, beliefs, and perceptions. In any event, the overt expression of negative thoughts, beliefs, and perceptions could be conceptualized as a type of excess behavior that would be important to change in its own right. Such changes might be achieved through operant mechanisms (e.g., teaching and reinforcing positive belief statements, extinguishing negative statements, etc.). By reducing expression of negative thoughts, beliefs, and perceptions and concurrently increasing the expression of more positive thoughts, beliefs, and perceptions, clinicians may be able to enhance some of the more subjective aspects of the person's quality of life.

3.5.3   Mechanisms of Change Underlying Family Therapy

One mechanism of change underlying family therapy is based on the reciprocal nature of parent–child interactions. That is the notion of changing parent behavior to affect changes in the child's behavior. Problem behavior, for example, often leads to a pattern of coercive parent–child interactions that can negatively affect family functioning (Patterson, 2002). With respect to adaptive behaviors, some children might fail to show gains in this area if parents provide few learning opportunities or complete tasks for the child, rather than facilitating child independence. This pattern of dependence also increases the burden of care for parents, which may in turn increase stress and reduce the quality of life (Woolfson & Grant, 2006). Breaking any coercive patterns of interaction and boosting the parents' confidence in their ability to promote child independence are two important ways in which family therapy seeks to improve the quality of life for children and adolescents with mental retardation and their families.

3.5.4   Mechanisms of Change Underlying Early Intervention

Early intervention often aims to improve general intellectual functioning by (a) increasing environmental stimulation and parent responsivity, (b) improving nutrition and health, (c) teaching adaptive behaviors, and (d) enhancing motivation. This combination of foci is presumed to boost IQ and thereby prevent or attenuate the severity of mental retardation (Gilhousen et al., 1990). There is some evidence to support such possible change mechanisms. Outcome studies on the effects of early intensive behavioral intervention for children with

developmental delay, for example, have consistently demonstrated positive changes in IQ scores (Lovaas, 1987; McEachin et al., 1993; Remington et al., 2007; Sallows & Graupner, 2005). Matson (2007a), however, cautioned that the reported changes in IQ scores might not necessarily stem from a general increase in intellectual functioning. Instead, such changes might reflect increased compliance and teaching to the test. Interestingly, increases in IQ scores from early intensive behavioral intervention are not always accompanied by significant improvements in critical areas of adaptive behavior functioning, such as communication and social skills (Remington et al., 2007).

3.5.5 Mechanisms of Change Underlying Special Education

Special education aims, in part, to improve a child's ability to profit from education. No one mechanism of change underlies special education practice. Instead, special education programs tend to adopt a variety of treatment approaches that are often fairly loosely related to behavior analytic principles. Direct, systematic, and intensive instruction, for example, is intended to produce enduring changes in the child's behavioral repertoire that will enable children to function more effectively once they exit school.

3.5.6 Mechanisms of Change Underlying Supported Employment

Upon exiting school, quality of life for individuals with mental retardation will depend to some extent on their ability to secure meaningful employment. Supported employment has a positive impact on their quality of life by developing job and employment-related skills that enable them to gain and maintain employment. This in turn produces a steady income, which improves one's objective quality of life. For individuals with mental retardation, doing well in a steady job – which often requires ongoing support – can also increase self-esteem, which in turn has a positive impact on one's subjective quality of life (Holloway & Sigafoos, 1999). Once in a stable employment setting, ongoing support is provided to develop social skills and build a network of positive social relationships that further enhance the quality of life.

3.5.7 Mechanisms of Change Underlying Pharmacological Treatments

Psychotropic medications are presumed to produce behavior change through two mechanisms: first, by having a corrective or compensatory effect on neurological functioning and second, by direct symptom reduction (Katic & Steingard, 2001). Risperidone, for example, appears to correct serotonin imbalances implicated in psychotic behavior. However, while widely used in the treatment of problem behaviors among individuals with mental retardation, its efficacy for this purpose is questionable (Singh, Matson, Cooper, Dixon, & Sturmey, 2005). With respect to the second presumed mechanism of change, psychotropic medications have demonstrated efficacy for symptom reduction (Luiselli, Blew, & Thibadeau, 2001). Reducing aggressive outbursts via some medication, for example, might then provide a window of opportunity for enabling greater participation in other therapy programs. On the other hand, mechanisms by which

psychotropic medications produce behavioral change in persons with mental retardation could also stem from other processes, such as a general sedative effect. This could make other forms of treatment more difficult to implement in some cases.

3.6   Basic Competencies of the Clinician

The basic competencies required of clinical psychologists working in the field of mental retardation include: (a) referral clarification, (b) initial assessment, (c) case formulation, and (d) developing, implementing, and evaluating evidence-based treatments. Competence in each of these areas is central to effective clinical practice for children and adolescents with mental retardation (Matson, Terlonge, & Minshawi, 2008; Sturmey, 2008). In all aspects of their work, clinicians must of course strive to maintain the highest level of ethical practice.

3.6.1   Referral Clarification

When a referral is made, clinicians should first clarify the nature of the referral. A request to assess the intellectual functioning of a young child showing developmental delay is very different from a request to differentiate between mental retardation and learning disability in an older child who is failing academically. Before taking on a case, the clinician must determine what competencies might be needed and whether she/he has those required competencies. If not, it is of course necessary and appropriate to refer the case elsewhere.

Clarifying a referral requires effective clinical interviewing skills (Lovitt, 1998). For beginning clinicians it can be helpful to develop a checklist of items that need to be covered during the initial referral interview. Often it can be the most basic information that the beginning clinician fails to record (e.g., child's name, age, contact details, history, recent changes in the child's behavior, illnesses, family crises, etc.). The clinician must learn to ask the right questions to the referring agent, seek follow-up information, and rephrase questions as necessary. The referring agent (e.g., parent, teacher) should be allowed to check the clinical summary of the initial referral interview for accuracy.

3.6.2   Initial Assessment

Once a referral has been clarified, the clinical psychologist will need to decide what initial assessments are warranted. A primary role of clinical psychologists has long been the diagnostic assessment of individuals suspected of having mental retardation. In cases where mental retardation is suspected, standardized assessment of intellectual and adaptive behavior functioning is warranted to confirm or rule out the diagnosis. This type of assessment data can also be very useful for prioritizing treatment goals and identifying required levels of support. Clinical psychologists therefore need to be familiar with a variety of psychological assessment techniques (Matson, 2007b), some of which require more expert competences (see Section 3.7: *Expert Competencies of the Clinician*). Assessment of intellectual and adaptive behavior functioning are arguably the two most important and basic competencies of clinical practice in mental retardation.

3.6.2.1 Intellectual Functioning

Selecting and administering IQ tests, and interpreting their results, are basic competencies for professional practice in clinical psychology. MacLean, Miller and Bartsch (2001) and O'Reilly and Carr (2007) reviewed several commonly used intelligence tests for assessing mental retardation. These tests include the (a) Bayley Scales of Infant Development, third edition (BSID-III) (Bayley, 2006), (b) Kaufman Assessment Battery for Children, second edition (KABC-II) (Kaufman & Kaufman, 2004), (c) Leiter International Performance Scale Revised (LIPS-R) (Roid & Miller, 1997), (d) Weschler Preschool and Primary Scale of Intelligence, third edition (WPPSI-III) (Weschler, 2002), (e) Weschler Intelligence Scale for Children, fourth edition (WISC-IV) (Weschler, 2003), and (f) Stanford-Binet, fifth edition (SB5) (Roid, 2003). It is important to note that each of these tests has strengths and limitations that will make each of them more or less suitable in specific circumstances. The BSID-III, for example, is a better choice for assessing young children (1–42 months of age) than the WISC-IV, whereas the Leiter, being a totally nonverbal test, is appropriate for individuals who lack speech.

3.6.2.2 Adaptive Behavior

To complement measures of intellectual functioning, clinical psychologists also need to acquire competence in assessing adaptive behavior and interpreting the results of such assessments. Commonly used measures for assessing adaptive behavior include the *Vineland-II Adaptive Behavior Scales* (2nd ed.) (Sparrow, Cicchetti, & Balla, 2005), *Adaptive Behavior Scale-School Version* (Lambert, Nihira, & Leyland, 1993), *Adaptive Behavior Scale-Residential and Community Version* (Nihra, Leyland, & Lambert, 1993), the *Scales of Independent Behavior* (Bruininks, Woodcock, Weatherman, & Hill, 1996), and the *Adaptive Behavior Assessment System II* (Oakland & Harrison, 2008). Carr and O'Reilly (2007) summarized several commonly used adaptive behavior scales and noted their strengths and limitations. As with IQ tests, clinicians should be aware of these various scales to ensure that they select and use appropriate instruments for the individual case. When interpreting the results of such scales, Dixon (2007) noted that deficits should be assessed relative to chronological age, gender, opportunity, and family and cultural expectations.

3.6.2.3 Assessment for Treatment Planning

In addition to their use in diagnosis and classification of mental retardation, results of intellectual functioning and adaptive behavior assessments can often be of tremendous value in treatment planning. Matson and Wilkins (2007) emphasized the need for clinicians to identify skill areas that would be most important to target for intervention. Along these lines, the extent of deficit in specific areas of intellectual or adaptive behavior functioning can be identified from appropriately administered tests and rating scales. The most substantial or important of these identified deficits could then be targeted for improvement through evidence-based intervention. In determining which areas to prioritize for intervention, clinicians should consider those that are most likely to enhance the individual's quality of life, as well as environmental demands, and family and cultural values. Clinicians will therefore need competencies in using

standardized assessment results not only for diagnostic purposes, but also to inform the content and procedures of individualized treatment plans.

3.6.2.4 Levels of Support

Identification of the types and amounts of needed support for individuals with mental retardation and their families should be guided by the goal to enhance their quality of life. Designing appropriate support services requires a systematic assessment of individual and family needs (Carr & O'Reilly, 2007). Along these lines, Thompson et al.'s (2003) *Supports Intensity Scale* was developed to assist clinicians in identifying the required amounts and types of supports for persons aged 16–70 years. The scale has good psychometric properties for its intended purpose and would certainly enhance other measures of adaptive behavior functioning. Competence in identifying the required levels of supports would no doubt be a clinical advantage for many reasons, including gaining funding for needed services (Carr & O'Reilly, 2007). Assessing levels of support, and indeed all of the above-mentioned assessments, will often need to be repeated in response to changes in the individual's development, as well as changes in family and environmental circumstances.

3.6.3 Case Formulation

Case formulation involves developing an organized summary of assessment data for use in treatment planning (Hersen & Rosqvist, 2008). Unlike other areas of clinical practice, where clients may present with a specific problem (e.g., test anxiety or a phobia), individuals with mental retardation have global deficits across a wide range of functioning areas. Children and adolescents also often present with numerous problem behaviors (Sturmey, 2008). Clinical practice in mental retardation therefore requires competence in linking a wide range of assessment data (e.g., IQ tests, adaptive behavior assessments) to a comprehensive array of services, including, for example, behavioral intervention, family therapy, and special education. In addition to interpreting the results of various types of assessments, clinicians will need to draw out the treatment implications from these assessments and develop specific treatment plans based on sound psychological theory and the best available evidence. To ensure that cases are conceptualized in ways that will enhance the quality of life, clinicians need to consider maintenance factors (e.g., genetic syndromes, learning impairment, operant conditioning, environmental impoverishment, and social barriers) that may moderate the efficacy of any proposed evidence-based treatments. Case formulations will often need to be modified as the child ages and in light of other changed circumstances (development of psychiatric symptoms, transition to high school, etc.).

3.6.4 Developing, Implementing, and Evaluating Evidence-Based Treatments

Once the case has been formulated, the clinician will need to develop more specific treatment protocols. Parents, teachers, and other staff will require training to be able to effectively

implement the treatment protocols. In addition to providing this training, clinical psychologists should evaluate the effects of treatment protocols on child behavior and family functioning.

Developing a treatment protocol involves systematically searching the literature to identify an appropriate evidence-based treatment procedure and then modifying that procedure to suit the unique characteristics of the child and context (Schlosser, 2003). For example, well-established techniques for teaching functional communication to children with severe mental retardation have been widely disseminated in the scientific literature, but the chosen technique may still need to be adapted to ensure success with any particular child (Sigafoos, Arthur-Kelly, & Butterfield, 2006).

The success of any treatment protocol depends on how well it is implemented. This in turn depends on the quality of training provided by the clinical psychologist. Training parents, teachers, and staff to implement treatment protocols can be accomplished using a combination of verbal and written explanation, demonstration, and practice with performance feedback (Wood, Luiselli, & Harchik, 2007). Training on protocol implementation should continue until a high level of treatment fidelity is achieved.

Treatment protocols need to be evaluated to demonstrate their effects on target behaviors. This type of evaluation requires competence in obtaining objective, reliable, and valid data on performance (e.g., frequency of target behaviors) (Kennedy, 2005). Repeated measures of performance in combination with an appropriate single-case experimental design will enable the clinician to evaluate the effects of the treatment program in ways that can demonstrate a functional relation between treatment and positive changes in target behaviors (Barlow & Hersen, 1984).

Evaluation data of this type will often reveal that the treatment program is not having the desired effects. Even well established interventions that are carefully and faithfully implemented, as per the treatment protocol, may fail to produce sufficient treatment gains. Clinicians therefore should be able to quickly identify when the protocol is not working and analyze the nature of any such problems so that appropriate steps can be taken to troubleshoot the floundering program. Data collection for evaluation purposes needs to be frequent, repeated, and ongoing. In some cases, the analysis will reveal technical aspects of the procedures (e.g., the rate of reinforcement) that require modification. In other cases, however, one may need to recognize that continued use of the protocol is unlikely to be helpful.

3.6.5 Ethical Practice

Understanding of the concepts of informed consent, confidentiality, breach of confidence, access to information, and reporting laws and how to apply these concepts in practice are basic competencies required of all clinical psychologists (Sales, DeKraai, Hall, & Duvall, 2008). Application of these concepts can present certain unique ethical challenges for clinical practice in mental retardation. One such challenge arises from the fact that individuals with mental retardation are often unable to fully comprehend and hence provide informed consent to assessment and treatment. This raises problems in relation to gaining assent and promoting self-determination in relation to treatment participation (Baer, 1998). Although this area will continue to present challenges, guidelines for obtaining informed consent exist that can assist clinicians in protecting individual's rights and self-determination (Iacono & Murray, 2003).

Another challenge arises from the fact that a diagnosis of mental retardation can have life-long impact for the individual's life course, opportunities, and self-esteem. One potentially detrimental effect is the self-fulfilling prophesy of lowered expectations leading to fewer learning opportunities for learning and less academic achievement (Eikeseth & Lovaas, 1992). In light of this, there may be pressure to avoid or alter the diagnosis to something that might be seen as less stigmatizing. Ethically, clinicians must resist any such pressure and ensure that an accurate diagnosis is followed by appropriate treatment. The diagnosis of mental retardation must be based solely on objective, reliable, and valid assessment data, not on any social or political factors.

A final issue that touches on ethical issues relates to the disclosure of the diagnosis of mental retardation. It is important to realize that when a child is referred for psychological assessment, the parents may be unprepared for a diagnosis of mental retardation (Blacher, Feinfield, & Kraemer, 2007). When a diagnosis of mental retardation is appropriate to make based on objective, reliable, and valid assessment data, then the results must be fully and openly disclosed to the parents. This news can be understandably disturbing to parents, and so it must be conveyed with empathy, but not false hope. Parents deserve and appreciate clear and accurate information about their child's diagnosis and what it means for family and child functioning. When informing parents that their child meets the definition for a diagnosis of mental retardation, clinicians should be prepared to offer sound, evidence-based advice about etiology, prognosis, and treatment options. Provision of parent-friendly information can be useful for this purpose, but many parents may need time to adjust to the diagnosis before this type of supplementary information is appreciated.

3.7 Expert Competencies of the Clinician

Enhancing the quality of life for children and adolescents with mental retardation and their families often requires ongoing assessment and treatment. This reflects the fact that mental retardation is pervasive and chronic, affecting multiple areas of functioning throughout the lifespan. Providing ongoing support will often require a level of expertise that moves beyond the basic competencies considered in the previous section of this chapter. Working with children and adolescents from diverse cultural backgrounds, for example, requires expertise in culturally sensitive practices. Similarly, expert competence is required when children present with severe excess behavior or profound and multiple impairments. The demands that arise in relation to each of the areas complicate the provision of ongoing assessment and treatment and are therefore likely to require greater clinical expertise.

3.7.1 Culturally Sensitive Practice

In many countries, including the United States, clinicians are increasingly likely to be involved in supporting children and families from diverse backgrounds. Dana (2005) noted that clinicians require expertise in supporting minority, indigenous, immigrant, and refugee families, for example. Vandenberghe (2008) described how the lack of cultural sensitivity could lead to misunderstandings that may negatively impact clinical practice. For example, behaviors interpreted as pathological from the clinician's perspective could in fact be typical and acceptable within the child's family or culture.

Providing effective clinical services to diverse families does not necessarily require that the clinician and client share the same culture (Vandenberghe, 2008). It is important, however, for the clinician to gain an understanding of various cultures and strive for a more culturally sensitive approach to practice. Ideally, this should occur before progressing beyond the initial referral stage.

Understanding and sensitivity can be gained by consulting with stakeholders from the relevant community or culture. For example, assessment of intellectual or adaptive behavior functioning for a child from an immigrant family may require the clinician to work through an interpreter, who understands both the family's language and cultural values. This will require the clinician to gain competence in working collaboratively with individuals from other backgrounds and cultures.

Effective clinical work with diverse families involves more than simply working collaboratively. With respect to diagnostic assessment, for example, it must be remembered that certain IQ tests and adaptive behavior scales might not necessarily be universally applicable. A clinician must therefore gain skills in evaluating the cultural appropriateness of instruments before using these to assess a child's intellectual or adaptive behavior functioning and identifying treatment priorities.

Cultural norms may also influence acceptable treatment practices. Parents with certain cultural or religious beliefs, for example, may be reluctant to implement a recommended evidence-based treatment. In some cases, this may create an ethical dilemma for the clinician. A family might, for example, want the clinician to support them in using unproven or ineffective assessments or treatments. In such cases, the clinician must have the expertise to make judgments about whether or not accommodation of the family's wishes would compromise ethical standards.

Along these lines, Vandenberghe (2008) described four aspects of maintaining ethical standards when working with culturally diverse families: These include (a) being aware of cultural differences (and we would add being aware of cultural similarities), (b) knowing about the child's culture, (c) being able to distinguish culturally acceptable patterns of behavior from the deficits, delays, or excesses associated with mental retardation, and (d) being competent in taking culture into account during the assessment and treatment process.

3.7.2 Treatment of Severe Excess Behavior

Clinical psychologists working in the field of mental retardation will often receive referrals to treat excess or problem behavior in children and adolescents with mental retardation. The general approach of identifying the variables that maintain the excess behavior and then teaching a relevant replacement behavior is usually sufficient for treating the more common types of excess behaviors (e.g., tantrums, noncompliance, disruption, and stereotyped movements) seen in children and adolescents with mental retardation (Sigafoos et al., 2003). Implementing this general approach requires basic competence in behavioral assessment and intervention. Matson et al. (2008) described the basics of this general assessment to intervention model for the treatment of excess behavior in individuals with mental retardation. To further facilitate this process, clinicians can draw upon a range of well-established and manualized assessment and intervention procedures that have demonstrated efficacy in the

treatment of excess behavior in children and adolescents with mental retardation (e.g., Carr et al., 1994; Durand, 1990; Sanders et al., 2004).

However, successful treatment of more severe forms of excess behavior (e.g., intense aggression, extreme self-injury, and criminal behavior) will often require a higher degree of clinical expertise than is required for implementing the basic assessment to intervention process represented in these manuals. While effective treatments for severe excess behaviors are also behaviorally based (Foxx, 2001), the design, implementation, and evaluation of such treatments is complicated by the very real potential for serious harm and consequent need for immediate and lasting response suppression (Foxx, 1996, 2003, 2005). Expert competencies are therefore required to assess the risk that severe excess behavior poses to the child and others and to determine when more intrusive treatments are indicated.

3.7.2.1 Risk Assessment

The main purpose of undertaking a risk assessment is to prevent harm (McEvoy & McGuire, 2007). One way to prevent harm from severe excess behavior is to provide effective behavioral treatment. However, behavioral treatments are rarely immediately effective in preventing or eliminating severe excess behavior. Thus, clinicians must consider the risks that the excess behavior represents to the child and others in treatment planning.

Risk needs to be considered in terms of the potential for injury, damage, and other negative effects (e.g., arrest, school suspension, and loss of employment). The form of the behavior does not always equate to the degree of risk or potential for harm. Physical attacks on others for example, could pose only a moderate risk of harm if these attacks have been rare and easily preempted. Frequent and persistent swearing at strangers in the community, on the other hand, might be viewed as having serious potential for harm, including restricting a person's access to the community. McEvoy and McGuire (2007) provided a list of questions that could be adapted to identify and assess the potential for harm from excess behavior (e.g., What could happen if the behavior occurs? Who is at risk if the behavior occurs? Under what conditions is the behavior likely to occur?). Other researchers have developed scales for assessing risk (Lindsey et al., 2008). Competence in the use of such risk assessment approaches is required when individuals present with severe excess behavior.

A risk assessment is also necessary before undertaking a functional assessment to identify the variables that evoke and maintain severe excess behavior. Because some such assessments expose the individual to analog conditions that could provoke excess behavior (Rojahn, Whittaker, Hoch, & Gonzales, 2007), it is important to determine whether the information that can be gained from direct assessment methods outweighs the risk that might arise if excess behavior occurs during the assessment. Clinicians can minimize or prevent this risk by using briefer versions of analog assessments or by using more indirect assessment protocols (Matson et al., 2008).

3.7.2.2 Intrusive Treatments

In some cases, risks associated with excess behavior may warrant the use of more intrusive or restrictive treatments to prevent and reduce severe excess behavior. Certain types of

treatments – including the use of protective equipment, physical restraint, or response-contingent aversive stimulation – have been defined as intrusive and their use is controversial (Repp & Singh, 1990). Many jurisdictions have restricted the use of some such procedures in the treatment of individuals with mental retardation (Sherman, 1991).

However, use of empirically supported intrusive procedures may be justified when the risk is high and when less intrusive treatments have failed (Didden, Duker, & Korzilius, 1997; Duker & Seys, 1996; Foxx, 2005). Obviously clinicians intending to use intrusive treatments must be prepared to justify this decision with evidence, ensure compliance with legal and ethical guidelines, and develop appropriate safeguards. When these conditions can be met, clinicians must gain the necessary expertise to use the procedures prior to implementation. During treatment implementation, clinicians will have to maintain a high degree of oversight and regularly monitor the effects and side effects of treatment (Duker & Van den Munckhof, 2007). The intensity of the required oversight can be demanding and must be considered in the decision to accept referrals for the treatment of severe behavioral excesses.

3.7.3 Profound and Multiple Impairments

Developing treatments to promote greater adaptive behavior functioning is one way by which clinical psychologists enhance the quality of life for children and adolescents with mental retardation and their families. The general approach is to identify the child's adaptive behavior deficits and then directly teach new adaptive skills to address these deficits (Lovaas, 2003). For example, children with mental retardation have been taught a range of adaptive behaviors (e.g., feeding, dressing, and toileting) using task analysis, response prompting, prompt fading, and reinforcement (Duker et al., 2004). Implementing this general approach requires basic competence in undertaking adaptive behavior assessments and implementing evidence-based instructional strategies.

However, this general approach may have limited efficacy for individuals with profound mental retardation and coexisting sensory, physical, or health impairments (Smith, Klevstrand, & Lovaas, 1995). The challenge for clinicians then is how to enhance the quality of life for children and adolescents with profound and multiple disabilities. Addressing this challenge would seem to require a higher level of expertise than is usually required for teaching adaptive skills to children and adolescents with fewer and less severe impairments.

Bailey (1981) noted that clinical practice for individuals with profound, multiple disabilities may require a shift in emphasis from adaptive skill training to stimulation programming. Along these lines, Lancioni and his colleagues have demonstrated how clinicians can make use of assistive technology and operant conditioning principles to provide stimulation while at the same time promoting more active engagement and movement in persons with profound and multiple disabilities (Lancioni et al., 2008a, b). For example, instead of merely exposing the individual to preferred sources of stimulation, a microswitch program may enable the person to obtain stimulation in a more active, self-directed manner (Lancioni et al., 2007a).

Promoting more active engagement is one way to enhance the quality of life for children and adolescents with profound mental retardation and coexisting conditions (Lancioni et al., 2007b). Doing so effectively requires expert competence in an area of practice that has been relatively neglected (Bruzek & Kennedy, 2007). Consequently, clinicians interested in this and

other specialized populations described in this section will benefit from adopting strategies to facilitate their transition from basic competence to expert clinician.

3.8   Transition from Basic Competence to Expert Clinician

The competency-based movement in professional psychology focuses on identifying the domains and levels of required competence (Hatcher & Lassiter, 2007). As noted by Kaslow, Dunn, and Smith (2008), the domains and levels of required competence vary across practice settings and client populations. In the field of mental retardation, the transition from basic competence to expert clinician can be viewed as one way to extend the limits of competence to a wider range of issues. Gaining expert competence in clinical interviewing to assess adaptive behavior, for example, can extend the limits of practice to include more culturally diverse families, whereas greater expertise in behavioral intervention may enable clinicians to more effectively treat individuals with severe behavioral excesses.

The transition from basic competence to expert clinician might be viewed as an ongoing development process (Kaslow et al., 2008; Lichtenberg et al., 2007). That is, there is no point at which a clinician achieves complete expertise. Rather, clinicians should continually seek out new knowledge and professional development opportunities to advance their skills. This developmental view recognizes the fact that mental retardation is a vibrant and evolving area of specialization, where new evidence is continually generating new and more effective practices.

In line with this developmental view, clinicians may benefit from developing a planned and systematic approach for gaining relevant new knowledge and clinical skills. Following successful completion of a clinical training program with practicum and internship experiences in the field of mental retardation, approaches for gaining more expert knowledge and clinical skills include: (a) systematic literature reviews, (b) mentoring, and (c) participation in professional development activities. A planned systematic approach to knowledge acquisition and skill development may help to ensure that clinicians identify relevant new knowledge and skills.

3.8.1   Systematic Literature Reviews

Keeping abreast of the latest and best research evidence is an essential component of evidence-based practice. Clinicians should therefore develop the habit of systematically searching the literature on a regular basis. The purpose of undertaking regular systematic literature searches is to identify high-quality studies relevant to a particular case or clinical practice. Indeed, an important initial step in developing any treatment plan – be it to improve social skills, teach language, or reduce disruptive behavior – is to identify well-established interventions that have been successfully used with similar cases. When relevant studies are identified, clinicians should have the basic competence to appraise the certainty of the evidence and eliminate from consideration any approaches that lack empirical support. When use of a particular approach is well established by a sufficient amount of high quality research, expert clinicians are able to incorporate the evidence-based procedures into their professional practice to improve quality of life outcomes for individuals with mental retardation and their families.

One practical and efficient way to search the literature is through the use of electronic databases, such as PsychINFO and MEDLINE. A PsychINFO search using mental retardation and assessment (or intervention) as keywords and covering only 2007, for example, yielded 187 publications. Clearly, there is a large amount of published literature that could be drawn upon to inform clinical practice. The need to sift through the huge volume of literature highlights the critical need for expertise in the critical appraisal of available research evidence.

At a more advanced level of competence, the transition to expert clinician is marked by the ability to identify emerging trends in the scientific literature and contribute to this literature in line with the scientist–practitioner model of clinical practice (Tryon, 2008). Major advances in identifying genetic syndromes and behavioral phenotypes associated with mental retardation (Oliver et al., 2007), for example, would seem to hold considerable promise for clinical practice. Translating emerging genetic and biomedical discoveries into more effective treatments is likely to require a high level of competence supported by opportunities for interdisciplinary collaboration.

3.8.2   Mentored Experiences

Mentoring in this context refers to seeking out a more experienced colleague for professional guidance, support, and advanced training. Two examples of such experiences include: (a) working collaboratively and constructively with a more experienced team of colleagues, and (b) entering into a more formal training arrangement with experienced colleagues. The purpose of seeking such mentoring experiences is to develop expert levels of competence in one or more specialized clinical skills.

Developing expert competence is more likely when the mentoring experience includes observation of the expert followed by opportunities to practice the skill while receiving performance-based feedback (Lichtenberg et al., 2007). Fluency in clinical skills will often require repeated opportunities to observe the expert and practice the skill while receiving feedback.

Unfortunately such mentoring experiences may be difficult for practicing clinicians to arrange. Difficulties can arise from the fact that there may be a shortage of experts who are willing and able to serve in a mentoring capacity. In addition, many professionals work on an individual basis in their own clinical practice (Hersen, 2004). These clinicians are likely to be isolated from senior colleagues and thus have few available mentors. In such settings, the clinician can gain new knowledge from handbooks and treatment manuals written by recognized experts (e.g., Hersen & Gross, 2008; Hersen & Reitman, 2008; Matson, 2007b) and undertake self-directed practice to gain fluency.

3.8.3   Professional Development

Professional development in this context refers to participation in formal accredited training programs. This may involve accredited university courses or training run by professional organizations, such as the American Psychological Association. The aim of this training is to acquire new knowledge and skills relevant to clinical practice.

This type of professional development training usually occurs over a brief period of time (e.g., a one-semester evening course or a 1–2 day workshop). The evidence for the effectiveness of such training is mixed (Miline, Keegan, Westerman, & Dudley, 2000; Miller, Yahne, Moyers, Martinez, & Pirritano, 2004) and probably depends as much on the quality of the material and presenter as it does on the commitment of the trainee to develop fluency in newly acquired knowledge and skills. There appears to be no shortage of opportunities for professional development training in the field of mental retardation.

Another form of professional development is to become actively involved in relevant professional organizations, such as Division 33 (Intellectual and Developmental Disabilities) of the American Psychological Association. Such organizations provide opportunities to network with experts and access targeted professional development opportunities.

3.9   Summary

Enhancing the quality of life for individuals and families is the overall objective of clinical psychology practice in mental retardation. To achieve this objective, a range of competencies, such as those outlined in this chapter, is required. The present chapter has hopefully contributed to the competency-based movement in professional psychology by articulating some of the basic and expert competencies that will enable clinical psychologists to be more successful in enhancing quality of life outcomes for children and adolescents with mental retardation and their families.

Because of the heterogeneous nature of mental retardation, effective clinical practice in the field requires basic and expert levels of competence. There are numerous causes for mental retardation and varying symptom presentation. For example, individuals with mental retardation can present with mild mental retardation and require only episodic support or with profound mental retardation and coexisting physical and sensory impairments requiring life-sustaining support. The expert clinician can recognize, assess, and treat mental retardation in all its various manifestations.

Mental retardation is pervasive and chronic. Because of this, many individuals with mental retardation require ongoing support across a range of settings (e.g., clinic, home, school, community, and vocational settings). A competent clinician must therefore be able to work from a lifespan perspective and coordinate services across multiple settings.

The two main areas of clinical practice in mental retardation are (a) diagnostic assessment and (b) evidence-based intervention to promote improved adaptive behavior functioning. To this end, clinicians can draw upon a range of evidence-based assessment and treatment approaches. This is a challenging task, as the heterogeneity of mental retardation means that clinicians will often have to adapt assessment and intervention strategies to suit the unique characteristics of the individual and context. Making effective adaptations of this sort requires a thorough understanding of the foundational principles that underlie evidence-based assessment and treatment approaches (Linscheid, 1999).

The transition from basic competence to expert clinician can expand the limits of one's practice to a wider range of clinical problems and issues. Expert competences are certainly needed to (a) work effectively with diverse families, (b) treat severe excess behavior, and (c) enhance participation of individuals with profound, multiple disabilities. To make this transition, a conscientious effort to keep informed of current literature and develop advanced

clinical skills through mentoring and professional development is required. Professionalism demands that clinicians strive to make the transition from basic competence to expert. Clinicians can be confident that their efforts to gain expertise in this challenging, but rewarding, field can greatly enhance the quality of life of individuals with mental retardation and their families.

4   Autism Spectrum Disorders

Cynthia R. Johnson

Abstract: Autism Spectrum Disorders (ASD) are biologically based, neurodevelopmental disorders of childhood onset characterized by significant impairment in social interactions and communication as well as restricted or stereotyped patterns of behavior and interests (American Psychiatric Association, 2000). As many as one in 150-500 children are affected (Center for Disease Control and Prevention, 2007; Fombonne, 2003). With the increased prevalence of ASD, many clinical psychologists will be charged with providing services to these children, adolescents, adults, and their families. In fact, the training of the needed services providers to serve this group of individuals has been the topic of national discussion (National Research Council, 2001). Clinically, the roles for this population fall primarily into 1) screening and referral services, 2) diagnostic services, 3) treatment development, delivery, and evaluation, 4) oversight and supervision of treatment delivery, 5) staff training, 6) parent education and training, and 7) consultation and staff training services. Given the heterogeneity of ASD, clinical competency across all ages, all functioning levels, and all levels of severity entail a broad range of professional skill sets. This chapter will provide an overview of ASD, the clinical roles in serving individuals with ASD, and then more detailed information about both basic and expert competencies required to in the delivery of these services.

4.1   Overview of Autism Spectrum Disorders

Autism Spectrum Disorders (ASD) are biologically based neurodevelopmental disorders of childhood onset characterized by significant impairment in social interactions and communication, as well as restricted or stereotyped patterns of behavior and interests (American Psychiatric Association, 2000). As many as one in 150–500 children are affected (Center for Disease Control and Prevention, 2007; Fombonne, 2003). This prevalence figure is dramatically higher than the previously accepted estimate of 5 per 10,000. The increase in the detected prevalence is due in large part to better community sampling methods, broadening the case definition, and improved diagnostic precision (Fombonne; Yeargin-Allsop et al., 2003).

It was Leo Kanner, a physician at Johns Hopkins, who in a seminal paper coined the word infantile autism in describing a group of 11 children who had a lack of social interest, communication deficits, and a resistance to change (Kanner, 1943). While these disorders share common characteristics of impairment in communication and social abilities along with restricted, repetitive, and stereotyped behaviors, there is considerable variability with respect to the extent and severity of the impairment. Furthermore, ASD very often co-occurs with global developmental delays and intellectual disability introducing additional variability. Between 26% and 75% of children with ASD also meet the criteria for intellectual disability (Chakrabarti & Fombonne, 2001; Joseph, Tager-Flusberg & Lord, 2002). Children with ASD may be functioning in the severe range of intellectual disability but may also be in the superior or gifted range of cognitive functioning. Furthermore, children and adolescents with ASD commonly exhibit

serious behavior problems such as tantrums, aggression, self-injury, hyperactivity, and non-compliance. An estimated 50–70% of children with ASD have co-occurring behavioral or emotional problems (Gadow, Devincent, Pomeroy, & Azizian, 2004; Tonge & Einfeld, 2003).

For children with ASD and their families, the impact of this disorder may be considerable and enduring. Research has shown that parents of children with ASD experience more stress than parents of children with other disabilities or illnesses (Dunn, Burbine, Bowers, & Tantleff-Dunn, 2001; Weiss, 2002). Not only do families have to cope with an often challenging child, but also they are confronted with additional stressors related to ensuring appropriate care for their child, as the barriers are often enormous. These include determining the availability and their eligibility of services typically across a number of service systems (educational, mental health, early intervention, medical subspecialists, etc.). Providing appropriate treatment for the growing number of children identified with ASD has become a challenge to the state and local systems (Croen, Grether, Hoogstrate, & Selvin, 2002).

4.1.1 Current Diagnostic Categories

Within the Diagnostic and Statistical Manual of Mental Disorder: Fourth Edition, Text Revision (DSM-IV-TR; APA, 2000), ASDs are in the group of diagnoses of pervasive developmental disorders and include (1) Autistic Disorder, (2) Asperger Disorder, and (3) Pervasive Developmental Disorder, Not Otherwise Specified (PDD, NOS). Also assumed under this class are two, much rarer disorders, which include (1) Rett's Disorder and (2) Childhood Disintegrative Disorder. While we will provide a description of all the ASDs in the next section, the focus of this chapter will be on Autistic Disorder, Asperger Disorder, and PDD, NOS. In this chapter, we will refer to these three disorders as ASD, as this terminology is now widely used for them.

4.1.2 Overview of Clinical Issues in Autism Spectrum Disorders

With increased prevalence of ASD, many clinical psychologists will be charged with providing services to these children, adolescents, adults, and their families. In fact, the training of the needed service providers to serve this group of individuals has been the topic of national discussion (National Research Council, 2001). Clinically, the roles for this population fall primarily into (1) screening and referral services, (2) diagnostic services, (3) treatment development, delivery, and evaluation, (4) oversight and supervision of treatment delivery, (5) staff training, (6) parent education and training, and (7) consultation and staff training services. Given the heterogeneity of ASD, clinical competency across all ages, all functioning levels, and all levels of severity entails a broad range of professional skill sets. Many psychologists specializing in ASD may focus on few of these clinical roles or focus on a particular age range (e.g., preschoolers).

As with any chronic, complex disorder, challenges of this population are many. Behaviorally, children with ASD can be extremely disruptive and even harmful to others and to themselves. Given the behavioral issues, both assessing and treating these individuals can be quite stressful. Progress in treatment may also be slow despite the best delivery of evidenced-based treatment. Moreover, the support systems for these children to include parents, teachers, and other service providers may be strained and overwhelmed in their roles with the child or adolescent with ASD. Lastly, as children and adolescents with ASD are provided services in a variety of settings

to include early intervention programs, mental health programs, and special education programs, knowledge of service systems and the ability to work with them are essential. Nonetheless, working in the ASD field affords an opportunity to have a dramatic impact on children with ASD, their families, and other service providers. Moreover, it is an exciting clinical area given the rapid, new developments with respect to what we are learning about etiology, earlier diagnostic features, and the development and refinement of treatments to meet the needs of this vastly heterogeneous group.

4.2   Recognition of Symptoms and Their Assessment

In this section, we will discuss criteria for each of the diagnoses under the ASD category. There is a considerable overlap, which is important to recognize but also to understand the differences to make an accurate diagnosis.

4.2.1   Autistic Disorder

This diagnostic label is preserved for the "classic" description of autism. By definition, these children display symptoms in all three categories with a total of at least six symptoms specified across the three categories of impairment: (1) impairment in social interactions, (2) impairment in communication, and (3) restricted repetitive and stereotyped patterns of behavior, interest, and activities. In the first category where two symptoms must be present, noted impairment in nonverbal social behaviors such as use of eye contact and use of gestures is required. While lack of eye contact is considered a hallmark of autism, children with autism also display deficits in other nonverbal social behaviors, such as the use of joint attention and facial expressions. Lack of the use of an index point has been found to be a very salient early arising deficit. Further, limited social reciprocity is a key feature of the overall social impairment. That is, there is a lack of understanding of the reciprocal back and forth nature of interacting with others. In the second category, behaviors include lack of speech development, atypical use of language to communicate, repetitive or idiosyncratic use of language, and lack of imitative play. Children with autism, as well as other ASD often display echolalic speech (repeating what they have heard), repetitive repeating of what they have heard from TV shows, videos, or other sources (often referred to as "scripting"). Many children with autism and other ASD develop none or a limited repertoire of functional speech.

What is commonly referred to as "third category" behaviors include many of the ubiquitous behaviors associated with autism, such as stereotypical body movements, attendance to a part of an object (spinning the wheels of a car or train), strong adherence to specific routines and rituals, and keen, unusual, and restricted interests. Children with autism may become extremely distressed when their need for sameness is not honored, leading to disruptive behaviors.

4.2.2   Asperger Disorder

Soon after Kanner described infantile autism, an Austrian pediatrician, Hans Asperger, described a small group of children who had strong cognitive and language skills, but who

nonetheless had social deficits, keen, and unusual interests and some motor "clumsiness" (Asperger, 1944). Also noted was a family history of such behavioral differences. Currently, DSM-IV diagnostic criteria include a qualitative impairment in social interactions and restricted, repetitive, and stereotyped patterns of behaviors, interests, and activities. However, by definition, there is no evidence of cognitive or language delay.

Over the last 2 decades, studies examining validity of the differential diagnosis of Asperger Disorder versus high functioning autism has resulted in further characterization of this clinical diagnosis. However, controversy remains over whether Asperger Disorder represents a separate category or is a milder presentation of high functioning autism. Some differences between the two groups have been shown in their cognitive profiles. It is generally accepted that individuals with Asperger Disorder have stronger verbal skills than nonverbal skills, which is opposite of what is held for high functioning autism. Many individuals with Asperger Disorder also have a history of hyperlexia (early, precocious reading abilities). Socially, it is believed that individuals with Asperger Disorder show more interest in social interactions but are unsuccessful due to the misinterpretation/lack of understanding of social cues. Emotionally, these individuals may have difficulty in modulating emotions, in that they may either be over reactive or under reactive to a situation. Similar to individuals with high functioning autism, individuals with Asperger Disorder may be quite literal in their interpretation of language, may be experts on obscure topics, and may have rigid rules about the world.

4.2.3 Pervasive Developmental Disorder, Not Otherwise Specified (PDD, NOS)

This diagnostic category is applicable for those individuals who display many of the characteristics of Autistic Disorder or Asperger Disorder, but have milder and fewer symptoms. In fact, it is often described as "mild autism." It is generally believed the prognosis is better (Gillberg, 1991). This diagnosis may also be used when there is not sufficient information gathered during the diagnostic process to determine a more specific ASD diagnosis.

4.2.4 Rett's Disorder

Rett's Disorder is a relatively rare disorder with a much lower incidence than other ASD and is believed to affect one in every 10,000–15,000 live female births. Rett's Disorder was first described by a physician in Austria in the 1960s and is characterized by apparent typical development followed by a period of loss of skills. Loss of skills includes loss of motor tone (hypotonia), which includes the loss of use of hands as well as the loss of speech abilities. While age of regression varies during the preschool years, the loss of skills can be quite sudden and dramatic. Loss of purposeful hand use is usually associated with the observation of repetitive hand wringing at midline. Other early symptoms include difficulty in crawling or walking and low levels of eye contact. Further behavioral characteristics associated with Rett's Disorder include bruxism (teeth grinding), chewing difficulties, seizures, and a wide-based gait when able to walk. Growth parameters, particularly head circumference, are usually slowed with onset.

Respiratory difficulties such as apnea, hyperventilation, and aerophagia (air swallowing) are commonly observed. Given some of the overlapping behavioral characteristics, such as limited eye contact, and repetitive behaviors, Rett's Disorder may be mistaken for autism or PDD, NOS. Most girls with Rett's syndrome have intellectual disabilities. Rett's Disorder is now known to be a genetic disorder with two genes implicated. Given the rarity of Rett's Disorder, much less is known about the long-term prognosis.

4.2.5 Childhood Disintegrative Disorder (CDD)

Even rarer than Rett's Disorder is Childhood Disintegrative Disorder. This disorder was originally described by Theodore Heller, a special educator, in 1908 (Heller, 1908). These children display behaviors consistent with autism, but after a longer period of typical development (3–5 years of age). A regression in skills is followed by minimal recovery of these skills. Hence, there is a difference in onset, and it is also believed the course and prognosis are different (Volkmar, Koenig, & State, 2005). These children may develop typical language, display social interests, and accomplish toilet training and other self-care skills. With the onset of CDD, loss of these skills is evidenced along with a general loss of interest in their environment. It is estimated that less than 2 children per 100,000 who are diagnosed with an ASD have CDD. These children are often evaluated for other neurological diseases and disorders because of the pronounced loss of skills. Prognosis for CDD is much more guarded than for Autistic Disorder, Asperger Disorder, and PDD, NOS.

4.2.6 Assessment of ASD

Assessment of ASD requires several levels. Clinical psychologists may be involved in a few if not all of these levels. Knowledge of best practices at each of these levels should be acquired consistent with clinical roles accepted.

4.2.6.1 Screening of ASD

With the growing evidence that early intervention at young ages can improve long-term outcome, the importance of screening for signs and symptoms has become increasingly paramount. The importance of screening has been the focus of several professional groups (American Academy of Pediatrics, 2007; Filipek et al., 2000; National Research Council, 2001). The American Academy of Pediatrics published a comprehensive resource toolkit to assist health care professionals in screening for children with ASD. It includes several screening measures that have been widely used. These include the Checklist for Autism in Toddlers (CHAT) (Baron-Cohen, Allen, & Gillberg, 1992), the modified-CHAT (Robins, Fein, Barton, & Green, 2001), and the Pervasive Developmental Disorders Screening Test (Siegel, 1996). Pediatricians and other primary care physicians involved in the care of young children have increasingly adopted the use of screening measures in their practices. If a child is screened to be at risk for ASD, a referral for a diagnostic assessment is warranted.

4.2.6.2 Diagnostic Evaluation

In light of the prevalence rates, it is not surprising that numerous children are referred for diagnostic evaluations of ASD. This group of disorders requires special considerations with respect to evaluation practices. Given the pervasive delays and deviances in multiple developmental domains in ASD, comprehensive assessments are best met with a multidisciplinary team of professionals. At the first step of a comprehensive evaluation, the diagnostic portion typically involves a direct interview with the parent/caregiver. The purpose of this interview is to gather detailed information on early medical history, the developmental course of the child, current and past communication abilities and differences, social functioning, level of play and leisure skills, acquisition of self-care skills, and the presence of atypical and challenging, disruptive behaviors. A parallel step in the diagnostic process is direct observations of the child. Observations of the child should optimally occur under various conditions (unstructured play, structured adult directed activity) and across settings (clinic, home, preschool/school). When the diagnostician is not able to gather much information directly, gathering information from others who observe the child is important.

4.2.6.3 Assessment of Cognitive, Neuropsychological and Adaptive Functioning

Psychologists may play a critical role in the diagnostic process, but also in other areas of assessment that are important to further understand the child and family and their intervention needs. These include administration of both standardized cognitive and neuropsychological measures as well as adaptive behavior measures. Understanding a child's cognitive strengths and weaknesses is imperative in treatment planning. For individuals with ASD who are higher functioning, neuropsychological testing to include measures of executive functioning is often warranted to discern differences in information processing. With the consistent finding that adaptive functioning in children with ASD is lower than their cognitive functioning, assessing these skill deficits is important in intervention planning.

4.2.6.4 Assessment of Communication and Language Skills

Discernment of communication and language skills is critical in evaluating the individuals with ASD. Communication assessment not only involves assessment of spoken speech, but prelinguisitic, nonverbal behaviors. In fact, it is the delay or deviance in nonverbal communication behaviors, which is more associated with ASD than the delay in expressive, verbal communication skills.

4.2.6.5 Behavioral Assessment and Behavioral Functional Assessment

Behavioral assessment in this population includes first the quantification of the behavioral concerns as well as the evaluation of co-morbid conditions, such as anxiety and depression. In planning for "functionally derived" interventions (behavioral interventions will be discussed

in a later section), a functional assessment of behavior is commonly conducted. The goal of the functional behavioral assessment is to identify the variables that contribute to the target behavior (Carr et al., 1999; Horner & Carr, 1997; Horner, Carr, Strain, Todd, & Reed, 2002). This involves comprehensive examination of underlying motivations, or functions, of the child's interfering behaviors. A functional behavioral assessment should identify environmental influences for particular, well-defined target behaviors. The environmental variables assessed include antecedents and consequences that may be contributing to or maintaining the behaviors. Antecedents assessed include details on what is happening prior to the behavior (e.g., who is present, what activity is taking place), what the setting is (e.g., classroom, recess), and possible physiological influences (e.g., illness, hunger). Consequences assessed include the outcome of the behavior, such as whether the child "escapes" the situation, receives the attention of adults or others, receives a preferred object, or is allowed to continue an activity.

4.2.6.6 Assessment of Sensory Features

Atypical sensory behaviors are observed in a large percentage of individuals with ASD (Baranek, Parham, & Bodfish, 2005). These include hypersensitivity or hyposensitivity to sensory input from the environment. Atypical responses occur across sensory modalities to include visual, auditory, tactile, proprioceptive, and olfactory. While not a core feature, assessment of these sensory behaviors may aid in treatment planning. Recent development of tools to assess this area is now available.

4.2.6.7 Assessment of Parental Stress and Family Functioning

Given the added burden and related stress placed on parents and family members caring for a child or adolescent with ASD, assessing these areas is important. There are several measures used in ASD.

4.3   Maintenance Factors of ASD

There are a number of contributory factors that play a role in the delays and deficits observed in ASD as well as the behavioral challenges such as aggression, tantrums, and atypical behaviors (e.g., ritualistic behaviors, stereotypical behaviors, etc.). While presented separately, they overlap in their impact on the individual with ASD.

4.3.1   Neurodevelopmental Factors

Early features of ASD include atypical use of eye contact (Rogers, 2001), lack of or diminished joint attention (Leekam, Lopez, & Moore, 2000; Mundy & Gomes, 1998), delayed emergence of other early communication skills (Charman et al., 1998), deficits in symbolic play (Charman et al., 1988), and deficits of imitation abilities (Rogers, Hepburn, Stackhouse, & Wehner, 2003). These early emerging deficits are believed to disrupt subsequent developmental stages in social,

language, and cognitive domains. Joint attention has been strongly correlated with later vocabulary development (Tomasello, 1995) along with social development. Imitation of familiar gestures is correlated with language comprehension (Abrahamsen & Mitchell, 1990). Symbolic play requires some level of "symbolism" and has been linked to the mastering of early cognitive skills. Strong evidence suggests that lack of imitation is related to later impairment in self-understanding and the social understanding of others (Sigman, Dissanayake, Arbelle, & Ruskin, 1997). Use of delayed imitation, pretend play, referential gestures, and words typically emerge in the second year of life and are considered signs of early conceptual abilities (Travis & Sigman, 2001). These early behaviorally observed impairments are speculated to in turn adversely impact subsequent brain development (Dawson et al., 2002; Mundy & Neal, 2001).

4.3.2 Abnormal Brain Development

Atypical brain development is posited to cause the atypical development and behaviors in ASD. With the advent of neuroimaging technology along with a few neuropathological studies, much has been learned in the past 15 years about atypical brain growth in early life (Courchesne, Carper, & Akshoomoff, 2003), likely reduced connectivity between brain regions (Vidal et al., 2006), and differences at a cellular level (Cassanova, Buxhoeveden, Switala, & Roy, 2002).

4.3.3 Genetic Factors

There is accumulating data to implicate ASD as a complex genetic disorder. Not only is there a great increased risk within families to have another with ASD when there is a sibling affected, there is substantial different concordance rates between monozygotic twins (over 90%) compared with dizygotic twins (10%) for ASD (Bailey et al., 1995; Jorde et al., 1991). While a few single genes have been associated with ASD, it is more probable that multiple genes will be found to be implicated. Behavioral features of ASD are often observed in a few identified genetic syndromes such as Fragile X syndrome. Genetics is presently a very active area of research in ASD.

4.3.4 Operant/Environmental Factors

As discussed in the section on Behavioral Assessment, environmental factors may greatly attribute to the maintenance of both behavioral excesses (aggression, destructive behaviors) as well as behavioral deficits (play skills, communication skills). Identifying operant conditions which either maintain a behavior or thwart the learning of alternative, more functional behaviors are essential in the treatment of ASD. The operant model will again be discussed in the treatment section and has important implications for those with ASD.

4.3.5 Service Delivery Factors

Unfortunately, ready access to comprehensive services is not available in all communities. In fact, there are great disparities in the availability and quality of assessment and treatment

services across the United States. Even within the same region, there may be variation in program availability and quality (Hume, Bellini, & Pratt, 2005). This disparity is fueled by both funding shortfalls and the lack of highly trained personnel issues.

4.4   Evidence-Based Treatment Approaches

Evidence-based practices are interventions which have a knowledge base attesting to their quality and efficacy (Hoagwood & Johnson, 2003). Evidence-based practices are just emerging in ASD. Currently, there are few approaches used in the treatment of ASD and its associated symptoms, which have an empirical base, including interventions based on applied behavior analysis (ABA) (Schreibman, 2000; Smith et al., 2006), comprehensive educational intervention (National Research Council, 2001), and pharmacotherapy (Scahill & Martin, 2005). The focus of intervention may be on the core symptoms of ASD and overall development. Alternatively, the intervention may focus on reducing specific target symptoms, such as stereotypic behaviors, hyperactivity, aggression, self-injury, or specific skill development, such as daily living skills, communication, or joint attention.

4.4.1   Applied Behavior Analysis (ABA) Interventions

The applied behavior analysis literature is replete with studies demonstrating the effectiveness of these procedures for individuals with ASDs (Matson, Benavidez, Compton, Paclawskyj, & Baglio, 1996; Schreibman, 2000). This model, based on operant learning theory, presumes that antecedent stimuli and consequences influence both the acquisition and maintenance of behaviors. Investigations into this approach have demonstrated attenuation of problematic behaviors (e.g., aggression, self-injury, tantrums, noncompliance, ritualistic behaviors, etc.) as well as the acquisition of skills (Lovaas, 1987; Mauric, Luce, & Green, 1996; Schreibman, 1997).

4.4.1.1 Managing Challenging Behaviors

Subsequent to conducting a functional behavioral assessment as described in the assessment section of this chapter, functionally derived behavioral procedures may be developed and implemented. Recent years have seen a shift in the ABA field toward prevention and antecedent management strategies (Luiselli & Cameron, 1998) and away from reliance on consequence-based strategies. These approaches include use of visual strategies, modifications in daily schedule, and rearranging the physical setting (Duker & Rasing, 1989; Mesibov, Browder, & Kirklan, 2002). Visual schedules have been used to improve on-task behavior as well as independence in following the classroom schedule (Bryan & Gast, 2000). Environmental adaptations include modification in lighting and sound and physical arrangement of the space.

Another antecedent strategy with considerable empirical support is functional communication training. The premise is that the challenging behavior serves a maladaptive, but effective form of communication. If children with ASD and communication deficits can be taught a more appropriate communication behavior, a decrease in the challenging behavior is expected

(Hanley, Iwata, & Thompson, 2001; Johnson, 2002). The alternative, communication behavior may be the use of a manual sign, use of a picture symbol, or the use of an augmentative communication device.

Ducharmé and Drain (2004) recently demonstrated an antecedent approach to increase compliance. In this errorless compliance training paradigm, high-probability requests are issued, while only very gradually introducing less preferred requests.

Antecedent management approaches are the most effective when implemented in concert with traditional behavioral strategies, such as the systematic reinforcement of alternative behaviors and extinction. A number of seminal studies has demonstrated efficacy of both positive and negative reinforcement in altering challenging behaviors in children with ASD (Carr, Newsom, & Binkoff, 1976; Wolf, Risley, & Meese, 1964). Investigations have highlighted the importance of carefully selecting reinforcers to be used for children with ASDs (Charlop, Kurtz, & Casey, 1990; Mason, McGee, Farmer-Dougan, & Risely, 1989). Charlop and colleagues have demonstrated the effectiveness of using the atypical behaviors the children chose to engage in on their own (obsessions, stereotypical behaviors such as spinning) as reinforcers in children with autism (Charlop-Christy & Haymes, 1996, 1998).

4.4.1.2 Comprehensive Behavioral/Educational Programs

ABA procedures are not solely the mainstay for the amelioration of challenging behaviors. The field also has a long history of contributing to instructional procedures for children with ASD and other developmental disabilities (Dunlap, Kern, & Worcester, 2001; Heflin & Alberto, 2001). These procedures include the systematic task analysis of skills to be taught, direct instruction and discrete trial instruction, and other behavioral techniques, such as prompting, shaping, chaining, and fading.

Comprehensive programs target not only specific problem behaviors (e.g., aggression, self-injury, tantrums, noncompliance, ritualistic behaviors, etc.) but also skill acquisition across broad domains such as communication and social skills over a relatively long period (e.g., 2 years) (Schreibman & Ingersoll, 2005). Such intervention packages include techniques such as incidental teaching (Fenske, Krantz, & McClannahan, 2001; McGee Morrier, & Daly, 1999), the Picture Exchange Communication System (Frost & Bondy, 1994), discrete trial training (Eiskeseth, Smith, Jahr, & Eldevik, 2007; Lovaas, 1987), and pivotal response training (Schreib-man & Koegel, 2005). Although the conceptual framework and interventions differ across such programs, there are many common features. Specifically, all programs emphasize the importance of early intervention, use of specially trained staff, a low staff to student ratio, a focus on the child's social development and communication skills, a high value on individualized treatment, and active involvement of the family (National Research Council, 2001). Differences include the degree of structure and level of intensity of the various program models. Several comprehensive educational programs have published outcome data showing developmental gains in language functioning or IQ (Kasari, 2002). These studies suggest that factors, such as level of cognitive functioning, presence of expressive language skills by age 5, and hours of service may predict positive treatment outcomes (National Research Council). Available research suggests that early intensive intervention is effective in maximizing long-term outcome for children with autism (Handleman & Harris, 2001).

4.4.1.3 Behavioral Parent Training

In the behavior analytic literature, persons administering specific behavioral interventions may be highly trained behavior analysts, teachers, trained one-on-one therapists, or parents. Research on training parents indicates that parents can learn ABA techniques for reducing problem behaviors and increasing compliance, as well as for increasing communication and other adaptive skills (Charlop & Trasowech, 1991; Drew et al., 2002; Ducharmé & Drain, 2004; Jocelyn, Casiro, Beattie, Bow, & Kneisz, 1998; Kaiser, Hancockm, & Niefeld, 2000; Smith, Groen, & Wynn, 2000; Tonge et al., 2006). In most studies, duration of parent training has been relatively small, totaling less than 20 hours. Most of the comprehensive treatment programs for children with ASD include a parenting training component and include a range of techniques that have been validated in separate, single-subject design studies (National Research Council, 2001).

Parent training programs share many common elements. For example, most seek to identify antecedents and consequences occurring in the environment that may be contributing to a behavior of interest. Parents are also typically taught to record the child's response in everyday settings and then to modify the child's behavior through environmental manipulation (prevention and antecedent management). Instruction in communication, play, or social skills may also be included. Appropriate use of positive reinforcement, extinction, and other reduction techniques are also commonly covered.

4.4.2 Psychopharmacology

Psychopharmacology treatment in ASD has been a long standing practice. Pharmacologic treatment is most often an adjunct to educational, behavioral, and other treatment approaches. In fact, 46% of respondents to a survey reported medication use for the family member with autism and prescription of medication use is associated with the increased age and increased severity level (Aman, Lam, & Collier-Crespin, 2003; Langworthy-Lam, Aman, & Van Bourgondien, 2002). Medications do not primarily treat the core behavioral symptoms of autism but rather target particular behavioral or psychiatric symptoms. These include disruptive and aggressive behaviors, attention and hyperactivity symptoms, and affective symptoms such as anxiety and depression. Despite wide use of psychotropic medications, efficacy studies of medications specifically in individuals with ASD have been limited (Handen & Lubetsky, 2005). Classes of medications prescribed for individuals with ASD include primarily stimulants, antipsychotics, antidepressants, and mood stabilizers. In the few double blind, placebo-controlled studies of methylphenidate, there were decreases in overactivity and inattention symptoms, but side effects were also observed (Handen, Johnson, & Lubetsky, 2000). Side effects include appetite loss, irritability, social withdrawal, and development of motor tics. Antipsychotic medications have an extensive history in the treatment of a range of behavioral symptoms to include hyperactivity, irritability, social withdrawal, and stereotypical behaviors. The "typical," older antipsychotic medication that has been most studied in ASD was haloperidol with some suggestion of improvement (Campbell et al., 1997). More recent years have seen a surge of the use of "atypical" antipsychotics in the treatment of ASD. These include clozapine and risperidone. The side effect profile of the atypical antipsychotics is an advantage over older, typical antipsychotics. Risperidone has been most widely studied and in fact was the first drug approved by the FDA for the treatment of disruption and irritability in ASD. Antidepressants

have had broad use in individuals with ASD to treat depressive and anxiety symptoms, obsessive and compulsive behaviors, ritualistic and stereotypical behaviors, and self-injurious behaviors. Clomipramine, a tricyclic antidepressant, was earlier studied with equivocal findings. This group of antidepressants has been associated with decreased seizure threshold and risk of toxicity with overdose. In more recent years, fluoxetine, a selective serotonin reuptake inhibitor (SSRIs), has been the most studied in ASD. Other SSRIs used in ASD but less studied include fluvoxamine, sertaline, and venlafaxine. While the SSRIs have a more benign side effects profile, the FDA now requires all antidepressants to carry a warning on the label about increased suicidality in children and adolescents (FDA Public Health Advisory, October, 2004). The last group of medications used with some frequency in ASD includes mood stabilizers. Anticonvulsants with mood stabilizing properties have been used in ASD. However, the empirical base is limited.

4.5 Mechanisms of Change Underlying the Intervention

An understanding of change mechanisms underlying the treatment approaches is important in the conceptualization of a case, as well as in the refinement or modifications of treatment over time. Ongoing treatment evaluation allows for the appraisal of treatment effectiveness and the need to make necessary changes.

4.5.1 Mechanism of Change Underlying Behavioral and Educational Interventions

Procedures of behavioral and educational interventions may be narrowly or more broadly based on those borne out of applied behavior analysis. While the early focus of operating conditioning was on the manipulation of consequences to change the probability of a behavior in the future, this two-term contingency has been expanded over the years. Application of operant conditioning to change human behavior, ABA, now includes consideration of antecedents. These antecedents include the establishment of discriminative stimuli to occasion a behavior (by a history of pairing with reinforcement) and by establishing operations to motivate the behavior. This is along with attention to consequences. Behavior analysts now operate within the assumption of a four-term contingency (discriminative stimuli, motivation operation, behavioral response, and consequence). The systematic application of these procedures has shown to result in behavioral change and also in the learning of new skills. Within an educational framework, behavioral interventions have varied from highly structured (discrete trial therapy) to more naturalistic settings (incidental teaching). However, the assumed mechanisms of change are the same.

4.5.2 Mechanisms of Change Underlying Psychopharmacological Treatments

As with other treatments for ASD, pharmacological treatment is not curative but rather alleviates behavioral symptoms or clusters of symptoms. Psychopharmacological agents target

different neurotransmitter systems in the brain, which are assumed to be the primary mechanism of change for this treatment modality. For example, methylphenidate is believed to increase norepindephrine, which results in improved attention. Fluoxetine, a serotonin reuptake inhibitor, thus increases the availability of serotonin, which is implicated in the regulation of mood. While these effects are inferred from use in other populations, the mechanism in children with ASD may in fact be side effects of the medication. That is, the behavioral change may be secondary to the sedating effects of the medication. For example, risperidone affects both the dopamine and serotonin systems, but can be quite sedating, particularly initially.

4.6 Basic Competencies

ASD are now considered a group of common neurodevelopmental disorders. Given the increase in prevalence, there is a pressing need for more psychologists to be prepared in all aspects of services to screen, diagnosis and assess and treat these children and adolescents. Psychologists who serve children of any age should have familiarity with the symptoms of ASD along with an understanding of typical child development.

4.6.1 Screening and Referral

Assumed at this level is that the clinician will be familiar with the criteria for ASD diagnosis. Psychologists should be competent in their knowledge of available screening instruments. If a screening instrument along with initial information gathered is suggestive of ASD, a clinician without the competencies to complete a diagnostic evaluation (as described below) for a child suspected of ASD should make the appropriate referral to a clinician with this expertise.

4.6.2 Diagnostic Evaluation

Clinical psychologists play a significant role in the evaluation of children to determine their diagnostic status. Clinical psychologists who accept the role of evaluating children where ASD is possible based on referral concerns should be skilled at ascertaining current developmental and behavioral concerns. Additionally, competency at gathering a very detailed account of the child's developmental course across developmental domain with particular attention to communication and social development is required. Case history should further include detailed account about medical issues with probes about possible co-occurring medication problems (e.g., seizures, sleep disturbance). Knowledge about not only the diagnostic criteria for ASD is required, but knowledge of the presentation of other developmental disorders is also necessary for differential diagnosis.

Likewise, astute direct observation of the child during unstructured and structured observation is essential. This should include observations of spontaneous communication behaviors, response to others communication along with social responsiveness, choice of play activities, and presence of atypical behaviors (e.g., repetitive play, repetitive movements).

4.6.3   Cognitive/Developmental and Adaptive Behavior Assessment

Assessing developmental/cognitive functioning in children with ASD is a critical aspect in treatment planning. Psychologists are typically trained in the administration of such instruments. Psychologists should be competent not only in the administration of such standardized measures, but should be particularly skilled in the administration to these measures to children with ASD. This requires a high degree of familiarity with the assessment tools as maintaining the attention and motivation of a child with ASD can be particularly effortful. The clinician must be knowledgeable about which tool is the best fit based on the age of the child, what is known about functioning, and even what the child finds interesting. For example, for a child who is reported to like to sort objects, starting with such test stimuli may be advisable to promote interest and cooperation. Skill at administering and interpreting adaptive behavior measures is of further importance.

Some of the intelligent and developmental tests recommended for children with ASD include the Weschler scales (Wescher, 2003), the Leiter International Performance Scale – Revised (Roid & Miller, 1997), the Differential Abilities Scales (Eliot, 2002), and the Mullen Scales of Early Learning (Mullen, 1995). The newest version of the Stanford-Binet Intelligences Scales: 5th Edition (Roid, 2003) has also been widely used. The Vineland Adaptive Behavior Scales (Sparrow, Balla, & Ciccetti, 2005) has been the most widely used adaptive behavior measure in ASD. Skill at administering a few of these measures should be mastered at this stage of competency. The Adaptive Behavior Assessment System (Harrison & Oakland, 2003) is another adaptive behavior measure which is growing in use in ASD.

4.6.4   Behavioral Assessment/Functional Behavioral Assessment

Informant behavior rating measures should be included to better quantify behavioral/ emotional issues. The Child Behavior Checklist (Achenbach & 2000; Achenbach & Rescorla, 2001) has been used for this purpose as has the Aberrant Behavior Checklist (Aman, 1994). The Aberrant Behavior Checklist has also been used as an outcome measures in the treatment studies in ASD. Psychologists serving children with ASD may also be called upon to complete a functional behavioral assessment as part of a comprehensive evaluation, in planning for a home-based treatment program, or for educational program planning. The psychologist should be skilled in determining environmental variables within an operant learning framework that may be implicated in the maintenance of disruptive behaviors, but also in determining variables contributing to lack of skill development.

4.6.5   Assessment of Parenting Stress and Family Functioning

Within the context of a comprehensive assessment, attention to the family functioning is important to meet the needs of the family as well as the child with ASD. The Parenting Stress Index (Abidin, 1995) is often used for an initial evaluation but also repeated as the child is re-evaluated to monitor progress. This is a 36-item parent-completed questionnaire (short form) for families of children 12 years of age and younger, which has been empirically validated. The General Health Questionnaire (Goldberg & Williams, 1988) has also been used in ASD

(Tonge et al., 2006). This brief questionnaire assesses parental mental health. The Family Crisis Oriented Personal Evaluation Scales (McCubbin, Thomas, & McCubbin, 1996) is a 30-item scale that assesses how families cope with stress. This measure has been used in other studies that have examined the functioning of families with children with autism.

4.6.6 Parent Education and Support

Given the chronic nature of ASD, the impact is likely to be a burden for the family. The social and communication deficits in autism may adversely affect the parent–child relationship. The presence of behavior problems is likely to impose additional strain. Indeed, mothers of children with ASD report higher levels of stress and depressive symptoms than mothers of children with intellectual disabilities uncomplicated by ASD or mothers of typically developing children (Olsson & Hwang, 2001; Yirmiya & Shaked, 2005). The challenge of parenting a child with ASD may undermine parental competence. Psychoeducational efforts may help parents understand the nature of autism, help align their expectations with reality, and help fix their vision of making certain that their child can achieve the highest level of functioning possible. This type of educational effort may be especially useful when a young child is first diagnosed with ASD.

4.6.7 Ethical Practices

Psychologists should be competent with respect to implementation of ethical practices related to confidentiality, informed concent, access and sharing of information, and reporting laws and procedures. These all apply in providing clinical care for children with ASD. Psychologists must be particularly sensitive to the sharing of information. It is often the situation where a child with ASD is provided services across a number of systems. However, parents may not wish to share the ASD diagnosis at all. Psychologists should also be sensitive to any dual roles that could arise. For example, a psychologist may provide diagnostic evaluations in their practice but also provide consultation in a school setting. Furthermore, with the range of intellectual functioning levels in individuals with ASD, obtaining informed consent may require different special steps for those adolescents who are no longer considered a minor. Fisher (2003) offers useful guidelines for determining an individual's capability to provide informed consent.

4.6.8 Culturally Sensitive Practices

There are data to suggest disparity in the early diagnosis of ASD. In a recent report, African Americans were found to be over two times less likely than Caucasians to be diagnosed with ASD on their first visit to a specialist (Mandell, Ittenback, Levy, & Pinto-Martin, 2007). African–Americans were instead more likely to be diagnosed with a behavioral diagnosis, such as Conduct Disorder or ADHD. Such findings underscore the immediate need for the implementation of more culturally sensitive practices in the diagnostic process. This applies to all aspects of care from careful choices in diagnostic and assessment measures, recognizing the cultural differences, which may be operating during this process, and to recognize possible

barriers in the treatment delivery. Mandell and colleagues suggest the needs for a greater aware-ness of possible ethnic differences in: (1) how behavioral and developmental differences are communicated, (2) how these differences are perceived, and (3) how the clinicians' beliefs about diagnoses in ethnic groups influence the rendering of a diagnosis (Mandell et al., 2007).

4.7 Expert Competencies

The extensive professional proficiencies required in the clinical care of ASD mirrors the exten-sive, complex needs of individuals with ASD. These needs vary across developmental levels and chronological ages as well as whether there are co-morbid conditions present. As already sug-gested, professional psychologists may display expert competencies in some, but not all of the clinical roles. For example, it is not uncommon for psychologists to gain expertise in the diag-nostic evaluation of children with ASD but only have basic competencies in some of the treat-ment practices. These psychologists may refer a child for treatment once they have rendered a diagnosis. Conversely, psychologists may develop expertise in the delivery of treatments borne out of ABA for preschoolers, but maintain basic competencies when it comes to the evaluation and treatment of older children or adolescents with ASD.

4.7.1 Expertise in Diagnostic Measures

Expert competency includes the mastery of use of the "gold standard" diagnostic mea-sures. Currently, widely used in the ASD field is the Autism Diagnostic Interview – Revised (ADI-R; Rutter, Le Couteur, & Lord, 2003). By using a standardized interview format, informa-tion is gathered in a more systematic manner. The ADI-R probes several areas to include early development, communication skills, social behaviors, play behaviors, and restricted interests and behaviors. Diagnostic assignment is made following an algorithm keyed into DSM-IV criteria for autism. The ADI-R also provides a dimensional measure of severity of autistic symptomatology. A standardized observational approach is the Autism Diagnostic Observation Schedule (ADOS; Lord, Rutter, DiLavore, & Risi, 2002). This direct observation measure may be administered in a clinic setting. It involves placing the child in naturalistic social situations demanding specific social and communication responses. Although the protocol follows stan-dard administration, the situations themselves are unstructured. Thus, the ADOS provides a sample of the child's behavior in a naturalistic setting. Behaviors are coded in the areas of social communication, social relatedness, play and imagination, and repetitive behaviors. The ADOS also provides a DSM-IV based algorithm for the diagnosis of autism, non-autistic ASD, and non-ASD.

In addition to a diagnostic interview and direct observation, there are ASD-specific infor-mant rating measures. The Social Communication Questionnaire (Berument, Rutter, Lord, Pickles, & Bailey, 1999) is the parallel parent report to the ADI-R. Other instruments include the Screening Tool for Autism in Two-Year-Olds (Stone, Coonrod, & Ousley, 2000), Childhood Autism Rating Scale (Schopler, Reichler, & Renner, 1988), and the Gilliam Autism Rating Scale (Gilliam, 1995).

4.7.2   Expertise in Assessing All Developmental/Cognitive Levels

Proficiency in administration of the range of developmental and cognitive measures to the range of developmental levels present in ASD is required at this level of competency. Hence, an expert in this area must be capable of administering a developmental measure to a 2 years or a 10 year old as well as administer cognitive assessments to 5–18 year olds with superior cognitive functioning. Expertise in a range of measures to best meet the assessment needs of the individual being evaluated is needed. Furthermore, training and adeptness in administering neuropsychological measures when assessing older, higher functioning children with ASD is critical, as often subtle differences in executive functioning and higher order information processing are often present.

4.7.3   Expertise in Assessing Communication and Language Skills

In view of psychologists' training in the administration of standardized tests, training in and the administration of communication and language measures is often important for those with expertise in ASD. This is particularly the case when a speech/language pathologist is not part of the assessment team. Standardized instruments appropriate for young children include the Preschool Language Scale (Zimmerman, Steiner, & Pond, 1992) and the Reynell Developmental Language Scale (Reynell & Huntley, 1987). There are also parent report measures to include the Communicative Development Inventory (Fenson et al., 1993), the Language Development Survey (Rescorla, 1989) and the Receptive-Expressive Emergent Language Scale (Bzoch & League, 1991). For children with more advanced language skills, instruments which measure more complex aspects of language and communication including pragmatics include the Comprehensive Assessment of Spoken Language (Carrow-Woolfolk, 1999) and the Test of Language Competence (Wiig & Secord, 1989).

4.7.4   Expertise in Conducting a Behavioral Functional Assessment

A thorough behavioral functional assessment often includes interviewing those caring for the child, the direct observation of a child in naturalistic contexts, and conducting functional analogue observations. At this later level of analysis, environmental variables are controlled and manipulated to determine how they may be maintaining a behavior or a group of behaviors and if altering them affects the behavior. Functional analysis procedures were first described in a seminal article by Iwata and colleagues (Iwata, Dorsey, Slifer, Bauman, & Richman, 1982). Since this time, this procedure has received considerable attention in the literature. Common analog observations include the following conditions: (a) Free play or control condition (no demands are placed on the child and preferred toys are available), (b) Attention (where an adult is instructed to attend to the child when engaging in the target behavior), (c) Demand (where the adult makes requests of the child), and (d) Tangible Restriction (where the child is faced with the removal of a highly desirable toy). Knowledge of procedures and skills to conduct a functional analysis along with the interpretation of the data are considered essential for those experts developing and implementing functionally derived behavioral treatment.

4.7.5 Expertise in the Assessment of Sensory Behaviors

Psychologists with expertise in ASD should be informed about the newly developed measures of sensory behaviors and their psychometric qualities. A couple of these include the Sensory Experiences Questionnaire (Baranek, 1999) and the Evaluation of Sensory Processing (Parham & Ecker, 2002), which are both informant report. Direct observation tools have also been developed but are less widely used. One of these include the Tactile Defensiveness and Discrimination Test – Revised (Baranek, 1998).

4.7.6 Expertise in Applied Behavior Analysis

In line with skill in conducting functional analysis, psychologists who are involved in the treatment, whether that is direct treatment delivery or oversight of treatment delivered by others, should have expertise in ABA procedures and interventions. While many if not most psychologists have some general training in the clinical application of operant and respondent conditioning, more in depth knowledge and training in ABA paradigms as applied in ASD is critical when involved in the treatment of individuals with ASD. This is based on the premise that treatments based on ABA have the strongest empirical base and have been used to improve a range of core symptoms as well as to attenuate challenging, interfering behaviors. Paradigms include discrete trial therapy and direct instruction, pivotal response training, incidental teaching, and communication training based on B.F. Skinner's analysis of verbal behavior.

4.7.7 Expertise in Parent Education/Training Model

Parent training or what might be referred to as parent mediated treatment is a very common form of treatment delivery in ASD. Parent training as a service delivery model is of interest not only given the central role that parents have in promoting the development of their children with ASD, but also in light of the lack of trained professionals to work with children with ASD. Providing parent training requires not only expertise in ABA but also expertise in rapport building with parents. While in direct treatment delivery, the psychologist is implementing the behavioral procedures, with parent training, the psychologist must not only teach the parent but motivate them to use the procedure at a later time. Parent training requires all the therapeutic skills needed for other, more traditional therapies.

4.7.8 Consultation and Staff Training

Psychologists with expertise in ASD are often sought out to provide consultation and staff training in a variety of settings. These might include consultation in school settings, mental health programs such as a partial hospital program, after care programs, and childcare programs. Consultation might be centered on a particular child with ASD. Staff training may be aimed at increasing knowledge of staff about ASD and strategies they can use in their respective settings. In light of the prevalence of ASD, more and more care providers across settings will need skills in working with children with ASD.

4.7.9 Expertise in Culture Sensitive Practices

Sensitivity to other cultures is called upon by those providing ASD treatment in particular. As treatment is often delivered within the home setting, clinical psychologists should be well-informed to a large extent of the cultural practices of families they are serving. This could be the supervisor of home-based therapy or a consultant role. Psychologists should also be sensitive to any cultural clashes with prescribed behavioral approaches. For example, some families may prefer the less structured approach of incidental teaching than the more structured approach of discrete trial training. Similarly, parents may find some behavioral procedures as more acceptable (positive reinforcement) than others (timeout) (Jones, Eyberg, Adams, & Boggs, 1998). Psychologists should clearly gather this information in ongoing treatment planning.

4.8 Transition from Basic Competence to Expert

With the movement in professional psychology toward a competency-based model, identifying those specific to the rapidly growing clinical needs of ASD is imperative. As Kaslow and colleagues have suggested, this transition is an ongoing process (Kaslow et al., 2004; Kaslow, Dunn, & Smith, 2008). This is particularly the case in ASD where the field is relatively young and substantial changes in our knowledge base are occurring at a brisk rate. The transition from basic to expert competencies in ASD can be conceptualized on a few levels. At one level, this may involve expertise in increasing the areas of service roles. Another level is more expertise in one particular area (e.g., treatments). At another, the transition may be increasing expertise with additional developmental stages. Acquiring higher level competencies may be accomplished by a range of professional activities. These include supplemental coursework, formal and informal mentoring and supervision, time-limited continuing education activities, and review of current professional literature.

4.8.1 Supplemental ASD Coursework

Clinical psychologists may wish to identify specific coursework on ASD to augment their knowledge base. Relevant courses may be in other closely related academic departments such as special education or early intervention programs when not available in the psychology training program. Coursework specific to the diagnostic assessment are often available and invaluable to gain more knowledge. A supervised practicum component is often an important part of such coursework.

For those psychologists interested in gaining expertise in treatment, coursework and practicum experiences in applied behavior analysis is highly relevant. There is a professional certificate program in behavior analysis offered through the Behavior Analysis Certification Board. This certification requires a certain level of training and successful examination completion to demonstrate competency as a Behavior Analyst. At the time of this writing, five graduate courses are required along with fairly intensive supervised practicum experiences to be eligible to sit for the certification exam.

4.8.2   Mentoring and Supervision

Development of expert levels of competency may be sought through formal mentoring and direct supervision of an already recognized expert. Such arrangements may be formal, such as a specialized internship or postdoctoral fellowship with a focus on ASD or less formal mentoring by an expert in the field. These mentoring opportunities afford repeated opportunities to both observe the expert and to be observed. For example, becoming competent in the use of ASD specific diagnostic measures requires many opportunities to observe their administration along with frequent opportunities to administer. It is challenging to develop expert competencies in ASD without ample exposure to this unique population. Likewise, becoming an expert in intervention requires many supervised intervention cases of sufficient heterogeneity.

4.8.3   Continuing Education Activities

Psychologists may move toward the acquisition of expert competencies by learning via ASD continuing education programs. For example, intensive training in diagnostic measures is offered by the developers (www.umaccweb.com/education). This training program offers not only didactic experiences but an occasion to be observed by the experts. Likewise, there are week-long autism conferences aimed at training a wide range of professionals to increase competency given the need for more providers in this area.

4.8.4   Review of the Literature

While ASD was much understudied until recent years, the last 2 decades have seen a proliferation of scientific publications addressing all levels of investigation. Most relevant to clinicians are those related to diagnostic and assessment practices as well as best practices with respect to treatment. There are now dedicated journals just to ASD. These include the *Journal of Autism and Developmental Disabilities*, *Autism*, and *Research in Autism Spectrum Disorders*. A two volume second edition comprehensive handbook on ASD was published in 2005 (Volmar, Paul, Klin, & Cohen, 2005). The two volumes compared with the one volume of the former edition attests to the rapidly advancing research and clinical interest in the area. For those psychologists looking to provide or supervise more direct treatment or to provide parent training, there are numerous ABA focused journals to include, the *Journal of Applied Behavior Analysis*, *Behavior Modification*, and *Behavioral Interventions* to name a few.

4.9   Summary

Clinical psychologists may play many important roles in the assessment and treatment of individuals with ASD. The purpose of this chapter is to provide an overview of this diagnostic category as well as an overview of the best clinical practices. In keeping with the competency-based movement, basic and expert competencies are discussed in several areas of clinical practice. These include assessment skills in screening, diagnostic evaluation, comprehensive assessment of developmental domains (e.g. cognitive, communication, adaptive skills), behavioral

assessment, assessment of atypical sensory behaviors, and finally assessment of family functioning and stress. Competency in treatment requires another set of skills with an in depth knowledge of ABA treatments. Psychologists may further play pivotal roles in providing consultation and staff training to other providers serving children with ASD.

In light of the heterogeneity and developmental nature of ASD, clinical psychologists may choose to develop basic or expert competencies in a few areas based on their clinical practices. All clinical psychologists should be knowledgeable about the diagnostic characteristics of this group of disorders given the increased prevalence. Psychologists who choose to develop a practice to serve children with ASD should take appropriate measures to acquire the necessary skills to do so. As the field of ASD is advancing rapidly, psychologists must take efforts to remain abreast of new findings related to their clinical practices.

5 Learning Disabilities

Johnny L. Matson · Jill C. Fodstad

Abstract: Learning disability (LD) is considered one of the most prevalent conditions in the educational system today. While the definition of what constitutes an LD varies, researchers, policymakers, educators, and clinicians agree that, generally, a child who has an LD has a marked discrepancy in performance in one or more major areas of learning while performing at or above peers in other domains. This deficit in learning has been shown to not only hinder the child with LD academically but is also linked to poorer long-term outcomes and other serious problems of adjustment. Therefore, early diagnosis and intervention of a child with LD is a high priority. Furthermore, it is imperative that the clinician is knowledgeable about what treatments are supported by the literature since LD is a fad magnet for ineffective and unsubstantiated treatments. Even in the midst of the nebulous and oft contested etiological theories, definitions, assessment and diagnostic techniques, and intervention practices, the clinician is given the task of being familiar with the many facets of LD while being competent enough to accurately assess, diagnose, and intervene upon this often nebulous childhood condition. In this chapter, a basic guideline regarding assessing, diagnosing, and treating LD is outlined. A thorough discussion regarding the current controversy pertaining to LDs is included. Additionally, the basic skills and various empirically supported interventions specific to LD are reviewed. The aim of this chapter, then, is to give the clinician aiming to work with individuals with LD an introduction into the competencies and skills that are essential. Taking what is delineated in this chapter coupled with a commitment to life-long learning and professional development will engender accurate clinical judgment and a high degree of professionalism in a field that continues to change.

5.1 Overview

Since its designation as a disability via federal legislation in 1968, learning disability (LD) has steadily become one of the most prevalent conditions represented in special education classrooms nationally (Donovan & Cross, 2002; President's Commission on Excellence in Special Education, 2002); however, it has remained one of the most nebulous and debated of the disabling conditions that affects students (Bradley, Danielson, & Hallahan, 2002; Dombrowski, Ambrose, & Clinton, 2007; Fuchs & Fuchs, 1998). The current US definition suggests that LDs are not a unitary entity, but are, in essence, a broad and heterogeneous group of conditions that result in impediments in learning. In particular, the literature converges into an organization of general academic aptitudes that are impacted by the conditions, which incur an LD including listening comprehension, oral expression, basic reading skills, reading comprehension, written expression, and mathematics (calculation and reasoning). It is in these academic skill sets that significant problems are evident and linked to underlying difficulties involving language use and abstract concepts (Swanson & Hoskyn, 1998).

In the UK, children classified as having an LD parallels that of intellectual disability (Berney, 2006; O'Brien, 2004). Unlike the use of the term in the UK, children in the US must not evince

pervasive learning deficits to be classified as having an LD. Rather, the US definition consists of marked discrepancies in performance in one or more major domains of learning, while performing at or above typically developing peers in other domains (Mitchem, Richards, Obiakor, Utley, & Rotatori, 2003). For example, the child may perform at grade level in math but have substantial deficits in reading. Thus, to a large extent, this definition has been on the basis of academic performance and how closely the child approaches average academic growth patterns. The underlying factors that result in LD can be generally subsumed under four domains: (1) IQ – achievement discrepancies, (2) presumption of central nervous system dysfunction, (3) psychological processing disorders, and (4) learning problems unrelated to environmental factors, intellectual disability, or emotional disorders (Hallahan & Kauffman, 1997). In this chapter, the US definition will be used when describing LD.

Despite this broad and agreed upon definition of LD, in practice, the differences in the specific characteristics of the condition and its definition vary markedly. In addition, the number of LD definitions has steadily increased since its inception in the early 1960s. Hammill (1990), for example, identifies 11 different definitions of LD. We believe that a major reason for this confusion is the high level of politization of the diagnosis. No disorder is defined in vacuum; however, typically researchers in the field, along with input from the leaders in the general culture, define the disorder through major mental health diagnostic manuals such as the DSM-IV-TR (American Psychiatric Association, 2000) or ICD-10 (World Health Organization, 1992). Definitions of ADHD and autism would exemplify this approach. In the case of LD, state and federal governments often develop much different definitions typically with an eye to pragmatic service provision needs in marked contrast to definitions developed by the leading researchers and clinicians in the field. For example, the recent reauthorization of the Individuals with Disabilities Education Improvement Act (IDEA) has resulted in yet another set of revised parameters. This federal mandate allows the use of the discrepancy model, as described earlier, for making a diagnosis based on "a comprehensive evaluation." In addition, this same mandate also allows the use of a process to determine if a student responds to scientific research-based intervention or other alternative research-based procedures to determine LD eligibility. Given that there is no standard protocol to this comprehensive evaluation, states are left to determine what they feel is the best way to assess and identify LDs. Thus, definitions and how LD is assessed are linked in a disjointed fashion the way few other disorders can lay claim.

These problems in varied diagnosis are often compounded by the fact that vague or nonspecific operational definitions are in commonplace. Flanagan, Ortiz, Alfonso, and Dynda (2006) note this problem and are among several researchers to propose solutions. On the basis of the available data, our view is that the most parsimonious definition for LD would take into account the following factors. First, the available research on etiology and nosology should drive the definition. Second, some agreement on methods for assessing LD would be very helpful. At present, there are two such camps; the cognitive abilities/processing and a codemic outcomes group, which relies on standardized testing, particularly IQ and achievement tests. The second group uses a more environmentally applied behavior analysis model, which emphasizes how well the child responds to intervention. Presumably, the child with LD would not respond as well as children who, for example, had a poor teacher and did not develop relevant phonetic building blocks. Alternatively, the type of learning strategies that were effective across these two groups might differ to some degree.

Therefore, differences in definition and methodology to establish definitions differ markedly in the LD field. Of the childhood disorders, it has perhaps the maximum disagreement on

definition. This state of affairs has existed since the inception of the diagnosis, and there is no sign that this controversy will abate anytime in the near future. In fact, researchers in the LD field have described these positions as "entrenched" (Dombrowski et al., 2007). Basically then, an LD diagnosis, in its most general form, refers to academic problems that are not primarily motivational or to the child who does not have an intellectual disability (as established with standard IQ and adaptive behavior measures). Furthermore, while some debate exists as to whether the child has marked strengths in some academic areas and major weaknesses in other areas, this is a common feature of many definitions. For this chapter then, we will use this broad definition with respect to our discussion on LD.

Whatever the definition, LD is a high incidence condition that results in a large percentage of those children who are referred to special education services. For example, the U.S. Department of Education (2000) notes that 70% of the children who meet eligibility criteria for special education have LD, mild intellectual disability, or emotional and behavioral disorders. Furthermore, experts in the field agreed that LD has the largest proportion of students receiving special education services of any childhood disability (Kirk, Gallagher, Anastasiow, & Coleman, 2006). The number of students with disabilities being served by public schools during the 1999–2000 school year exceeded 5½ million, and over ½ of these had an LD diagnosis. In addition, the percentage of children with an LD diagnosis has grown over 300% in the 25 years leading up to this figure (Richards, Dooley, Burkhardt, Obiakor, & Rotatori, 2004). These high rates are underscored by the fact that special education placement results in a poorer long-term prognosis than is the case for persons who do not meet this criteria (U.S. Department of Education, 1997). To a large degree, this would seem intuitive. Those children in special education have more learning and other school-related problems, thus higher school drop out rates. However, a commonly held belief by many professionals is that contained specialized programs, in fact, exacerbate existing school-related problems at a rate not seen in classrooms for typically developing children. As we have discussed, definition is important. Furthermore, whatever definition is implemented, without taking state-to-state variation into account, rates of LD persist and, as such, continue to be one of the most important childhood disabilities.

5.2   Recognition and Assessment

The lack of an acceptable LD definition has resulted in significant problems in agreement on classification and diagnostic efforts. The many beliefs that exist among researchers, educators, advocates, and clinicians permeate the literature and seem to add to the general confusion. In addition, IDEA (2004) has mandated that more than one method needs to be used to establish the eligibility for LD services; however, there is no stipulation as to the "standard protocol" clinicians should follow to arrive at an LD diagnosis. Given this ambiguity, being able to administer and provide a comprehensive assessment of students "at risk" for LD is critical to the correct identification of students for accommodation eligibility, curriculum modifications, evaluating academic intervention, and determining the appropriate educational services.

An LD assessment should be an objective process of collecting information on a broad range of topics. It is suggested, then, that information is obtained on the following areas: (1) academic, intellectual, perceptual, motor, and behavioral functioning; (2) health history; (3) developmental history, developmental delays, and prenatal and perinatal complications;

(4) personality, temperament, effect, motivation, and interpersonal relations; (5) family history of learning problems; and (6) cultural factors, peer group factors, pedagogical factors, and school factors.

The information collected during this comprehensive assessment can be used for three related, but somewhat different, purposes: (1) screening and referral; (2) diagnosis and placement; (3) instructional planning and evaluation of student progress.

Screening and Referral. The screening phase involves identifying students "at risk" for having or developing an LD. This phase of the assessment process is carried out in its entirety in the school system based on the classroom behavior of the child combined with academic performance grades and scores on curriculum-based measurements. Typically, the child's primary teacher would provide global judgments of the child's performance, as they have the most direct contact and, therefore, would be the most reliable authority (Bryan & Wheeler, 1972). The outcome of this screening process would determine the degree to which the student is performing academically when compared with his or her peers and their expected scholastic growth given their current level of skills. Those found to have deficient skills relative to peers should have further testing to determine the student's strengths and weaknesses, and overall academic progress across the current curriculum being taught. From the information gathered, educators should be able to pinpoint the student's deficit academic readiness skills, the steps of a learning task the student is able to complete, the individual learning style of the student, and the specific academic domain(s) (e.g., reading) that are the most problematic.

Diagnosis and Placement. After screening and referral, the next step in the assessment sequence is diagnosis and placement. As noted, the main purpose of a comprehensive assessment is to gather information and data about an individual to determine the individual's eligibility for special education services, to describe the specific nature of the student's LD, and to develop a relevant program plan for the individual once eligibility has been established. For most clinicians, a reliance on standardized testing is the basis by which a diagnosis of LD is established. This point is particularly important given the oft vague LD definition and the manner in which, per history, an LD assessment has been made. The best approach to determining LD eligibility is an IQ-achievement discrepancy (Bailey, 2003). This model stipulates that for children to be classified as having LDs, a severe discrepancy must be found between ability, usually defined by an intelligence test score, and achievement, usually defined by a reading, mathematics, or written expression test score or by an overall achievement test score. Employing a regression-to-the mean equation, the discrepancy arises when the child performs at a low level in a specific academic skill area than a higher level predicted by the model, given the individual's general intelligence (e.g., a child with average IQ who is reading far below grade level). According to the DSM-IV-TR, a discrepancy of 2 standard deviations between the predicted and observed scores generally qualifies as severe, but in specific cases (e.g., comorbid psychopathology, general medical condition, or ethnic or cultural barriers) 1–1.5 standard deviations may be used (American Psychiatric Association, 2000).

While the IQ-achievement discrepancy model is easy to implement, there are some problems with its use. Perhaps the greatest problem in the application of the discrepancy formula is that many children will not be identified as having an LD in their early school years. Because children's achievement abilities cannot be reliably measured before the age of 9 years, children having 6–8 years may not receive adequate services until later when they have failed a grade or are showing severe deficits in basic academic skills (Sattler & Lowenthal, 2006). If an LD exists that affects language or other cognitive development from the earliest years, a child might

experience much of his or her formative years with a handicap before anything is done about it. Since LD becomes more problematic the longer the remedial action is delayed (Lyon, 1996), waiting until the learning problems are evident may cause intellectual and other academic skills to be compromised. This phenomenon, termed "wait to fail," has been the single biggest criticism of the discrepancy model.

Another model that has been proposed as useful in the diagnosis of LDs is called response to intervention (RTI). In an LD assessment incorporating an RTI approach, children are given standard instruction in a regular classroom and those who are making poor progress are given specialized intensive and systematic instruction at increasing intensity (Sattler & Lowenthal, 2006). Only until it is apparent that the child is unresponsive to any of the interventions is he or she placed in special education and given an LD diagnosis. The main benefit that advocates for this model suggests is that it circumvents the "wait to fail" phenomenon associated with the IQ-achievement discrepancy. Since RTI referral rests largely on student performance on curriculum-based measures, educators are able to refer "at risk" children earlier and, therefore, intensive remedial instruction is able to begin in a timelier manner. RTI, furthermore, boasts that because direct instruction can begin at the early stages of academic development a decrease in children being labeled as LD may result (Donovan & Cross, 2002). But because this method is still in its infancy, more longitudinal outcome data are needed.

The RTI approach to LD diagnosis has been gaining popularity as the push for evidence-based interventions has proliferated and expanded into the educational arena. However, to date, there is not enough substantial research and data to attest to the validity of the RTI model as a complete substitution for other models for LD assessment. Problems with RTI arise when a closer look into the inner workings of the RTI model is taken. For instance, the RTI model inherently focuses on the reading ability of children to identify who is "at risk" and in need of specialized instruction (Kavale, Holdnack, & Mostert, 2005). The instruction provided is largely based on a database of evidence-based treatments with, at best, moderate effects (see National Reading Panel, 2000). Still unchallenged, these reading interventions focus primarily on decoding and phonological processing and are implemented without considering math, writing, or reading comprehension deficits (Kavale et al., 2005). Another problem with this approach is that there is no standard for what interventions are implemented, who is qualified to implement them, what is considered a successful response to instruction, and how long these interventions must be continued until the child is identified as having a learning disability. Lastly, for the child who advances through the RTI assessment and is ultimately found to be eligible for special education, it is uncertain how clinicians determine what the individual needs. It would appear that those who fail to respond during the RTI process would need a comprehensive evaluation of intellectual/cognitive, academic, and psychosocial functioning to determine the unique needs of the individual. If the purpose of the RTI model is to forgo the need for standard assessment, then it seems unlikely to suppose that the model will provide all the relevant data to develop interventions tailored to the individual without further testing.

Whatever mode is chosen (i.e., RTI or IQ-achievement discrepancy), it is our belief that any procedure for identifying children as learning disabled must take into account other factors in addition to low achievement and an inability to respond to interventions. Among such factors that should be considered include a low level of intelligence, poor health, physical disabilities, limited motivation, boredom, absenteeism, emotional problems, a mismatch between the child's skills and the curriculum, learning style, cultural factors, and poor teaching. Furthermore,

clinicians should keep in mind that low scores on an achievement test do not inevitability reflect a unique disability and may simply represent the lower end of a distribution of scores. Classifying an individual as having an LD, therefore, should only be used to indicate under-achievement related to specific processing deficits whose presumed origin is neurological dys-function. Additionally, it is important to remember that a formula that uses two test scores exclusively or the results of an intervention procedure is not a viable substitute for skilled clini-cal judgment and a synthesis of all relevant information available about a child.

Placement, Instructional Planning, and Evaluation. The third purpose of assessment is place-ment, instructional planning, and evaluation of progress once a student is classified as having an LD. An Individualized Education Plan (IEP) is typically formulated and implemented soon after an LD diagnosis is determined. The IEP is a legal document that promulgated from PL 94–142 to ensure appropriate education and to guarantee the civil rights of handicapped chil-dren and their families. The intent of the IEP is to involve educators, parents, and clinicians in determining the proper level of education (e.g., special education, resource room, regular class-room) that will benefit the individual most, given the appropriate supports, services, and cur-riculum modifications (Heward, 2003). To ensure that the IEP is tailored to the specific needs of the individual, data are gathered pertaining to the student's social, academic, physical, and behavioral management problems that interfere with the acquisition of academic curriculum objectives (Rotatori & Wahlberg, 2004). Tools that may be used to gather this information include criterion-referenced assessments, curriculum-based measures, portfolio review, natu-ralistic observations, determining the individual's learning style, and a functional behavior assessment. The outcome of these types of assessments influences instructional planning, goal development, and progress monitoring.

5.3   Maintenance Factors

A major reason for the high rates of LD and the difficulties in defining the condition are related to a very heterogeneous set of symptoms. Despite these factors, there are core features, which appear to define LD. Researchers in the field stress the value of studying this condition at the macro-level to further extrapolate the underlying factors rather than studying skill deficits only (Zera & Lucian, 2001). For example, a core factor of LD appears to be that it is a neurode-velopmental condition, which is evident in the earliest stages of life. One factor researchers have been able to point to is extremely low birth weight, which is directly linked to low IQ (Anderson & Doyle, 2003; Doyle & Casalaz, 2001). While in some cases children with LD may have superior intellect, the large majority of children evince below average intelligence. Specific cognitive impairments have also been studied with respect to functional outcomes. Working memory, for example, has been studied because it affects many domains including language comprehension, writing, and reading comprehension (Gathercole, Alloway, Willis, & Adams, 2006). Furthermore, skilled readers evince better working memory than children with marked reading deficits (Swanson & Jerman, 2007). Geary, Hoard, Byrd-Craven, Nugent, and Numtee (2007) have also attested to what they call mathematical LD. These deficits are considered to be neurodevelopmental in origin, based on one prominent theory. Butterworth (1999, 2005) has applied their model to math problems, and refers to its etiology as being largely innate. Rousselle and Noel (2007), along these same lines, found that LD children were slower and less accurate when comparing Arabic numbers.

In addition to neurodevelopmental variables, environmental factors also appear to maintain and exacerbate difficulties encountered by the child with LD. For example, low achievement in school is a defining characteristic of the condition, and is correlated with a host of poor long-term outcomes including social skills deficiencies, low sociometric status, behavioral difficulties (particularly when they are externalized such as aggression or tantrums), and poor self-concept (Lambros, 1999; Sideridis, Switzky, Hickson, & Schalock, 2006). Other factors that are known to correlate with LD include low SES, being male, coming from a large family, and having a father older than 40 (Mannerkoski, Aberg, Autti, Hoikkala, Sarna, & Heiskala, 2007).

More recently, Leftwich, Montague, Scruggs, and Mastropieri (2005) note that low achievement and academic performance and a high number of negative comments by teachers were most likely to be critical variables associated with a special education placement. Thus, children identified as "at risk" are referred if they are failing academically, but are not referred if they are able to succeed. This is troublesome because low academic achievement has been found to reflect more than skill deficits in reading, writing, and arithmetic. Intertwined with academic failure is poor social interpersonal relationships, behavior problems, and motivation problems (Walker, Block-Pedego, Todis, & Severson, 1991). This point is embellished by the fact that one of the most pronounced characteristics of juvenile offenders is much poorer academic performance when compared with nondelinquent teens (Davis, Sanger, & Morris-Friehe, 1991; Finn, Stott, & Zarichny, 1988; Grigorenko, 2006). These data are consistent with a large body of research that, generally speaking, demonstrates a strong relationship between LD and a number of antisocial difficulties, challenging behaviors, psychopathology, and a host of other difficulties. Thus, LD may be conceptualized as a core set of pivotal problem behaviors, which are, at the very least, related and may contribute to other problems that can lead to life-long disabilities (Grigorenko, 2006). These data reinforce the necessity to intervene on the problems of LD. The condition does not appear to be something the child will "grow out of." Rather, these data appear to suggest that without effective treatment, LD tends to continue and other serious problems of adjustment tend to coalesce around it. Therefore, treatment of LD would appear to be a high priority for professionals.

5.4   Mechanisms of Change

While political and social factors guide the development of issues in developmental disabilities and mental health for children, no topic is more politically charged than LD. This government and legal intervention has been a primary mechanism for change in the LD field. The Americans with Disabilities Act in 1990 (PL 101–336) (Henderson, 2001) is perhaps the most prominent of these forces, and has had a profound effect on LD nationally. This act is civil rights legislation that applies to almost every phase of American life and requires "reasonable accommodations" for all persons with disabilities. The ADA defines impairment as physical or mental. LD is covered under the ADA definition and is further underscored by the definition presented in the Federal Register (1999). These criteria for LD include perceptual disabilities such as brain injury, dyslexia, and aphasia, and the presence of academic difficulties. They also include minimal brain dysfunction. However, as a practical matter, this behavior has not been adequately defined and it cannot be measured in a reliable or valid manner. In addition to requiring specific interventions for children identified as having LD, a secondary effect has been a dramatic

increase in the number of people identified as LD. From 1976 to the present, the number of identified cases has tripled (Grant et al., 2004).

A second major change mechanism with respect to LD is the adoption of what proponents describe as an "inclusion model" of education. Rather than providing specialized services in a homogenous setting, from the standpoint of skill level, inclusion advocates suggest teaching children with myriad levels of skill sets and abilities in the same setting. This model has gained considerable traction not only in the U.S. but internationally (Lambe, 2007; Mdikana, Ntsangase, & Mayekiso, 2007; Obeng, 2007; Raver, 2007). This approach cannot be overestimated in its impact on how children with LD are educated. However, few specific evidence-based methods of intervention are typically discussed with respect to this change model. Rather, emphasis is on "integration" of LD children into mainstream education, training teachers about the "values" of inclusion, including core courses in special education for general elementary education, ensuring that adequate resources are available to promote inclusion, practice teacher placements in inclusive classrooms, and teaching strategies that take into account sameness while paying proper regard to differences and diversity of learners. Little has been done to study the actual outcomes of many of these goals. However, they are widespread and likely to continue to be seen as a major change agent in schools for some time to come. We stress the importance of operationalizing problems and experimentally testing treatment methods. The framework of applied behavior analysis (ABA) seems to best fit these criteria for evidence-based treatments. The ABA model is compatible with government mandates and an inclusive model, the two most prevalent change mechanisms in LD. A review of specific treatments will be covered next.

5.5   Evidence-Based Treatment Approaches

The development and application of evidence-based treatments can be particularly challenging for children with LD. This circumstance exists because of the large number of interventions with minimal or no research to support them. Many of these treatments are spread by word of mouth. One of the greatest challenges for the clinician is to educate and, if possible, convince parents, teachers, and other caregivers to be good consumers of evidence-based interventions rather than unproven therapies.

Tilly and Speilberger (2004) do a nice job of providing an overview of many of these unsubstantiated interventions. Some of the more prominent of these techniques are: (1) modality training, (2) perceptual motor training or sensory integration training, and (3) psycholinguistic training. Modality training is determining the manner or modality in which a child learns best (i.e., visual, kinesthetic, or auditory learner) and then matching the intervention to the individual's strengths. For example, a child who is a kinesthetic learner is taught vocabulary words by "finger spelling" each word in the air to gain an understanding of the physical sensation of writing the word. Perceptual motor training (a.k.a., sensory integration training) involves practicing particular motor skills. One of the most unusual procedures involves having the child practice crawling using left-to-right movements. This is also referred to as "patterning." The idea is that improved left-to-right crawling movements will generalize to the left-to-right movement in reading. Brain Gym is another method practitioners of the technique claim is useful. However, as with patterning, no evidence exists to support the procedure. The developers of Brain Gym stress that improvements in thinking and learning can

occur by increasing physical movement. This added motor behavior is believed to improve neuromuscular routes and, thus, cognitive skills (Hannaford, 1997). For example, prior to taking a test, students are encouraged to drink a glass of cold water to facilitate relaxation and increase concentration, which will allow a person to perform to the best of their abilities. Yet another technique touted to have some utility involves increasing handwriting speed. Developers of this method claim that this approach enhances learning and self-esteem (Boyle, 2007). Finally, psycholinguistic training is an approach to intervention where individuals are trained on the discrete psycholinguistic deficits (i.e., auditory and visual reception, auditory and visual association, verbal expression, manual expression, grammatic closure, visual closure, and auditory and visual sequential memory) they are believed to be deficient in.

There are many other methods that have been employed with LD children. However, evidence-based for us means well-conducted studies using conventional research or single-case designs to validate the procedures. Furthermore, the effects of the procedure should have been replicated in a number of studies. Using this set of criteria, we arrived at a variety of ABA procedures for use in remediating LD. Bredberg and Siegel (2001) break these procedures into three general categories: (1) develop fundamental reading skills such as phonological decoding and word identification, (2) social skills and psychopathology, and (3) to enhance academic performance. We will briefly discuss each of these categories and offer the reader a synthesized set of empirically based interventions. The list of interventions given is by no means exhaustive; however, it is felt that the selected studies provide a general framework on which a clinician may base a cohesive "treatment package."

5.5.1 Reading Skills

Reading is a particularly difficult skill to master and, consequently, is the most common form of LD. Estimates of up to 60–90% of all children identified as having an LD are given that classification due to reading difficulties (Kavale & Reese, 1992; Lerner, 1989). Of all those diagnosed with LD, the majority have deficits in reading. In addition, deficits in basic reading skills (i.e., phonological awareness, decoding and recognition, comprehension, and drawing inferences) tend to be the most prevalent in children who have LD (Carlisle, 1999; Tractenberg, 2002). Difficulties in the rudimentary skills prove to be problematic, especially as academic expectations shift from learning to read to more complex tasks such as expository reading, mathematical word problem solving, and narrative writing (Barton, 1997; Berkeley, 2007). For an individual with LD, deficits in reading can hinder success in many areas of academic instruction and can have deleterious effects in multiple domains later in adulthood. A longitudinal study by Shaywitz, Fletcher, and Shaywitz (1994) found that approximately 74% of children identified as reading disabled in the third grade continued to manifest reading difficulties throughout high school, despite the fact that many received special education.

Because of the significant effects that reading difficulties have on a person's academic, social, and occupational well-being, a substantial amount of research in the area of prevention and remediation of reading problems has taken place in the last decade. This has occurred, primarily, as a result of an increase in emphasis for evidence-based treatments in the educational and LD literature. Interventions to increase reading ability must, first, take into account the skill set of the child with LD. A child with LD does not evince reading deficits in the same way when compared with other children with LD and non-LD children; therefore, clinicians must

consider a child's specific strengths and weaknesses. The comprehensive evaluation that gave the diagnostic classification of an LD is a good resource to refer to when determining what skills to target for intervention.

There are many simple and effective methods that can be used to increase proficiency in the basic reading skills of phonics and word recognition. Strategies such as using appropriate-level materials, repetition, consistency, reinforcement, previewing materials, drills, choral or paired reading, a token economy, error correction, and immediate feedback are easy to implement and have been found to lead to improvements in a child's ability to read and understand printed text (Carnine, Silbert, Kame'enui, & Tarver, 2004; Mastropieri, Leinart, & Scruggs, 1999; O'Connor, Bell, & Harry, 2002; Rankhorn, England, Collins, Lockavitch, & Algozzine, 1998). Increasing the basic requisites is a good starting point for intervention, given that most children with reading difficulties experience problems at the rudimentary level and these skills are essential for more complex reading skills such as reading fluency, comprehension, and spelling (Mastropieri & Scruggs, 1997; Mastropieri, Scruggs, Bakken, & Whedon, 1996). Additionally, children who have a solid grasp on literacy basics, such as phonemes, are more likely to achieve reading and academic success (Share, Jorm, Maclean, & Matthews, 1984).

Researchers agree that one of the most effective ways to remediate basic reading skill deficits is to implement a phonics instruction intervention (Torgesen et al., 2001; Vellutino, Scanlon, & Spearing, 1995; Wagner & Torgesen, 1987). Phonics, as per definition, is the study and manipulation of the sounds of words. To systematically teach phonics, the clinician must stress the acquisition of letter–sound correspondences and their use to read and spell words. There are several different instructional approaches that have been shown to be effective in teaching phonics to the struggling reader, including synthetic phonics, analytic phonics, embedded phonics, auditory depth discrimination, analogy phonics, onset-rhyme phonics, and phonics through spelling. While each of these programs differs across a number of features, they all effectively utilize a planned, sequential method to teach the full array of letter–sound correspondences and other phonemic elements explicitly and systematically. For this type of intervention to be effective, it must not occur in isolation and should be tailored to the individual's needs and combined with explicit, intensive, and supportive training in the use and application of the alphabetic principle, comprehension, fluency, and word recognition. This integration with other techniques will enable the individual to have a balanced reading program and will foster a better understanding of language.

As mentioned previously, utilizing a systematic approach to ameliorate phonics deficits is recommended. There are many of these types of programs; however, it does not appear that any one method of phonics instruction is superior. In a study by Torgesen et al. (2001), two phonics instruction methods, Embedded Phonics and the Auditory in-Depth Discrimination Program (ADD; Lindamood & Lindamood, 1998), were compared using 60, 8- to 10-year-old children who had previously been diagnosed as having LD and had, in addition, been determined to have severe reading difficulties. The Embedded Phonics program stimulated phonemic awareness through writing and spelling activities, taught phonemic decoding strategies directly (e.g., common spelling variations, phonetic rules and patterns, modeled by the instructor how to blend sounds, and practice) and devoted a large amount of time to reading and writing using connected text. Conversely, the ADD program taught phonemic awareness through articulatory cues (e.g., "lip poppers" or "tip tappers") and spent the majority of time building phonemic/articulatory awareness (e.g., distinguishing between mouth form and the sounds of common phonemes) and individual word-reading skills. Outcomes suggested that both programs

produced significant improvements in reading comprehension. These gains were maintained at both 1 and 2 year follow-ups. Given the results of the study by Torgesen et al., it would seem intuitive that the clinician should choose the phonics intervention based on the ability, skill set, and learning style of the child with LD since both methods were effective.

In a similar study, Rashotte, MacPhee, and Torgesen (2001) found that utilizing an integrative phonics-based approach to learn was an effective method to increase the reading ability of struggling readers. Spell Read P.A.T., the program used, is a phonological auditory training program that focuses on ameliorating reading and writing deficits through incorporating instruction in phonemic awareness, phonics, and reading and writing for meaning. The program is a three-phase hierarchy composed of a total of 140, 50-min sessions. Rashotte et al. (2001) only studied the utility of the first phase of the Spell Read P.A.T. program with 115 first-through sixth-grade impaired readers. The participants were instructed by their teachers in small groups of 3–5 students.

Each session was composed of 30 min of phonemic activities, 15 min of "share" reading, and 5 min of free writing. Phonemic activities were focused on building phonological awareness through the use of sound card activities that included building combinations of different syllables using single sounds (e.g., the student would form /sh/ /oo/ with the respective sound cards while saying each sound and then the syllable "shoo"), blending single consonant sounds with vowel sounds (e.g., the child forms the syllable "moo" with the sounds /m/ and /oo/ while sounding out the sounds and the syllable), and breaking syllables into its constituent parts (e.g., given the syllable "toy" and the sound /oy/, the student the student must sound out /t/, /oy/, and "toy"). During the "share" reading time, the students were instructed to take turns reading aloud while the teacher instructed the children to sound out unfamiliar words. Reading was reinforced with verbal praise. Next, the teacher led a discussion about the material to increase comprehension. The end of each session concluded with free writing where each student wrote about what they read. Rashotte et al. (2001) found that, in small groups, the intensive auditory training program significantly increased the phonological awareness, decoding, reading accuracy, comprehension, and spelling skills of the children regardless of grade or level of reading deficiency.

While it is suggested that increasing the basic reading skills in a child with LD is crucial, the competent clinician must also incorporate strategies that will increase reading fluency and comprehension. These are also necessary elements to fostering a solid reading foundation. One approach that has been shown by numerous researchers to increase reading fluency is the method of repeated reading. To implement this simple technique, children identified as having reading difficulties are given short reading passages that contain simple and easily recognizable words. They are then asked to read the passage repeatedly until a predetermined fluency criterion is attained, at which point they begin reading a new passage. The logic behind this approach is that repetition of unknown text until fluency is reached aids in the solidification of the material into memory, thereby enabling the person to rely more on their memory to assist them.

Using a parent implemented protocol, Burns and Kondrick (1998) utilized the repeated reading paradigm to increase the word comprehension of 10 third- and fourth-grade children with LD who were struggling readers. Each therapy session was divided into four phases: single-word flash card drills, paragraph reading drills, story reading drills, and comprehension questions. During each phase, the parent prompted the child to read the specific material aloud. Correct responses (i.e., reading a single word, paragraph, or story without error or answering a comprehension questions correctly) were rewarded with a token that could later be exchanged for money. If an error was made, the parent assisted the child in sounding out the word. Then,

the child had to repeat the word aloud. This procedure continued until each stimulus (e.g., word, paragraph, or story) was read without error. The children also completed comprehension questions after the story reading phase and were given a vocabulary review test to check their proficiency with the material. It is noteworthy to mention that the difficulty of the reading materials began with first-grade curriculum and progressed sequentially up to a fifth-grade level. All the children showed significant gains on standardized measures of reading aptitude and had, in addition, increases in their self-perception of his or her competence in reading.

Similar strategies to Burns and Kondrick's (1998) intervention have been used by other researchers and have shown that success can be achieved with repeated reading through a variety of modes such as teacher models (O'Donnell, McLaughlin, & Weber, 2003), a peer reading buddy (Gut, Bishop-Goforth, & Farmer, 2004), and books on audiotape (Daly & Martens, 1994). A study by Rankhorn et al. (1998) stressed that repeated reading's success is dependent on the use of age-appropriate materials, promoting independent reading, repetition, consistency, reinforcement, and immediate feedback and correction. The intervention implemented by Rankhorn et al. involved using a failure-free reading program for 30 min a day over a period of 7 months. In addition, the printed text was simple, controlled, and easy to understand. Children were encouraged to preview the material to be read, listen to the story being read, answer factual, inferential, and learning questions, and read and review the material.

Another method that can be used to increase the reading ability of children with LD is peer tutoring. Most researchers who utilize a peer tutoring method focus on the use of a collaborative modeling method where children with reading difficulties are paired with a more proficient same-aged peer in their class. Mathes, Howard, Allen, and Fuchs (1998) used a peer-assisted learning strategy with 32 first graders who were identified as being at risk for a reading disability. The child and their partner were guided through activities focused on sounds, words, and reading aloud. During these activities, each child took turns completing the activity. The stronger reader always went first so as to provide a model to the weaker reader. The teacher gave instructions to all the children on how to correct errors (e.g., point out the word, pronounce the word, and have the weaker student say the word) and how to ask comprehension questions during the partner read-aloud phase. Outcomes suggested that the intervention was successful in improving the reading skills (e.g., reading fluency, comprehension, phonemic skills, and word recognition) of the at-risk participants and, alternatively, was not detrimental to the stronger readers.

While peer tutoring may not be a feasible option for the clinician, the logic behind this method of remediating reading difficulties would be easy to incorporate into a more user-friendly mode of intervention. The rationale behind collaborating with a more proficient reader is to give the struggling reader a model of the correct language of reading (i.e., grammar, phonetics, tone modulations, etc.). Therefore, any individual (e.g., clinician, sibling, parent, caregiver, etc.) who is a fluent reader can fulfill the role of the tutor (Nes, 2003). A method similar to the one used by Mathes et al. (1998) can also be used to teach phonics and word recognition. Strategies such as modeling and imitation using flashcards or an audiotape (Chiang, Thorpe, & Darch, 1980; Freeman & McLaughlin, 1984) and antecedent and contingent modeling (Hendrickson, Roberts, & Shores, 1978) can be used in lieu of narrative reading.

The use of graphic organizers in school curriculum has been shown by researchers to be another effective tool to increase reading comprehension of children with LD. Graphic organizers such as story maps, semantic organizers, framed outlines, and Venn diagrams are visual and spatial displays designed to facilitate the learning of textual material. Through the

use of arrows, lines, and a spatial arrangement to describe text content, structure, and key concepts, the material read is made more meaningful and, thus, describing text content, structure, and key concepts becomes an easier task to accomplish (Darch & Eaves, 1986). The addition of a graphic organizer, either during or after reading a passage, enables the student to connect their existing knowledge base to facilitate conceptualization and comprehension of novel or difficult material. For students with LD, being able to utilize their background knowledge in this manner can be rather difficult, as they often have a poor foundation in metacognitive skills and strategy use (Mastropieri et al., 1996). This difficulty can, subsequently, hinder their ability in assimilating, organizing, and critiquing information and in making inferences. Making the critical information of a passage easier to access through the use of a graphic organizer can help the student with LD be able to identify the most pertinent information and increase their ability to comprehend what is read.

Story maps have been shown to be one type of graphic organizer that is useful in assisting the comprehension of narrative texts in children with LD. This type of graphic organizer provides students with a visual guide to understanding and retelling stories through the identification of the most pertinent ideas and events (i.e., setting, problem, goal, action, and outcome) to establish the meaningful links between concepts or facts within a passage (Reutzel, 1985). In a study by Idol (1987), students with LD were found to use story maps effectively after their teacher properly demonstrated how a story map is utilized through modeling, prompting, error correction, and feedback. The story map procedure enabled them to substantially recall more relevant information, to answer more implicit comprehension questions about the stories, and they were able to label more parts of the story when prompted to verbally recall what was read.

As students progress though school, reading increasingly involves expository text from which students are expected to learn factual information. The scientific, technical nature of expository material is oftentimes full of abstract concepts, complex and varied syntactical structure, and may not be clearly organized (Armbruster, 1984). Because of the level of competency needed to be successful, expository text can be very problematic for the student with LD who already has difficulty with reading and studying. This, therefore, can induce a cascading effect across all the academic domains. To accommodate the difficulties associated with expository texts, graphic organizers can continue to be effective when used in combination with additional strategies such as previewing text, mnemonic devices, semantic deciphering, paraphrasing, self-questioning, and critical thinking (Boyle, 2000; Brigham, Scruggs, & Mastropieri, 1995; Wong & Jones, 1982).

5.5.2 Social Skills and Psychopathology

In addition to difficulties in learning, many children with LD also exhibit significant deficits in social competence. It has been estimated that approximately 75% of students with LD manifest some facet of social deficits that is distinguishable from typically developing same-age peers (Kavale & Forness, 1996). Furthermore, these deficits in social skills coupled with poor academic achievement increases the likelihood that the child or adolescent with LD will be rejected by his or her peers (Vaughn, Sinagub, & Kim, 2004; Weiner, 1987). This ineptitude in social interaction is primarily attributed to a lack of skills in initiating and sustaining positive social interactions (Bauminger, Edelsztein, & Morash, 2005). This deficiency translates into a lack of social insight and reciprocity, less nonverbal social interactions (Agaliotis & Kalyva, 2008),

fewer same-age friends (Wiener & Schneider, 2002), social–emotional difficulties or psychopathology (Schachter, Bless, & Bruck, 1991), a higher rate of school dropout, and conduct problems (Loeber, Lahey, & Thomas, 1991). Since social competency predicts school readiness and success throughout the lifespan, it is imperative that the clinician incorporates social skills training in any treatment of a child or adolescent diagnosed with an LD.

There are numerous intervention strategies to assist in teaching appropriate social skills to students who have an LD. The purpose of these various techniques is to enable the individual to recognize and utilize a complex set of appropriate behavioral responses, thereby allowing them to adapt to various problems that occur in social situations. For the clinician, teaching social skills requires implementing principles of effective instruction, including identifying target behavior(s), pretesting or assessment, teaching, modeling, rehearsing, role playing, behavioral contingencies, reinforcement, corrective feedback, practicing, and monitoring progress. There are various social skills that the clinician may choose to target. Included are the individual's ability to solve social or interpersonal problems and make decisions quickly, body language, adapt to situations that are new or unexpected, use coping strategies for responding to emotional upsets, communicate effectively with others, and making and maintaining friends. We suggest that a thorough assessment of the child's social ability be conducted prior to initiating any social skills training package to ensure that individual needs are met.

Prater, Bruhl, and Serna (1998) provide a good example of evidence-based social skills training for students with LDs that incorporates modeling, role-playing, and feedback. In their study, three different social skills interventions (teacher-directed instruction, a naturalistic approach, and group-think discussion) were compared. Only the teacher-directed instruction will be discussed here. The primary components of the training were modeling, verbal description, and imitation, in that order. The three skills that the researchers determined the intervention would focus on included listening, problem solving, and negotiating. Each skill was divided into a task analysis composed of small steps. For example, the task analysis for the skill of listening was broken into the following steps: (1) face the person with shoulders parallel to each other; (2) make eye contact; (3) use a relaxed facial expression; (4) stand up straight; (5) stay in close proximity. Other behaviors that the participants were encouraged to perform included head nods, respond to the person, ask for clarification, and do not interrupt. The teacher initiated each training session by talking about the specific social skill to be learned and explaining why it is important to master the skill. Next, the teacher modeled the skill steps for each task. The students were prompted to memorize and recite one skill step at a time until all steps could be recalled. Then, the teacher and student engaged in a role-playing session. After the role-play was over, the teacher provided feedback in the form of error correction and reinforcement. Role-playing continued until the child successfully engaged in each of the skill steps of the social behavior. All the children in the teacher-directed instruction significantly improved skill performance on all three social behaviors. When compared with the other two social skills intervention groups, participants who received teacher-directed instruction were better able to understand the importance of learning and use it in the classroom.

Social stories (Gray & Garand, 1993) are a cost-effective technique that could be incorporated into an effective social skills program for the student with LD. In this type of intervention, a social story is read, which depicts a central character with whom the child can identify. The central character then confronts a social situation. The reader is given a description of the behaviors, thoughts, and feelings the character has as (s)he tries to accomplish the behavioral goals identified in the story. Through the narrative, the reader is provided with a concrete

example of how a person can cope with interpersonal problems and resolve conflicts in a socially appropriate manner.

Social stories have primarily been shown to be an effective strategy to teach socially appropriate behaviors, problem-solving skills, communication skills, and play skills with children with autism spectrum disorders (Sansosti, Powell-Smith, & Kincaid, 2004). There is preliminary evidence that this technique can be used with children who have LDs.

Kalyva and Agaliotis (2008) evaluated the utility of a social story paradigm for 63 children with LD, between the ages of 10 and 12 years. These children had been previously identified as having interpersonal conflict resolution problems. Participants were divided into two groups: an experimental (i.e., received the social story intervention) and a control group (i.e., listened to and answered questions about a children's book). The social story read on eight separate occasions to the experimental group depicted a scenario where two friends were in conflict about the ownership of a favorite edible treat (e.g., chocolate). The resolution strategy proposed was compromise and sharing, as opposed to a negative outcome. Next, both groups were interviewed about conflict resolution using a different social scenario and then rated on a social skill questionnaire by the teacher. Kalyva and Agaliotis (2008) found that children in the experimental group were more likely to choose predominantly positive strategies for conflict resolution both after the intervention and at follow-up when compared with the controls. In addition, the experimental children were rated post-intervention as engaging in significantly less inappropriate social behaviors.

In a similar study, Rahill and Teglasi (2003) used a social story-based program, STORIES, to increase the social cognitions of 35 children in grades 2–6 who evinced learning, behavioral, and emotional difficulties. This program emphasized thinking and problem-solving through emotionally charged or hostile peer encounters presented in a story format. The students' ability to accurately process social cues increased markedly. Furthermore, the children were able to recall and apply a wider range of positive coping strategies than children who were in a non-specific counseling group.

Incorporating training on interpersonal problem-solving (i.e., anger management, conflict resolution, relaxation, self-monitoring, etc.) would be an appropriate addition to a social skill training program for a child with LD who experiences emotional or behavioral difficulties. The goal of training interpersonal problem-solving skills is to teach individuals how to employ a wide range of strategies that allow them to develop and maintain positive relationship with others through coping with difficult social situations, solving problems, and resolving conflict with others. To ensure successful problem resolution, the student must, at a minimum, be able to identify and define the problem, generate alternative solutions, evaluate possible consequences of each alternative, and implement the solution (Spivack, Platt, & Shure, 1976). This approach may require rehearsal and modeling. Whereas these four components are characteristic of most interpersonal problem-solving programs, many include additional components and procedures.

Amish, Gesten, Smith, Clark, and Stark (1988) conducted a social problem-solving intervention with 40 students who had serious emotional disturbances and had various degrees of learning difficulties. The intervention consisted of 15 structured lessons that occurred for approximately 40 min once a week. Throughout the duration of the program, the participants were taught six essential problem-solving steps: (1) say what the problem is and how you feel; (2) decide on a goal; (3) stop and think before you act; (4) think of many possible solutions; (5) think about the outcomes of each possible solution; and (6) find the best possible solution

and implement it. Students were asked to rehearse and implement each step during group discussion. Similar programs to the one proposed by Amish et al. (1988), such as FAST and SLAM, have also been shown to be effective in improving social problem-solving skills through the use of mnemonics, thereby making the steps easier to remember (McIntosh, Vaughn, & Bennerson, 1995; Vaughn & Lancelotta, 1990).

There are numerous intervention strategies that assist in teaching appropriate social skills to students with LD. Social stories, interpersonal problem-solving training, modeling, direct training, and role playing are just a few examples of strategies that are easy to implement and have been shown to be effective. It is important for the clinician to tailor the specific intervention to the individual needs and deficits of the child when conducting a social skills training procedure. By increasing the ability to effectively handle a myriad of social situations and resolve conflicts effectively, this will enable the individual to engage in more appropriate behaviors that are necessary to make and maintain friendships with peers. The child with LD who is able to achieve success in their social world will have more confidence and self-esteem which, as a result, may translate into better outcomes in the classroom.

5.5.3   Academic Performance

It is well known that students with LDs experience a wide range of problems with learning or performing academic skills in classroom environments. These difficulties are further exacerbated by attention deficits and inadequate self-management skills. Researchers have found that students with learning disabilities often have low levels of attention to tasks, are inattentive, easily distracted, and are dependent on teachers to mediate their learning (Larkin & Ellis, 2004). This set of factors can make it problematic for the acquisition of adequate independent work habits. Since these deficits further hinder success in academic tasks, it is imperative to develop supports and services to bolster the individual abilities of the student and enable the student to perform his or her best in the classroom.

An essential element of effective instruction for students with LD is the use of scaffolding (Coyne, Kame'enui, & Simmons, 2001). Scaffolding, in the classroom, refers to temporarily adjusting and extending instruction so that the student is challenged and able to develop new skills. To optimize a scaffolded instruction model, the individual needs of the student with LD must be considered when determining the type of task, materials, group size, pace, presentation, and so on. First described by Vygotsky (1962), scaffolding was conceived after it was observed that, when given adult assistance, children who had difficulty in learning could perform tasks they previously could not accomplish independently. The learning that occurs with scaffolding is due to, what Vygotsky termed, the *zone of proximal development*. The "zone" refers to the difference between the child's ability to independently solve problems given his or her actual developmental level and the level of potential development given adequate supports, adult guidance, or collaboration with capable peers (p. 86). Therefore, as the child becomes more adept with problem-solving on his or her own, more control of the learning strategy is relinquished to the student. To scaffold the instruction effectively, new content is introduced in manageable steps with explicit, systematic instruction for each step and practice is provided until the student is confident and able to perform the skill independently.

There are numerous models of scaffolded instruction; however, each has the same general premise: students gradually move from more assistance to less assistance to achieve

independence (Kame'enui & Carnine, 1998). New concepts, which are meaningful and interesting to the child, are introduced just beyond the child's current level of understanding or control. Breaking the task into small steps, the instructor is able to provide specific instructions. This approach increases the likelihood that the student will achieve success with these manageable components and provides a better determination of what subskills have been mastered and what still needs additional instruction and practice. In addition to teaching in small segments, skills are systematically introduced in a hierarchy of increasing difficulty with the addition of explicit instruction techniques such as modeling, guided and independent practice, graphic organizers, previewing materials, question prompts, and feedback (Larkin & Ellis, 2004). As each step is mastered, less supports are needed as the student becomes more independent in their ability to perform the skill or strategy. Scaffolding has been shown to be an effective method of instruction for a variety of academic skills and domains. It has been criticized, nonetheless, as being extremely difficult for the typical general education classroom teacher to use. Since scaffolding is individualized to meet the needs of the student, teachers must be knowledgeable about the curriculum and the individual problems their students experience to be able to generate a variety of supports to stimulate student thinking in an appropriate direction (Stone, 2002). Given this difficulty though, the critical elements of scaffolding (e.g., providing assistance to meet student needs, motivate the child to pursue academic goals, and assist in the student becoming an independent learner) should be the building blocks of any intervention aimed at increasing the academic performance of a student with LD.

Self-monitoring is another strategy that can help facilitate independency in the classroom. This type of intervention enables the individual to learn how to regulate his or her own actions. Through providing opportunities to self-instruct, set goals, monitor their behaviors, evaluate their own learning, and provide self-reinforcement, self-monitoring facilitates, self-reliance on one's own abilities, and helps the individual to become more cognizant of his or her performance (Larkin & Ellis, 2004). This, therefore, allows the student to learn that by engaging in positive behavior leads to positive outcomes (King-Sears & Cummings, 1996). One of the goals of self-monitoring is that by increasing awareness of one's own behavior(s) in the classroom, any gains or benefits seen will generalize to other settings and situations outside of the school environment. Not only applicable to increasing academic performance (i.e., on task behavior, academic productivity, task accuracy), self-monitoring has also been shown to be an effective technique in alleviating problem behaviors and increasing pro-social behaviors (Carr & Punzo, 1993; Digangi, Maag, & Rutherford, 1991).

In a study by Rock (2005), nine children with an LD or developmental disability were taught to use a self-monitoring strategy during reading and mathematics lessons. Each child had been referred for various behavior challenges (e.g., out of seat behavior, staring, talking with peers, arguing with peers and teacher, toying with personal objects, etc.) that made independent seatwork problematic in the classroom setting. The strategy implemented, ACT-REACT, is a mnemonic device that represents a self-monitoring of attention and performance procedure that includes the following six steps: *A*rticulate your goals, *C*reate a work plan, *T*ake pictures, *R*eflect using self-talk, *E*valuate your progress, and *ACT* again. After training on how to use the mnemonic strategy, participants were instructed to monitor their progress during independent seat work in a reading or mathematics classroom. To assist them in this task, a self-monitoring think-sheet was created that stated the child's academic performance goal statement (e.g., "I will complete 15 math problems today), academic attention prompts

(e.g., "Am I staying focused and working like I am in my picture?"), and performance evaluation statement (e.g., "How many math problems did I complete?"). During each session, the participants monitored their attention or engaged in academic behavior by comparing it to a photograph that depicted on-task behavior at 5-min intervals. If their present behavior resembled the ideal behavior depicted in the photograph, they were instructed to record a check mark on their self-monitoring think-sheet. In addition, they were taught to monitor their performance by recording the number of pages read or math problems completed at the end of each 5-min interval. A multiple-baseline-across-subjects design with an embedded reversal demonstrated the value of this approach. All the participants had increases in academic productivity (i.e., total number of problems completed or pages read) and task engagement and decreases in problem behaviors.

Assistive technology is now becoming a more widely accepted practice in school curriculum. For the child with LD, incorporating the use of assistive technology in the classroom aids in making the learning environment more accessible, increases individual productivity and success, and provides alternate modes of performing academic tasks (Lewis, 1998). From low level supports, such as highlighter pens, to high-technology devices, such as computers, assistive technology can reduce various barriers to learning by presenting information in multiple modalities through the use of using programs (e.g., word processors, spelling and grammar tools, etc.) to organize writing, and by providing alternatives to how material is learned (e.g., through audiotapes, videotapes, and computers). Devices such as handheld calculators, books on tape, electronic organizers, calendar and time management programs, and digital clocks are low technology devices that are readily available for students with LDs and are easy to use. In addition, more advanced technology, such as computer-assisted instruction and videotapes, can also be effective in giving more individualized instruction when one-on-one instruction is not possible.

Hetzroni and Schrieber (2004) conducted a systematic single-subject ABAB designed study to determine the utility of using a word processor for enhancing the academic outcome of three junior high school students who were diagnosed with LD and had specific writing difficulties (e.g., illegible handwriting, made spelling mistakes, text copying difficulties, writing incomplete or illogical sentences, and poor text organization skills). In the study, the participants were instructed to answer questions presented during a classroom discussion, write an independent creative summary, and copy a list of the day's homework assignments either using paper and pencil or using a personal laptop equipped with a word processor program. The outcome indicated that there was a significant difference in the quality (i.e., number of spelling and reading errors, number of words written, and text structure and organization) between the handwritten and computer-assisted phases. When using the word processor, the participants produced written materials that had less spelling mistakes and reading errors, and had a higher overall quality of organization and structure than when they were instructed to use paper and pencils.

In a similar study using assistive technology, Herbert and Murdock (1994) contrasted computer-aided instruction output modes to support the vocabulary learning of students with LDs. The participants were given one of three output modes (no speech, synthesized speech, or digitized speech) during a computer-based vocabulary training program. Participants who received the vocabulary words in combination with either of the two speech output modes made significant improvements on post-training vocabulary tests when compared with those who did not receive the addition of speech to their training program.

5.6   Basic Competencies of the Clinician

The clinician working with LD children has three primary areas of basic competence that must be mastered. These topics include basic principles of applied behavior analysis (ABA), an understanding of federal and state definitions as well as an overview of inclusion, and third, unique characteristics of LD and typical problems that are most likely to be encountered.

ABA. An understanding of the basic operant learning principles and their application to real-world problems is a critical factor in providing treatment for the child with LD. This process is twofold. First, the clinician should have a basic understanding of terminology and concepts such as shaping, chaining, fading, reinforcement, functional assessment, and related empirically supported learning strategies. These are the building blocks of effective programming. Second, the clinician should have experience in the application of these principles to real-world problems. A common difficulty is that the clinician may be able to recite definitions of various ABA terms, but they cannot translate these definitions into working examples for real-world problems. Similarly, the novice clinician may be able to apply a procedure with one child in one setting but cannot apply this strategy to similar problems. These issues of problem and treatment strategy recognition and application are evident for a variety of LD problems of children that must be developed by practicum and related clinical experiences until the clinician has enough examples in real-world settings to be able to apply these principles on their own.

Governmental Definitions, Core Programs, Inclusion, and Advocacy. The field of LD was not born primarily from scientific inquiry, but through the influence of parents, lobbyists, and educators. Advocacy groups (e.g., Adults and Children with Learning and Developmental Disabilities (ACLD), Learning Disabilities Association of America (LDA), etc.) have developed over time to meet the clinical and educational needs of children that were not being addressed by the existing policies. The LD classification came about in response to the need to understand individual differences among children in the educational system who were of average general intelligence but evinced specific deficits in spoken and written language. An additional goal was to provide services to students who were not being adequately provided for by the general educational system. In 1968, LD became the first recognized disability to receive federal assistance. Since that time, the field of LD has progressed rapidly. The historical trends and stages have been thoroughly documented in several sources (refer to Hallahan & Cruickshank, 1973; Hallahan & Mercer, 2002; Kavale & Forness, 1985). We urge the reader to consult these additional references for a more comprehensive review.

In brief, Public Law 94–14 (The Education of all Handicapped Children Act, 1975), Public Law 101–476 (Individuals with Disability Education Act, 1990), the ADA, and the IDEA 1997 and 2004 revisions (Individuals with Disability Education Act, 1997, 2004) mandate that students who meet the federal government criteria for specific LDs receive reasonable accommodations. These statutes were created to ensure that individuals with LD are provided with a free and appropriate public education, a nondiscriminatory evaluation, and due process. Appropriate accommodations include full inclusion, mainstreaming, a one-on-one paraprofessional, a learning disability specialist or classroom, resource rooms, individualized education plans (IEP), and progress monitoring.

In addition to delineating the criteria for accommodation, the aforementioned statutes provide a federally recognized definition. LD is a special education category based on deficits in a specific academic area that are not due to low intelligence, behavioral difficulties, sensory

deficits, or environmental, cultural, or economic disadvantage. Although the definition in federal law governs the identification of and services available to children with LD, the specific guidelines for the identification and classification of learning disabled students varies from state to state. Therefore, it is up to the clinician to become familiar with his or her local and state definition and to be knowledgeable about the specific guidelines mandated for assessing and diagnosing LD.

Currently, one of the major debates in the field of LD between advocates, parents, and educators pertains to determining the most appropriate level of educational services. While the reauthorization of IDEA in 2004 provided expanded options on how to screen, assess, and categorize a learning disabled child, it left the interpretation of the "least restrictive setting" up to educators and parents. This term *restrictive*, in an educational sense, refers to the extent to which the student is educated with nondisabled peers. Therefore, with the increased emphasis on academic performance goals and measures of accountability that are consistent with standards for students without disabilities, resolving the debate of what is the proper and effective continuum of services provided to these students is imperative (Fuchs & Fuchs, 1994; Vaughn & Schumm, 1995). At the crux of the debate is determining the benefits of full *inclusion* of the child with LD versus *mainstreaming*. Inclusion refers to the integration of students with disabilities in general education classrooms for instruction and to provide additional supports to ensure success in this setting. Mainstreaming is the placement of students with disabilities at least part-time in general education classes. Advocates for full inclusion support the idea that all students with disabilities, regardless of their special education needs, should be placed in a general education setting for the duration of the school day (Dunn, 1968; Kavale & Forness, 2000). The proponents of this position assert that through inclusion, children with disabilities will become more socially and academically accepted by their peers and will be kept at a standard equal to that of their peers. On the other hand, opponents of mainstreaming suggest that general education teachers are not adequately trained, nor do they possess the ability to appropriately plan for students with special needs. Therefore, expecting general education to meet the needs of the individual is unrealistic (Vaughn & Schumm, 1995).

LD Characteristics and Associated Problems. LDs represent a heterogeneous category of academic deficits classified into seven different areas: (1) listening comprehension (receptive language; (2) oral expression (expressive language); (3) basic reading skills (phonological awareness, decoding, and word recognition); (4) reading comprehension; (5) written expression; (6) mathematics calculation; and (7) mathematics reasoning. These separate types of LDs share many common characteristics and, as such, frequently co-occur. Furthermore, there are secondary characteristics of LDs that are found in many, but not in all, cases. It is important to note that LDs are defined by the primary characteristics of the disability (i.e., specific deficits and functional problems in the development of academic skill sets), not by the secondary characteristics. Although associated problems, these characteristics might nevertheless be extremely disruptive and interfere with the child's progress in school. Therefore, just because they are secondary does not mean that they are of little consequence (Lerner, 2006; Smits-Engelsman, Wilson, Westenberg, & Duysens, 2003; Swanson, Cooney, McNamara, & Bernice, 2004).

Common secondary characteristics of LDs include deficits in fine or gross motors skills, auditory or visual perception, sustaining attention, short-term memory retention, language processing, and social competence and emotion regulation problems such as inattention, hyperactivity, noncompliance, and psychopathology. For example, children with LD are often described as not being able to attend to a task for long periods. These children may, as a result,

become restless, easily distracted, forget details, and fail to follow directions (Cutting & Denckla, 2003). Owing to these difficulties, there is an overlap between LD and Attention Deficit Hyperactivity Disorder (ADHD). Researchers suggest that approximately 30% of students with LDs are also diagnosed with ADHD, and about 30–40% of students with ADHD have a diagnosable LD (National Institute of Mental Health, 1999).

One misconception that many clinicians have is that because LDs and ADHD share many characteristics, children with LD should be diagnosed with ADHD. It is important to keep in mind that some children with LD have co-morbid ADHD, but this is not true in all cases. For the child with LD, their attention difficulties are related to the processes of learning (Cutting & Denckla, 2003). For example, they may have difficulty in staying on task, deciding what is important and what is not while listening to a lecture or reading a paragraph, and sustaining attention on particular tasks. While this can hinder their ability to stay on task and comprehend material, for two-thirds of students with LDs, these problems are not severe enough to warrant a diagnosis of ADHD (Sattler & Lowenthal, 2006). It is up to the clinician to use his or her clinical judgment to determine the pervasiveness of the individual's inattention and, if present, hyperactivity.

As mentioned previously, it has been well documented that children with LDs have secondary social–emotional and, to a lesser degree, behavioral difficulties. These issues partially arise owing to these children being reminded of his/her inabilities either through social labeling or repeated academic failure (Bryan, Burstein, & Ergul, 2004; Cooley & Ayers, 1988). This situation can translate into a host of social–emotional problems pertaining to low self-esteem, social isolation/phobia, anxiety, depression, panic, social information processing dysfunction, and frustration (Bauminger et al., 2005; Bryan et al., 2004; Svetaz, Ireland, & Blum, 2000). Clinicians should also be alert for signs that an individual with a learning disability is lonely, depressed, or suicidal. In addition, clinicians need to be competent in how to identify, screen for, and refer to the appropriate professionals who are having significant problems. Furthermore, a number of researchers' studies reported by Bryan et al. note that negative or inappropriate behaviors are indicative of students with LD. Behaviors that a clinician should expect to see include a lack of social skills, aggression, negative verbal behaviors, shyness, disruptions, insensitivity, and attention-seeking behavior. Students with LDs have also been found to be less socially accepted and, as such, often have younger friends and tend to be bullied more by same-age peers (Mishna, 2003; Weiner, 2004).

The clinician must be able to differentiate between what are the primary and secondary problems at the individualized level. For example, a child with LD may have depression because of their academic difficulties. On the other hand, a child who is clinically depressed may have academic problems owing to their depression hindering them from concentrating and performing optimally. This variable can be a major problem in diagnosis, especially since the definition of LD is one of exclusion. Therefore, a child whose primary concern is psychopathic in nature cannot be diagnosed as having an LD. This is not to say that a child with LD cannot be depressed or have some other psychopathology (Magg & Reid, 2006). One of the limitations in the perception of children with LD is that serious anxiety problems are symptomatic of the primary condition and, therefore, these symptoms are not likely to be improved without improving the primary condition first. There are many effective behaviorally oriented treatments for children with anxiety problems, which have been shown to be able to be successfully applied to children who have LDs. These direct treatments will not reduce the primary disability (i.e., the LD), but it will help to increase the child's quality of life by ameliorating those secondary issues.

5.7 Expert Competencies of the Clinician

As previously discussed, basic behavioral principles are a must for the clinician working with a child who evinces LD. However, those skills, while sufficient to carry out a treatment program for academic skills, would not be sufficient to design and monitor the effectiveness of the program. To ensure success, the expert clinician would need to have, first, an understanding of the specific treatment procedures that would have the best evidence to support them for various learning-based problems. Additionally, the therapist would need to know what assessment methods would be best for general screening and for pinpointing specific learning deficits. Along these same lines, they would need to be able to match treatments to identified deficits.

In addition to an understanding of assessment and treatment as it applies to academic issues, the issue of challenging behavior and comorbid psychopathology must be considered. Challenging behaviors such as temper tantrums, aggression, noncompliance, and a general lack of motivation are among the problems most frequently encountered with this group.

5.8 Transition from Basic Competence to Expert Competence

Transitioning from a novice to an expert clinician is essential in any area of study, but for the field of LD it is crucial. Given the nebulous state of what is known and agreed upon as evidence-based practices, proper definitions, and assessment procedures, becoming a competent and proficient professional who is able to think on his or her feet, solve problems, and make confident treatment recommendations is essential to effectively ameliorate the multifaceted nature of LDs. In any field of study, the two defining qualities of an expert are superior knowledge and a proficiency of performance within one's relevant domain of expertise (Eveleth, 1999). As mentioned previously, for the clinician working in the field of LD topics that must be in their repertoire of mastery involve behavioral principles, specific treatment procedures, supporting research, various assessment instruments and techniques, and the ability to understand and be able to apply various treatment methodologies while acknowledging the uniqueness of each individual client and their specific difficulties. This extensive domain-specific knowledge must be organized in a manner where the clinician is able to successfully access and apply such knowledge to the demands of the environment (Benderly, 1989; Chi, Glaser, & Farr, 1988). When this deep solidification of knowledge, practice, and application in one's repertoire occurs, the expert clinician is able to be effective not only because they "know" the fundamental rules and routines, but because they are able to respond from an understanding of the total situation owing to their breadth of experience. This ability enables him or her to focus specifically on only the most important aspects of a situation without wasting time on irrelevant information (Dreyfus & Dreyfus, 1986). In addition, the expert's performance is fluid, flexible, highly proficient, and is virtually automatic unless a novel problem arises for which a greater analysis is required.

As expected, moving from being a novice to being an expert is something that requires long-term commitment to learning and practice. This level of understanding is only accomplished through extensive training, practical experiences, seminars, professional education programs, and supervision by an experienced licensed professional. The clinician aiming to work with individuals with LD must be committed to life-long learning and professional development. This is attained through continually gaining practical experience while keeping abreast

of current research literature, governmental and state laws, educational policies, and using the most effective evidence-based practices. This level of competence will enable accurate clinical judgment and encourage a higher level of professionalism in a field that continues to change.

5.9   Summary

LD is perhaps the most visible of all the childhood problems encountered in the schools. It is the most common of all the disabilities. Furthermore, if left untreated, a series of additional problems can result, which are very serious. Juvenile delinquency, school failure and drop out, problems with interpersonal relationships, job loss and poor job success, drug-related problems, and many other social ills can result. LD thus places the individual at risk for a host of life-long adjustment problems. For these and related reasons, early diagnosis and intervention are essential.

In this chapter, we have highlighted the controversy that exists around the best way to assess and define LD. No resolution of the issue has occurred to date, and is not likely to occur anytime in the near future. What is clear, however, is that definition and assessment are linked and are broken down into two camps, which might best be described as a traditional psycho-metric approach using IQ scores and standardized measures of academic performance, versus an ABA approach where differential diagnosis is tied to treatment response. What both camps can agree to is that some innate deficits are likely, that the child is not intellectually disabled, and that the child is doing poorly or failing in school. Thus, the debate is more on a technical/programmatic level, based on the theoretical model one responses.

To a large extent, LD has also proven to be a fad magnet for ineffective and unsubstantiated treatments. Many of these interventions and variants of them have been in use for many years. A quick look at the internet will turn up a bewildering array of potential treatments. Most of these interventions have dramatic, often unsubstantiated claims of potential effectiveness. This situation can, of course, be a dramatic challenge to parents, other caregivers, and teachers who often do not have the time or the resources to separate the wheat from the chaff. The expert clinician then has this burden. It is his or her ethical duty to be familiar with what works and what does not work based on the available research and to communicate this information in as straightforward and nontechnical fashion as possible.

6 Conduct Disorder and ODD

Ross W. Greene

Abstract: Social, emotional, and behavioral challenges in children are best understood through transactional models of development emphasizing factors associated with the child and environment and their reciprocal influences. Along these lines, conduct problems – often categorized as oppositional defiant disorder (ODD) and conduct disorder (CD) – can be conceived as the byproduct of incompatibility between child and environment, or what can be referred to as "child-environment incompatibility." The goal of assessment is to understand these incompatibilities; the goal of intervention is to address them. Numerous models of psychosocial treatment have been applied to conduct problems, many of them evidence-based. However, the fact that conduct problems remain a significant public health issue suggests that greater innovation in thinking and intervention are needed. The primary focus of this article was Collaborative Problem Solving, an innovative, "hybrid" psychosocial treatment model. The CPS model combines elements of social learning theory, systems theory, and research in the neurosciences, and its effectiveness has been examined in families, schools, inpatient psychiatry units, residential facilities, and juvenile detention facilities. CPS is a challenging model to implement, and effectiveness of a clinician in doing so hinges on experience and supervised practice.

6.1 Overview

Oppositional defiant disorder (ODD) refers to a recurrent childhood pattern of developmentally inappropriate levels of negativistic, defiant, disobedient, and hostile behavior toward authority figures (APA, 1994). Specific behaviors associated with ODD include temper outbursts, persistent stubbornness, resistance to directions, unwillingness to compromise, give in, or negotiate with adults or peers, deliberate or persistent testing of limits, and verbal (and minor physical) aggression. These behaviors are almost always present at home and with individuals the child knows well (APA).

The following are considered associated features of ODD (APA, 2000). As developed in this chapter, these features may have even greater implications for assessment and treatment of ODD than the specific behaviors comprising the disorder:

▶ In males, the disorder has been shown to be more prevalent among those who … have problematic temperaments (e.g., high reactivity, difficulty being soothed) or high motor activity. … there may be low self-esteem (or overly inflated self-esteem), mood lability, low frustration tolerance, swearing … and a vicious cycle in which the parent and child bring out the worst in each other. ODD is more prevalent in families … in which harsh, inconsistent, or neglectful child-rearing practices are common (pp. 100–102).

The essential feature of conduct disorder (CD) is a repetitive and persistent pattern of behavior in which the basic rights of others or major age-appropriate societal norms or rules are violated (APA, 1994). These behaviors fall into four main groupings: aggressive conduct that causes

physical harm to other people or animals; non-aggressive conduct that causes property loss or damage; deceitfulness or theft; and serious violations of rules. Youth meeting diagnostic criteria for CD may bully, threaten, or intimidate others, initiate frequent physical fights, use a weapon that can cause serious physical harm, be physically cruel to people or animals, steal, force someone into sexual activity, destroy others' property, lie or break promises, break curfew, run away from home overnight, and skip school. The following are the associated features of CD (APA, 2000); not surprisingly, they overlap to some degree with the associated features of ODD:

► Individuals with Conduct Disorder may have little empathy and little concern for the feelings, wishes, and well-being of others. Especially in ambiguous situations, aggressive individuals with this disorder often misperceive the intentions of others as more hostile and threatening than is the case and respond with aggression that they then feel is reasonable and justified. They may be callous and lack appropriate feelings of guilt or remorse. … self-esteem may be low. … poor frustration tolerance, irritability, temper outbursts, and recklessness are frequent associated features (ppm. 93–98).

Although the validity of the taxonomy for CD has been questioned (see Tremblay, 2003), two subtypes (childhood-onset and adolescent-onset) of the disorder are presently recognized, both occurring in a mild, moderate, or severe form (APA, 2000). Youth meeting criteria for the former have more disturbed peer relationships, exhibit more persistent CD behaviors, and are more likely to develop adult anti-social personality disorder than those meeting criteria for the latter.

Two thirds of children diagnosed with ODD do not subsequently develop CD (Hinshaw, 1994; Hinshaw, Lahey, & Hart, 1993; Lahey & Loeber, 1994). Yet, CD rarely occurs outside the presence of ODD (Frick et al., 1991; Greene et al, 2002; Hinshaw et al., 1993; Lahey, Loeber, Quay, Frick, & Grimm, 1992; Loeber, Green, Lahey, Christ, & Frick, 1992), and ODD has been shown to be a significant predictor of family dysfunction and social impairment even when a wide range of other psychiatric conditions – including CD – are controlled (Greene et al., 2002). Such findings suggest that the central feature of ODD – noncompliance – confers particular risk for more serious outcomes, perhaps especially because of how it has traditionally been conceptualized and the corresponding manner to which it has been responded.

6.2   Assessment of Symptoms and Maintenance Factors

Now would probably be a good time for the author of this chapter to disclose his general lack of enthusiasm for using diagnoses to describe youth with social, emotional, and behavioral challenges. *Coming to a definitive conclusion regarding a diagnosis is not the goal of assessment*, and for several reasons. Diagnoses cannot possibly reflect the complex combination of individual and environmental factors that set the stage for disadvantageous patterns of behavior, and often serve only to "pathologize" one element of the equation (in this case, the child or adolescent). Thus, saying that an individual "has ODD" or "has CD" is, as a practical clinical matter, fairly meaningless (the need to satisfy managed care reimbursement requirements notwithstanding). As is made clear in the ensuing pages, the term "child–environment incompatibility" would be preferable. Nonetheless, for ease of exposition and the sake of familiarity, the

term "conduct problems" will be the primary descriptor for the remainder of the chapter. Yet, all too often, a diagnosis is used as the litmus test for determining treatment selection (in clinical settings), for establishing that a sample in a study was selected with sufficient rigor (in research settings), or for certifying that a child qualifies for additional services (in schools). In the case of the latter, an individual's failure to meet diagnostic criteria for a specific psychiatric disorder carries the risk of the determination that the individual "has no problems" and therefore "has no need for additional services." In this chapter, it will be assumed that if a child or an adolescent is exhibiting conduct problems, then there is most assuredly "a problem" and that the need for additional help is abundantly clear.

Before turning our attention to mechanisms of assessment, it might be a good idea to ponder what is it exactly, that we are trying to assess. The theoretical orientation of this chapter derives from research underscoring the reciprocal nature of interactions between parents and their difficult offspring (Anderson, Lytton, & Romney, 1986; Dumas & LaFreniere, 1993; Dumas, LaFreniere, & Serketich, 1995) and from models emphasizing transactional or reciprocal influences (Bell, 1968; Belsky, 1984; Chess & Thomas, 1984; Cicchetti & Lynch, 1993, 1995; Gottlieb, 1992; see Sameroff, 1975, 1995). These models posit that a child's outcome is a function of the degree of "fit" or "compatibility" between the characteristics of the child (e.g., temperament, neuropsychological profile, activity level, ability to inhibit impulses) and the characteristics of his or her environment (e.g., adult caregivers, socioeconomic status, neighborhood). Studies on the reciprocal nature of interactions between children and adults have primarily focused on children and their parents, but the model can also be applied to lesser-studied interactions between children and other important adult caregivers, such as teachers (see Greene, 1995, 1996; Greene et al., 1997). A higher degree of compatibility between child and environment is thought to contribute to optimal outcomes, whereas a lesser degree of compatibility is thought to contribute to less advantageous outcomes. From this perspective, conduct problems can be understood as one of many possible expressions of child–environment incompatibility. Indeed, it is these incompatibilities that give rise to conduct problems and these very same incompatibilities, left untreated, that further fuel and exacerbate conduct problems once they are set in motion.

Yet, much research on conduct problems (and aggression) in youth has focused on "main effects" rather than on the transactional interplay between child and environmental characteristics. An impressive, indeed daunting, array of child and environmental characteristics has been identified as contributing to the development of conduct problems. And while one could roughly summarize these characteristics as follows – "conduct problems are usually caused by the combination of a lot of really bad things" – greater specificity might be useful.

As for child characteristics, sometimes the focus has been on comorbid diagnoses. We know, for example, that it is extremely rare for conduct problems to occur outside the context of other psychiatric disorders. A majority of youth with ODD and CD has comorbid ADHD (Abikoff & Klein, 1992; Greene et al., 2002; Hinshaw et al., 1993; Lahey & Loeber, 1994). Mood and anxiety disorders (Angold & Costello, 1993; Greene et al., 2002) and language processing disorders (Beitchman, Hood, & Inglis, 1989; Beitchman, Hood, Rochon, & Peterson, 1990; Baker & Cantwell, 1987; Greene et al., 2002; Moffitt & Lynam, 1994) are common comorbidities as well.

Sometimes the focus has instead been on dimensional constructs. So it is also known that conduct problems are associated with executive skill and other neuropsychological and cognitive deficits, aggression, difficulties in emotion regulation and temperament, lack of empathy, recklessness/novelty-seeking, and poor tolerance for frustration (see Lahey & Waldman,

2003, for an excellent review), along with obsessiveness and cognitive rigidity (Garland & Weiss, 1996; Budman, Bruun, Park, & Olson, 2000).

A similarly impressive list has been compiled for environmental factors, and includes pregnancy complications (such as viral infections or mother's poor nutrition), delivery complications (such as hypoxia or lack of oxygen to the fetus during labor; see Brennan, Grekin, & Mednick, 2003, for a review), parents who are neglectful or harsh and inconsistent disciplinarians (Moffitt & Caspi, 2001), and low socioeconomic status (SES) (see Harnish, Dodge, & Valente, 1995; Kilgore, Snyder, & Lentz, 2000). Psychosocial and medical interventions applied in individual cases should also be considered important environmental factors, but are not typically taken into account by studies examining causes of conduct problems. Yet, these interventions have the potential to function (when they are effective) in a protective capacity or (when they are ineffective) to confer greater vulnerability.

So, while it might be tempting to simply engage in a mechanical process of counting risk factors to explain a child's developmental progression to conduct problems, or to identify one or two factors that seem to exert the greatest impact (in other words, true "main effects"), such an endeavor would move us further away from the ultimate goal of assessment: *to achieve an understanding of the incompatibilities between characteristics of a child and his or her environment and, based on this understanding, to pinpoint potential factors to be addressed by intervention.*

In other words, it is good to know that a child or adolescent has or had difficult temperament, high motor activity, mood lability or irritability, low frustration tolerance, a lack of empathy or concern for the feelings, wishes, and well-being of others, and/or misperceptions of the intentions of others (known as cognitive distortions or cognitive biases). But it is worth noting that, taken independently, these characteristics do not usually lead to serious conduct problems. Thus, there must be some other dynamic at work: namely, how these characteristics influence and are influenced by characteristics of the environment (parents' marital discord, parents' harsh and inconsistent parenting practices, access to quality mental health care, interventions that were or were not effective) in ways that increase or decrease incompatibility and thereby heighten or reduce the likelihood of advantageous or disadvantageous outcomes.

Child–environment incompatibility can begin even before a child is born (for example, if the mother is exposing the fetus to substances that are not conducive to optimal development), but it is at the point at which it exceeds the "threshold of adversity" that conduct problems (and other disadvantageous outcomes) can be expected to emerge. The earlier the threshold of adversity is reached, the more disadvantageous the long-term outcome is likely to be. Of course, as noted by Lahey and Waldman (2003), even in youth whose conduct problems appear in adolescence, these problems do not "come (from) out of nowhere." Early child–environment incompatibility may be manifested in many different ways, but it is the onset of chronic child noncompliance – again, the core feature of ODD – that is perhaps the clearest signal.

Let us consider briefly why this might be the case. As I have written elsewhere (e.g., Greene & Doyle, 1999; Greene, Ablon, & Goring, 2003), the skill of compliance – defined as the capacity to defer or delay one's own goals in response to the imposed goals or standards of an authority figure – can be viewed as one of many developmental expressions of a young child's evolving capacities for self-regulation and affective modulation (also see Amsel, 1990; Hoffman, 1975; Kochanska, 1995; Kopp, 1982; Stifter, Spinrad, & Braungart-Rieker, 1999). Demands for self-regulation and affective modulation begin at birth, and more sophisticated mechanisms for these skills develop as children mature, but most dramatically during the toddler years,

when children learn to use language to label and communicate their thoughts and feelings, develop cognitive schemas related to cause-and-effect, and generate and internalize strategies aimed at facilitating advantageous interactions with the environment (Kopp, 1989; Mischel, 1983). But these skills do not develop independently of environmental influences and environmental influences typically do not occur in a vacuum. Compliance can therefore be viewed not only as a complex skill and as a critical milestone on the trajectory of emerging self-regulation and affective modulation in a child (Hoffman, 1983; Kochanska & Askan, 1995; Kopp, 1989), but also as a primary indicator of compatibility between a child and his or her environment.

Thus, true to our definition of assessment – *to achieve an understanding of the incompatibilities between the characteristics of a child and his or her environment and, based on this understanding, to pinpoint potential factors to be addressed by intervention* – assessment should examine any and all incompatibilities between child and environment, with an emphasis on (but not limited to) factors known to contribute to the development of conduct problems.

A variety of assessment instruments would be useful (and others perhaps less useful) in this endeavor. A *situational analysis* provides indispensable information about the conditions under which child–environment incompatibility occurs. In other words, with *whom* (mother, father, peers, sibling, teacher, soccer coach), *when* (when hanging out with peers outside of adult supervision, when asked to perform a difficult academic task, when truant from school), and *where* (at a peer's apartment, in his own home, between classes at school, in math class, on the school bus) are conduct problems occurring? Be forewarned: often those upon whom the assessor is relying for assessment information may not be highly skilled at thinking about behavior in situational terms (they may be more naturally inclined to view behaviors as reflective of unvarying "traits"). Sometimes asking reporters to recount (in story form) situations in which conduct problems occurred can be a useful device. More fair warning: the stories are likely to begin with a description of the behaviors themselves (understandable, since the behaviors are usually the primary concern of the reporters) rather than a description of the conditions that preceded the behaviors (this information should be much more important to assessors). Thus, it is often necessary to ask reporters to "rewind the tape" so as to uncover the actual circumstances leading up to the problematic behavior, which are usually more complicated than originally presented.

In gathering information about the contexts and conditions under which conduct problems occur, assessors gather information about the characteristics of the child and environment contributing to incompatibility. In other words, embedded within every "incompatibility episode" are clues about the temperament, expectations, cognitive biases and distortions, belief systems, frustration tolerances, problem-solving skills, flexibility, and social skills of the interaction partners, and disciplinary practices of the adult caregivers. Such clues provide opportunities to gather much more detailed information in these domains.

In an effort to capture the above assessment information, I have developed a "discussion guide" (regrettably, it does look a bit like a checklist) called the *Assessment of Lagging Skills and Unsolved Problems* (ALSUP), which is comprised of a list of the skills found lagging in children with social, emotional, and behavioral challenges, as well as a list of the unsolved problems that commonly precipitate incompatibility episodes. Note that the ALSUP has not been developmentally normed, for it is intended to serve as a means of taking a highly individualized look at the lagging skills and unsolved problems relevant to a specific child rather than coming to conclusions about whether the child "has a problem" based on comparison to individuals of the same age, grade, or gender. In other words, if a child is having difficulty communicating his

needs or concerns to those around him, and if this difficulty is contributing to incompatibility episodes, then there is most assuredly "a problem," whether the child is a 2-year-old female or a 17-year-old male. The ALSUP is shown in ⊙ Table 6.1.

Because conduct problems do not occur in a vacuum, a *developmental history* is the mechanism through which information about all these domains can be placed in an historical context and a general sense can be obtained of duration of child–environment incompatibility. What was the child like as an infant? What were the subjective and overt responses of the adult caregivers? When did the caregivers first notice "behavior problems" in their child? What was their understanding of, and response to, these behavior problems? Were there any extenuating circumstances affecting the caregivers or family at the time behavior problems emerged or at any other point in the child's development?

Along these lines, a *school history* will also be crucial. Anecdotally, children and adolescents whose conduct problems occur cross-situationally (i.e., at home *and* at school) tend to have a more difficult behavioral profile and tend to be more difficult to treat than children whose difficulties are confined to the home environment. Are conduct problems occurring at school? Under what conditions and with what interaction partners are these problems occurring? To what degree do "incompatibility episodes" coincide with particular academic demands, or in unstructured situations, or with certain peers or teachers? Is the child accessing the school discipline program, and to what degree has the program been effective (if, as is often the case, the child is accessing the school discipline program frequently, then the ineffectiveness of the program is probably self-evident)?

It will also be important to gather information about the *treatment history* of the child and key adult caregivers; as noted above, ineffective prior treatment can fuel alienation, hopelessness, and cynicism and can color an individual's perspective on the prospects for current treatment and must be taken into account in formulating treatment plans (some of the most difficult-to-treat children have bounced from one treatment program to another, and have lost faith that the "system" will ever be helpful). What was the nature of the prior treatment? Individual therapy? Family therapy? Parent management training? Was the treatment effective or did it exacerbate or increase the frequency of incompatibility episodes? Why was it terminated? What does this tell us about the expectations of those involved and the degree to which they were able to participate in treatment and execute treatment recommendations? Have any diagnoses been rendered? How do the different interaction partners understand the meaning of the diagnoses? Has psychotropic medication ever been prescribed for any of the interaction partners? What were the target symptoms of the medication? Was the medication helpful?

Given the prior discussion as to cognitive factors contributing to the development of conduct problems, the assessor should also inquire about prior *formal assessment* that may have been conducted, both for the purposes of recommending such assessment (if it is needed) and for obtaining additional information about the general cognitive skills, executive skills, language processing skills, and other cognitive factors that may have bearing on interactions between a child and key people in his or her environment.

The behavior checklist is very common tool for assessing children, and many instruments are available for assessing conduct problems (see AACAP, 1997, 2007). While such "objective" instruments do provide an efficient overview of the problematic behaviors a child is exhibiting, there are important limitations to their use. They tend to focus on only one element of child–environment incompatibility (the child) and therefore tend to steer assessment in a direction that pathologizes children (rather than in the direction of examining incompatibilities between

Assessment of Lagging Skills and Unsolved Problems

Assessment of Lagging Skills and Unsolved Problems (Rev. 12/5/08)	
Child's Name	Date
LAGGING SKILLS	
Difficulty handling transitions, shifting from one mind-set or task to another (shifting cognitive set)	
Difficulty doing things in a logical sequence or prescribed order	
Difficulty persisting on challenging or tedious tasks	
Poor sense of time	
Difficulty reflecting on multiple thoughts or ideas simultaneously	
Difficulty maintaining focus for goal-directed problem-solving	
Difficulty considering the likely outcomes or consequences of actions (impulsive)	
Difficulty considering a range of solutions to a problem	
Difficulty expressing concerns, needs, or thoughts in words	
Difficulty understanding what is being said	
Difficulty managing emotional response to frustration so as to think rationally (separation of affect)	
Chronic irritability and/or anxiety significantly impede capacity for problem-solving	
Difficulty seeing the "grays"/concrete, literal, black-and-white, thinking	
Difficulty deviating from rules, routine, original plan	
Difficulty handling unpredictability, ambiguity, uncertainty, novelty	
Difficulty shifting from original idea or solution/difficulty adapting to changes in plan or new rules	
Difficulty taking into account situational factors that would suggest the need to adjust a plan of action	
Inflexible, inaccurate interpretations/cognitive distortions or biases (e.g., "Everyone's out to get me," "Nobody likes me," "You always blame me," "It's not fair," "I'm stupid")	
Difficulty attending to or accurately interpreting social cues/poor perception of social nuances	
Difficulty starting conversations, entering groups, connecting with people/lacks other basic social skills	
Difficulty seeking attention in appropriate ways	
Difficulty appreciating how his/her behavior is affecting other people	
Difficulty empathizing with others, appreciating another person's perspective or point-of-view	
Difficulty appreciating how s/he is coming across or being perceived by others	
UNSOLVED PROBLEMS	
HOME	
Waking up/getting out of bed in the morning	
Completing morning routine/getting ready for school	
Sensory hypersensitivities	
Starting or completing homework or a particular academic task

characteristics of a child and his environments). Thus, they tend to provide very little information about the expectations, biases, disciplinary practices, and other characteristics of the important adult caregivers doing the checking and how these characteristics influence, and are influenced by, characteristics of the child.

Another common assessment practice, perhaps especially in schools, is the "functional assessment," which is based on the belief that a given behavior is "working" at (or serves the function of) getting a child something he wants (for example, attention) or enabling the child to escape or avoid something unpleasant, difficult, tedious, or uncomfortable (for example, homework). However, this definition of function tends to lead to interventions aimed at convincing a child that his behavior will not work (this is usually accomplished through use of punishment) or encouraging the performance of replacement behaviors that adults believe will work better (this is usually accomplished through use of incentives). Interestingly, such interventions are sometimes characterized as being reflective of transactional thinking, perhaps because they involve both interaction partners (the child, who is now on the receiving end of formal, imposed consequences, and the adults, who are now on the administering end). Yet, the logic of this form of intervention could well be called into question if the goal was to address the transactional processes known to contribute to the development of conduct problems.

Elsewhere (Greene, 2008), I have recommended a revised conceptualization of function, flowing from the following questions: If a child had the skills to go about getting, escaping, and

avoiding in an adaptive fashion, then why is she or he going about getting, escaping, and avoiding in such a maladaptive fashion? The fact that the child is going about getting, escaping, and avoiding in a maladaptive fashion is evidence of the fact that she or he does not have the skills to go about getting, escaping, and avoiding in an adaptive fashion. As described below, this definition of function leads to interventions aimed at teaching skills and solving the problems that are giving rise to child–environment incompatibility in ways that are realistic and mutually satisfactory.

6.3 Evidence-Based Treatment Approaches

Diverse psychosocial treatment approaches have been applied to children's conduct problems. Models known alternatively as "parent training" (PT) and "behavioral family therapy" have focused primarily on altering patterns of parental discipline that contribute to the development of oppositional behavior and problematic parent–child exchanges (McMahon & Wells, 1998). Skills typically taught to parents in such models include positive attending, use of appropriate commands, contingent attention and reinforcement, and use of a time-out procedure (see McMahon & Wells). In general, research has documented the efficacy of these procedures (see Brestan & Eyberg, 1998, for a comprehensive review), and several intervention programs emanating from these models have been identified as either "well-established" (the *Living with Children* program [Patterson & Gullion, 1968] and videotape modeling parent training [Webster-Stratton, 1984, 1990, 1994]) or as "probably efficacious" (including parent–child interaction therapy [Eyberg, Boggs, & Algina, 1995]).

However, this same body of research has also documented various limitations of PT. First, parents receiving PT often do not fully comply with implementation or drop out of treatment altogether (e.g., Prinz & Miller, 1994), suggesting that this form of intervention may, in fact, not be well-matched to the needs and characteristics of many of those responsible for implementation. Most studies examining efficacy of PT have presented data only for those who remained in treatment rather than those who began treatment. Among those who remain in treatment, PT has been shown to produce statistically significant changes in oppositional behavior, but very few studies have reported clinically significant changes (Kazdin, 1997). Indeed, 30–40% of those children remaining in treatment continue to evidence behavior problems in the clinical range at follow-up (Webster-Stratton, 1990). Data have shown that a significant percentage of children – perhaps higher than 50% – are not functioning within the normal range when such treatment is completed (Dishion & Patterson, 1992). Finally, most studies examining efficacy of PT have not included clinically referred youth (Kazdin; Patterson & Chamberlain, 1994), and have typically failed to examine long-term treatment effects (Kazdin, 1993, 1997). In view of these limitations, it is reasonable to conclude the following about PT: (a) a meaningful percentage of children and parents do not derive substantial benefit from PT; and therefore (b) alternative treatments that more adequately address the needs of these children and parents must be developed and studied (Greene, 2005).

Alternative models of intervention have placed relatively greater emphasis on *cognitive* factors underlying ODD rather than on behavior per se (see Coie & Dodge, 1998; Crick & Dodge, 1996; Kendall, 1985; 1991; Kendall & MacDonald, 1993), and emanate from research highlighting the frustration and emotional arousal that often accompany externally imposed demands for compliance. As described above, a variety of factors may compromise a child's skills in these domains, and these alternative models of intervention have focused on addressing

the cognitive deficiencies and distortions of oppositional or aggressive children. Several such intervention models have been identified as "probably efficacious," including problem-solving training (Kazdin, Esveldt-Dawson, French, & Unis, 1987; Kazdin, Siegel, & Bass, 1992), anger management programs (Feindler, 1990, 1991, 1995; Lochman, 1992; Loch-man, Burch, Curry, & Lampron, 1984; Lochman, Lampron, Gemmer, & Harris, 1987), and multisystemic therapy (Henggeler, Melton, & Smith, 1992).

A fairly recent addition to the array of evidence-based psychosocial treatment options for conduct problems is a model of care called Collaborative Problem Solving (CPS; Greene, 1998, 2001, 2005, 2008). The CPS model aims to help adults (1) conceptualize children's social, emotional, and behavioral challenges as a byproduct of lagging cognitive skills and unsolved problems, in other words, as a form of developmental delay; (2) identify, in each child, the lagging skills underlying, and unsolved problems precipitating, incompatibility episodes; and (3) to begin using a collaborative approach to problem solving to address, in a realistic and mutually satisfactory manner, predictable, long-standing issues of disagreement so as to reduce the likelihood of incompatibility episodes and increase child–environment compatibility. Research has shown that the model is effective in both outpatient (Greene et al., 2004) and inpatient (Greene, Ablon, & Martin, 2006; Martin, Krieg, Esposito, Stubbe, & Cardona, 2008) settings. Because the mechanisms of change and basic competencies of clinicians in treating conduct problems differ across the different psychosocial treatment approaches, and because the CPS model is the expertise of the author, these mechanisms and competencies are discussed for the remainder of this chapter as they apply specifically to this model.

6.4   Mechanisms of Change Underlying the Intervention

From a transactional perspective, *the goal of treatment is to improve child–environment compatibility*. So, how can the CPS model be considered transactional if it primarily targets the lagging skills of the child? The answer: it could not, and the CPS model does not. So it might be instructive to distinguish between theory and good strategy. Adults who live or work with children with conduct problems are typically quite convinced that it is the "identified patient" (the child) who has "the problem." Trying to dissuade adults from this perspective too quickly can cause them to precipitously abandon the therapeutic ship. While adult caretakers will doubtless need to be convinced of their role in incompatibility episodes, timing is everything. But let there be no doubt, the lagging skills listed on the ALSUP may be just as applicable to adults. Moreover, unsolved problems typically involve two interaction partners, and the practice of collaboratively solving problems provides an opportunity for all interaction partners to participate in the problem-solving process and learn new skills.

This does not mean that all interaction partners must always receive direct treatment for child–environment incompatibility to be impacted. Some distinctly unidirectional interventions – pharmacotherapy being an obvious example – can have a significant impact on child–environment incompatibility, even though all of the interaction partners are not directly receiving treatment. For example, it is entirely possible that, by reducing a child's hyperactivity and poor impulse control through use of stimulant medication, important elements setting the stage for child–environment incompatibility would be addressed and incompatibility episodes would be dramatically reduced. However, if it is also the case that adult caregivers have, for example, unrealistic academic and behavioral expectations or unrealistic notions about changes

that will be achieved through administration of stimulant medication, then, even if a child had a positive response to the medication, child–environment incompatibility might not be sufficiently impacted and treatment would need to be expanded to factors unaffected by the initial intervention.

Let us consider in greater detail each of the three treatment components delineated in the last section, for each has implications for the mechanisms of change involved in the CPS model.

1. *Conceptualize children's social, emotional, and behavioral challenges as a byproduct of lagging cognitive skills and unsolved problems.* For many adults, CPS involves a paradigm shift. Helping adults – parents, teachers, or staff in an inpatient, residential, or juvenile detention setting – understand how a child came to develop conduct problems so as to view the child through accurate, compassionate lenses, is an indispensable (and usually first) component of CPS treatment. This shift alone can have dramatic effects on adult–child interactions, but also sets the stage for subsequent intervention ingredients. Some adults do not readily abandon their pre-existing paradigms, and may need some evidence that the CPS model is going to improve their lives before they adjust their thinking.

Parents often bring children and adolescents who are exhibiting conduct problems into treatment asking the question, "What should I do?" The first goal is to help parents shift, at least initially, to a different set of questions ("Why is my child acting this way and why is what seems to work with other children not working with this one?"), because it will be very difficult to answer the former without first considering the latter. In schools and treatment facilities, unidirectional explanations that imply intent (e.g., attention-seeking, manipulative, coercive, limit-testing, unmotivated), labels that imply fixed character (e.g., sociopath, psychopath, conduct disordered), and explanations that elevate some of the facts that are known about a child to "causal status" ("he was born addicted to cocaine," "his parents are divorced," "his mother's crazy," "his father's in jail," "you know what neighborhood he lives in," "his brother's the same way") often color the perspectives of those responsible for intervention. Moreover, children who have evidenced conduct problems for many years often come with large "portfolios" filled with massive and overwhelming amounts of information, prior testing, and past treatment plans. In CPS, there are two important "filters" for sorting through this information: *lagging skills* and *unsolved problems*. While much of a child's history is interesting as background information – typically providing countless sobering examples of child–environment incompatibility – the goal is to identify "actionable" information. The advantage of focusing on lagging skills and unsolved problems is that the skills can be taught and the problems solved; thus, these filters may be more likely to set the stage for productive, systematic intervention than focusing on past events about which the child, and those trying to help him, can do little to change.

2. *Identify, in each child, the lagging skills underlying, and unsolved problems precipitating, incompatibility episodes.* In CPS, treatment is highly individualized. Each child has a unique profile of lagging skills (in the parlance of CPS, lagging skills are the "why" of challenging behavior) and unsolved problems (the "who, what, where, and when" of challenging behavior), and it is crucial for the key adults who interact with a child to come to a consensus about his or her specific lagging skills and unsolved problems and, as part of this process, to establish priorities for what to begin working on first (because it will not be possible to "fix everything at once"). The ALSUP will be an important tool for these purposes. This process, and the consensus that emerges from it, propel CPS treatment into its next phase.

Yet, this consensus can be particularly difficult to achieve in schools and treatment facilities, where communication can be challenging across classes and shifts and where, therefore, it can be extremely difficult to intervene in a cohesive, consistent manner in which the "left hand knows what the right hand is doing." Of course, CPS is not the only model of treatment requiring good communication; any *effective* model of care has the same requirement. Thus, while the creation of mechanisms for effective communication is not an ingredient specific to the CPS model, it is typically an extremely important focal point when the model is being implemented.

This treatment ingredient helps adults recognize that incompatibility episodes occur in the context of specific problems, and promotes the understanding that, if a problem can be solved, it will not precipitate challenging behavior any longer. Solved problems do not precipitate challenging behavior, only unsolved problems do.

3. *Begin using a collaborative approach to problem solving to address, in a realistic and mutually satisfactory manner, predictable, longstanding issues of conflict or disagreement so as to reduce the likelihood of incompatibility episodes and increase child–environment compatibility.* In most cases, this next phase involves working with children and their adult caretakers to solve the problems that are precipitating disadvantageous behavior. Adults are taught that the manner by which adults pursue unmet expectations and solve problems with a child is a major factor influencing the frequency and intensity of incompatibility episodes. Imposition of adult (in the parlance of CPS, this approach is referred to as "Plan A") is one way to pursue unmet expectations and solve problems, but is also the most common precipitant of acute (but highly predictable) incompatibility episodes. Removing an expectation (known as "Plan C") is effective at reducing tension between the child and the adult, but not effective at helping adults pursue unmet expectations. Collaborative Problem Solving ("Plan B") is an effective way to pursue expectations without increasing the likelihood of incompatibility episodes while simultaneously training and practicing emotion regulation, frustration tolerance, problem solving, flexibility, and a host of other lagging skills (in both interaction partners). The three Plans can serve as useful "shorthand" for helping adults communicate and think about how they are approaching problems. The ultimate goal, of course, is to help adults reduce their use of Plan A (thereby reducing incompatibility episodes), set priorities (this is where Plan C comes in), and dramatically increase their use of Plan B so that problems are resolved in a realistic, mutually satisfactory, durable manner. This combination of ingredients sets the stage for new interaction patterns in which adult caregivers are imposing their will a lot less, collaboratively solving problems a lot more, communicating more effectively, and fighting less.

The key to the creation of these new patterns is to help adults and children solve problems *proactively* rather than *emergently*. Adult caregivers (and many children) are surprised to learn that most of the problems precipitating incompatibility episodes are actually highly predictable and can therefore be discussed in a planned manner. The reality is that Emergency Plan B tends to be far less productive than Proactive Plan B, the former being more of a crisis management tool and the latter a crisis prevention mind-set. The primary disadvantage of emergent Plan B is heat (as in "the heat of the moment"), which makes solving problems far more challenging. Incompatibility episodes are merely a signal that there is a problem that has not yet been solved (proactively). Upon reflection, it is almost always the case that the problems causing incompatibility episodes were already highly predictable.

Plan B consists of three ingredients. The first, historically referred to as the "empathy step," involves having adult caregivers gather information from a child so as to achieve the clearest possible understanding of the child's concern or perspective on a given problem. The second ingredient, known as the "define-the problem" step, involves having the adult be highly specific about his or her concern or perspective on the same problem. There are now two concerns (but no solutions, yet) that have been entered into consideration. The third ingredient, called the "invitation", is where the adult and the child brainstorm solutions that will address the concerns of both parties.

Helping adult caregivers and the challenging children in their charge become proficient at these three ingredients is hard work. In outpatient work, an overview of the three ingredients is provided once the clinician has introduced the philosophical and theoretical underpinnings of the CPS model and a profile of lagging skills and unsolved problems has been established and priorities identified. Typically, treatment then continues with the clinician directly involved in the first few in-session Plan B discussions between parent(s) and child (focusing on items drawn from the list of unsolved problems), moves on with the parent(s) attempting Plan B in session, with guidance and feedback from the clinician, and continues with the parent(s) using Plan B outside of the clinical setting, with increasing independence and decreased reliance on the clinician for feedback. In schools and therapeutic facilities, it is equally important to begin with philosophical and theoretical underpinnings, but because the message is being delivered to many staff, unevenness in acceptance of the philosophy is to be expected. Thus, mechanisms must be in place to provide opportunities for staff to resolve philosophical differences and then to practice and receive feedback on their use of Plan B.

It is worth noting that the CPS approach differs from some other anger management and problem-solving training programs in its emphasis on helping adults and children develop the skills to resolve issues of disagreement *collaboratively*. I and others have argued that the equivocal effects of many interventions aimed at training cognitive skills to have likely been due, at least in part, to the manner in which such interventions were delivered (e.g., Greene & Barkley, 1996; Hinshaw, 1992). For example, in a majority of studies cognitive skills have been trained *outside* the settings where skills were actually to be performed. It has been suggested that training cognitive skills proximally to the setting(s) where, and the interactions partners with whom, new skills are to be performed might greatly enhance the maintenance and generalization of trained skills and would be more congruent with a transactional perspective (e.g., Greene & Doyle, 1999).

6.5   Basic Competencies of the Clinician

CPS is a process-oriented but directive form of psychosocial treatment drawing upon multiple lines of influence, including social learning theory, systems theory, and research in the neurosciences. Implementing CPS in an outpatient setting requires an array of skills, including: (a) the knowledge of the lagging skills setting the stage for challenging behavior; (b) the ability to transmit this knowledge to adult caregivers in a way that is persuasive but not dogmatic; (c) the ability to develop therapeutic alliances with adult caretakers and challenging kids so as to keep them engaged in the process (even when the going gets rough) and maintain a sense of realistic optimism; (d) the ability to empathize with each party about what they havee gone through and are going through (even when the child is not a willing participant in treatment)

and deal effectively with each party's misgivings and conceptions about this form of intervention; (e) the ability to take complex scenarios and reduce them to their basic ingredients: lagging skills and unsolved problems; (f) a capacity for neutrality, for it is not the role of the clinician to take sides or serve as judge and jury; (g) the ability to keep bringing participants back to the key themes of the intervention when they go astray, recognize when participants are having difficulty with key aspects of Plan B, and provide feedback and guidance on these aspects; (h) a sense of whether and when family members are able to converse directly with each other and the ability to prevent discussions from spinning out of control; (i) patience and persistence, because long-standing problems and conflictual patterns of interaction tend not to resolve quickly; (j) flexibility and creativity, because kids with conduct problems and their adult caretakers have been bumping up against inflexible systems for a very long time and have problems that often are not readily resolved through conventional solutions; and (k) energy, an "activist" mentality, and an understanding of how systems work, because the participants may well need someone to advocate on their behalf in a society where Plan A is still quite popular, especially as it relates to challenging kids.

Let us consider a few of these skills in greater detail, beginning with one aspect of item "d" (dealing effectively with misgiving and conceptions about the CPS model). It is quite common for adult caregivers – who have historically been relying heavily on consequences, have had only two options in their repertoires (Plan A and Plan C), and have therefore been engaged in the practice of "battle picking" – to conclude that Plan B is the equivalent of giving in, to feel that they are relinquishing authority by using Plan B, and to believe that the CPS model involves dropping all adult expectations. The competent CPS clinician takes the time to inquire about these concerns and is skilled at helping caregivers talk about and move beyond them. Adults are pursuing expectations and "setting limits" with both Plan A and Plan B, and Plan B has significantly greater upside (and significantly less downside) than Plan A.

Let us think about item "f" (a capacity for neutrality) as well. As I have written elsewhere, this is one of the most important facets of the CPS model:

▶ There is a temptation, in almost any form of therapy, to ally oneself with the "offended party." Moreover, parents and children often come into therapy with the expectation that the therapist will be the arbiter of right and wrong. It is no accident that people have this mind-set, for (unfortunately) we live in an era where "winning" versus "losing" and rigid definitions of "right" versus "wrong" pervade many issues facing our society. Thus, when working with and their adult caretakers, the temptation can break in either direction, such that therapists can find themselves agreeing with the child when they feel that the adults are being unreasonable and agreeing with the adults when they feel that the child is being unreasonable.

▶ In the CPS model, there are much more productive ways to insert oneself into a system than by taking sides. Indeed, it is actually counterproductive for the therapist to take sides. In succumbing to temptation, the therapist assumes the role of power broker. This is not an ideal role. If the therapist is busy meting out justice, when precisely do the parties learn to work things out with each other?

▶ Indeed, the CPS model requires *finely honed neutrality* on the part of the therapist. The role of the therapist is to accurately represent both sides and to ensure that both concerns make it into the discussion. *The best protection against taking sides is remaining focused on understanding and clarifying each person's concerns* (Greene & Ablon, 2006).

The competent CPS clinician adopts the stance that the concerns of both parties are legitimate and need to be addressed for a problem to be durably solved. Adults often find the clinician's neutrality to be a bit disarming, as they may be accustomed to therapies (or general child-rearing trends in society) in which the goal is to give children the incentive to satisfy adult concerns. The adults are reassured that their concerns are legitimate and will be addressed through the process of collaboratively resolving problems. Kids tend to be receptive to finally having their concerns heard and legitimized, but have often had little practice at generating alternative solutions and contemplating the degree to which the solutions are mutually satisfactory. The clinician helps the child appreciate the legitimacy of the adult concerns (or at least take the adult concerns into account). The ultimate goal is to help kids and adults work toward mutually satisfactory solutions, and it is the child and the adults, rather than the therapist, who determine whether a proposed solution is indeed "mutually satisfactory." A recurring point of emphasis along these lines is to help participants clearly distinguish between *concerns* and *solutions.*

Finally, a little more on item "g" (the ability to keep bringing participants back to the key themes of the intervention when they go astray, recognize when participants are having difficulty with key aspects of Plan B, and provide feedback and guidance on these aspects). There are some fairly typical ways in which participants struggle with the ingredients of Plan B. Adults tend to have an affinity for the *emergent* form Plan B, even if the clinician has expounded on the significant advantages of a more proactive approach to solving problems. The competent CPS clinician reminds participants that most unsolved problems are highly predictable, brings participants back to the list of unsolved problems generated early in treatment, provides opportunities (in sessions) for practicing Proactive Plan B, and monitors the continued effectiveness of solutions upon which they have agreed.

Adults also have a tendency to rush through the empathy step (a pattern I have referred to as "perfunctory empathy") and often lack the ability to "drill" for greater specificity regarding a child's concerns. Adults often fear that they are on the verge of capitulating if they should demonstrate a willingness to consider a child's concerns (another misconception that would need to be addressed) or simply are not sure what to say in an effort to seek additional information. It is also quite common for adults to insert solutions (rather than concerns) into the define-the-problem step. This is often because adults are not exactly certain what their concerns are (this is often contrasted by their certainty over how a particular problem should be solved). The competent CPS clinician takes the time to help adults clarify their concerns. And many people new to Plan B struggle with the Invitation step because they have simply had very little practice at considering solutions that would address not only their own concerns but those of another person. The competent CPS clinician provides opportunities for such practice and, early on at least, potential ideas for realistic and mutually satisfactory solutions. Solutions that do not stand the test of time typically are not as realistic and mutually satisfactory as the interaction partners originally thought they were. And, in a majority of instances, the first solution seldom solves the problem durably; successful problem solving is an incremental process. The competent CPS clinician helps participants return to Plan B and formulate new solutions based on information gleaned from solutions that did not stand the test of time.

Implementation of CPS in schools and therapeutic facilities requires some additional skills, including: (a) knowledge of the politics of larger systems, an awareness of the need to understand the politics and hierarchy within each individual system prior to beginning training in CPS, and strategies for helping large systems bring people on board and deal effectively

with the "politics of change"; (b) knowledge of the difficulties in communication inherent in large systems and of ways to help such systems establish optimal mechanisms for communication; and (c) recognition that things are likely to get worse before they get better.

Moreover, in such facilities, the individuals with whom (or situations in which) a child typically has difficulty in the outside world may not be readily accessible. This does not mean that Plan B cannot occur, but simply that staff may have to serve as the mouthpiece for those individuals. Fortunately, interactions and problems in restrictive facilities often imitate real life; the skills the children were lacking and problems they are having in the facility are the same as those that they were having in the "real world" (and that prompted their placement), so solving problems and teaching skills in the facility is not a pretense, it is the real deal.

CPS is not a passive model of intervention. Pre-existing belief systems and practices do not disappear quickly or easily. Adults have legitimate concerns about whether they will still be in control, whether they (and perhaps the children) will be safe, and whether chaos will ensue when one is implementing the CPS model. Fortunately, data from the studies cited earlier suggest that parents feel significantly more competent, set limits more effectively, and feel significantly better about their relationship with their child after CPS treatment. Conduct problems are significantly reduced in response to CPS; and, in restrictive facilities, use of chemical, physical, mechanical restraint and locked-door seclusion are significantly reduced (along with staff and patient injuries) when CPS is implemented.

Finally, the competent CPS clinician has an awareness of the potential benefits of pharmacologic intervention and of the factors such intervention can be effective in addressing. The target of medical intervention typically is not conduct problems or aggression per se, but rather the underlying or co-occurring factors – such as hyperactivity, poor impulse control, irritability, or emotional over-reactivity – with the intent of reducing oppositionality and aggression as associated symptoms (Connor & Steingard, 1996).

6.6   Expert Competencies of the Clinician

The primary factors setting the stage for expert status in CPS in a clinician are largely the same ones that set the stage for skilled application of the model in non-clinicians or with practically any other model: experience and supervised practice.

My experience is that many clinicians (and non-clinicians), on first learning about the CPS model, come to the fairly rapid conclusion that they are "already doing this" or that implementation will be fairly straightforward. As for the former, there is no question that CPS incorporates clinical ingredients that overlap with other models of care: empathy, relationship-building, talking, listening, clinical expertise, and so forth. However, as regards the latter, clinicians new to the model do tend to find it challenging in some characteristic ways: (a) maintaining neutrality while simultaneously protecting and strengthening therapeutic alliances; (b) being directive while simultaneously allowing the process of problem solving to unfold in individual cases; (c) spending too much time talking about the model in sessions and not enough time helping people practice; and (d) being enthusiastic about the model and eager for rapid acceptance and implementation while simultaneously appreciating that everyone has their own pace of change. It is also typical for clinicians new to the model to get pulled into dealing with the "hot" problem a family presents each week (rather than keeping track of unsolved problems and monitoring the degree to which they are durably

solved), to focus primarily on Emergency Plan B (rather than Proactive Plan B), to struggle with kids who "won't talk," to become frustrated with parents and staff members who "just don't get it," to pontificate rather than clarify and validate concerns, or to become overwhelmed by the complexity of certain problems and personalities. Hearing or reading about these challenges is quite different than experiencing them first-hand. Let us consider a few of the above patterns in greater detail.

Among the many experiences that would move clinicians toward expert status is working with families in which it is clear that a child and an adult are not yet able to exchange ideas without a dramatic rise in hostilities. Under such circumstances, an important role for the therapist is that of mediator or conduit between the two parties, at least until the factions are better able to tolerate direct interactions:

▶ The therapist explores possible solutions to conflicts between the two parties without the parties interacting directly with each other. Although this circumstance does not provide child and adult with any practice at directly talking things through, it does set the stage for some early successes with Plan B. Even when direct discussions are possible, the therapist is keeping a watchful eye on each family member's capacity for remaining engaged without becoming emotionally overloaded and remaining sensitive to moments when one family member or another may need a break from the conversation …(when) there is the potential for all hell to break loose in the therapist's office, the therapist is taking decisive action to prevent discussions from deteriorating past the point of no return, sometimes by interrupting, sometimes by asking someone to leave the office temporarily. There is nothing to be gained by watching a family discussion degenerate to the point that family members are at their worst. The therapist can gather relevant information about the factors setting the stage for deterioration well before the family hits the proverbial "brick wall" (Greene & Ablon, 2006).

Another essential experience is working with children who are having difficulty communicating their concerns; in other words, those who respond to inquiries about their concerns with either "I don't know" or silence. The task for the clinician is to figure out what kind of "I don't know" or silence it is. It turns out that silence and "I don't know" could mean many different things. Some children simply do not have the communication skills to articulate their concerns (intervention would involve creating mechanisms for these skills to be trained). Some children have already forgotten the question (this is often evident from their facial expression). Some children really do not know what their concerns are, perhaps because they have never been asked (and therefore have never given the matter any thought). Plan B gives children the opportunity to give the matter some thought. Along these lines, some clinicians need to get comfortable with silence. For some clinicians, even some seasoned ones, silence is uncomfortable, and there is the strong temptation to fill the void with the sound of one's own voice. Resisting this temptation not only facilitates the gathering of information, it also provides a crucial model for adult caregivers. If time to think does not accomplish the mission, the clinician would have an opportunity to model something else: hypothesis-testing and educated guessing. For some children, "I don't know" or silence can be a sign that they do not yet trust the process, or the clinician, or that they fear there will be "hell to pay" when the session ends. Educated guessing would be helpful here as well; then, ways in which these concerns could be addressed can take place.

Finally – well, not really finally, but our last example – in some families, as well as in schools and other facilities, there are adults who dominate conversations, shoot down ideas, minimize

the input of others, and prevent the free flow of ideas. There are other adults who are more passive and submissive and serve as spectators as the process of change unfolds. Handling these and other personality/communication patterns in an empathic, respectful, nonjudgmental, effective manner is a significant challenge, and one that tends to come more easily with experience.

Of course, experience is useful only if one is learning from it, and this typically requires supervised practice. As a relatively new model, opportunities for supervised practice are, at present, fairly limited. However, the author is working diligently to increase opportunities for such practice. Alas, it is, as of this writing, an unsolved problem, but not for long.

6.7 Transition from Basic Competence to Expert

Having now read of the author's discomfort with diagnoses, then you probably will not be surprised to read that he is similarly uncomfortable with fixed designations such as "expert," preferring instead to think in terms of levels of proficiency and comfort. The CPS model continues to evolve; presumably, clinicians practicing CPS do as well. So there are no formal criteria designating "expert" status in CPS, nor, at least at this point, any formal certification process.

But, as with any new skill, with experience and supervised practice clinicians implementing CPS become more comfortable and instinctive and less "mechanical" in their application of the model. They are still thinking and reflecting, but they are thinking and reflecting less about the formal, technical aspects of the model and more about how to tailor the model to a specific child, family, staff member, setting, or situation. Clinicians proficient in the model feel confident in their ability to handle the various bumps in the road that can occur during implementation, while relishing situations that will require a somewhat different tack than has been applied previously.

Here is a potentially useful analogy. The author of this chapter is an average athlete who had no experience in snow skiing until about 15 years ago. His spouse is a good athlete and has been skiing since childhood. The author has received some direct instruction in skiing and some supervised practice. He has gone skiing dozens of times in the past 15 years. Yet, when he is out on the slopes, he tends to stay on the easier trails and, if he does not think fairly continuously about what he is doing, has an outstanding likelihood of an embarrassing display. His spouse – who was interviewed for purposes of this chapter – thinks primarily about how much fun she is having when she is skiing; she tends to look at what is ahead only when she is skiing mogul courses and, even then, is in little danger of self-embarrassment or injury.

Transactional thinking is relevant here as well: a major determinant of treatment outcome is the degree to which intervention ingredients are well-matched to the needs and characteristics of individuals, or what could be referred to as "person–treatment compatibility". While the CPS model is comprised of some specific ingredients, how it is presented and explained should differ depending on the specific needs of the individuals with whom a clinician is working.

Indeed, as I think on the matter, proficiency and comfort are constructs that tend to be model-specific. A different construct – *effectiveness* – is perhaps of greater importance. Effectiveness refers to the degree to which a clinician is actually improving lives, and presumably includes person variables that are not always trainable through experience and supervised practice. For example, there is an excellent chance that, no matter how much instruction and supervised practice the author receives in skiing, he may still never be highly skilled in the activity and at this point, he is attributing this unwelcome reality to advancing age.

6.8   Summary

Children and adolescents with conduct problems represent an enormous challenge, not only clinically but also societally. Their difficulties are best understood not through "main effects," but rather through models of development emphasizing factors associated with the child and environment and their transactional influences. In this chapter, conduct problems were conceived as the byproduct of significant incompatibility between child and environment, or what was referred to as "child–environment incompatibility." The goal of assessment is to understand these incompatibilities; the goal of intervention is to address them.

Numerous models of psychosocial treatment have been applied to conduct problems. The fact that conduct problems remain a significant public health issue suggests that greater innovation in thinking and intervention are needed. The primary focus of this article was a model called Collaborative Problem Solving, an innovative, "hybrid" psychosocial treatment. In many families, schools, and treatment facilities, this evidence-based model represents a significant departure from the traditional models of care. The CPS model combines elements of social learning theory, systems theory, and research in the neurosciences, and its effectiveness has been examined in families, schools, inpatient psychiatry units, residential facilities, and juvenile detention facilities. CPS is a challenging model to implement, and the effectiveness of a clinician in doing so hinges on experience and supervised practice.

7 Attention Deficit Hyperactivity Disorder

Arthur D. Anastopoulos · Lisa M. DeGrass

"Once he learned how to walk, all hell broke loose"
"I heard about the terrible twos, but my son is 10 now, when is he going to grow out of them?"

Abstract: This chapter addresses competencies that are important for clinicians to have in order to work effectively and ethically with child and adolescent AD/HD populations. As background, this chapter begins with a brief review of the primary symptoms of AD/HD, its associated features, and the factors thought to cause and/or maintain AD/HD across the lifespan. Next, evidence-based treatment approaches and the conceptual mechanisms by which therapeutic change presumably occurs are discussed. Against this background, competencies for beginning clinicians, as well as competencies for more advanced clinicians, are presented. Distinctions between beginning and expert clinicians are made along several dimensions, including: clinician knowledge of AD/HD as a disorder; the degree to which clinicians adhere to field-accepted criteria for AD/HD; clinician selection and use of assessment procedures; the manner in which the developmental deviance of AD/HD symptoms is addressed; the attentiveness of clinicians to comorbidity and diversity issues; clinician awareness of the fact that they are likely to be treating problems presented not only by the child with AD/HD but also his or her family; clinician recognition of and commitment to a multimodal treatment approach. The path from being a clinician with basic competencies to one with more advanced competencies requires not only experience but also an ongoing commitment to excellence and self-improvement, which serves as motivation for seeking out new and better ways of conducting assessments and providing treatment services.

7.1 Overview

At some point in their careers, most child health care professionals hear comments like these, uttered by parents who are frustrated by their inability to control their child's behavior. Although there are many possible explanations for viewing a child or adolescent who behaves in this way, such statements often come from parents whose children display features of attention-deficit/hyperactivity disorder (AD/HD; American Psychiatric Association, 1994). Some parents do not know a great deal about the disorder and, therefore, are not inclined to attach such a label. Nevertheless, they know that something is wrong, or at the very least "different," about their child. They might then turn to pediatricians, psychologists, psychiatrists, school counselors, or other health care professionals for further insight and guidance. They might also take the matter into their own hands, searching the Internet for clues about what is wrong with their child and for advice about how to bring about improvements in their child's behavior. Unfortunately,

the guidance that they receive about evaluation and treatment services for AD/HD can vary tremendously from one source to the next.

Why do so many variabilities exist in the assessment and treatment of AD/HD? Some of these variabilities stem from differences in professional training. But knowing whether a person holds an M.D., Ph.D., Psy.D., Ed.D., or M.S.W. tells little about the type of evaluation or treatment a particular health care professional is likely to employ. One's beliefs about the causes of psychopathology in general, and of AD/HD in particular, exert an even stronger influence on his or her approach to the assessment and treatment process. So too does one's level of experience in working with children and adolescents who have AD/HD. Although less obvious, another important element is the degree to which clinicians incorporate methodological rigor into their clinical practice – that is, the degree to which they use evidence-based assessment and treatment approaches. Further complicating matters is that the field is now saturated with a large number and variety of assessment procedures that purportedly measure AD/HD symptomatology, as well as a myriad of intervention approaches for treating AD/HD. Thus, for many health care professionals, deciding which assessment procedures and treatment strategies to employ can be rather confusing, not to mention, overwhelming at times.

So how does one sort through the confusion? In keeping with the theme of this handbook, this chapter addresses the competencies that are important for clinicians to have in order to work effectively and ethically with AD/HD populations. As background for understanding these competencies, this chapter begins with a brief review of the primary symptoms of AD/HD and its associated features. This is followed by a description of the factors thought to cause and/or maintain AD/HD across the life span, after which evidence-based treatment approaches are reviewed. Our current understanding of the conceptual mechanisms by which therapeutic change occurs is then discussed. Against this background, competencies for beginning clinicians, as well as for more advanced clinicians, are presented.

Before proceeding, two caveats are in order. First, while it is recognized that AD/HD affects individuals of all ages, a complete and thorough discussion of competencies across the life span is beyond the scope of this chapter. Thus, for the purposes of this volume, this chapter discusses competencies as they pertain to the clinical management of children. Second, readers need to keep in mind that the competencies outlined in this chapter are not necessarily universally held by all those who deal with AD/HD populations. Some might agree, and some might disagree with what has been proposed. The acceptance or accuracy of these competencies is not what is important here. What is relevant – given that systematic discussion of competencies for assessing and treating AD/HD has not been well addressed in the literature – is that this chapter puts forth a perspective that represents a starting point for discussing what these competencies might eventually be.

7.2 Recognition of Symptoms and Their Assessment

Most health care professionals would agree that developmentally inappropriate levels of inattention, impulsivity, and hyperactivity are the primary symptoms of AD/HD. Despite this consensus, professionals and lay individuals alike are sometimes unclear about what constitutes an AD/HD diagnosis. Some of these uncertainties arise in part from confusion over what is a primary AD/HD feature versus an associated feature of this disorder. For example, while noncompliance and low self-esteem are often associated with AD/HD, neither is a defining feature.

For this reason, clinicians must be thoroughly familiar with items that the field recognizes as primary AD/HD features, as well as those that constitute other disorders. Such symptom descriptions for diagnosing AD/HD appear in the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition (DSM-IV; American Psychiatric Association, 1994).

As defined by DSM-IV, inattention symptoms include the following: failing to give close attention to details or making careless mistakes, difficulty in sustaining attention to task, not listening when spoken directly, not following through on instructions and failing to finish assigned tasks, organizational difficulties, avoiding tasks that require sustained mental effort, often losing things, distractibility, and forgetfulness. Impulsivity may be expressed in terms of blurting out answers to questions before they have been completed, difficulties awaiting one's turn, and often interrupting or intruding on others. Examples of hyperactivity include fidgeting, leaving one's seat when remaining seated is expected, running about or climbing excessively, difficulty in playing quietly, appearing on the go or driven by a motor, and talking excessively.

On the basis of factor analytic results, DSM-IV presents these three primary symptoms in the context of two symptom lists, each of which comprises a total of either nine inattention symptoms or nine symptoms of hyperactivity-impulsivity. Six or more symptoms from at least one list must be occurring frequently and be developmentally inappropriate in order to meet the first of five DSM-IV criteria for establishing an AD/HD diagnosis. The other DSM-IV criteria include: having onset of these symptoms before 7 years of age, displaying some impairment from these symptoms in two or more settings, showing clear evidence of clinically significant impairment in daily functioning, and documenting that these symptoms are not better explained by another condition. Assuming all five DSM-IV criteria are met, an AD/HD diagnosis may be established according to one of three major subtype classifications. If an individual displays six or more inattention symptoms, six or more hyperactive-impulsive symptoms, and all other criteria are met, a classification of AD/HD, Combined Type is established. If six or more symptoms of inattention are present, less than six symptoms of hyperactivity-impulsivity occur, and all other criteria are met, a diagnosis of AD/HD, Predominantly Inattentive Type is appropriate. Conversely, if less than six symptoms of inattention are present, six or more symptoms of hyperactivity-impulsivity occur, and the rest of criteria are met, a classification of AD/HD, Predominantly Hyperactive-Impulsive Type is in order. In clinical practice, most children present with a Combined Type classification, followed in frequency by the Predominantly Inattentive Type classification. The Predominantly Hyperactive-Impulsive Type classification is much less common, occurring most often among preschool age children.

Having AD/HD places individuals at risk for a multitude of psychosocial difficulties across the life span (Anastopoulos & Shelton, 2001). For example, preschoolers with AD/HD place enormous caretaking demands on their parents and frequently display aggressive behavior when interacting with siblings or peers. Difficulties acquiring academic readiness skills may be evident as well, but these tend to be of less clinical concern than the family or peer problems that preschoolers present. As children with AD/HD move into the elementary school years, academic problems take on increasing importance. Together with their ongoing family and peer relationship problems, such school-based difficulties set the stage for the development of low self-esteem and other emotional concerns. Similar problems persist into adolescence, but on a much more intense level. New problems may develop as well (e.g., traffic violations, experimentation with alcohol and drugs), stemming from the increased demands for independence, self-regulation, and self-control that teenagers with AD/HD face.

In addition to being affected by its primary symptoms, children and teens with AD/HD are at increased risk for having secondary or comorbid diagnoses (Jensen, Martin, & Cantwell, 1997). Oppositional defiant disorder is especially common early on, affecting approximately 40% of the preschoolers and elementary school-aged children who have AD/HD. As many as 20–30% of these children will eventually display secondary features of conduct disorder. When AD/HD is accompanied by either ODD or CD, there is also an increased risk for depression and anxiety disorders to be present, especially during adolescence (August, Realmuto, MacDonald, Nugent, & Crosby, 1996). Antisocial personality disorder, major depression, and substance abuse are just a few of the many comorbid problems that may be found among adults with AD/HD (Barkley, Murphy, & Fischer, 2008). In combination with AD/HD, such comorbid conditions increase the severity of an individual's overall psychosocial impairment, thereby making treatment of such individuals more challenging and their prognosis less favorable.

Whether alone or in combination with various comorbid conditions, AD/HD can also have a significant impact on the psychosocial functioning of parents and siblings (Barkley, 2006). Research has shown, for example, that parents of children with AD/HD very often become overly directive and negative in their parenting style. In addition to viewing themselves as less skilled and less knowledgeable in their parenting roles, they may also experience considerable stress in their parenting roles, especially when comorbid oppositional defiant features are present (Anastopoulos, Guevremont, Shelton, & DuPaul, 1992). Parental depression and marital discord may arise as well. Whether these parent and family complications result directly from the child's AD/HD is not entirely clear at present. Clinical experience would suggest that they probably do, at least in part, given the increased caretaking demands that children with AD/HD impose on their parents. These include more frequent displays of noncompliance, related to the child's difficulties in following through on parental instructions. In addition, parents of these children often find themselves involved in resolving various school, peer, and sibling difficulties, which occur throughout childhood and into adolescence as well.

7.3   Maintenance Factors of the Disorder

Several lines of evidence point toward biological factors being involved in the etiology of AD/HD. In particular, research has identified potential abnormalities in brain chemistry (e.g., dopamine deficiencies) and/or function (e.g., diminished blood flow, decreased glucose metabolism) in the prefrontal limbic area of the brain as being the source of AD/HD difficulties (Pliszka, McCracken, & Maas, 1996; Zametkin et al., 1993). Multiple pathways presumably lead to such abnormalities. Among these, genetic mechanisms (e.g., dopamine transporter and receptor gene abnormalities) and certain pregnancy complications (e.g., maternal smoking during pregnancy) likely account for the largest percentage of children who have AD/HD (Biederman et al., 1992; Milberger, Biederman, Faraone, Chen, & Jones, 1997). Some children may acquire AD/HD after birth due to head injury, elevated lead levels, and other neurobiological disturbances. Although helpful in increasing our understanding of how AD/HD arises, such neurobiological findings have yet to translate into the development of reliable and valid procedures for diagnosing AD/HD. Such knowledge has, however, provided a clearer

understanding of why certain evidence-based treatments – in particular, pharmacotherapy – are effective in ameliorating AD/HD symptoms.

Building on what is now known about the biology of AD/HD, recent neuropsychological theories have cast a new perspective on how these presumed biological deficits affect daily psychological functioning (Barkley, 1997a; Nigg, 2001). Common to all of these perspectives is an emphasis on impairment in the neurologically based behavioral inhibition system that sets the stage for impulsivity to occur via disruption of executive functioning. In particular, what seems to be happening is that the part of the brain that allows an individual to stop, delay, or inhibit is not functioning properly because it is underaroused or underactive. Such under-arousal or underactivity is presumably due to the aforementioned diminished availability of dopamine, decreased blood flow, etc. in that part of the brain. This deficit in one's capacity for behavioral inhibition exerts a direct impact on the individual's capacity for executive functioning, including working memory, emotion regulation, and verbal self-regulation functions, as well as a process called reconstitution. Impairment in these various forms of executive functioning is what then leads directly to the expression of AD/HD symptoms, thereby helping to explain the various disruptions in cognitive, behavioral, and social functioning found within AD/HD populations.

In addition to factors that may cause AD/HD symptoms, it is important to consider circumstances that may serve to maintain or exacerbate such symptoms. One such consideration, which is of tremendous clinical utility, is the situational variability of AD/HD symptoms. Contrary to what many believe, AD/HD is not an all-or-nothing phenomenon, either there are all the time or not at all. Research has consistently shown that AD/HD symptoms fluctuate significantly in response to situational demands (Zentall, 1985). These symptoms are much more likely to occur under repetitive, boring, or familiar situations versus novel or stimulating conditions. Symptoms are also much more likely to arise when feedback is dispensed infrequently or on a delayed basis. Presumably due to increased demands for self-regulation, group settings are also far more problematic for children with AD/HD than are one-on-one situations. Another determinant of situational variability is the amount of imposed structure, such that AD/HD symptoms are much more likely to arise when demands are made or rules are in place for behavior. Because children with AD/HD are highly sensitive to such changes in their environment, they often display inconsistency or variability in their performance on school work and chores, both in terms of their productivity and accuracy. Although all children display some variability in these areas, it is clear from clinical experience and research findings that children with AD/HD exhibit this to a much greater degree. Thus, instead of reflecting "laziness," the inconsistent performance of children with AD/HD represents yet another manifestation of their disorder. Put another way, it is not so much that children with AD/HD lack the ability to perform assigned home or school tasks; instead, it is their ability to perform these tasks *consistently* that is problematic. As such, it would seem most appropriate to think of AD/HD as a disorder of performance variability rather than inability.

As noted earlier, individuals with AD/HD frequently display secondary or comorbid diagnostic conditions, such as oppositional defiant disorder conduct disorder, depression, anxiety, or learning disabilities. The reasons why individuals with AD/HD are at increased risk for these conditions are not yet well understood. Thus, little can be said about the factors that serve to cause, maintain, or exacerbate these associated features within an AD/HD population.

7.4   Evidence-Based Treatment Approaches

In view of its chronicity, pervasiveness, and comorbidity, AD/HD is not a condition that lends itself to one-dimensional treatment approaches. To address all of the problems that children and adolescents with AD/HD so often present, clinicians must employ multiple treatment strategies in combination, each of which addresses a different aspect of the child's or adolescent's psychosocial difficulties. Among those treatments that have received adequate or, at the very least, preliminary empirical support are pharmacotherapy, parent training (PT) in contingency management methods, and classroom modifications. Despite such support, these interventions should not be viewed as curative of AD/HD. Instead, their value lies in their temporary reduction of AD/HD symptom levels and in their reduction of related behavioral or emotional difficulties. When such treatments are removed, AD/HD symptoms very often return to pretreatment levels of deviance. Thus, their effectiveness in improving prognosis presumably rests on their being maintained over long periods of time.

Among various evidence-based treatments available for AD/HD, pharmacotherapy is by far the one used most often and for which there is the most empirical support (Greenhill, Halperin, & Abikoff, 1999). Many different classes of medications have been used to treat AD/HD but stimulant medications are generally considered the first line of treatment for this disorder. Many stimulant medications are now available, falling into one of two categories – methylphenidate or amphetamine products. Within these two categories, stimulant medications may be further subclassified in terms of whether they are immediate or extended release in nature. Virtually, all stimulant medications begin working within 30 min of ingestion. Most immediate-release products begin to lose their effectiveness within 3–4 h. Extended-release medications can last anywhere from 6 up to 12 h. Within 24–48 h, traces of stimulant medication generally clear from the body. This helps to explain why stimulants do not need time to build up to a therapeutic level to begin working, and also why they may be stopped for a short period of time and then restarted without difficulty. Most stimulant medications are delivered orally, but a transdermal patch version has recently appeared on the market. The exact manner in which stimulants are delivered into the bloodstream is highly variable, with some medications being dispensed in bimodal bursts, mimicking twice-daily dosaging, while others release more gradually and evenly over the duration of their therapeutic effectiveness.

Perhaps the best known of the immediate-release methylphenidate products is Ritalin, which has been around for quite some time but is no longer used that widely any more. Concerta is the leading extended-release methylphenidate product on the market today. Other extended-release methylphenidate products include Ritalin LA, Focalin XR, Metadate, and Methylin, all of which are ingested orally, along with Daytrana, which is a transdermal patch. For quite some time Adderall XR was the most frequently prescribed extended-release amphetamine product. A recently developed, long-acting prodrug amphetamine product, Vyvanse, is now on the market and being used with increased frequency.

Generally speaking, decreased appetite and decreased need for sleep are the two most common side effects associated with stimulant medication use. Less often, individuals taking stimulants may experience headaches, stomachaches, irritability, and sometimes tics. Recent concerns have also emerged with respect to the impact that stimulants may have on heart rate and blood pressure, primarily among individuals with personal or family histories of cardiac problems.

For those who not respond positively to stimulant treatment, nonstimulant medications may be appropriate. Among these, Strattera (aka Atomoxetine) is by far the one most commonly used, presumably due to its effectiveness in improving attention via its capacity for increasing the availability of the neurotransmitter, norepinephrine. Other alternatives to stimulants include atypical antidepressants, such as Wellbutrin, and to lesser extent, tricyclic antidepressants, such as Imipramine. Antihypertensive medications, such as Clonidine and Guanfacine, have also shown some promise of being effective alternatives to managing AD/HD and its associated symptoms, especially aggression. Unlike stimulants, Strattera and these other nonstimulant medications require time to build up to therapeutic levels in the bloodstream and their half-lives are substantially longer. Moreover, they are not associated with significant appetite problems or sleep suppression side effects. In theory, therefore, they have the potential to provide 24/7 therapeutic coverage. However, evidence in support of this contention is generally lacking.

When used as a monotherapy, stimulant medications have been shown to be effective in up to 80–90% of the child and adolescent population and for a slightly lower percentage of adults (Greenhill et al., 1999). Stimulants work primarily by reducing the severity of AD/HD symptomatology, thereby setting the stage for improved performance in school, at home, and with peers. Such changes in daily functioning do not automatically occur as a result of taking stimulant medication, thereby creating the necessity for other treatments to be used in combination with medication.

Among these, parent training (PT) is certainly worthy of further consideration. Although many different versions of PT exist, most PT programs include training in the use of specialized contingency management techniques, such as positive reinforcement, response cost, and/or time-out strategies (Barkley, 1997b; Cunningham, 2006). Still others combine contingency management training with cognitive therapy strategies and AD/HD-counseling, aimed at increasing parental acceptance, knowledge, and understanding of AD/HD (Anastopoulos, Rhoads, & Farley, 2006). Most of these interventions utilize 8–12 weekly therapy sessions.

Several recent reviews have converged on the same conclusion that PT is an evidence-based approach for treating children with AD/HD (Chronis, Chacko, Fabiano, Wymbs, & Pelham, 2004; Pelham & Fabiano, 2008). Along with traditional group-based approaches, many well-designed case study reports have appeared in the recent literature, lending further support to the efficacy of PT interventions (Chronis et al., 2001). In addition to producing changes in child behavior, PT interventions have contributed to improvements in various aspects of parental and family functioning, including decreased parenting stress and increased parenting self-esteem (Anastopoulos, Shelton, DuPaul, & Guevremont, 1993; Sonuga-Barke, Daley, & Thompson, 2002). Following the lead of Pisterman et al. (Pisterman et al., 1992), many recently published studies have examined the impact of PT on preschoolers with AD/HD (Sonuga-Barke, Daley, & Thompson, 2002; Shelton et al., 2000), thereby emphasizing a more preventive approach.

Information about efficacy of PT also comes from studies in which this form of treatment was combined with other interventions, such as school-based modifications and social skills training (Shelton et al., 2000). Findings from the recently completed MTA study have further shown that the efficacy of psychosocial treatment depends in large part upon the type and context of the outcome being assessed (Jensen et al., 2001; Swanson et al., 2002). When using changes in primary AD/HD symptomatology as a yardstick for therapeutic change, the MTA study found that a rigorously controlled medication regimen was equal to or better than either

a psychosocial treatment package that included a PT component or the combination of medication and the PT-psychosocial treatment package. However, in subsequent analyses that utilized indices of functional impairment (e.g., family functioning) and other ecologically valid measures (e.g., consumer satisfaction) to assess outcome, the combination of medication and the PT-psychosocial treatment package produced therapeutic benefits above and beyond those from medication alone. Moreover, certain types of children with AD/HD, such as those with comorbid anxiety, also seemed to benefit more from the combination of medication and PT-psychosocial treatment versus medication alone.

Along with PT, school interventions are another evidence-based psychosocial approach that may be used in the treatment of children and adolescents with AD/HD (DuPaul & Stoner, 2003). There are many different ways to address AD/HD in the school setting, but most school-based treatments can be conceptualized as falling into one of two categories: antecedent-based strategies (Zentall, 1993) or consequence-based strategies (Pfiffner, Barkley, & DuPaul, 2006). Examples of the former include classroom environment changes (e.g., preferential seating, closed rather than open classrooms), academic task modifications (e.g., color highlighted instructions, shorter assignments, reminder cards taped to desks), computer-assisted instruction, and curriculum changes. Consequence-based strategies, emphasizing positive reinforcement/punishment, may be delivered via token economy systems, sticker charts, or strategic teacher attention. Such treatment programming typically involves only the student with AD/HD and one or more of his or her teachers, but it may extend to other students and to parents as well. Group-based contingency programming involving the entire class is an especially effective way to address the needs of the student with AD/HD without singling out or stigmatizing that student. Classwide peer tutoring is another example of how classmates may be brought into the process of assisting students with AD/HD in a very effective yet naturalistic way. Likewise, setting up a daily report card system that goes back and forth between the classroom and the child's home allows teachers and parents to communicate more regularly and to collaborate more effectively in promoting academic success and behavioral self-control in the classroom.

Much evidence exists in support of using many of the aforementioned school-based interventions for treating AD/HD (DuPaul & Stoner, 2003). As was the case for PT, additional support may be inferred from the results of the MTA study, whose psychosocial treatment component included not only PT, but also a school-based intervention piece. This school-based intervention was delivered in two primary contexts: a behavioral intervention in the classroom by a paraprofessional during the first 3 months of the school year, followed by teacher-administered classroom interventions for the remainder of the school year. When combined with medication, this school-based treatment produced outcomes that were above and beyond that of medication alone.

7.5 Mechanisms of Change Underlying Evidence-Based Interventions

As noted earlier, many experts in the field today view AD/HD as a condition characterized by neurologically based deficits in the process known as behavioral inhibition (Barkley, 1997a; Nigg, 2001). Given that these neurological deficits are thought to arise from genetic abnormalities, prenatal complications, and other biological factors, it is easier to understand why current

treatments do not cure or eliminate AD/HD symptoms and must remain in place in order to be effective. While accounting for this limitation, this same neurobiological–neuropsychological conceptualization also helps to explain some of the mechanisms by which the aforementioned evidence-based treatments presumably exert their therapeutic impact.

A consideration of stimulant medication is the best starting point for discussing this connection. To some, it would appear to be a contradiction to treat AD/HD, a condition characterized by hyperactivity and other self-regulatory deficits, with stimulant medication. After all, why would you want to stimulate someone who is already overstimulated? An answer often given to this question is that stimulant medication has a "paradoxical" effect on individuals with AD/HD. Although intuitively appealing at some level, there is no scientific evidence to support such a conceptualization and therefore nothing could be further from the truth. Instead, findings from both human and animal lines of research converge on the same conclusion, suggesting that stimulant medication does exactly what its name suggests it is supposed to do – that is, stimulate. But in this case, what is stimulated is not the individual's behavior but rather the behavioral inhibition areas of the individual's brain that are underactive, underaroused, and understimulated.

In particular, stimulant medications are thought to be responsible for increasing availability of dopamine and other neurotransmitters in the prefrontal limbic area, the primary locus of behavioral inhibition. With increased availability of these neurotransmitters, neurophysiological functioning (e.g., blood flow, glucose metabolism) in this region of the brain is enhanced, thereby increasing the arousal level of the behavioral inhibition system. As activity level of behavioral inhibition improves, and perhaps even normalizes, it becomes possible for the individual with AD/HD to inhibit behavior more effectively, leading to improvements in working memory and other executive functioning processes. With a greater capacity to delay before responding, to stop in the middle of an ongoing activity, and to block out interference, individuals with AD/HD are thus able to function more normally.

It is primarily in this way that stimulant medication brings primary AD/HD symptoms under better control. And to the extent that primary symptoms interfere less with an individual's functioning, this also helps to explain how stimulant medication can sometimes result in reduced levels of aggression and other features commonly associated with AD/HD. It is important to remember that stimulant medication sets the stage for learning and behavioral control to occur, but does not necessarily guarantee it. For improvements in academic, social, and family functioning to occur with greater certainty, other treatments (e.g., parent training, classroom modifications) often need to be combined with medication management in order to maximize therapeutic outcome.

Although not yet empirically validated, the aforementioned neuropsychological conceptualization of AD/HD (Barkley, 1997a, 1997b; Nigg, 2001) may also have bearing on understanding some of the mechanisms underlying the therapeutic changes brought about by parent training (PT). In particular, to the extent that deficits in behavioral inhibition and executive functioning are central to understanding this disorder, this suggests that children with AD/HD are not very adept at thinking through the consequences of their actions. Such a limitation arises because children with AD/HD are less proficient in their working memory skills, thereby limiting their capacity to reflect back on their learning experiences or to think ahead with respect to future consequences that may follow their behavior. This impaired capacity to regulate behavior relative to time and to anticipate future consequences is of particular relevance. To the extent that the child's awareness of the connection between his or her behavior and

the consequences that are likely to follow can be enhanced, AD/HD symptoms will be less evident, giving way to greater external control, as well as self-control, over behavior. It is in this way, therefore, that PT is thought to reduce the severity of primary AD/HD symptoms as has been reported in the literature.

In addition to facilitating reductions in the severity of primary AD/DH symptoms, PT interventions can lead to improvements in secondary externalizing symptoms, parenting stress levels, parent–child relations, and overall family functioning. To understand how these changes may come about, it is first necessary to consider findings from the field of developmental psychopathology that have implicated the possibility of a developmental pathway, leading from AD/HD to ODD and CD (Loeber, Keenan, Lahey, Green, & Thomas, 1993). If having AD/HD greatly increases the risk of developing ODD/ CD, then it would seem to be of utmost clinical importance to begin treatment as soon as possible to reduce this risk among children not yet affected by these comorbid conditions. Research of this sort has yet to be conducted. However, the fact that environmental factors (e.g., coercive parenting, parental psychopathology, family stress), more so than biological factors, are thought to be intimately involved in the etiology of both conditions (Patterson, 1982) provides some justification for speculating that PT may serve to reduce, or perhaps even prevent, the development of comorbid ODD and CD features among children with AD/HD.

Although not yet widely recognized, cognitive therapy strategies, which are sometimes embedded in PT programs, may be used to alter the way that parents and other family members view a child with AD/HD, as well as their own capacity to parent that child. Such changes may help parents to become more accepting and tolerant of their life circumstances, which presumably may account for some of the reductions in parenting stress levels that have been reported in the literature. Another factor that may contribute to reducing parenting stress may be inferred from a consideration of the fact that PT also serves to address problems that exist in the attachment security, or emotional bonding, between parent and child. Because PT interventions teach parents how to interact with children in more effective and more positive ways, this form of treatment may contribute to improvements in the emotional bonding between parent and child. This in turn would serve to reduce parenting stress and, more generally, to enhance the overall emotional climate within the family. Finally, family systems theory (Minuchin & Fishman, 1981) may provide an explanation for why PT often serves to improve overall family functioning. According to this viewpoint, having a child with AD/HD places the family at increased risk for disruptions in normal family relations. When such circumstances arise, family systems theory would predict that changes in the structure of the family need to occur to normalize family functioning. To this end, PT may strengthen the alliance between parents by teaching them common ways to parent the child with AD/HD. In doing so, both marital and overall family functioning may be enhanced.

Many of the therapeutic benefits resulting from consequence-based interventions in school settings can also be understood in terms of the same conceptual mechanisms underlying the PT effectiveness. For example, just as children with AD/HD are not very adept at thinking through the consequences of their actions at home, they likewise do not think through the consequences of their actions in school. As was true for PT, to the extent that consequence-based treatments can increase the child's awareness of the connection between his or her classroom behavior and the consequences that are likely to follow, AD/HD symptoms are likely to diminish, allowing for greater external control, as well as self-control, over behavior and classroom performance.

Complicating school-based management of AD/HD is that the demands for self-regulation in the classroom are far greater than that typically encountered at home. More specifically, classroom activities occur in a group format and the content of classroom tasks is often highly familiar, repetitive, and potentially boring. Together, such situational circumstances set the stage for AD/HD symptoms to occur. To the extent that these classroom conditions can be altered ahead of time, AD/HD symptoms are less likely to arise. It is in this way that antecedent-based interventions are thought to exert their therapeutic impact in the classroom.

7.6 Basic Competencies of the Clinician

Based upon the preceding discussion, it is now possible to discuss the kinds of clinical competencies that are necessary to evaluate and treat children with AD/HD. This section will begin with a description of basic competencies, after which more advanced or expert competencies will be discussed. Within each of these sections clinical competencies will initially be described in terms of their application to assessment issues, followed by treatment considerations.

In terms of assessment competencies, it is first necessary to make a distinction between a screening assessment and a comprehensive evaluation. For the purposes of screening AD/HD, very few competencies are required. Such a process might merely involve, for example, administering a child behavior rating scale and simply counting up the number of AD/HD symptoms that are present or absent. For purposes of this chapter, clinical competencies will be discussed exclusively in the context of a more comprehensive evaluation that not only evaluates AD/HD concerns, but also addresses features commonly associated with this disorder.

So what are the basic competencies that a clinician should have in order to evaluate AD/HD comprehensively? First and foremost, clinicians need to be aware that there are many different types of clinical and research criteria for diagnosing AD/HD. For example, in addition to the DSM-IV criteria, used primarily in North America, criteria for AD/HD type conditions may also be found in the International Classification of Diseases, Version 10 (ICD-10). Despite availability of these formal criteria, it is not uncommon to encounter clinicians who diagnose AD/HD based on their own idiosyncratic conceptualization of this disorder. This is by no means a minor point and needs to be carefully considered by beginning clinicians. To facilitate communication among practitioners and researchers, it is essential that a common language and common operational definition be used to describe AD/HD and other mental health conditions. Thus, while it can be argued that the DSM-IV is flawed and by no means a perfect system, it nevertheless provides a common operational definition of AD/HD for which there is far more empirical evidence than would be the case using idiosyncratic definitions of this disorder. Thus, the first basic assessment competency involves both an awareness of multiple ways to classify AD/HD and a commitment to use formal diagnostic criteria that are widely accepted within the field.

Another basic competency pertains to one's adherence to these criteria. As was noted previously in this chapter, listed within DSM-IV are five major criteria for arriving at an AD/HD diagnosis. All too often, clinicians may claim to have used DSM-IV criteria when in fact they only used portions of the DSM-IV criteria for making an AD/HD diagnosis. Perhaps the best example of this practice can be found among clinicians who simply count up the number of frequently occurring inattention/hyperactive-impulsive symptoms as a basis for establishing a diagnosis. Although this is certainly an important aspect of making an AD/HD

diagnosis, symptom frequency alone is insufficient for establishing this condition. Counting up the number of symptoms that may or may not be present simply establishes that there is a high level of these symptoms. It does not systematically address the many possible explanations for these elevated symptoms. For example, while high levels of inattention might be due to AD/HD, it is just as likely that they could be due to depression, anxiety, or the secondary effects of learning disabilities. Thus, it is very important for clinicians to address all five criteria for establishing an AD/HD diagnosis in order to ensure that it is AD/HD, and not other conditions, accounting for the observed symptom patterns.

Assuming that one is committed to using formal diagnostic criteria in their entirety, the next basic assessment competency involves the manner in which assessment procedures are selected. Several factors influence this decision-making process. First, as any student in training knows, assessment procedures need to be reliable and valid. Although this may seem self-evident, all too often clinicians select assessment procedures based on their face validity, rather than more sound psychometric considerations. Lessons learned in the classroom about the reliability and validity of measurement devices must therefore be carried into clinical practice. Along with psychometric considerations, it is necessary to choose assessment procedures that yield data that can be mapped onto the DSM-IV criteria for AD/HD. Certain assessment procedures, such as psychological tests, do not yield symptom counts or address the cross-situational pervasiveness of AD/HD symptoms. More generally, there is currently no assessment procedure that addresses the DSM-IV criteria in their entirety. Thus, it becomes necessary to use multiple assessment procedures in combination in order to ensure that enough data are generated to allow for an accurate determination of whether the DSM-IV criteria for AD/HD have been met. Among the many procedures available for this purpose, structured and semi-structured clinical interviews come the closest to meeting this requirement. Child behavior rating scales do a reasonably good job of addressing the DSM-IV criteria, and many psychological tests yield data that have direct bearing on a final AD/HD diagnosis. The point to be made is that clinicians need to be aware of the fact that many assessment procedures are available for evaluating AD/HD and that some are better suited to this purpose than others.

The fact that AD/HD symptoms are subject to situational variability is another factor affecting assessment competence. This is by no means a minor point. The purpose of any psychological evaluation is to gather data that accurately reflect how a person is functioning in real life. Knowing that AD/HD symptoms can fluctuate as a function of changing situational demands, clinicians need to be keenly aware of the conditions under which they are gathering their assessment data. To the extent that conditions in the clinic, for example, are different from conditions in real life, there is an extremely high probability that evaluation data gathered in the clinic may not be a valid representation of what is truly going on in the child's daily life. Thus, clinicians need to be sensitive to this possibility in order to select assessment procedures that capture AD/HD symptoms in a more ecologically valid fashion.

Another important yet commonly overlooked aspect of evaluating children and adolescents referred for AD/HD concerns is that such individuals frequently present with diagnosable conditions above and beyond AD/HD. In fact, research has shown that up to 60% of the clinic referred AD/HD population carries with it one or more comorbid diagnoses. Therefore, an important basic competency for clinicians to have is being aware of this possibility and including assessment procedures to address this possibility.

Likewise, as noted earlier, parents and families of children with AD/HD frequently present with personal and relationship problems of their own. This may include, for example, parental

AD/HD, parental depression, high levels of parenting stress, and perhaps even marital difficulties. Such parent and family difficulties are by no means the cause of the child's AD/HD; they may, however, unintentionally exacerbate existing child difficulties or perhaps even interfere with parental efforts to implement recommended treatments strategies on behalf of their child. For this reason, another important competency for clinicians to have during the evaluation process is an awareness that children with AD/HD function within multiple systems, including the family system. Such systems can exert an influence over the course and severity of the child's AD/HD and/or comorbid features. Thus, clinicians need to be aware of the importance of addressing these parental and family issues as part of their overall evaluation of the child with AD/HD.

Once the assessment process is completed, clinicians may then shift their attention to planning, initiating, and implementing treatment. Ideally, such treatment planning flows smoothly and logically from the results of the completed comprehensive assessment. Knowing whether or not a child has AD/HD, what type of AD/HD, and whether or not comorbid conditions are present is minimally necessary for generating treatment recommendations. To the extent that parental and family difficulties have been identified as well, knowledge of these circumstances may lead to additional treatment recommendations. In short, a fundamental treatment competency is for clinicians to be aware of the fact that they are likely to be treating multiple problems presented not only by the child with AD/HD, but also his or her family.

Related to this competency is the fact that multiple treatment strategies will need to be used in combination to address these multiple problem areas. Thus, a second treatment competency is a recognition of and commitment to a multimodal treatment approach.

Although there is ample research support for multimodal treatment of AD/HD and its associated features, little empirical guidance is available to help clinicians decide which treatments should be used with which children and families under which conditions. In other words, there is no evidence-based formula for deciding how to tailor multimodal treatment to the needs of individual children and their families. To achieve this goal, it then becomes necessary for clinicians to conduct a thorough functional analysis of the child's problems. At a minimum, this would involve determining when and where the child's AD/HD difficulties are interfering with daily functioning. This same strategy, of course, can be used in regard to comorbid features. Conducting this type of functional assessment is extremely important to the overall success or failure of any treatment plan. To illustrate this point, consider for a moment child whose AD/HD symptoms primarily affect home functioning rather than school performance. Clinicians lacking these treatment competencies may mistakenly try to incorporate a one-size-fits-all approach involving the use of stimulant medication. After all, the reasoning goes, if the child has AD/HD and stimulant medication is an evidence-based treatment for AD/HD, then the child should be treated with stimulant medication. The problem with this simplistic approach is that the primary therapeutic benefits of stimulant medication occur during daytime hours when the child is in school rather than in the late afternoons and evenings when the child is at home. Under such conditions, the child in this example would be receiving an evidence-based treatment that would have little impact in the home setting where the child is experiencing most of his or her AD/HD problems. For reasons such as these, an important treatment competency for clinicians is to have the ability to determine the conditions under which evidence-based treatments can be employed most effectively.

As noted earlier, stimulant medication therapy is by far the treatment for which there is the most empirical evidence available to support its use in treating children and adolescents with AD/HD. Physicians, rather than psychologists and other nonmedical model health

professionals, are therefore the only professionals in a position to prescribe this form of treatment. To some, this may suggest that psychologists and other nonmedical professionals need not have knowledge of the various medications that can be used to treat AD/HD. Nothing could be further from the truth. Even though they cannot prescribe, psychologists and other nonmedical mental health professionals should have knowledge of these medications in order to understand how their own psychosocial treatments may be used in combination with pharmacotherapy.

As for implementing parent training and classroom modifications, it is important for clinicians to possess sound training in behavior theory and in applied behavior therapy techniques. Another important treatment competency for clinicians to have is familiarity with the assessment and treatment of oppositional defiant disorder and other childhood conditions that are often comorbid with AD/HD. To the extent that behavioral techniques are taught to parents on behalf of their child, clinicians also need to be tuned into adult psychopathology issues, as parental AD/HD and depression may interfere with efforts to implement recommended parent training strategies. And finally, because many parents ask lots of different questions about AD/HD, it is very important for clinicians to possess competence in their overall knowledge of this disorder and its associated features. This is especially important in order to dispel misconceptions about AD/HD that parents often encounter through their exposure to AD/HD information presented through various media outlets and on the Internet.

7.7 Expert Competencies of the Clinician

Adhering to the DSM-IV criteria for AD/HD in their entirety is an important assessment competence for beginning clinicians to have. More advanced or expert clinicians possess competencies that make for a smoother evaluation process and at the same time address some of the shortcomings in the DSM-IV criteria. For example, beginning clinicians might conduct an interview with a parent of a child suspected of having AD/HD by asking questions that address the criteria for AD/HD in the order in which they are presented in DSM-IV. Thus, the first thing that a beginning clinician might try to clarify is the number of inattention and/or hyperactive-impulsive symptoms that the child seems to be displaying. Next, the beginning clinician might ask about the onset of these symptoms, followed by a question concerning the different settings in which these symptoms occur. Continuing to adhere to the ordering of the DSM-IV criteria, the beginning clinician might then ask about functional impairment issues, etc. While gathering information in this way is technically correct, most advanced clinicians would find this ordering of questions somewhat awkward if not clinically illogical. So while remaining committed to addressing all five criteria for AD/HD, the more advanced or expert clinician might address these criteria in a different sequence or ordering. As would be the case for any other mental disorder, the most appropriate place to start this questioning is to ask about functional impairment. What is the child doing or not doing that causes concern for parents, teachers, or the child himself or herself? The more advanced or expert clinician would also seek to establish objective documentation of this functional impairment, rather than rely solely on subjective parental report. This might include use of school records, psychological test results, and so forth. Once the matter of functional impairment has been established, the advanced or expert clinician might then begin the process of determining whether or not AD/HD symptoms are present that might reasonably account for the impairment in daily

functioning. If so, the expert clinician would then seek to determine whether those symptoms rise to the level of AD/HD in terms of frequency and developmental deviance, as well as fitting the cross-situational, temporal, and exclusionary requirements for this diagnosis. Regardless of the exact order of questioning that is taken, the point to be made is that a more advanced or expert clinician would conduct questioning that addresses all of the DSM-IV criteria in a way that is more clinically meaningful. In so doing, the questioning becomes more comfortable for the parent being interviewed, resembling a conversation one might have in real life rather than a somewhat rigid, mechanistic discussion.

Another assessment competency that is often found among expert clinicians is the manner in which the developmental deviance of AD/HD symptoms is addressed. DSM-IV requires that such deviance be documented but provides no guidance as to how this may be accomplished. One way to do so is to incorporate assessment procedures for which norms are available to draw comparisons between the identified child and that child's age and gender-appropriate comparison group. Whether it involves parent and teacher completed child behavior rating scales or psychological tests, such normed assessment procedures provide the clinician with a relatively more objective determination of the degree to which the child's AD/HD symptoms deviate from what is expected developmentally. Using predetermined cut points (e.g., about the 93rd percentile), expert clinicians may then use evidence of statistical deviation to help them formulate a clinical decision as to whether the criteria for developmental deviance have been met.

Although considered excellent clinical practice, use of assessment procedures that allow for normed statistical comparisons are not without any problems. One commonly encountered shortcoming is the fact that most norms that are available for child behavior rating scales and psychological tests have been constructed using population samples in which minority groups are not well represented. In short, such assessment procedures may be culturally biased and therefore of questionable utility in working with children and families from culturally diverse backgrounds. Advanced or expert clinicians are aware of this possibility and take this into consideration when interpreting findings.

Yet another important distinction between beginning and more advanced clinicians may be seen in their capacity of identifying comorbid conditions. Commonly, beginning clinicians correctly identify AD/HD, but then mistakenly conclude that several other comorbid diagnoses are present. An example of one such combination of comorbid conditions might be oppositional defiant disorder, conduct disorder, separation anxiety disorder, generalized anxiety disorder, and social phobia. For both empirical and conceptual reasons, the likelihood of all of these comorbid conditions occurring along with AD/HD is quite low. Moreover, some of these diagnoses are subsumed by others, as would be the case for conduct disorder superseding oppositional defiant disorder. A more advanced or expert clinician would recognize this problem and aspire to finding a more parsimonious conceptualization of the child's diagnostic status, rather than accepting at face value that all such comorbid diagnoses exist. This diagnostic conceptualization might be simplified, for example, by emphasizing the presence of generalized anxiety disorder and assuming that this condition subsumes the other anxiety conditions. Advanced or expert clinicians also possess the competence that allows them to make sometimes difficult differential diagnoses between AD/HD and overlapping conditions such as bipolar disorder and central auditory processing disorder.

In terms of stimulant medication issues, expert clinicians not only possess the knowledge that allows them to understand how different medications work in conjunction with psychosocial treatment, but also the expertise that can assist prescribing physicians in assessing

the efficacy of their medication trials. Of particular relevance is the expert clinician's familiarity with assessment procedures that can be used in a cost-effective way to assess not only improvements in symptom presentation and performance, but also the possible presence of side effects. Working in collaboration with the prescribing physician, the expert clinician can coordinate dissemination and collection of parent and teacher completed rating scales distributed prior to the start of the medication trial, at the end of different titration periods, and at the completion of the trial. Similarly, the expert clinician may conduct pretrial and posttrial psychological testing using continuous performance tests and other indices sensitive to the effects of medication. Once such data are collected, the expert clinician can summarize and interpret the findings and then offer the prescribing physician an expert opinion as to whether or not there is evidence of a positive response to medication in the absence of significant side effects.

With regard to parent training interventions, advanced or expert clinicians are in an excellent position to supplement what is outlined in the manuals for these treatments. This might include, for example, systematically incorporating cognitive therapy strategies into the delivery of the behaviorally based parent training program. To the extent that expert clinicians can help restructure faulty parental cognitions about themselves or their children, it may then be possible to remove barriers that so often interfere with parental efforts to implement recommended treatment strategies. Perhaps the best example of this type of situation comes from parents who pessimistically state that "my child does nothing right" or that "nothing can help my child." By pointing out data that contradict these perceptions, advanced or expert clinicians can help parents restructure their beliefs about their children and themselves in ways that reduce distress and increase their motivation to comply with the treatment program.

The school setting provides advanced or expert clinicians with additional opportunities for providing helpful consultation that would otherwise be difficult for beginning clinicians to offer. Such expert clinicians would possess intimate knowledge of the rights of children with AD/HD within a particular school system and be thoroughly familiar with the types of regular classroom accommodations and exceptional child services that may be available. Armed with such knowledge, expert clinicians very often can serve to mediate differences of opinion between parents, who want to provide maximum school accommodations for their child, and school staff, who must find a way to balance the needs of individual children against the needs of other children served by the school. In a manner not dissimilar from that working with physicians, expert clinicians can also provide consultation to classroom teachers in setting up daily report card systems and other school contingency management programming, in ways that are tailored to the needs of a child with AD/HD. An example of how this might occur may be found with respect to setting up daily report card systems. In typical daily report card systems, children receive feedback about a particular behavior on one occasion at the end of the school day. Knowing that children with AD/HD function best when feedback is more immediate and more frequent, the expert clinician might suggest to the teacher that feedback about this same behavior be delivered every 30 min, thereby increasing both the immediacy and frequency of the feedback.

7.8 Transition from Basic Competence to Expert

As would be the case for most mental health disorders, the path that one takes from being a beginning clinician with basic competencies to a more advanced clinician with expert

competencies depends heavily on acquired experience. However, clinical experience alone is insufficient to ensure that this pathway leads to its intended goal. Many things need to accompany the experience that is acquired.

First and foremost among these is the clinician's need to maintain a life-long thirst for learning. Aspiring to excellence and adopting an attitude that there is always room for improvement can also serve to motivate a clinician to seek out new and better ways of conducting assessments and providing treatment services. This can be accomplished in part through ongoing reflection and self-assessment. Reading journal articles and book chapters on a regular basis makes it possible to keep up with the AD/HD research literature, from which new assessment ideas and treatment techniques can be put into clinical practice. Another useful way to keep up with changes in the AD/HD field is by attending clinical workshops on the topic. Here, however, is where one needs to keep in mind the admonition: "buyer beware." This is because the marketplace is saturated with individuals and companies offering half-day, full-day, and week-long training seminars on AD/HD. To ensure that they receive training that is up to date and evidence based, clinicians must take a critical look at the credentials of the presenter and then attend only those workshops conducted by reputable clinical researchers in the AD/HD field. Yet another way to improve one's competency level is through peer consultation and review. To the extent that a clinician has ongoing opportunities to discuss clinical matters with colleagues, the more likely it is that self-advancement can occur. For clinicians in academic settings, similar opportunities for self-improvement may arise indirectly from the clinical supervision that they provide to students working under their supervision.

For clinicians whose main vehicle for self-advancement is through the experience they garner in their clinical practice, one additional admonition is worth mentioning; that is, as clinicians begin to acquire clinical experience, there is an immediate and steep increase in their expertise, followed by what might be described as reaching a competency plateau. For many clinicians, reaching this plateau is a signal that expert competency has been achieved. And at times that may indeed be the case. More often than not, however, such a plateau is not really evidence of expert competency, instead a temporary leveling off of clinical skills that is a direct function of the limited number of cases that have been seen. Given the opportunity to see even greater numbers of cases, clinicians are likely to encounter yet another incline in their clinical competence, followed by yet another plateau. In this way, therefore, the path from basic to expert competence is not direct or linear. Instead, more often than not, it occurs in a stepwise fashion. Thus, only with significant increases in the number of cases that one sees can the opportunity for taking the next step be possible.

7.9   Summary

AD/HD is a chronic and pervasive condition characterized by developmentally inappropriate levels of inattention, impulsivity, and/or hyperactivity that cause significant impairment in multiple domains of daily functioning. Symptoms of AD/HD fluctuate as a function of changes in environmental demands and are often accompanied by co-occurring behavioral, emotional, social, family, and learning difficulties. Neurobiological and neuropsychological factors are thought to be involved in the etiology of AD/HD. These same factors help to explain, at least in part, the conceptual mechanisms by which evidence-based treatments for AD/HD presumably work. A great deal of variability exists in the way that various health care professionals provide

clinical services to this population. The source of such variability is not entirely clear but may stem from differences in clinical competency levels across professionals. To the extent that clinicians recognize this distinction and are receptive to the notion of self-improvement, there are many possible avenues by which they may increase their competence in providing both assessment and treatment services to AD/HD populations. Many of these competencies were enumerated in this chapter, but as was stated at the outset, in no way was this listing intended to be definitive or exhaustive. Many other competencies could be added to this list. Thus, for readers who have reached this point in the chapter, it is hoped that their interest has been piqued and that they have been stimulated to think more about clinical competencies as they apply to the clinical management of children with AD/HD.

8 Enuresis and Encopresis

Patrick C. Friman · Kurt A. Freeman

Abstract: In this chapter, we describe the assessment and treatment of enuresis and encopresis. We first review literature on the symptoms, causes, and evidence-based treatments of each condition separately. We also incorporate a discussion of the mechanisms of change underlying effective intervention. Then, using Ryle's (1949) distinction between "knowing how" and "knowing that" as a framework, we discuss the basic competencies one should possess to address these clinical issues. A major reason for distinguishing between the "knowing how" and "knowing that" skill sets is that some clinicians teach and others practice. Based on this framework, we argue that demonstration of basic competency entails the clinician having the skills to conduct effective assessment and treatment of enuresis and/or encopresis, or the skills necessary to tell others (e.g., supervisees) how to do so. These skills include a thorough knowledge of the physiology of urination and defecation, potential pathophysiology of elimination disorders, the ability to effectively interface with medical providers regarding their treatment, and a strong working knowledge of evidence based treatments and their mechanisms of change. In our discussion of expert competency, we use no such distinction between "knowing how" and "knowing that", as an expert should be skilled in both. Further, expert competency in enuresis and encopresis entails the verbal and performance knowledge base to make scholarly contributions to the field, either by conducting one's own research or serving as a consultant to other research programs. Thus, an expert in this area is well poised to contribute to the field of elimination disorders as a master clinician, a specialty supervisor, and/or as a contributing researcher.

8.1 Overview

Child clinical and pediatric psychologists confront a diverse set of problems that challenge children and their families. Often overlooked, but critically important, is the ability to successfully evaluate and intervene the challenges that may, at first glance, seem either medically based or within the realm of "typical" child behavioral problems. Among the most common, persistent, and stressful presenting complaints in primary medical care for children are two disorders involving developmentally inappropriate elimination of waste – enuresis (urine) and encopresis (feces). Evidence of their commonality and persistence is found in prevalence and age-range estimates. Prevalence estimates range as high 2% of 5-year-old children for encopresis and 25% of 6-year-old children for enuresis and, although both are much less prevalent by the teenage years, they are not rare. For example, as many as 8% of boys and 4% of girls are still enuretic at the age of 12 (Byrd, Weitzman, Lanphear, & Auinger, 1996; Foxman, Valdez, & Brook, 1986; Friman & Jones, 2005; Friman, 1986, 1995, 2007, 2008; Gross & Dornbusch, 1983). Nocturnal enuresis (NE) and encopresis usually occur independently, but can co-occur.

While relatively common, elimination disorders are associated with a significant amount of stress. Evidence for their stress inducing properties for parents can be found in the relationship between elimination disorders and child abuse; incontinence is one of its leading causes

(Finn, 2005; Helfer & Kempe, 1976). Evidence is also found in surveys of child reported stress; incontinence is exceeded only by divorce and parental fights (Van Tijen, Messer, & Namdar, 1998). Thus, successful treatment of these disorders can have widespread benefits.

This chapter focuses on the evaluation and treatment of enuresis and encopresis. Although a biobehavioral conceptualization is appropriate for both the conditions, specific physiological and behavioral processes underlying these disorders differ markedly, as do interventions; thus, each disorder is discussed separately. Within the discussion of each disorder, the following issues are addressed: (a) recognition of symptoms and their assessment, (b) maintenance factors, and (c) evidence-based treatment approaches and the mechanisms of change underlying those interventions. Following the description of both the conditions, the knowledge and skill sets needed to establish basic and expert competency in elimination disorders are discussed, followed by the measures one should pursue for the successful transition from basic to expert competence.

8.2   Enuresis

8.2.1   Recognition of Symptoms and Their Assessment

8.2.1.1 Symptom Definitions

The current criteria for enuresis (nocturnal and diurnal) from the *Diagnostic and Statistical Manual, Fourth Edition, Text Revision* (DSM-IV-TR; American Psychiatric Association [APA], 2000) are (a) repeated urination in bed or clothing; (b) at least two occurrences per week for at least 3 months, or a sufficient number of occurrences to cause clinically significant distress; (c) chronological age of 5 years, or for children with developmental delays, a mental age of at least 5 years; and (d) not exclusively owing to the direct effects of a substance (e.g., diuretics) or a general medical condition (e.g., diabetes).

There are three subtypes of enuresis: nocturnal only, diurnal only, and mixed nocturnal and diurnal. There are two courses, primary and secondary. The primary course includes children who have never established continence, and the secondary course involves children who, after establishing continence, resume having accidents.

Even the most conservative research-based estimates show that enuresis is a very common problem, particularly NE. The National Health Examination Survey reported that as many as 25% of boys and 15% of girls were nocturnally enuretic at the age of 6, with as many as 8% of boys and 4% of girls still enuretic at age the of 12 (Gross & Dornbusch, 1983; see also Foxman et al., 1986). Prevalence studies from outside the United States indicate that at least 7% of all the 8-year-old children wet their beds with an approximate 2:1 ratio of boys over girls (Verhulst et al., 1985). Estimates of the percentage of cases of primary NE begin at 80–90% (Friman, 1986, 1995, 2007, 2008; Friman & Jones, 2005; Mellon & Houts, 1995).

8.2.1.2 Evaluation

The initial stage of an enuresis evaluation should include both specific inquiry regarding toileting habits and patterns, as well as general screening for broader child and family variables that

may be of direct or indirect importance. Once those tasks have been completed, a "go no further" maxim should be observed. That is, once the history has been obtained and preliminary psycho-educational information about enuresis has been shared with the parents and the child, the psychologist should go no further with direct treatment until a medical examination has been conducted. As indicated in the etiology section presented later, a number of pathophysiological variables can cause enuresis (see Section 8.2.2), and although these are rare, they may be a possibility and hence, must be ruled out medically before a primary treatment plan is implemented. This emphasis on initial medical examination should not be construed as undermining the role of the psychologist. The medical examination is but one of the numerous components necessary for effective management of enuresis, most of which could (and typically would) be implemented by the psychologist. Effective management involves direct and indirect components, and the medical examination merely precedes the direct components.

While considering the history, the psychologist should include questions derived from the earlier subsection on defining the characteristics (e.g., primary vs secondary) and regarding the etiological factors (e.g., family history of enuresis, disease history, mental health history, etc.) mentioned later. Furthermore, some screening for mental health problems should be included (e.g., behavior checklists, related inquiry). Mental health problems do not appear to have a direct forward causal relationship with enuresis (i.e., they are much more likely to be caused by enuresis than being the cause of enuresis; see Section 8.2.2.7). However, if the child presents with mental health problems, these should be addressed in the ultimate treatment plan.

Particularly, for primary enuresis, which is most often likely to present when children are younger, the evaluator must screen for readiness of the child to master toileting skills. Six areas of readiness should be assessed: (a) physical readiness (e.g., can pull up and down pants, pick up small objects, sit independently), (b) bladder readiness (e.g., dry for several hours), (c) language readiness (e.g., have learned "toileting words"), (d) instructional readiness (i.e., can follow at least one-step commands), (e) proprioceptive readiness (i.e., shows some signs of awareness of need, act, or outcome of urinating), and (f) emotional–social readiness. Generally, success with toilet training is indicated when all the six areas of readiness are intact. However, with regard to some populations (e.g., children with developmental delays), protocols have been developed to assist with toilet training even if all six areas are not intact (e.g., Azrin, 1973; Foxx & Azrin, 1973). Nevertheless, many of these protocols focus on establishing continence with the aid of care givers, rather than independent toilet. In contrast, the goal with typically developing children is to establish independence in toileting habits. Thus, for this population, attention to all of these areas is important.

In addition to addressing the medical and psychological complications, the initial evaluation and early management of enuresis should also address three other very important topics. First, the psychologist should probe all the aspects of the child's life to determine the sources of punishment for wetting, and take steps to neutralize them. This can be accomplished directly by warning the parents to refrain from punishment and indirectly, by educating them that the incontinence is beyond their child's immediate control. Second, the psychologist should assess the motivational level and availability of social resources of the parents. If the parent is minimally motivated and/or has few social resources (e.g., single working parent), then the number of treatment components that they would be able to implement may be limited. Third, the psychologist should assess the motivation of the child. As will be seen in the treatment section, optimal treatment plans involve multiple components and require compliance from the

child for accomplishing most steps. An unmotivated or noncompliant child would be difficult to treat with any method known to cure enuresis. Fortunately, enuresis itself usually contributes to the afflicted child's motivation. As the number of pleasant experiences missed (e.g., sleepovers, camp) and unpleasant experiences encountered (e.g., wetness, social detection, embarrassment) accumulate, motivation typically naturally increases.

8.2.2   Etiological and Maintenance Factors

8.2.2.1 Physiology of Urination

Enuresis (similar to encopresis) involves a composite of physiological and psychological factors, and thus, a full clinical understanding of how it is caused (and treated) requires at least a modest familiarity with its physiology. The bladder, an elastic hollow organ resembling an upside-down balloon with a long narrow neck, is the primary organ in a complex set of physiological systems that govern urination. It has two primary mechanical functions, storage and release of urine (Vincent, 1974). Extended storage and volitional release are the defining properties of urinary continence. The body of the bladder is composed of smooth muscle and its nerve supply is autonomic; thus, it cannot be directly controlled by volitional behaviors – it cannot be "willed" to contract or relax. Nonetheless, continence requires personal control over bladder contraction and relaxation.

Fortunately, there are components of the urogenital system (other than the bladder itself) that can allow such control. These involve three large muscle groups, the thoracic diaphragm, the lower abdominal musculature, and the pubococcygeus (anterior end of the levator ani; Muellner, 1960, 1961). Deliberate urination at all levels of bladder filling involves a coordination of these three groups, resulting in intra abdominal pressure directed to the bladder neck. This coordinated action lowers the bladder neck resulting in reflexive contractions of the bladder body, opening of the internal and external sphincters, and emptying of the bladder.

Urine retention generally involves a reversal of the process described earlier. That is, except during imminent or actual urination, pelvic floor muscles remain in a state of tonus or involuntary partial contraction that maintains the bladder neck in an elevated position and sphincter muscles closed (Vincent, 1974). Even after the initiation of urination, contraction of the pelvic floor muscles can abruptly raise the bladder neck and terminate urination; however, this requires some training and concentrated effort. Optimal bladder training requires detection of bladder filling and either urination in an appropriate location or retentive contraction of pelvic floor muscles (Friman, 1986, 1995, 2007, 2008; Friman & Jones, 2005; Mellon, Scott, Haynes, Schmidt, & Houts, 1997).

Thus, the voluntary components of the bladder system can be used to initiate the involuntary components to achieve urination or continence. Establishing nocturnal continence involves a sequence of continence skills, including awareness of urgency, initiating urination, inhibiting actual and impending urination while awake, and inhibiting actual and impending urination while asleep. Mastery of continence skills requires abundant practice, especially for enuretic children. Optimal bladder training requires detection of bladder filling and either urination in an appropriate location or retentive contraction of pelvic floor muscles (Friman, 1986, 1995, 2007, 2008; Friman & Jones, 2005; Mellon et al., 1997).

Enuresis has a variable clinical presentation, which makes the establishment of its precise etiology a difficult assignment. Not only are its initiating causes and maintaining factors variable and often different from child to child, they can actually differ within the same child at different points of time (Friman, 1986, 1995, 2007, 2008; Friman & Jones, 2005). The etiological variables that have received the most scientific investigation are family history, maturation, functional bladder capacity (FBC), sleep dynamics, physical pathology, psychopathology, and nocturnal polyuria.

8.2.2.2 Family History

Research on family history shows that the probability of enuresis increases as a function of closeness or the number of blood relations with a positive history (Kaffman & Elizur, 1977). It is possible that families convey tolerant attitudes toward bedwetting and not enuretic "genes." However, even in settings where family custom plays a minimal role in child development, there is a high correlation between family history and enuresis (Kaffman & Elizur).

8.2.2.3 Maturation

The possibility of a genetic connection suggests a biologic factor for enuresis, and one plausible candidate for which is maturational lag. For example, children with decreased developmental scores at the ages of 1 and 3 years are significantly more likely to be enuretic than those with higher scores (Fergusson, Horwood, & Sannon, 1986). There is also an inverse relationship between birth weight and enuresis at any age. Enuretic children tend to lag slightly behind their nonenuretic peers in Tanner sexual maturation scores, bone growth, and height (Gross & Dornbusch, 1983). The increased prevalence of enuresis in boys also suggests maturation lag, because boys generally have a slower rate of development than girls throughout childhood and adolescence. Finally, enuretic children exhibit a 15% annual spontaneous remission rate which is consistent with the notion that they are lagging behind in the acquisition of continence, a developmental milestone for all children (Forsythe & Redmond, 1974). Despite the apparent maturational lag in many (perhaps most) enuretic children, their scores on standardized intellectual tests are in the average range. Thus, the maturational lag appears more anatomical and/or physiological than intellectual, and its cardinal expression is delayed bladder control (Friman, 1986, 1995, 2007, 2008; Friman & Jones, 2005; Gross & Dornbusch, 1983).

8.2.2.4 Functional Bladder Capacity

The FBC refers to voiding capacity as distinguished from true bladder capacity (TBC) that refers to the bladder structure (Troup & Hodgson, 1971). The FBC is established in various ways, examples of which include the higher volume in either of the first two voidings after ingestion of a specified water load (e.g., 30 ml/kg body weight), the average of all voidings in 24 h, or the average of all voidings in 1 week. The FBC of enuretic children is generally lower than that of their nonenuretic siblings and peers, but their TBC is about the same. Overall, the research on FBC suggests many enuretic children urinate more frequently with lesser volume

than their nonenuretic peers and siblings. Their urinary pattern has been compared with that found in infants and very young children (Friman, 1986, 1995, 2007, 2008; Friman & Jones, 2005).

8.2.2.5 Sleep Dynamics

By definition, NE is a sleep problem. It is also regarded as parasomnia by most sleep researchers, as a manifestation of sleep disturbance by some sleep researchers, and as an outcome of deep sleep by most parents (Friman, 1986, 1995, 2007, 2008; Friman & Jones, 2005). Still, sleep dynamics have not been established as a cause of enuresis. Wetting episodes occur in all stages of nonrapid eye movement (NREM) sleep, and the probability of their occurrence appears to be a function of the amount of time spent in each stage. Enuretic episodes also rarely occur during REM sleep, therefore, thematically related dreams (e.g., dreaming of urinating) may be a result rather than a cause of wetting.

A final issue pertaining to sleep involves whether it is more difficult to wake up enuretic children than their nonenuretic peers. Generally, findings from most studies are mixed and marred by experimental limitations (e.g., sleep stages not established). A pertinent study with 15 enuretic boys and 18 controls addressed this problem by employing sleep EEGs and auditory tones delivered via earphones (Gellis, 1994). During 512 arousal attempts, the enuretic children awoke 8.5% of the time compared with 39.6% of the time for the controls. Thus, the common parental complaint about bed-wetting children who are difficult to awaken may have an empirical basis. However, the high percentage of the time that children in both the groups did not wake up suggests that being a "deep sleeper" is probably not the primary cause of NE.

8.2.2.6 Pathophysiology

There are numerous well-known potential physiopathological causes of enuresis. These include urinary tract infection, urinary tract anomaly, bladder instability, spina bifida occulta, tethered cord, epilepsy, diabetes mellitus, and sleep apnea. Most of these causes can be ruled out by complete history, physical exam, and urinalysis. When unanswered questions remain, other more elaborate laboratory examinations such as voiding cystourethrogram or polysomnographic evaluation are available (Gross & Dornbusch, 1983). Although these issues are rarely the cause of enuresis, their possibility underscores the importance of thorough medical evaluation before pursuing treatment.

8.2.2.7 Psychopathology

Although remnants of the once prominent (if not dominant) notion that enuresis is a function of underlying psychopathology remain, the majority appears to be that psychopathology is not a causal variable for primary enuresis. The extent of increased behavior problems in enuretic children, may probably be a result of than a cause of enuresis (e.g., Friman, Handwerk, Swearer, McGinnis, & Warzak, 1998; also see, Friman, 1986, 1995, 2007, 2008; Friman & Jones, 2005). Moreover, longitudinal research showing that maturational variables were predictive of

enuresis also showed that psychosocial variables such as emotional disposition were not predictive (Fergusson et al., 1986). A possible exception to the above mentioned observation involves increased emotional problems in children with secondary enuresis. As noted earlier in the physiology section, continence involves skilled practice, and necessary skills can be lost, regained, and lost again. Thus, secondary enuresis, by itself, does not indicate the presence of emotional problems, but major life stressors (e.g., loss of a parent, moving, academic failure) may result in various types of temporary skill loss, including continence skills (Friman; Friman & Jones).

8.2.2.8 Nocturnal Polyuria

The presence of antidiuretic hormone (ADH) or arginine vasopression causes the kidneys to increase the concentration of urine (by increasing the reabsorption of free water in the renal-collecting duct). Theoretically, serum ADH levels increase at night, and thus, protect sleep from urinary urgency and facilitate nocturnal continence. Research has shown that a subset of enuretic children do not exhibit the normal diurnal rhythm of ADH secretion and perhaps, wet their beds as a result of increased urine production while sleeping (e.g., Norgaard, Pedersen, & Djurhuss, 1985). Earlier (and subsequent) related research showed desmopressin (DDAVP), an intranasally administered vasopressin analogue, reduced nocturnal enuretic episodes in children (e.g., Dimson, 1977; and see *Antidiuretics* under Treatment below). However, whether the effectiveness of DDAVP is due to the restoration of insufficient nocturnal ADH or is merely the result of decreased urine volume (due to increased concentration) and thus, not a primary causal variable, is still unknown (Houts, 1991). In fact, evidence for decreased nocturnal ADH as a primary causal variable is still quite limited, for several reasons. The sample sizes in the related studies were small (e.g., Norgaard et al., 1985), less than one-quarter of treated bed-wetting children achieved short-term dryness (Moffatt, Harlos, Kirshen, & Burd, 1993), and not all children with known urine concentrating problems wetted the bed (e.g., only 50% of children with sickle cell anemia are enuretic). Lastly, lower ADH has not been linked in any empirical way to the question on why children do not wake up to full bladders, and not all people (children included) wake up to a full bladder or wet their bed because they do not awake. As indicated earlier, NE is determined based on multiple factors, and abnormality in nocturnal ADH secretion is nothing but one of the several possible causal contributors.

8.2.3 Evidence-Based Treatment Approaches

Treatments for NE predate modern civilization, and for hundreds of years, were focused on punitive and invasive strategies (e.g., penile binding, being forced to wear urine-soaked pajamas – Glicklich, 1951). The evolution of treatment for NE that began in earnest early in the twentieth century abandoned the physically harsh treatments in favor of approaches that were more humane from a physical perspective, but still problematic from a psychological one. Specifically, with the rise of Freudian psychodynamics, psychopathological characterizations of common childhood problems such as enuresis were identified (Friman, 2002). Although more protected from harsh physical treatment than their ancestral peers, early twentieth-century enuretic children were often subject to stigma, isolation, and other negative social consequences.

8.2.3.1 Behavioral Interventions and Their Mechanisms of Change

The advent of behavioral theory and the conditioning-type treatments derived from it, inaugurated a virtual paradigmatic shift in the treatment for enuresis. Specifically, behavioral theory rendered psychopathological interpretations obsolete and aversive physical treatments unnecessary (e.g., Christophersen & Friman, 2004; Friman, 1986, 1995, 2007, 2008; Friman & Jones, 2005). Instead, treatments focused on skills acquisition and conditioning paradigms.

Urine alarm devices. The cardinal conditioning-type treatment for NE has been the urine alarm and, if not the first, certainly the foremost early user of it was Herbert Mowrer (Mowrer & Mowrer, 1938). Since the mid 1970s, psychological research on medically uncomplicated NE in children has been dominated by either the development of alternative behavioral procedures based on operant conditioning or improving urine-alarm treatments (Houts, 2000; Mellon & McGrath, 2000).

The urine alarm uses a moisture-sensitive switching system that, when closed by the contact with urine seeped into the pajamas or bedding, completes a small voltage electrical circuit and activates a stimulus that is theoretically strong enough to cause waking (e.g., buzzer, bell, light, or vibrator). While various types of devices exist, all function in essentially the same way. Specifically, a pad is placed either inside the child's pajamas/underpants or under the sheets of the target enuretic child's bed. The pad typically involves two aluminum foil pads, one of which is perforated with a cloth pad between them. The perforated side is turned toward the child (small pad inside pajamas/underpants) or faces up under the sheets (bed device versions). A urinary accident results in urine seeping through perforations in the top pad, collecting in the cloth pad, and causing contact with the bottom sufficient to complete an electrical circuit and activate an alarm mechanism. Variations in the devices include systems whereby two wire leads connected to an alarm are attached to the child's pajamas/underpants, and the absorption of the urine by the pajamas completes the electrical circuit between the two wire leads and activates the alarm.

Regardless of the system, in principle, the intervention components are the same. Specifically, the awakened child turns off the alarm and completes a series of responsibility training steps associated with the accident, such as completing urination in the bathroom, changing pajamas and sheets, and returning to bed. In practice, the alarm often alerts parents first, who then wake up the child, and guide the child through the training steps (Friman, 1986, 1995, 2007, 2008; Friman & Jones, 2005).

Controlled evaluations of the urine alarm indicate that this relatively simple device is 65–75% effective, with a duration of treatment around 5–12 weeks, and a 6-month relapse rate of 15–30% (e.g., Butler, 2004; Doleys, 1977; Houts, Berman, & Abramson, 1994; Mellon & McGrath, 2000). Further, regarding youth who relapse after an initial course of treatment with the urine alarm, the vast majority respond successfully to additional trials of the intervention (Schmitt, 1984). Most of this research has been conducted using the bed device and, less frequently, the pajama device. Treatment involving the alarm used alone, or in strategic combinations with other treatment components, has been established as "effective treatments" according to the criteria established by the American Psychological Association (Mellon & McGrath). Thus, the urine alarm is a core treatment component that can be augmented by a range of other strategies.

The mechanism of action in alarm-based treatment was initially described as classical conditioning, with the alarm as the unconditioned stimulus, bladder distention as the conditioned

stimulus, and waking as the conditioned response (Mowrer & Mowrer, 1938). More recent literature emphasizes a negative reinforcement or avoidance paradigm (Friman, 1986, 1995, 2007, 2008; Friman & Jones, 2005; Ruckstuhl & Friman, 2003), in which the child increases the sensory awareness to urinary need, and exercises anatomical responses (e.g., contraction of the pelvic floor muscles) that effectively avoid setting off the alarm (Mellon et al., 1997). However, cures are obtained slowly, and during the first few weeks of alarm use, the child often awakens only after voiding completely. Nevertheless, the aversive properties of the alarm inexorably strengthen those responses necessary to avoid it.

Other behavioral interventions. A variety of other behavioral interventions have been described in the literature, none of which appear to be as effective as the urine alarm. However, their combination with urine alarms can be advantageous, and their use may be preferred by some youth despite decreased likelihood of effectiveness (Freeman, 2004).

Retention control training (RCT) has received some attention in the empirical literature as a method of addressing NE. While several variations in specific aspects of RCT have been described in the literature (for review, see Freeman & Dexter, 2002), all the reported protocols generally involve daytime instructions to the enuretic child to delay micturition from the time that he or she first senses the urge to urinate. In this manner, the child learns to increase the amount of urine that can be held in the bladder prior to urination, thus, establishing appropriate inhibitory responses and potentially strengthening the sphincter muscles. In addition to delaying urination, children are typically instructed to increase fluid consumption above normal levels. By doing so, they experience more frequent urges to urinate, providing more opportunities for mastering retention control. The RCT has been shown to increase FBC, as expected, and result in cessation of bedwetting in 30–50% of children (see Freeman & Dexter, 2002).

Another approach that is often utilized is some form of night-waking schedule. With this approach, the youth is awakened (either by an adult or an alarm) at a predetermined time and is prompted to use the restroom. Often, the waking time is systematically altered on the basis of the presence or absence of continence. For instance, if wetting is discovered to occur at approximately 1:00 am, then the initial waking time may be set for 12:30 am. Subsequently, after a specified consecutive number of dry nights, the waking time may be shifted to 1:00 am, and then 1:30 am, and so on, based on the absence of accidents. By systematically shifting the waking time, theoretically, the child is strengthening the inhibitory responses for progressively longer periods of time, potentially decreasing the sensitivity to urine in the bladder and/or strengthening the sphincter muscle. Some evidence suggests that waking schedules may reduce or even eliminate bedwetting episodes (e.g., Bollard & Nettlebeck, 1982). However, others have questioned the effectiveness of this approach. In general, evidence suggests that this approach is less effective than the urine alarm, although it may be a useful component of a package intervention (Warzak & Friman, 1994).

Other interventions that have been described in the literature include reinforcement contingent on continence, self-monitoring, dry bed training, and use of stream interruption exercises (i.e., starting and stopping the flow of urine). Evidence suggests that, although these strategies may be effective in some instances and/or as components of package interventions, they are not as effective as the urine alarm (Friman & Warzak, 1990; Lyman, Schierberl, & Roberts, 1988). Thus, for most youth, they should be considered as an adjunct to treatment.

8.2.3.2 Medications and Their Mechanisms of Change

Imipramine. Historically, tricyclic antidepressants were the drugs of choice for the treatment of enuresis, and imipramine was the most frequently prescribed drug treatment (Blackwell & Currah, 1973; Foxman et al., 1986; Stephenson, 1979). The mechanism by which imipramine reduces bedwetting is still, for the most part, unknown (Stephenson). However, it is important to note that imipramine somehow reduces premature contractions of the bladder following partial filling, thereby increasing FBC (Stephenson).

While imipramine produces initial reductions in wetting in a majority of children often within the first week of treatment (Blackwell & Currah, 1973), therapeutic gain appears to be constrained to only the period when the child is taking the drug. Reviews on both short- and long-term studies show that enuresis usually recurs when tricyclic therapeutic agents are withdrawn. The permanent cure produced with imipramine is reported to be 25% (ranging from 5% to 40%; Blackwell & Currah; Houts et al., 1994). However, we did not find any study that factored in the annual spontaneous remission rate of 15%, which could reduce this already low figure considerably.

More importantly, the use of imipramine does not teach continence skills. In fact, by diminishing bladder contractions, it reduces the opportunities for learning sensory awareness of those contractions and the practice of needed responses. This reduced opportunity to learn may account for the high relapse rate following termination of the medication as well as the reports showing that drug regimens can impair subsequent continence skill-training programs (Houts, Peterson, & Liebert, 1984). Finally, imipramine can cause several untoward side effects ranging in severity, from excessive sweating, irritability, nausea, and vomiting to convulsions, collapse, coma, and death (e.g., Cohen, 1975).

Given its low cure and high relapse rates, side effects, potential to diminish skill development, and potential toxicity, imipramine should not be used as a primary treatment for enuresis. However, as its effects are seen so quickly (when they occur), it can be a valuable adjunct to treatment, especially when other methods are failing and a dry night is needed to heighten motivation, or when a child plans to attend camp or a sleepover (Friman, 1986, 1995, 2007, 2008; Friman & Jones, 2005).

Antidiuretics. As described in the section on nocturnal polyuria, Norgaard et al. (1985) reported on a small number of enuretic children who had abnormal circadian patterns of plasma vasopressin concentration. As a result of these reports and because of its known antidiuretic properties, DDAVP rapidly became a popular treatment for enuresis and has now displaced the tricyclics as the most prescribed treatment. DDAVP concentrates the urine, thereby decreasing the urine volume and intravesical pressure, which makes bladder neck to descent, bladder contraction less probable, and nocturnal continence more probable.

Research on DDAVP has yielded mixed results and a review of the literature indicated that fewer than 25% of children became fully dry on the drug, and, similar to tricyclics, its effects appeared to last only as long as the drug was taken and were less likely to occur in younger children or children who had frequent accidents (Moffatt et al., 1993; see also Houts et al., 1994). In addition, DDAVP is very expensive. Finally, because DDAVP reduces urine output, it also reduces the opportunities to practice continence skills.

Nonetheless, DDAVP typically produces immediate effects. Previous research also suggests that it has fewer side effects than imipramine (e.g., Dimson, 1986; Norgaard et al., 1985),

thus, making it more preferable. However, recent reports by the U.S. Food and Drug Administration (FDA) have raised concerns on the serious side effects of desmopressin distributed in its most popular form – nasal spray. As a result, the U.S. FDA has recommended that the nasal spray form of DDAVP should not be considered as a front-line intervention for NE (US FDA, 2007). This recent recommendation is likely to have a notable impact on the interventions for NE, given the pervasiveness of the problem and the popularity of DDAVP as a treatment. Importantly, pediatric psychologists may be able to successfully capitalize on the gap in treatment options available to medical providers, by offering behavioral intervention services.

8.3 Encopresis

8.3.1 Recognition of Symptoms and Their Assessment

Functional encopresis (FE) is a common, undertreated, and often overinterpreted form of fecal incontinence. Although all forms of incontinence require evaluation and treatment, when left untreated, FE is more likely to lead to serious and potentially life-threatening medical sequelae and seriously impaired social acceptance, relations, and development, than other forms. The reasons for the medical sequelae will be summarized briefly. The primary reason for the social impairment is that soiling evokes more revulsion from peers, parents, and important others than other forms of incontinence (and most other behavior problems). For example, severe corporal punishment for fecal accidents was recommended by professionals in the late nineteenth century (Henoch, 1889). The professional approach to FE has evolved substantially since then, but the approaches by lay persons (and still some professionals) are not keeping pace. Children with FE are still frequently shamed, blamed, and punished for a condition that is almost totally beyond their control (Chrisophersen & Friman, 2004; Friman, 2003, 2007, 2008; Friman, Hofstadter, & Jones, 2006; Levine, 1982).

The definition of FE has remained relatively consistent across versions of the DSM; the DSM-IV-TR (APA, 2000) lists four criteria for FE: (1) repeated passage of feces into inappropriate places, whether involuntary or intentional; (2) at least one such event a month for at least 3 months; (3) chronological age of at least 4 years (or equivalent developmental level); and, (4) the behavior is not exclusively due to the direct physiological effects of a substance or a general medical condition, except through a mechanism involving constipation. The DSM-IV-TR describes two types: primary, in which the child has never achieved fecal continence, and secondary, in which incontinence returns after at least 6 months of continence. Further, one can specify whether encopresis is associated with constipation and incontinence overflow versus that without constipation. Approximately 3% of the general pediatric population meets these criteria.

8.3.1.1 Evaluation

Initial evaluation of FE should include attention to toileting habits, bowel movement frequency, consistency of fecal matter (e.g., hard, packed matter or loose, almost liquid-like diarrhea), and

strategies that parents use to address toileting, more generally, and soiling, more specifically. Further, screening for general emotional and behavioral status, as well as family and parenting characteristics that may be of indirect or direct importance (e.g., harshness in discipline) should be carried out.

Screening regarding bowel movements is somewhat complicated by the lack of empirical evidence regarding the typical frequency of bowel movements in healthy, non-constipated children. Research has shown that, in healthy children, typical colonic transfer time (i.e., the time for matter to travel through one's system from mouth to expulsion) ranges from 25 to 84 h (Wagner, Shankar, Turnock, Lamont, & Baillie, 2004). Thus, one should expect notable variability in the frequency of bowel movements. The clinical convention is often to consider the frequency of bowel movement of every 3 days as the upper limit of normal. Indication that a child is regularly experiencing 3 or more days between the bowel movements is probably a strong sign that constipation is present, showing that decreased motility is occurring.

Similar to enuresis, after initial assessment by psychologist, the plan should follow a "go no further with treatment" maxim until the child has received a medical evaluation. One fundamental reason is the rare but real possibility of organic disease (discussed later). Another is the very serious problem of excessive waste accumulation in an organ with a finite amount of space (i.e., colon). An unfortunate, all too frequent presenting problem in medical clinics is the prevalence of encopretic children who have been in extended therapy with nonmedical professionals whose initial evaluation did not include referral for a medical evaluation, and whose treatment did not address known causes of FE (e.g., diet, behavior, constipation). As a result, the children's colonic systems can become painfully and dangerously distended, sometimes to the point of being life threatening (e.g., McGuire, Rothenberg, & Tyler, 1983).

Estimates of the presence of constipation in children with encopresis range from 80% to 95% (Hatch, 1988; Partin, Hamill, Fischel, & Partin, 1992). For example, in an early study on 102 children with FE, 81 were found to have stool impaction at the time of the first visit. Of these 81 children, 39 were treated for constipation in infancy (Levine, 1975). This fact by itself seriously undermines any general discussion on the psychosocial etiology for FE. In most cases, the parents need to be assured that their child's FE is not their fault and is not caused by a psychological disturbance. The medical examination can contribute substantially to this assurance. The physician will typically take a thorough medical, dietary, and bowel history. In addition, an abdominal examination and rectal examination is often necessary to check for either large amounts of stool or very dry stool in the rectal vault, and to check for poor sphincter tone. Approximately 70% of the constipation can be determined on physical exam, and 90% is apparent from viewing a KUB (Barr, Levine, Watkins, & Mulvihill, 1979), which is a plain abdominal radiological film (focused on the kidney, ureter, and bladder; hence, KUB) and is helpful in determining FE when a fecal mass is not detected during a physical examination, when working with children difficult to treat, such as those who refuse a rectal exam or are obese (Loening-Baucke, 1996).

Some medical conditions (e.g., Hirschsprung's disease), if identified, may preclude referral to a behavioral practitioner. Levine (1981) provided an excellent tabular comparison for the clinician to differentiate FE from Hirschsprung's disease (the most common organic cause for bowel dysfunction that is present from birth), which was reproduced in the work of Christophersen and Mortweet (2001). Additionally, the absence of weight gain in a child who

is below the growth curve for weight may be suggestive of one of the variety of malabsorption syndromes that are known to be present in a small percentage of children (cf. Barr et al., 1979). These possibilities, therefore, necessitate the evaluation by a physician, often a pediatric gastro-enterologist, before embarking on psychosocial interventions.

8.3.2 Etiological and Maintenance Factors

8.3.2.1 Physiology of Defecation

The large intestine or colon is the distal end of the alimentary tract that is sequentially composed of the esophagus, stomach, biliary tract, and the intestines (small and large). The colon is a tubular organ shaped like an inverted 'U' that connects to the small intestine via the ileum, from which it receives nonnutritive (fecal) waste in liquid form. It is best understood in terms of six components, the ascending, transverse, descending, and sigmoid colons, and the rectum and anus. The colon has three major functions: storage of, fluid absorption from, and evacuation of waste. Extended storage and planned evacuation of fecal waste into an appropriate location are the defining features of fecal continence. Evacuation is achieved through a motor function called peristalsis, involving a wavelike motion of the walls of the colon. Retrograde peristalsis in the ascending colon keeps the liquid fecal waste in contact with the walls of the colon that absorb the moisture, resulting in gradual solidification of the waste that begins to move forward as it takes on mass. Movement occurs over an extended period and is stimulated by external events. Examples of these events include gross motor activity, resulting in the orthcolonic reflex, and eating, resulting in the gastro-colonic reflex.

Typically, the rectum contains little or no fecal matter, but when colonic movement leads to contraction of the sigmoid colon, feces are propelled into the rectum and its distension stimulates sensory receptors in the rectal mucosa and the muscles of the pelvic floor. Two muscle-based "switching systems", the internal and external sphincters, regulate the fecal progression from that point. The internal sphincter is involuntary and opens only through the stimulation generated by the process described earlier. As fecal mass distends the rectum, the external sphincter can be manipulated using three muscle groups (thoracic diaphragm, abdominal musculature, levator ani) to start or stop defecation (these muscle groups are also used to start or stop urination). Thus, fecal continence requires appropriate responses to stimulation generated by a waste-receiving organ system. In very general terms, the purpose of fecal toilet training is to acquaint the child with the proprioceptive feedback from the colon and to coordinate the relaxing of the external anal sphincter with the appropriate positioning over a potty chair or a toilet (for additional information on bowel function, see Chrisophersen & Friman, 2004; Friman, 2003, 2007, 2008; Friman et al., 2006; Levine, 1982; Weinstock & Clouse, 1987; Whitehead & Schuster, 1985).

8.3.2.2 Constipation

Constipation affects the delicate system in place to move fecal matter through the final components of the alimentary tract. Specifically, large masses of fecal matter stretch the colon,

reducing the ability of the muscles to engage in peristalsic movements. Further, nerve endings in the colon habituate to the sensation of fecal matter that typically signals the need for peristalsic movements; in other words, the sensation decreases, and thus, the likelihood of experiencing the urge to defecate decreases.

Successful treatment for FE targets the processes that cause the condition, and 90–95% of the cases occur as a function of, or in conjunction with, constipation and fecal retention, and the various behavioral/dietary contributing factors including: (1) insufficient roughage or bulk in the diet; (2) irregular diet; (3) insufficient oral intake of fluids; (4) medications that may have the side effect of constipation; (5) unstructured, inconsistent, and/or punitive approaches to toilet training; and (6) toileting avoidance by the child. Any of these factors, singly or in combination, puts the child at risk for reduced colonic motility, actual constipation, and corresponding uncomfortable or painful bowel movements. Uncomfortable or painful bowel movements, in turn, negatively reinforce fecal retention, and retention leads to a regressive reciprocal cycle often resulting in regular fecal accidents. When the constipation is severe or the cycle is chronic, the child may develop fecal impaction, a large blockage caused by the collection of hard dry stool in the colon. Not infrequently, liquid fecal matter will seep around the fecal mass producing "paradoxical diarrhea." Although the child may actually be constipated, he or she may appear to have diarrhea. Some parents will attempt to treat this type of "diarrhea" with the over-the-counter antidiarrheal agents, which would only worsen the problem. Alternatively, parents may not appreciate the possibility of constipation because their child continues to have bowel movements.

Of note is that a small minority of cases of encopresis do not involve any problems with colonic motility or constipation; they involve regular, well-formed, soft bowel movements that occur somewhere other than the toilet. The process underlying these cases is not well understood, except that they tend to be treatment resistant (Chrisophersen & Friman, 2004; Friman, 2003, 2007, 2008; Friman et al., 2006; Landman & Rappaport, 1985).

8.3.2.3 Developmental and Behavioral Issues

The attainment of full continence is a developmental milestone and thus, FE itself is a developmental issue. In children with general developmental disabilities, the attainment of continence is almost always delayed, although authoritative epidemiological research on the extent of those delays in that population is unavailable. Early descriptive studies describe developmental delay, mental retardation, and/or neurological impairment as a factor in up to 30% of the cases of FE (Wright, Schaefer, & Solomons, 1979). Beyond the possible correlations with learning disability, no research has demonstrated that FE in typically developing children is associated with delays in specific areas of development other than delayed continence.

Historically, the development of FE was believed to be the result of psychopathological processes, particularly in the areas of behavioral and personality disturbance (e.g., Wright et al., 1979). Yet, at least three early studies and one recent study have failed to confirm this position (Cox, Morris, Borowitz, & Sutphen, 2002; Friman, Mathews, Finney, & Christophersen, 1988; Gabel, Hegedus, Wald, Chandra, & Chaponis, 1986; Loening-Baucke, Cruikshank, & Savage, 1987), and instead, show that only a subset of children with encopresis experience clinically relevant emotional or behavioral problems. Thus, as a group phenomenon, the development of FE cannot be traced to psychopathological variables. And the research on positive

behavioral changes following successful treatment suggests that elevated psychological problems, when present, may be more of a consequence than a cause of FE (Levine, Mazonson, & Bakow, 1980; Young, Brennen, Baker, & Baker, 1995).

Yet, there are several caveats to this conclusion. For example, encopretic children with elevated psychological problems are also at risk of treatment failure (Levine & Bakow, 1976; Stark, Spirito, Lewis, & Hart, 1990). This risk may be related to treatment resistance, because a cardinal constituent of any set of child-behavior problems is noncompliance. Because of the physiology of fecal elimination, delays in toileting resulting from resistance can lead to stool retention (see section on physical factors influencing behavior). Early papers on the functional position on FE, as well as the current literature reviews on delayed toilet training, argue that when children are predisposed to constipation, opposition to training can devolve delayed toilet training into chronic FE (Chrisophersen & Friman, 2004; Friman, 2003, 2007, 2008; Friman et al., 2006; Levine, 1982; Levine & Bakow, 1976).

The most recent research involving developmental implications has explored this argument by focusing on delayed toilet training or resistance to it, rather than FE itself. Blum, Taubman, and Osborne (1997) showed that constipation is significantly more prevalent in children who resist fecal-continence training. A subsequent study (Blum, Taubman, & Nemeth, 2004) attempted to determine the functional subcomponents of toilet-training resistance and their association with constipation. The study investigated the relationship between general oppositional behavior, difficult temperament, and child resistance to fecal-continence training. Using a semistructured interview and a specific task (room clean-up) to explore oppositional behaviors as well as a standardized instrument to explore temperament, the results obtained showed no differences in oppositional behavior between children resisting toilet training and those who were fully trained. There was a trend toward a significant elevation ($p = 0.068$) in temperamental difficulties in the children resisting toilet training. A follow-up study investigated the relationship between "stubbornness," a colloquial term for a cluster of temperamentally relevant behaviors, and pediatric constipation. The primary finding was that children exhibiting constipation also exhibited significantly more stubbornness, in general, and toileting-related stubbornness, in particular (Burket et al., 2006).

8.3.2.4 Learning and Modeling

All toileting-relevant behavior occurs in a learning context, and all family members and peers who exhibit such behavior in the presence of an encopretic child serve as possible models. In early attempts to sketch the accounts of FE in learning-based terms, Levine et al. described a developmental trajectory guided forward by disordered defecation dynamics and their subsequent influence on toileting behaviors (Levine, 1982; Rappaport & Levine, 1986). Not surprisingly, the cardinal variable in this account was constipation. The delay was found to increase the difficulty and discomfort that accompanies bowel movements (see section on physical factors affecting behavior), and there are numerous studies showing that effort and discomfort can cause avoidance (Friman & Poling, 1995). Avoidance of discomfort associated with bowel movements negatively reinforces toileting resistance. In turn, successful toileting resistance leads to stool withholding, which has the same effects on bowel movements as constipation itself, and thus, it is possible that the resistance rather than the constipation is the more important consideration. However, research on this question has suggested that constipation usually

precedes toileting refusal, and thus, it is more likely to be the primary influence. Other research has shown that children who resist toilet training often have histories of painful bowel movements and/or constipation (Luxem, Christophersen, Purvis, & Baer, 1997; Taubman, 1997).

The account offered by Levine includes other types of experiences that contribute to the learning-based dimensions of FE (Levine, 1982; Rappaport & Levine, 1986). These include an array of events that are potentially aversive, but which are also often a part of the toileting training process. For example, children sitting on an adult toilet with unsupported feet can experience discomfort in their legs. Children may experience aversive levels of vulnerability, if they are required to have a bowel movement away from home. To avoid such experiences, children may forestall the urge to defecate and in so doing, retard the natural progression of the peristaltic process leading to situational constipation. There are several other possible experiences, such as inconsistent schedules, family strife, inconvenient bathrooms, and isolation, and all these can have learning-based influences on toileting and thus, on the possibility of FE.

8.3.2.5 Parental Issues

As parents (or primary child caregivers) are responsible for toilet training, they are inextricably involved in their children's failure to attain continence. This failure can be attributable to a broad range of variables ranging from parental abuse and neglect to inability to effectively manage protracted constipation and extreme child resistance. To date, these variables have been the subject of conceptually and clinically derived descriptive accounts, much more than they have been the object of focused research (e.g., Levine, 1982; Rappaport & Levine, 1986; Schaefer, 1979). Although no scientific evidence exists for extreme attributions about parental involvement in FE found in psychodynamic accounts (e.g., mothers domineering and lacking warmth, fathers ineffectual and bossy), clearly, parents can play an important role in the development and progression of FE as well as its sequelae. For example, incontinence has been described as a leading cause of child abuse (Helfer & Kempe, 1976). More frequently, it can lead to parental responses that, although not abusive, are indeed punitive. A common diagnostic question in the assessment of FE is whether the target child ever attempts to obscure evidence of accidents (e.g., hides underwear), and it is often answered in the affirmative (Levine, 1982). Such behavior is the result of punishing experiences that were initiated by the parents, although not always intentionally. For example, parents faced with their children's unexpected fecal accidents may unintentionally express disappointment or frustration, which in turn could have punitive effects on children who want nothing more than to please their parents. However, clearly, the punitive response to fecal accidents is sometimes intentional. For descriptions of how such responses may come about, refer to selected early accounts of FE (e.g., Levine, 1982; Rappaport & Levine, 1986; Schaefer, 1979).

A parent variable that has some empirical support involves the extent to which parents bring their children under effective instructional control. One of the prerequisite skills necessary for successful toilet training is the child's ability to follow multiple one-step commands. The skill is needed, because toilet training is a complex process, and training episodes, especially in the early stages, require multiple parent-issued, child-followed instructions. Children may be developmentally capable of following such instructions, but reluctant to do so owing to general oppositionality, aversion to toileting, or both. To contend with such problems, parents must be able to bring about good child compliance (i.e., training) with toileting-based

instructions. Related research shows that parents of children at risk for FE owing to toileting refusal have significantly more difficulty in setting limits and establishing instructional control than those of children who are not at risk (Taubman, 1997).

8.3.2.6 Life Events

The alimentary system is exquisitely sensitive to life events and because fecal elimination is the terminal response of the system, it is also highly responsive to these events. However, beyond psychosocial issues that affect the quality of toilet training (e.g., poverty, size of family), life events are much more likely to contribute to secondary than primary FE. For example, a study on classification of incontinence (Fritz & Anders, 1979) showed a large increase in the onset of secondary FE in children who had recently experienced a stressful life event (e.g., hospitalization, parental separation).

8.3.2.7 Genetic Influences

In contrast to the substantial literature on the genetics of enuresis, there is only limited literature on the genetics of FE, which is dated. For example, Bellman (1966) reported that 15% of the fathers of the children in her study had a history of FE. Furthermore, Abraham and Lloyd-Still (1984) reported that 55% of their chronically constipated patients had a positive family history of constipation. Despite the design limitations and time period of these studies, the results suggesting positive family history in the development of FE, at a minimum, seem to supply an inducement to study genetic influences further.

8.3.2.8 Drugs Affecting Behavior

There are a number of medications prescribed for children that can influence elimination. For example, most prescription level medications for pain relief, and especially those that involve opiates or their derivatives, can cause constipation. In addition, most antibiotics can cause temporary diarrhea. Antidepressant medications, especially those involving selective serotonin-reuptake inhibition, can cause either diarrhea or constipation. However, all these medications are accompanied upon receipt with a thorough and minutely detailed description of side effects, and those that involve the GI tract will almost certainly be familiar to the prescribing physician. Rather than going into further detail here, the most useful advice is to incorporate caution about medications and their influence on fecal elimination, and clarify any doubts with the supervising physician.

8.3.2.9 Cultural and Diversity Issues

There is much less epidemiological research on FE than on NE. Presently, there is virtually nothing to be found in the peer reviewed literature on cultural issues, beyond the occasional suggestion that FE is more likely to be found in families with lower incomes. Yet, even this

suggestion has been dismissed as inaccurate and based on biases in populations sampling (Fritz & Armbrust, 1982). However, some early research on prevalence indicated that FE is much more frequent in boys than in girls with the ratios ranging from 3:1 to 6:1 (e.g., Fritz & Armbrust; Wright et al., 1979). Some of the relevant research was conducted in foreign countries (e.g., Stockholm; Bellman, 1966), but the samples were primarily Caucasian from industrialized cultures and thus, not substantially different from the populations studied in this country.

8.3.3   Evidence-Based Treatment Approaches

Although the child is the target of treatment, the parent (or primary caregiver) is the delivery agent and thus, the primary recipient of the information about the treatment. Discussing treatment in general terms with the child while expressing optimism about the outcome is a good practice. Additionally, any punitive parental responses toward fecal accidents, intentional and unintentional, should be terminated immediately. Requesting a related promise from the parent in the presence of the child can increase the child's interest in participation. Treatment is subsequently laid out in a series of steps. Numerous protocols and variations in treatment have been described in the literature (e.g., Levine & Bakow, 1976; Stark, Owens-Stively, Spirito, Lewis, & Guevremont, 1990; Stark et al., 1997; Taubman, Blum, & Nemeth, 2003; for summaries, also see McGrath, Melton, & Murphy, 2000; van Dijk, Benninga, Grootenhuis, Onland-van Nieuwenhuizen, & Last, 2007). Evidence from existing research supports an approach that involves (a) education about the physiological and learning variables associated with toileting, (b) disimpaction, (c) increased structure surrounding toileting activities and use of motivational strategies, (d) dietary and fluid intake interventions, and (e) maintenance of interventions.

8.3.3.1 Demystifying FE

During or immediately following the evaluation, the entire elimination process including its disordered manifestations should be "demystified" (Levine, 1982). The belief, from longstanding characterological and psychopathological perspectives on FE, that bowel retention and bowel accidents are generally associated with personality development, and specifically, with characteristics such as stubbornness, immaturity, or laziness, can result in parents shaming and blaming their children to make use of the bathroom. However, a disordered process of elimination such as FE should no more be a target for censure and blame, but should be a disordered process of respiration, digestion, or motor movement. As indicated earlier, the literature does not reflect a significant association between psychological profiles and child bowel problems.

8.3.3.2 Bowel Evacuation

The primary goal of FE treatment is the establishment of regular bowel movements in the toilet, and the first step is to cleanse the bowel completely of the resident fecal matter. A variety of

methods are used, the most common of which involve enemas and/or laxatives. Although the therapist can assist with the prescription of these (e.g., with suggestions about timing, interactional style, behavioral management), the evacuation procedure must be prescribed and overseen by the child's physician. Typically, evacuation procedures are conducted in the child's home, but severe resistance can necessitate medical assistance, in which case they must be completed in a medical setting. The ultimate goal, however, is complete parent management of evacuation procedures, because they are to be used whenever the child's elimination pattern suggests excessive fecal retention.

8.3.3.3 Toileting Schedule

The parent and therapist should choose a regular time for the child to attempt bowel movements. The time should not be during school hours, because unpleasant social responses to bowel movements in the school setting can cause regressive responses to treatment (e.g., retention). Choosing among the times that remain (morning, afternoon, or evening) should be guided by the child's typical habits and child–parent time constraints. Establishing a time shortly after food intake can increase chances of success through the influence of the gastrocolonic reflex. In the early stages of treatment or in difficult cases, two scheduled attempts a day (e.g., after breakfast and dinner) may be necessary. The time the child is required to sit on the toilet should be limited to 10 min or less, to avoid unnecessarily increasing the aversive properties of the toileting experience. The child's feet should be supported by a flat surface (e.g., floor or a small stool) to increase comfort and maintain circulation in the extremities, and knees should be bent at approximately 90% angle, to facilitate the abdominal push necessary to expel fecal matter from the body. The time should also be unhurried and free from distraction or observation by anyone other than the managing parent. Allowing the children to listen to music, read, or talk with the parent can improve the child's attitude toward toileting requirements. Generally, toileting should be a relaxed, pleasant, and ultimately private affair.

8.3.3.4 Response to Toileting Efforts

If the child has a bowel movement in the toilet, he or she should be praised. In the early stages of treatment, it is also helpful to have a reward system in place. An easy system involves a dot-to-dot drawing and a grab bag. The child identifies an affordable and desirable prize, and the parent draws (or traces) a picture of it using a dot-to-dot format with every third or fourth dot bigger than the rest. The child connects two dots for each bowel movement in the toilet and when the line reaches a larger dot, they earn access to a grab bag with small rewards (e.g., small toys, edibles, money, privileges). When all the dots are connected, the child earns the prize (Jenson & Sloane, 1979; also see Chrisophersen & Friman, 2004; Friman, 2003, 2007, 2008; Friman et al., 2006). For children who are resistant to various aspects of the toileting process (e.g., sitting, taking medicine) or for whom producing regular bowel movements has been severely disrupted owing to persistent constipation, it may be advisable to develop a reward system, whereby completing each component of the treatment (e.g., sitting, taking medicine) earns connections, while some acts (e.g., defecating in the toilet) warrant connecting more

dots. If such a system is developed, then the larger dots that lead to the grab-bag prizes should be distributed farther apart. A less elaborate, more naturalistic, but also more time-intensive procedure, involves the provision of special time. For example, following successful toileting, a child might be allowed 10–15 min of special time with a parent, during which the child is allowed to choose the activity (Christophersen & Mortweet, 2001). If the child does not have a bowel movement, his/her effort should be praised and another session should be scheduled for later in the day. Regardless of the specific reward system pursued, the goal remains the same: to create motivation for completing toileting-related activities and the benefit for successful defecation.

8.3.3.5 Response to Accidents

Accidents should not be the object of punishment or criticism. However, the child should participate in cleaning up the mess that has been made. With younger children, this may merely mean bringing soiled clothing to the laundry area and allowing themselves to be cleaned by the parent. With older children, it may mean managing entire mess themselves including doing the laundry and cleaning themselves. Children should earn praise and rewards for any bowel movements in the toilet, even if they had a prior accident.

   However, in treatment resistant cases, mild aversive consequences are sometimes used. Although there is limited documentation of their effects, there is ample evidence of their use. One example, a procedure called positive practice, involves intensive practice of appropriate toileting behaviors following detection of an accident (e.g., a series of "dry run" trips to the bathroom from locations near the detection of the accident; see Christophersen & Mortweet, 2001). Another example, for which a small amount of data has been published, involves a response cost procedure – using small tokens to reward toileting success and withdrawal of tokens (i.e., small "fines") for accidents (Reimers, 1996). Again, for children resistant to various aspects of treatment (e.g., taking prescribed laxative), mild aversive consequences may be applied to instances of noncompliance. Any use of mild aversive consequences should always occur in the context of a comprehensive intervention that includes specific reward strategies.

8.3.3.6 Cleanliness Training

Successful toileting is a complex arrangement of small tasks, and the two tasks that are critical to overall success but often overlooked in fecal incontinence programs are wiping and flushing. The therapist should provide the parents instructions on how to motivate and teach children to complete these tasks. Direct instruction to the child regarding methods of wiping, as well as the importance of persistence in wiping until the paper is free from fecal matter is often important.

8.3.3.7 Monitoring

Frequent monitoring accomplishes at least three goals, early detection of accidents, assessment of progress, and multiple opportunities for praise. Two levels of monitoring are usually

employed. The first involves regular "pants checks" that result in praise when pants are accident-free, and carrying out the procedure for accidents described earlier when they are not. One should consider the developmental age of the child when determining whether the pant checks are completed by the parent (younger child), or are prompted by the parent for completion by the child (older child). The second involves a record completed by the parent that documents toileting successes and accidents, and the size and consistency of both. The latter record is made easier by providing the parent with a user-friendly data sheet.

8.3.3.8 Dietary Changes

As discussed in the section on underlying processes, diet often plays a causal role in FE, and dietary changes are almost always a part of treatment. One of the keys to establishing full fecal continence is a regular diet with a high level of dietary fiber. Fiber increases colonic motility and the moisture in colonic contents and thus facilitates easier and more regular bowel movements. To aid the parents in increasing the fiber content in their child's diet, an educational handout can be helpful (e.g., see Christophersen & Mortweet, 2001). Dietary changes can also be enhanced with over-the-counter preparations with dense fiber content (e.g., Benefiber, Metamucil, Perdiem). Further, while not empirically demonstrated to be a necessary component of treatment, increasing fluid intake is often prescribed in conjunction with high-fiber foods (e.g., Stark et al., 1990, 1997).

8.3.3.9 Facilitating Medication

Successful treatment for FE will almost always require inclusion of medications that soften the fecal matter, ease its migration through the colon, and/or aid its expulsion from the rectum. The decision to use medication and the type used should be made by the consulting physician; however, the therapist can inform the decision and educate the parent about its use. Generally, it is best to avoid interfering with the sensitive biochemistry of the alimentary system, the colonic portion of it in particular, and thus, inert substances are usually used. Formerly, the most frequently used substance was mineral oil, used either alone or in combination with other ingredients such as magnesium. As indicated, prescription of the substance is the physician's prerogative, but ensuring compliance with the prescription is typically a psychological task. Children will often resist ingesting substances with odd tastes and textures. Therefore, to gain their cooperation, it is often necessary to mix the substances with a preferred liquid (e.g., orange juice) and follow ingestion with praise, appreciation, and possibly, a reward. A recent development, however, has made this task even easier, while also improving the outcomes for children with FE. Polyethylene glycol (trade name, Miralax) is an odorless, tasteless powdered laxative that can be mixed with food or liquid with limited possibility of child detection, and it has produced excellent results in treatment of childhood constipation and FE, and is increasingly becoming the preferred medical treatment option (e.g., Bishop, 2001; Pashankar & Bishop, 2001). Further, its transition to an over-the-counter medication has increased its accessibility.

A more invasive substance involves glycerin suppositories. Some physicians prescribe these because their use increases the predictability of bowel movements and reduces the likelihood

of an out-of-home accident. When prescribed, suppositories should be used in the following sequence. Prior to the meal closest in time to the regularly scheduled toileting, the child should attempt a bowel movement. If successful, regular procedures are followed and no suppository is given. If unsuccessful, a suppository should be introduced by the parent in the meal eaten by the child, and another attempt should be made after the meal. The combination of the gastro-colonic reflex initiated by the meal, and the lubrication and mechanical stimulation provided by the suppository is usually sufficient to induce a bowel movement. Despite these advantages, inserting suppositories into a child's body can engender resistance, and in such cases, the therapist can assist the process by teaching the child on how to relax under stressful circumstances, and the parent on how to use instructional and motivational procedures to enhance compliance.

8.3.3.10 Fading Facilitative Medication

Being aware that medication is the area of the physician, therapists can assist with its use by establishing methods to ensure it is taken (as stated earlier), and design systematic steps for its ultimate withdrawal. Obviously, partnership with the consulting physician is necessary in both the cases. Before pursuing fading-out medications, it is important to ensure that *both* regular bowel movements of sufficient size and continence occur for successive days, to ensure that the child is not inadvertently becoming constipated via withholding so as to avoid accidents.

A frequently used withdrawal method is to eliminate the medication on one day a week contingent, upon a series of consecutive accident-free, toileting success days (e.g., 14 days). The child is allowed to choose the day on which to do so. If another similar series of accident-free days occurs, another day is chosen. If the child has an accident, then the medication is replaced on one day. The parent and the child go back and forth inside this system, until the medication is completed faded out.

8.3.3.11 Treatment Resistance

As indicated earlier, in some cases, direct FE treatment may be forestalled by, or conducted in conjunction with, the treatment for the resistance (e.g., with instructional control training, and/or psychotherapy). However, some treatment-resistant cases involve abnormal defecation dynamics (e.g., rectal distension, decreased sensitivity), much more than abnormal externalizing or internalizing behavior problems. For these cases, various forms of biofeedback have been used to increase awareness and establish bowel habits (e.g., Loening-Baucke, 1990).

8.3.3.12 Intervention Delivery Approaches

Treatments for encopresis have been shown to be effective when delivered to individual children and families (see McGrath et al., 2000 for review), as well as through group therapy (Stark et al., 1990, 1997). Recently, Ritterband et al. (2003) demonstrated that an internet-based method of delivering behavioral interventions for encopresis may be a useful adjunct to management by

primary-care physicians. While more questions need to be answered regarding child and family characteristics influencing the effectiveness of delivering intervention via the internet, these preliminary data provide evidence for a method of treatment with potential for easy and wide distribution.

8.3.4   Mechanisms of Change Underlying the Intervention

Comprehensive treatment of FE addresses both biological and behavioral influences of the condition. Various medical and dietary interventions are employed to treat the primary underlying cause of FE in 90–95% of cases, which is constipation. Regular passage of fecal matter allows the colon to resume proper shape and sensitivity to the presence of fecal matter. As this may take time, prescribing physicians may recommend that a child continue medications for a sustained period before gradually reducing the dose. Strategies used to promote regular and easily passed bowel movements also aid in avoidance learning processes that may contribute to stool withholding. Specifically, softening of the stool via medications or dietary means leads to the passage of bowel movements that are not painful. This can serve as a counter-conditioning experience, whereby the passage of feces is disassociated with pain, thus, decreasing the likelihood of future avoidance attempts.

While medical and dietary interventions are important for the treatment of FE, effective management and behavioral strategies are critical for the ultimate success. Specifically, structuring toileting experiences (e.g., scheduled sits) and behavioral-management strategies facilitate the (re)learning on the part of the child, to initiate specific toileting behaviors in response to physical signs of impending bowel movements, provide motivation to leave current activities to enter into the bathroom to attempt a bowel movement, and assist in teaching children the benefit of avoiding accidents through correct defecation.

8.4   Basic and Expert Competencies of the Clinician

There are myriad ways to describe basic and expert competencies for clinicians confronted with either of the major incontinence disorders, enuresis and FE. For this discussion, we will use the epistemological distinctions offered by Gilbert Ryle (1949) in his classic book, *The Concept of Mind*. Ryle distinguished between "knowing how" and "knowing that." More colloquially, he distinguished between knowing how to do something and knowing how to say what is or must be done. Verbal humans possess multiple capacities for describing performances that they are unable to execute competently. For example, most golfers know they should keep their head down and eye on the golf ball when they hit it with their club. That is, they are able to describe to themselves or others that this must be done. Few golfers, however, are able to actually do it with any degree of consistency. Conversely, all humans possess the capacities for performances that they are unable to describe verbally. A classic example of this was offered by the former Supreme Court justice, Felix Frankfurter, who reported that he knew pornography when he saw it but he could not put it into words. Other examples include initiating physical activities such as yawning or crying. Performing these activities is a simple affair; but describing how to initiate them, challenges even the most sophisticated physiologist.

8.4.1   Basic Competencies of the Clinician

Using Ryle's distinction as a guide, we assert that the basic competencies of the clinician involve either being able to assess and treat enuresis and FE effectively, or being able to describe how they should be assessed and treated. In other words, the basically competent clinician should have the skills to conduct effective assessment and treatment or tell the persons how to do so. Knowing how to tell others to conduct assessment and treatment comprises the "knowing that" skill set. Knowing how to actually conduct assessment and treatment comprises the "knowing how" skill set. Although there is obviously an intersection between the two skill sets, they are also independent from each other in important ways. For example, as stated earlier, when first faced with questions about treating enuresis or FE, ensuring that a medical evaluation has occurred is critical, before moving forward with direct behavioral or psychosocial interventions. A clinician possessing the "knowing that" skill set would be able to competently and persuasively tell others (e.g., students, parents) about the importance of the evaluation. A clinician possessing the "knowing how" skill set would be able to contact the physician, schedule the appointments, consult on tests needed, and possibly even attend and participate in the evaluation (both authors have attended and participated in numerous evaluations). As a more general example, a clinician possessing the "knowing that" skill set would be able to competently verbally convey all the assessment and treatment options for enuresis and/or FE described in this chapter. Included in this skill set would be the capacity to convey information that does not directly pertain to implementation of treatment (e.g., etiology, probability of success, behavioral mechanisms responsible for change). A clinician possessing the "knowing how" skill set would be able to actually conduct all the assessment and treatment options discussed in this chapter. Although exhibiting the "knowing how" skill set in its entirety would rarely be necessary when working with children and caregivers on an outpatient basis (e.g., parents would regulate fluid intake, modify diet, fasten alarms, facilitate toilet sits, etc.), it may often be necessary when working with children in inpatient or residential care programs.

A major reason for distinguishing between the "knowing how" and "knowing that" skill sets is that some clinicians teach and others practice. The teachers may be excellent at teaching and deficient at practice. Conversely, the practitioners may be excellent at practice and deficient at teaching. Both, however, are capable of exhibiting core basic competencies. Some clinicians are able to do both extremely well and we will use this comprehensive level of competency as the defining feature of expert competency in the subsequent related section. Another reason for using the distinction is that although a degree of teaching is needed in most cases (e.g., teaching parents how to use the urine alarm), in some cases, the clinician may be required to conduct treatment himself or herself (e.g., with clients who are inpatients or in residential care).

As indicated earlier, there is an intersection between the "knowing that" and "knowing how" skill sets. As a prime example, basically competent clinicians must be able to characterize enuresis and FE as biobehavioral conditions. Prolonged urinary or fecal incontinence, not caused by disease or other physiopathic variables, can easily lead caregivers and even medical and psychosocial professionals to assume that the accidents are caused by psychopathological factors. As was noted earlier, enuresis and FE are biobehavioral conditions, and psychological constructs such as psychopathology are rarely relevant (Friman, 1986, 1995, 2002, 2007, 2008; Friman & Jones, 2005). A related basic competency is to assess the notions (e.g., held by parents, children, students, professionals) on causes of enuresis and/or FE, so as to address inaccuracies.

Educating persons who are confronted with enuresis and/or FE to think about either conditions as a biobehavioral problem can move them toward workable solutions (e.g., proprioceptive cues of impending defecation have been disrupted owing to persistent constipation), and away from unconstructive and potentially harmful psychological or characterological interpretations of afflicted children's behavior (e.g., child is lazy). As may be evident, Ryle's distinction is pertinent here as well. Knowing that caregivers and children must be persuaded to adopt the biobehavioral model is a core basic competency. Furthermore, knowing how to persuade them to do so is also a core basic competency. It is not difficult to imagine persons who would be good at one and not the other. Ideally, they would be good at both, but this would be evidence of expert, not basic, level competency, which will be discussed later.

Another basic competency common to "knowing that" and "knowing how" skill sets involves eliminating caregiver's use of punishment, shaming, or blaming for toileting-related issues. Owing to frustration with perpetuated incontinence, coupled with the belief that the afflicted child is fully capable of controlling urination and/or defecation, caregivers can resort to harsh judgments and punitive consequences. However, rather than being helpful, harsh and/or punitive approaches are more likely to lead to additional undesired behavioral side effects, such as untruthfulness about the occurrence of accidents, refusal to discuss toileting-related topics, avoidance of bathroom-related activities, and unwanted emotional responses. These side effects can, in turn, exacerbate caregiver frustration and intensify harsh punitive approaches to the incontinent child. Punitive approaches can, in turn, worsen the behavioral side effects exhibited by the child. In other words, a punitive approach can lead to a reciprocally devolving process, resulting in avoidance of effective treatment by incontinent children and their caregivers. Therefore, knowledge pertaining to the importance of eliminating punishment is a core, basic competency. Although knowledge about the problems with punishment is a generic basic competency, the Rylean distinction also applies. Being able to describe punishment in its obvious and not so obvious forms, as well as the reasons it should not be used, comprises one dimension of the core competency. Having the facility to fully dissuade the caregivers from using it comprises the other.

Core basic competence related to the treatment of elimination disorders also requires a thorough appreciation for queries to be used, to assess the medically informative details about toileting habits (see ❯ Table 8.1 for example questions). Inquiry about specific elimination patterns and habits is informative, for two primary reasons. First, if the child is yet to see a pediatric healthcare provider regarding the elimination problem, answers to these questions may be provided to the healthcare worker to assist with medical diagnosis. Psychology clinicians should avoid presuming that a thorough medical examination has been completed, and thus, offering some initial assistance in this area to inform the healthcare provider can be useful. Second, even if it is determined that elimination problems are not related to an underlying physiological problem, knowledge about their presence may inform selection of behavioral interventions. For example, a child who presents with sudden, strong urges to urinate during the day with limited ability to delay micturition may benefit from RCT, in addition to interventions to directly treat bedwetting. Again, the distinction between "knowing that" (i.e., being able to describe the importance of and type of questions one should ask about elimination habits) and "knowing how" (i.e., being able to successfully gather pertinent information in a manner that is useful for medical providers) is relevant.

Familiarity with patterns of responsiveness to behavioral interventions is also important for a clinician with basic competence. Unlike medications used to treat enuresis and physiologic

🔷 **Table 8.1**

Sample questions to investigate the possible biological influences on enuresis and encopresis

Enuresis
1. Does your child ever dribble in his or her pants during the day?
2. Does your child need to go more frequently than you think is normal? Can your child delay urination for a period of time after sensing the urge without having an accident?
3. Does your child complain that it doesn't feel like he or she has completely emptied his or her bladder when finished?
4. Does your child ever complain of burning when he or she urinates? Have you ever noticed any irritation around the end of his penis or her meatus?
5. Has your child ever had a work-up for a urinary tract infection or any other urinary problem?

Encopresis
1. How often does soiling happen? Does it occur at the same time each day?
2. Describe the consistency of accidents and bowel movements (e.g., hard/pebbles, soft, runny).
3. How often does your child have a bowel movement? How long has this pattern been present?
4. When your child has a bowel movement, does it smell worse than it should?
5. Does your child have a history of painful bowel movements?

components of encopresis (i.e., constipation), behavioral interventions typically require implementation for a period of time before improvement is observed. However, understanding that signs of progress may be apparent even before a decrease in the frequency of accidents is evident can assist the clinician in offering guidance to children and families. For example, a study using measures of the size of urine spots, instead of the more conventional counts of wet versus dry nights, showed that urine-alarm treatment produced gradually but steadily shrinking urine spots (Ruckstuhl & Friman, 2003). This novel approach to assessing the effects of alarm treatment allowed researchers, parents, and their bedwetting children in treatment to readily observe the progress leading up to continence. There are often other signs of preliminary progress with both enuresis and encopresis prior to cessation of accidents, which are more subtle (e.g., forward movement of the urine accident in time, say from 10:30 pm to 1:30 am; increased frequency of bowel movements indicating successful treatment of constipation, while frequency of accidents remains unchanged), and thus, may require explanation from the clinician. The ability of a clinician to help youth and parents recognize and appreciate the signs of progress, despite continued accidents, is critical for ensuring persistence with treatment. This area of basic competence pulls from both the "knowing that" skills (i.e., staying abreast of research findings) and "knowing how" skills (i.e., being able to communicate findings in a clinically relevant and family-friendly manner).

8.4.2   Expert Competencies of the Clinician

Expert-level competency is easier to define than basic competency, because it is all inclusive and requires no complex philosophical distinctions. The expert knows how to fully describe enuresis and/or FE including, for example, the physiology of urination or defecation, prevalence

rates of urinary and/or fecal incontinence, the composition of comprehensive assessments, a broad range of treatment options and the relative levels of empirical support for them, the behavioral mechanisms underlying the effects of treatment, and the methods establishing and maintaining motivation to participate in treatment. More generally, the expert would be able to describe about all the information on enuresis and/or FE.

In addition to their ability to fully describe either or both conditions, the expert also knows how to conduct assessments and implement treatment, as well as how to train others in doing so. In other words, an expert clinician would have fully mastered the "knowing that" and "knowing how" skills, and can successfully implement both. Expert clinicians are able to easily transit between the roles of teacher (e.g., of medical students, graduate students) and provider working with families. As such, achieving expert competence in elimination disorders makes the practitioner highly desirable for a variety of contexts (e.g., medical school/university hospital, pediatric practice office, private practice).

Finally, owing to the broad range of verbal- and performance-based knowledge of incontinence, the expert is also able to consult to relevant research programs or conduct them himself or herself. As expert competence would include fluency in both biomedical and psychosocial aspects of elimination disorders, the expert focused on a scientific perspective may be well prepared to expand the scientific basis for the biobehavioral perspective on incontinence. While much research has been conducted in the area of elimination disorders, particularly with NE, still much remains to be investigated (e.g., treatment options for individuals who fail to respond to established treatments; treatment preferences of families and children; models of treatment delivery that lead to optimal outcome, such as pediatric primary care versus specialty care). Thus, novice child psychologists could establish a pediatric dimension to their careers by developing expertise in elimination disorders, as this area presents rich opportunities for clinical and/or scientific contributions.

8.5   Elimination Disorders: Transition from Basic Competence to Expert

While the specific pathophysiology and behavioral variables affecting enuresis and encopresis are different, the process of transitioning from basic to expert competence is similar for both the conditions. That is, to establish basic competence for both the conditions, one needs to develop a full appreciation and understanding of the combined biobehavioral aspects, become comfortable in behavioral strategies for supporting medical recommendations (e.g., addressing adherence, creating long-term maintenance plans), and be prepared to provide prescriptive interventions to address relevant treatment issues (e.g., parental use of punishment, child-generalized noncompliance). Clinicians for whom the goal is to establish basic competence in the treatment may wish to emphasize either "knowing how" or "knowing that" skills, based on their professional roles and likely interactions with the subject matter. For example, a university-based professor engaged in graduate training may emphasize on skills pertinent to effectively describing issues related to the assessment and treatment of elimination disorders. Emphasis on these skills is likely to result in successful training within a classroom environment. Conversely, a clinician working in a pediatric setting may chose to place emphasis on "knowing how" skills, and be less concerned with his or her ability to train others (beyond parents and families) in the care of youth with elimination disorders.

Establishing expert competence involves combining multiple skill sets related to (a) providing direct services to youth with elimination disorders, (b) consulting with others (e.g., medical professionals), (c) training the next generation of psychologists and other health-care providers (e.g., medical students) to provide appropriate care, and (d) conducting research on issues pertinent to the care of youth with elimination disorders. Achieving successful expert competence is demanding and is probably influenced by a variety of factors (e.g., working in a setting that supports endeavors in all arenas). Further, establishing expertise in this area is likely to require the pursuit of specialized education beyond that typically offered in psychology graduate training programs. Thus, reviewing medically oriented journals, attending either specialized psychological or medical conferences, and establishing collaborative relationships with existing experts are all recommended for the transition from basic to expert competence.

8.6   Summary

Elimination disorders are a prevalent concern for many children, and persistent elimination problems are often associated with a significant amount of distress for children and their families (e.g., Van Tijen et al., 1998). Increasing number of child psychologists with biobehavioral expertise in the assessment, treatment, and scientific study of enuresis and FE would correspondingly increase the probability that the psychosocial dimensions of both the conditions would be successfully addressed in practical settings and productively studied in research settings. The biomedical aspects of both the conditions have been reasonably well understood and competently addressed in the medical settings for many years. The psychosocial aspects, however, have often been misunderstood and undertreated, overtreated, and unfortunately, mistreated, even in the professional settings, and the gap in the knowledge and expertise underlying this state of affairs has only recently begun to be filled. Psychologists with basic and expert level of biobehavioral competencies are not only important, but are actually necessary to advance this progress, so that it parallels the success already obtained in the biomedical domain.

9 Tic and Habit Disorders

Christine A. Conelea · Benjamin T. P. Tucker · Douglas W. Woods

Abstract: Repetitive behavior disorders, including tic and habit disorders, are thought to be relatively common among children and adolescents. Tic disorders are characterized by repetitive, sudden movements and/or vocalizations that are seemingly purposeless in nature. Habit disorders are typified by repetitive behaviors focused on the body and include trichotillomania, skin picking, nail biting, thumb sucking, and cheek chewing. Although these disorders may in some cases be benign and short-lived, clinical attention may be needed for children experiencing psychosocial impairment, physical damage, or emotional distress. The current chapter provides an overview of these disorders, their diagnostic assessment, and their purported etiology. Next, evidence-based psychosocial treatments for tic and habit disorders are described. The final portion of the chapter discusses the basic and expert clinician competencies needed to treat tic and habit disorders. Basic competencies include the ability to accurately implement function-based interventions and Habit Reversal Therapy, while expert competencies generally involve the ability to modify treatment for complex or non-responsive cases. The chapter concludes with suggestions to aid a clinician in the transition from basic to expert competence.

9.1 Overview

9.1.1 Tic Disorders

Tic disorders are characterized by repetitive, sudden, and seemingly purposeless motor movements and/or vocalizations. Tics can range from simple behaviors that go unnoticed by the casual observer (e.g., forceful eye blinks or throat clearings) to highly conspicuous and complex vocal and motor patterns (e.g., complete words and phrases or complex hand gestures). Tics are commonly found in pediatric populations, with recent epidemiological studies finding tics in 17–21% of children (Kurlan et al., 2002; Peterson, Pine, Cohen, & Brook, 2001). Estimates of the prevalence of Tourette Syndrome (TS), the most severe tic disorder diagnosis, are relatively varied. However, recent research indicates a prevalence of 0.15–1.1% in school-aged children, and a male to female ratio of 4:1 to 6:1 (Coffey et al., 2000; Kadesjö & Gillberg, 2000).

Tic disorders typically develop during early childhood and tend to follow a waxing and waning course, with symptom characteristics changing over time. The onset usually occurs between the ages of 5 and 8 years (Jagger et al., 1982; Leckman, King, & Cohen, 1999; Peterson et al., 2001). Simple motor tics in the head and face region usually appear first, and may be followed by the development of motor tics in the mid-section and extremities, vocal tics, and complex tics (Jagger et al.; Leckman et al., 1999). Also, most children eventually develop bodily sensations (i.e., premonitory urges) preceding their tics, which may be relieved upon tic occurence (Leckman, Walker, & Cohen, 1993; Woods, Piacentini, Himle, & Chang, 2005). Symptoms tend to reach peak severity around the ages of 10–12 years, followed by a steady decline and minimal symptoms as the adolescent reaches adulthood (Bloch et al., 2006; Coffey

et al., 2000; Leckman et al., 1998). Adults who retain TS diagnostic status tend to be the most severe patient population (Leckman et al., 1999).

Children with tic disorders often experience impairment in psychosocial functioning and psychiatric comorbidity. Obsessive-compulsive disorder (OCD), attention-deficit/hyperactivity disorder (ADHD), anxiety, mood, and disruptive behavior disorders commonly co-occur and are more likely to be seen in children with tic disorders than those without (Kadesjö & Gillberg, 2000; Kurlan et al., 2002). Presence of comorbidities contributes significantly to negative psychosocial outcomes, but the tics themselves also have been found to be related to negative peer perceptions, poorer social desirability, more negative family functioning, and lower academic performance (e.g., Boudjouk, Woods, Miltenberger, & Long, 2000; Packer, 2005; Stokes, Bawden, Camfield, Backman, & Dooley, 1991; Wilkinson et al., 2002; Woods, 2002).

9.1.2   Habit Disorders

Habit disorders are characterized by body-focused repetitive behaviors (BFRBs), such as hair pulling, skin picking, nail biting, thumb sucking, and cheek chewing. With exception of hair pulling, which may be diagnosed as trichotillomania (TTM), formal diagnostic categories for most BFRBs do not exist and are usually considered stereotypic movement disorders (SMD).

The BFRBs appear to be relatively common among children and adolescents. In many children, these behaviors can be relatively benign and short-lived. However, others will experience significant physical and psychological impairment. Prevalence estimates of BFRBs in children are relatively sparse and mostly limited to hair pulling. An epidemiological study of hair pulling among youth found a lifetime prevalence of 1% and current hair pulling in 0.5% (King, Zohar et al., 1995). It has been suggested that 20–60% of post-preschool age children bite their nails (Friman, Byrd, & Oksol, 2001). In adults, pathological skin picking has been found in approximately 2% of dermatology patients (Griesemer, 1978) and 4% of college students (Bohne, Wilhelm, Keuthen, Baer, & Jenike, 2002; Keuthen et al., 2000). However, skin picking has been relatively under-studied in child populations.

Retrospective reports by adults with BFRBs indicate a typical onset during childhood. The average age of onset for TTM is in early adolescence (around the ages of 12 and 13 years; Christenson, Mackenzie, & Mitchell, 1991; Cohen et al., 1995) and is 15 years for skin picking (Wilhelm et al., 1999). Adults with other BFRBs also report onset during childhood (Croyle & Waltz, 2007). However, these behaviors may begin at any age, with reports ranging from <1 year to late adulthood (Christenson et al., 1991).

The BFRBs can cause significant tissue damage (e.g., skin lesions and hair loss) as well as impairment in functioning and quality of life. Individuals with BFRBs commonly report elevated levels of depression, anxiety, and stress; and low self-esteem, shame, and impairment in social, home, and occupational functioning (Croyle & Waltz, 2007; du Toit, van Kradenburg, Niehaus, & Stein, 2001; Flessner & Woods, 2006; Stemberger, Thomas, Mansueto, & Carter, 2000; Woods et al., 2006). Those presenting with pathological BFRBs commonly meet the criteria for additional psychiatric diagnoses. Depression, anxiety, substance-use disorders, eating disorders, body-dysmorphic disorder, and personality disorders are the most common (Christenson, 1995; Christenson et al., 1991; Wilhelm et al., 1999). Little is known about

comorbidity in children with BFRBs. However, small clinical samples of children with TTM have identified comorbid psychiatric conditions in the majority of subjects, with depression, anxiety, and disruptive behavior disorders being especially common (Hanna, 1997; King, Scahill et al., 1995; Reeve, Bernstein, & Christenson, 1992).

9.2 Recognition of Symptoms and Their Assessment

A comprehensive clinical assessment of tic and habit disorders includes gathering information (a) for differential diagnosis, (b) to describe symptom topography, (c) to ascertain maintaining factors, (d) to determine functional impact, and (e) to examine possible comorbid conditions.

9.2.1 Tic Disorders

The DSM-IV-TR (American Psychiatric Association, 2000) includes four tic disorder diagnoses: TS, chronic motor or vocal tic disorder (CMTD, CVTD), transient tic disorder (TTD), and tic disorder not otherwise specified (TDNOS). TS is characterized by the presence of at least two motor tics and at least one vocal tic at some point during the client's life, with daily or intermittent occurrence for more than 1 year, during which there may not be a tic-free period lasting for more than 3 consecutive months. The onset must occur before the age of 18 years. Criteria for CMTD and CVTD are identical to TS, except that only motor or vocal tics, but not both, are present. TTD may be diagnosed if tics occur many times a day, nearly everyday for at least 4 weeks, but no longer than 12 months. TDNOS is reserved for presentations that do not meet the criteria for a specific tic disorder (e.g., onset after the age of 18 years or tics lasting less than 4 weeks; American Psychiatric Association).

In conducting a differential diagnosis, the clinician should be aware of conditions that have presentations similar to tic disorders. For instance, symptoms of OCD can resemble complex tics (e.g., repetitive touching and tapping). In these cases, it is important to determine whether significant anxiety and obsessions (e.g., a feared consequence for not performing the behavior) precede the target behavior, in which case, the movement or vocalization may be a symptom of OCD. A SMD may also appear similar to a tic disorder and should be considered if a pervasive developmental disorder is also present and/or the movements appear rhythmic, intentional, and self-soothing. In some cases, it will be necessary to refer the client to a neurologist or psychiatrist to rule out alternative neurological conditions (e.g., Sydenham's chorea or Huntington's disease) causing the movements suspected as tics.

The clinician should list each tic and gather detailed information on its topography, frequency, intensity, functional interference, controllability, and associated premonitory urge phenomena. The use of self-report instruments (e.g., The Yale Tourette Syndrome Symptom List-Revised; Cohen, Detlor, Young, & Shaywitz, 1980; The Parent Tic Questionnaire; Chang, Himle, Tucker, Woods, & Piacentini, in press; The Premonitory Urge for Tics Scale; Woods et al., 2005) and semistructured clinical rating scales (e.g., The Yale Global Tic Severity Scale; Leckman et al., 1989) can facilitate this process and should be delivered throughout the course of treatment. The clinician should also conduct a functional assessment by interviewing the child and the parent/guardian regarding environmental antecedents and consequences

(e.g., parental reaction to tics and stressful and anxiety-provoking situations) that may play a role in tic maintenance. A thorough diagnostic assessment of other psychiatric disorders should be included, because frequently comorbid conditions (e.g., disruptive behavior disorders, ADHD, and anxiety) can be more impairing than the tics themselves (Kadesjö & Gillberg, 2000).

9.2.2 Habit Disorders

As discussed previously, the DSM-IV-TR does not include diagnoses for specific BFRBs, with the exception of hair pulling which may be diagnosed as TTM. Criteria for TTM include (a) recurrent pulling out of one's hair causing noticeable hair loss; (b) an increased sense of tension immediately before pulling or when attempting to resist pulling; (c) pleasure, gratification, or relief during pulling; (d) the behavior not better explained by another mental disorder (e.g., OCD or a psychotic disorder) or medical condition (e.g., alopecia); and (e) the pulling that causes clinically significant distress or impairment (American Psychiatric Association, 2000). However, in the case of a child, a diagnosis may still be warranted even in the absence of criteria (b) and (c), because a young client may be unable to verbalize these feelings, and a large percentage of youngsters with significant hair pulling do not report associated tension and/or gratification (American Psychiatric Association; Hanna, 1997). A SMD diagnosis should be considered for patients presenting with other BFRBs. The essential features of a SMD are a repetitive, seemingly driven, nonfunctional motor behavior that interferes with functioning or causes physical injury requiring treatment (American Psychiatric Association). If mental retardation is also present, the behavior must be severe enough to become a focus of the treatment (American Psychiatric Association). Again, one should also rule out other medical or psychiatric conditions as the cause of the behavior or the observed tissue damage. Other possible psychiatric diagnoses to consider include body dysmorphic disorder, psychotic disorder, and OCD.

Prior to beginning treatment, it is essential that the clinician gathers detailed information on the topography of the BFRB, severity of symptoms, and environmental antecedents and consequences. It is helpful to establish operational definitions of the BFRB by asking the client to describe the ways in which they perform the behavior (e.g., the use of fingernails to pick skin, or tweezers to pull hair) and the bodily location(s) on which it occurs. Measures of symptom severity should also be taken throughout the course of treatment to evaluate treatment progress. However, to date, the only severity measure for child and adolescent populations with acceptable psychometric characteristics is the Trichotillomania Scale for Children, which includes a child- and parent-report version (TSC; Tolin et al., 2008). A detailed functional assessment of the BFRB of interest should be conducted to facilitate treatment planning. Furthermore, detailed information should be gathered on the environmental situations and internal events (e.g., body-related cognitions or negative affect) that precede the target behavior as well as its consequences (e.g., reduction of negative affect affect or pleasurable bodily stimulation). It is also important to examine the areas of life impacted by the behavior (e.g., impairment in home and school responsibilities, peer relationships, and general well-being and quality of life). Finally, a thorough assessment of possible comorbid disorders should be included, since, like tic disorders, symptoms of other disorders (e.g., depressive symptoms) may be more impairing than the habit itself (Diefenbach, Tolin, Hannan, Crocetto, & Worhunsky, 2005; Keuthen et al., 2004).

9.3 Maintenance Factors of the Disorder or Problem

9.3.1 Tic Disorders

Symptoms of tic disorders are maintained by both underlying neural dysfunction and environmental antecedents and consequences that develop tic-controlling properties (Himle, Woods, Piacentini, & Walkup, 2006).

Research on the biological bases of tic disorders has focused primarily on the role of cortical-striato-thalomo-cortical (CSTC) circuits and the neurotransmitter dopamine (DA). The CSTC circuits are involved in the planning, modification, and initiation of motor movements, and the involved brain structures communicate through DA and other neurotransmitters, such as glutamate and gamma-aminobutyric acid (GABA). It has been proposed that tic disorders arise and persist because of excessive excitation and decreased inhibition in cortical regions involved in CSTC circuits and increased DA production and receptor sensitivity (see Leary, Reimschisel, & Singer, 2007 for a review).

Tics arise from dysfunction in these brain structures and neural circuits and may be influenced and partially maintained by internal and external environmental events and consequences. Perhaps, the most frequently examined environmental factor in the maintenance of tic disorders is the premonitory urge. Premonitory urges seem to develop after the initial appearance of tics (Leckman et al., 1993) and may eventually develop controlling properties over the tics themselves, as the reduction or removal of the urge following a tic can function as a negative reinforcer (Himle et al., 2006; Woods et al., 2005). As will be discussed later in this chapter, decreasing the premonitory urge's control over tics potentially is an important mechanism of change in successful behavioral treatment.

A number of other environmental antecedents and consequences seem to play a role in the waxing and waning pattern of tic disorders, and to a certain extent, the maintenance of the disorder itself. Antecedent variables such as presence of others, social situations, tic-related talk, and emotional distress have all been associated with increases in tics (O'Connor, Brisebois, Brault, Robillard, & Loiselle, 2003; Silva, Munoz, Barickman, & Friedhoff, 1995; Watson & Sterling, 1998; Woods, Watson, Wolfe, Twohig, & Friman, 2001). Consequence variables such as social attention and tangible reinforcers have also demonstrated controlling properties over tic frequency (Watson & Sterling, 1998; Woods & Himle, 2004).

9.3.2 Habit Disorders

Less is known about the etiology of habit disorders than that of tic disorders. However, like tic disorders, BFRBs seem to be maintained by environmental antecedents and consequences. Mansueto, Stemberger, Thomas, and Golomb (1997) have proposed a behavioral model of TTM, in which conditioned stimuli associated with the urge to pull, discriminative stimuli for pulling itself, various behaviors associated with pulling, and reinforcing consequences for pulling all play a role in TTM maintenance. Many of these factors have been supported by subsequent research and seem to play a role in the persistence of TTM and other BFRBs.

Most attention has been given to the reinforcing effects of BFRBs and their role in the persistence of the behavior. Research using both self-report and experimental designs has suggested that BFRBs often result in decreased tension, anxiety, and boredom (Diefenbach,

Mouton-Odum, & Stanley, 2002; Diefenbach, Tolin, Meunier, & Worhunsky, 2008; Wilhelm et al., 1999). Other researchers have emphasized the role of positively reinforcing consequences in BFRBs. Individuals often report increased pleasure and satisfaction while engaging in a body-focused habit (Diefenbach et al., 2008; Wilhelm et al., 1999), and subsequent behaviors such as manipulating pulled hair with one's hands or mouth can be positively reinforcing (Mansueto et al., 1997; Rapp, Miltenberger, Long, Elliot, & Lumley, 1998). The tendency to perform BFRBs in a conscious, goal-directed manner (e.g., to achieve a reinforcing consequence) has been termed "focused" pulling/skin picking (Christenson et al., 1991; du Toit et al., 2001; Flessner et al., 2007; Walther, Flessner, Conelea, & Woods, 2009).

The BFRBs can also be maintained owing to their occurrence outside of one's awareness. It is quite common for sufferers to report engaging in the behavior while distracted by a different activity (e.g., reading or watching TV) and realizing what has been done only after seeing the product of the behavior (e.g., the accumulation of pulled hair). This behavioral style has been termed "automatic" pulling/picking, and the extent to which automatic pulling/picking occurs varies across individuals (Christenson et al., 1991; du Toit et al., 2001; Flessner et al., 2007; Walther et al., 2009).

9.4   Evidence-Based Treatment Approaches

9.4.1   Tic Disorders

Although the mainstay of tic disorder treatment is pharmacotherapy, a growing body of support exists for psychosocial treatments, particularly Habit Reversal Training (HRT). There is also limited support for the use of an adapted version of Exposure and Response Prevention (ERP).

HRT is a multicomponent behavioral treatment package designed to (a) increase the client's ability to detect tics and their warning signs; (b) teach the client a behavior that is incompatible with the tic (i.e., a competing response) that can be performed following a tic or a warning sign; (c) enhance motivation to practice the techniques and recruit social support; and (d) provide for the generalization of tic awareness and competing response performance to the everyday environment (Azrin & Nunn, 1973). Commonly used techniques include awareness training, self-monitoring, competing response practice, relaxation training, contingency management, and tic inconvenience reviews (Azrin & Nunn, 1973; Azrin & Peterson, 1990; Wilhelm et al., 2003; Woods et al., 2008). HRT also includes psychoeducation about tic disorders and function-based interventions designed to target antecedents and consequences to the tics (Woods et al.).

HRT and simplified forms involving at least awareness training, competing response training, and social support (Miltenberger, Fuqua, & McKinley, 1985; Woods et al., 1996) have demonstrated considerable effectiveness as treatments for tic disorders (Himle et al., 2006). Studies utilizing single-subject experimental designs (multiple baselines or alternating treatments) and direct observation as outcome measures have shown mean decreases in tic frequency ranging from 38% to 96% posttreatment, and maintenance of treatment gains for the majority of subjects at follow-up (see Himle et al. for a review). In single-subject studies of HRT for children with tics, large reductions at posttreatment and follow-up have been observed in vocal tics (Woods & Twohig, 2002; Woods, Twohig, Flessner, & Roloff, 2003)

and motor tics (Azrin & Peterson, 1989; Finney, Rapoff, Hall, & Christophersen, 1983; Miltenberger et al., 1985).

Several studies utilizing randomized controlled group designs have shown HRT to be superior to several control conditions including wait-list (Azrin & Peterson, 1990), negative practice (Azrin, Nunn, & Frantz, 1980a), and supportive psychotherapy (Deckersbach, Rauch, Buhlmann, & Wilhelm, 2006; Wilhelm et al., 2003). Cook and Blacher (2007) recently conducted an analysis of the empirical literature on psychosocial treatments for tic disorders (consisting of studies using either single-subject or randomized controlled trial designs) and concluded that HRT could be considered a well-established treatment according to the criteria established by the American Psychological Association Task Force for Promotion and Dissemination of Psychological Procedures (1995) (Chambless et al., 1998).

ERP has also shown promise as a treatment for tic disorders. It is most typically used as a treatment for OCD and involves repeatedly exposing the patient to his/her obsessions, while preventing the performance of neutralizing compulsions. Given the frequent co-occurrence of OCD and TS, and similarities in the functional relationship between obsessions and compulsions to that of premonitory urges and tics, ERP has been adapted as a treatment for TS. In this approach, the client is exposed to the premonitory urge sensations that precede his/her tics and must prevent the occurrence of tics, in the hope that habituation to the premonitory urge will occur and result in subsequent reductions in tic frequency.

In a recent outcome study, Verdellen, Keijsers, Cath, and Hoogduin (2004) compared HRT to ERP in 43 participants with TS (aged 7–55 years). HRT and ERP were found to produce equivalent reductions in both objective measures of tic frequency and tic severity scores. The results of this study indicate that ERP can be considered as a *probably efficacious* intervention for tic disorders that warrants further investigation and independent replication (Cook & Blacher, 2007).

9.4.2   Habit Disorders

Although the treatment outcome literature for habit disorders is under-developed when compared to that of tic disorders, especially among child and adolescent populations, a few approaches have shown promise. The approach most frequently examined and with the strongest empirical support is HRT. There is also growing evidence to support the use of a combination of acceptance and commitment therapy (ACT; Hayes, Strosahl, & Wilson, 1999) and HRT for BFRBs (Twohig & Woods, 2004; Woods & Twohig, 2008; Woods, Wetterneck, & Flessner, 2006).

HRT for BFRBs was also developed by Azrin and Nunn (1973); it follows the same general protocol as HRT for tic disorders. Patients are taught to recognize the behavior and its warning signs as they occur and to perform a competing response. Social support, psychoeducation, and function-based interventions are also important components.

The outcome studies generally support HRT's effectiveness for a range of BFRBs. Early group studies compared HRT with negative practice for the treatment of TTM (Azrin, Nunn, & Frantz, 1980b), nail biting (Azrin, Nunn, & Frantz, 1980c), and other oral habits (e.g., lip biting and chewing; Azrin, Nunn, & Frantz-Renshaw, 1982). In each report, HRT outperformed negative practice. More recent outcome studies have also shown positive results for HRT. Twohig, Woods, Marcks, and Teng (2003) conducted a trial comparing HRT with a

placebo control for the treatment of nail biting. Significantly greater increases in nail length were observed at posttreatment and follow-up in the HRT group than in the placebo control group. Also, a recent trial compared HRT for skin picking with a wait-list control condition, and found a significantly greater decrease in self-reported skin-picking episodes and independent ratings of physical damage in the HRT group, with maintenance of gains at follow-up (Teng, Woods, & Twohig, 2006). Also of note, van Minnen, Hoogduin, Keijers, Hellenbrand, and Hendriks (2003) conducted a randomized controlled trial comparing behavior therapy, fluoxetine, and wait-list control in patients with TTM. The results demonstrated significantly greater reductions in symptom severity in the behavior therapy group when compared with the fluoxetine group and the wait-list control group. Importantly, the behavior therapy condition largely consisted of techniques commonly used in HRT (e.g., self-monitoring, stimulus control, and incompatible responses). Controlled group studies of behavioral treatments for BFRBs in children are quite limited. However, in a recent open trial of Cognitive Behavioral Therapy (consisting of HRT components, cognitive restructuring, and relapse prevention) for pediatric TTM, decreases in pulling severity at posttreatment and follow-up were observed, with the majority of subjects being identified as treatment responders (Tolin, Franklin, Diefenbach, Anderson, & Meunier, 2007).

There has been recent interest in combining HRT with ACT as a treatment for TTM. ACT seeks to decrease the influence of aversive internal states on behavior through techniques designed to increase one's ability to accept rather than avoid or deliberately alter these experiences. Because pulling is often performed to manage negative affect or reduce an urge (Christenson, Ristvedt, & Mackenzie, 1993), incorporating techniques to promote the acceptance of urges or feelings into HRT may improve treatment effectiveness. A recent trial compared HRT plus ACT to a wait-list control condition, and found significantly greater reductions in pulling severity, anxiety, and depression in the treatment group (Woods et al., 2006). This combined treatment package has also demonstrated effectiveness in the majority of subjects in single-subject experimental studies for both TTM (Flessner, Busch, Heideman, & Woods, 2008; Twohig & Woods, 2004) and skin picking (Flessner et al., 2008). There is some evidence to suggest that ACT without HRT may be a promising treatment for BFRBs (Twohig, Hayes, & Masuda, 2006), but further investigation is needed. It is also important to note that the ACT plus HRT treatment package is yet to be investigated in pediatric populations.

9.5   Mechanisms of Change

9.5.1 Tic Disorders

Behavioral treatments for tic disorders are effective, and several hypotheses have been proposed regarding the mechanisms through which they have their effect. Although no outcome studies have directly examined potential mediators using established data analytic techniques (see Baron & Kenny, 1986), indirect evidence from treatment trials, laboratory experiments, and correlational studies suggest several potential mediating variables.

A functional magnetic resonance imaging study of tic suppression (Peterson et al., 1998) provides clues regarding the possible role of CSTC circuits in mediating response to behavioral treatments. In this study, significant changes in activation were observed in several brain regions involved in CSTC circuits during a tic suppression task. These findings suggest that

effective behavioral treatment incorporating tic suppression training (i.e., HRT) could exert its effect by producing changes in brain activity in regions implicated in voluntary tic suppression. Another important proposed mechanism of change is habituation to the premonitory urge. Tics appear to be maintained partially by the negatively reinforcing effect of their removal or reduction of the premonitory urge (Himle, Woods, Conelea, Bauer, & Rice, 2007). Therefore, decreasing the premonitory urge's control over tics may be an important mediator of successful behavioral treatment. In support of this hypothesis, ERP, the behavioral treatment of choice for OCD, whose effects seem to be due to habituation to the anxiety response (Grayson, Foa, & Steketee, 1982), may also be effective in tic disorders (Verdellen et al., 2004). It has also been demonstrated that subjective ratings of urge severity decrease both within and between ERP sessions, suggesting that habituation to the urge may be a mechanism of change in behavioral treatment (Verdellen et al., 2008).

9.5.2 Habit Disorders

Although behavioral treatments for BFRBs appear to be quite effective, little is known about the factors that may mediate their effect. However, as is the case in tic disorder, indirect evidence from several lines of research has implicated some candidates for a mechanism of change.

One possible mechanism of change in BFRB treatment is reduction of experiential avoidance. Experiential avoidance is a behavioral tendency to avoid unpleasant internal states and is believed to be a common maintaining factor in many psychiatric disorders (Hayes, Wilson, Gifford, Follette, & Strosahl, 1996). BFRBs are often performed to reduce aversive feelings (Christenson et al., 1993; Diefenbach et al., 2002, 2008; Walther et al., 2009; Wilhelm et al., 1999), suggesting that experiential avoidance may play a role. In support of this proposition, research has shown that experiential avoidance is positively correlated with symptom severity (Begotka, Woods, & Wetterneck, 2004) and may mediate the effect of negative cognitions on pulling (Norberg, Wetterneck, Woods, & Conelea, 2007). Furthermore, in subjects treated with ACT plus HRT, decreases in pulling severity were moderately correlated with decreases in experiential avoidance (Woods et al., 2006). Despite these preliminary supportive findings, the experiential avoidance hypothesis needs to be tested using more methodologically rigorous studies.

Another possible mechanism of change is increased awareness of the BFRB. As mentioned previously, BFRBs are often performed without the patient's knowledge while he/she is distracted by another activity. A major goal of HRT is to increase awareness of the behavior, which may be an important mechanism of change for those who engage in the habit in a more "automatic" fashion.

9.6 Basic Competencies of the Clinician

In addition to nonspecific therapeutic skills central to all behavioral interventions, the basic competencies needed by a clinician treating TS and BFRBs include providing a treatment rationale, delivering psychoeducation, conducting a functional assessment and implementing function-based interventions, conducting HRT, assigning homework, maintaining motivation,

and taking care to prevent relapse. A list of both basic and expert competencies associated with behavioral treatment of TS and BFRBs is provided in ◉ Table 9.1.

Providing a treatment rationale. Client expectations should be addressed at the onset of therapy. Given the chronic nature of TS and its waxing and waning symptom pattern, clinicians working with this population should ensure that the child and parent have a reasonable picture of "treatment success." Within the treatment rationale, clinicians should emphasize that HRT aims to help the child learn to manage tics to his/her satisfaction rather than to "cure" tics. It may also be beneficial to help the client attribute gains to the treatment, as some clients may have the tendency to attribute symptom reduction to natural waning or other extraneous situations (e.g., less stress during a summer vacation).

The treatment rationale provides the client with information regarding the two major features of treatment: function-based interventions and competing response training. When presenting the rationale for function-based interventions, clinicians should ensure that the client understands the treatment well, and in part, focus on modifying the client's environment to help reduce the likelihood of the behavior and/or its impact. The clinician should explain that the treatment, particularly the competing response, is designed to help the client manage symptoms rather than completely eliminate them (particularly in the case of tics).

A metaphor can sometimes help children and their families understand the rationale better. For example, many children are familiar with asthma, so the clinician can explain that a competing response is a tool used to manage tics/habits, just like an inhaler used as a tool to manage asthma symptoms. To parallel the function-based intervention component, the clinician could point out that children with asthma also try to change situations to make their symptoms less likely to happen (e.g., stay away from allergens, avoid too much exertion, try to stay relaxed). Using such a metaphor can also help to normalize and destigmatize the child's experience and help them to be more willing to engage in treatment.

Psychoeducation. Often, children and their parents seek information about the disorder. Also, clients often come to treatment with inaccurate information obtained through hearsay or unreliable sources on the internet. Psychoeducation is designed to address these issues and can

◉ **Table 9.1**

Basic and expert clinician competencies associated with the treatment of tic and habit disorders

Basic competencies	Expert competencies
• Provide the treatment rationale • Provide accurate psychoeducation about tic disorders and BFRBs • Conduct a functional assessment • Design and implement function-based interventions • Implement core HRT procedures, including awareness training, competing response training, and social support • Assign homework • Maintain motivation and reduce noncompliance • Establish procedures to prevent relapse	• Adapt treatment to meet the needs of children with commonly occurring comorbid disorders (e.g., ADHD, OCD, ODD, PDD) • Address compliance difficulties related to the premonitory urge • Enhance awareness training for those with limited awareness of the target behavior • Troubleshoot client complaints related to competing response procedures • Apply HRT to complex tics • Address BFRBs that occur at night or during sleep • Ensure generalization of treatment gains to multiple settings

help to address issues of stigma and anxiety related to the child's diagnosis by normalizing the child's and family's experiences.

Before implementing psychoeducation, clinicians should have sufficient understanding of tic and habit disorders. Basic psychoeducation competencies include being able to describe and/or answer questions about the definition of a disorder and its differences from other diagnoses, etiology, common symptoms and phenomenology, prevalence, commonly co-occurring difficulties or disorders, course, and prognosis. Psychoeducation can also be used to inform the family about outside resources, such as national organizations or local patient support groups, or to dispel myths related to the disorder (see Woods, Conelea, & Walther, 2007). Clinicians can access psychoeducation information by reading relevant research studies, review articles, or books (e.g., Swain, Scahill, Lombroso, King, & Leckman, 2007; Woods & Miltenberger, 2001; Woods, Piacentini, & Walkup, 2007). The clinicians can also access information on support group websites designed to educate treatment providers (TS: www.tsa-usa.org; Trichotillomania: www.trich.org).

Functional assessment and function-based interventions. Functional assessments are interviews conducted with the goals of operationally defining the target behavior; predicting the situations, settings, or times when the target behavior is most likely to occur; and identifying behavioral functions that may maintain or exacerbate expression of the behavior (Kratochwill & McGivern, 1996).

Creating operational definitions of the child's tics/habits is an important step early in the treatment. This step aids the clinician in the functional assessment process and may begin to enhance awareness by encouraging the child and parents to understand the behavior in greater detail. Clinician skills needed for this step include being able to generate detailed and comprehensive definitions that include antecedent and consequent phenomenological events, balance perceptions of the behavior that may differ between parent and child, and identify behaviors that the family may not be aware of (especially in the case of TS). For those with TS, it can be beneficial to adopt a child's name for his/her own tics to help the child feel more comfortable describing or modeling them.

In the case of children with TS or multiple habits, hierarchies based on symptom distress are usually created to aid in treatment planning. Subsequently, HRT can be implemented for the child's most distressing symptom first as a way to reduce functional impairment or interference. If hierarchies are used, the clinician should be able to help the child quantify the distress associated with each symptom. In addition, if the clinician is able to determine the reasons for the child's distress (e.g., peers teasing the child), the clinician may also identify additional areas for intervention (e.g., peer education).

After defining the tics, the clinician should conduct a functional assessment interview. Competent clinicians should be familiar with the behavioral principles on which functional assessments are based, such as positive and negative reinforcement, stimulus control, and broader motivating factors. Clinicians should be able to apply this basic knowledge to identify possible antecedent factors that precipitate the behavior as well as the potential maintaining consequence variables. In cases where hypothesized maintaining factors can be re-created in session, the therapist may want to use functional analytic techniques to verify the effect of those factors by observing them directly. Familiarity with functional assessment and analysis procedures can be gained by reading general information about these procedures (e.g., mini-series edited by Neef & Iwata, 1994; Mace, Lalli, & Lalli-Pinter, 1991) and their use specifically in relation to TS and TTM (Miltenberger, Woods, & Himle, 2007).

After relevant antecedent and consequence variables have been identified, the clinician should use this information to develop function-based interventions. Function-based interventions generally fall into one of two categories (Newcomer & Lewis, 2004). First, for behaviors that are maintained by factors that are difficult to manipulate, intervention consists of teaching the child a functionally equivalent behavior as an alternative to the target behavior. HRT itself is built to address this function by teaching the use of a competing response as an alternate to the tic/habit. Second, when a functional assessment identifies contextual variables that exert stimulus control over the target behavior, interventions are designed to make changes specific to those variables. Woods et al. (2008) outlined five principles that clinicians can use to guide the development of function-based interventions. First, situations or settings associated with increases in the target behavior should be eliminated or minimized if possible. Second, maintaining events that follow occurrences of the target behavior should be eliminated, such as parent comfort or excusal from homework. Third, children should be reminded to use competing responses when situations associated with target behavior increases. Fourth, the child should be taught strategies (e.g., stress-reduction techniques) to minimize emotional reactions that may contribute to an increase in the target behavior. Fifth, the impact of the tic/habit on the child should be minimized. For example, the child's peers could be educated about the child's condition to reduce teasing. In addition to following these principles, clinicians may find it beneficial to familiarize themselves with the types of interventions that are recommended for situations and settings commonly reported to exacerbate tics or habit behaviors (for a review of commonly reported tic-exacerbating factors, see Conelea & Woods, 2008a).

For example, in the case of TTM, clients often report that the bathroom mirror elicits the urge to pull hair. In this case, possible interventions could include limiting the child's time in the bathroom, dimming bathroom lights to make it harder to see individual hairs, putting a note on the mirror to remind the child to use a competing response, or asking the child to wear gloves while in the bathroom to make pulling more difficult. Clinicians can read published treatment literature to familiarize themselves with other examples of function-based interventions for TS (e.g., Carr, Sidener, Sidener, & Cummings, 2005; Woods et al., 2008), TTM (e.g., Rapp, Miltenberger, Galensky, Ellingson, & Long, 1999; Rothbaum, 1992; Woods & Twohig, 2008), and nail biting (e.g., Woods et al., 2001).

Core HRT skills. Core HRT skills include awareness training, competing response training, and social support.

Awareness training is used to enhance the child's ability to recognize the target behavior and its "warning signs," which can include urge sensations or movements preceding the behavior, such as raising the arm to start pulling. This segment of therapy is an interactive process that includes therapist modeling of the child's tics/habits. The child also practices identifying the target behavior and its preceding sensations. Occurrences of target behaviors that are not recognized by the client are pointed out by the therapist. During this process, sensitivity on the part of the clinician is needed to ensure that the child does not feel mocked or scrutinized. Depending on the age of the child, it may be appropriate to couch awareness training as a "game" that the child can "win" by catching his/her own or therapist-simulated target behaviors. Verbal praise for correctly identified target behaviors can often help children stay engaged in the activity and reduce discomfort related to the activity.

Although awareness training for tics often involves detection of the urge, it is important to note that the urge is not a universal phenomenon among those with TS or TTM. Research suggests that many children do not report experiencing an urge (Banaschewski, Woerner, &

Rothenberger, 2003), and this finding seems to be particularly true for children aged 10 years and younger (Woods et al., 2005). When children do not experience an urge, clinicians can focus awareness training entirely on recognizing other behaviors that tend to occur before the target behavior. For example, a child with a head-shaking tic may drop his/her chin slightly prior to a tic, or a child with TTM may engage in hair twirling or stroking prior to pulling. Clinicians can also direct more treatment efforts toward function-based interventions to reduce the likelihood of target behavior occurrences. Functional assessment results can also be used to recommend high-risk situations in which the child and parent can practice additional awareness training.

During *competing response training*, the clinician helps the child identify a behavior that is physically incompatible with the target behavior, maintainable for at least 1 min, socially inconspicuous, and compatible with the child's usual activities. A basic competency for HRT is familiarity with commonly recommended competing responses, as well as the ability to work with the child to design a competing response for a less common behavior (e.g., an atypical tic).

Treatment manuals included in the book edited by Woods and Miltenberger (2001) contain possible competing responses. For BFRBs, competing responses consist of behaviors that prevent or limit hand movements, such as making a fist while holding the hand to the side, crossing the arms, putting the hands in pockets, or grasping an object, such as a pencil or a toy. Competing responses for tics vary depending on the type of tic the child has. For example, the competing response for a tic involving head movements is contraction of the neck so that the head is tilted downward slightly, while the competing response for a leg movement tic would be pressing the feet flat against the floor. Descriptions of other competing responses can also be found in a paper by Carr (1995).

For children who experience an urge prior to their tic or habit, it is important for the clinician to monitor the child's experience of the urge during in-session competing response practice. The negative reinforcement hypothesis suggests that removal of the urge following the tic/habit negatively reinforces the behavior, making it more likely to occur in the future. Therefore, if a child's urge has not dissipated while he/she is holding the competing response, the procedure may not be effective. Clinicians can monitor urge intensity by asking the child for subjective ratings during competing response practice. In this way, the clinician can ensure the loss of urge before the child releases the competing response. It is often helpful for the clinician to provide encouraging statements when the urge is particularly aversive. Clinicians may also want to graph the child's urge experience to show the child that urge intensity can decrease on its own. Doing this across several trials may also help the child to see that urge intensity will decrease more quickly with additional practice.

For the *social support* component of HRT, clinicians can identify a person in the child's life who is able to reward the child for using competing responses and remind the child to use them when tics or habits go unnoticed. In most cases, the best candidate for this role is the parent. However, clinicians should attend to the relationship dynamics between the child and individuals in his/her social environment to ensure that appropriate support persons are selected. For example, if an adolescent and his parents frequently argue, it may be more beneficial to recruit a friend or sibling to serve in the support role. Modifications to social support procedures could also be made, such as asking the parents to only focus on helping the adolescent a few times per week or developing less invasive reminders, such as a hand signal or code word.

Homework. Homework in HRT consists of self-monitoring and competing response practice. Self-monitoring generally occurs prior to competing response development to enhance the child's awareness of the target behavior. Here, again, clinician's competency with functional assessment procedures can be beneficial, as the clinician can recommend that homework assignments be completed during times or situations in which tics/habits are most likely to occur. Once the child learns the competing response for the tic/habits, competing response practice can also occur during these high-risk times or situations.

Given the importance of homework in HRT, clinicians should be capable of creating manageable homework assignments, rewarding homework compliance, and dealing with homework noncompliance. For children who frequently do not complete homework assignments, clinicians can use behavioral reward programs or a problem-solving process to identify and reduce any barriers to completion. Clinicians should also attend to the demands being placed on the child to ensure that homework assignments are reasonable. Shaping procedures can be used to reinforce gradual improvements in compliance. If the child is having difficulty implementing the competing response outside of therapy sessions, the clinician can work closely with the social support person to ensure that competing response use is prompted and rewarded on a regular basis.

Maintaining motivation. As HRT for tics and BFRBs is difficult, it is often useful to have strategies in place to enhance motivation and reduce noncompliance. Behavioral reward programs are often for this purpose. In a typical reward program, target behaviors are identified with the help of the child and parents. Such behaviors typically include attending therapy sessions, participating during in-session activities, and completing homework assignments. Rewards are identified and linked to specific point values, which can be attained by engaging in clearly identified treatment-related behaviors. Should a child demonstrate noncompliance or motivational difficulties, adjustments to the reward system may be beneficial, such as giving the child rewards or points for successive approximations to the desired behavior. In order to decrease frustration that comes with attempting to alter long-standing behavior patterns, it is important that rewards be contingent upon the child's efforts and attempts to comply with the treatment, rather than on actual symptom reductions.

Relapse prevention. Given the chronic nature of TS and some BFRBs, relapse prevention is an important component of treatment. Clinicians should be able to discuss the likelihood of symptom relapses with the family and frame relapses as opportunities to focus on diligently using the tools learned throughout treatment. The clinician can help the family prepare for potential relapses by revisiting function-based recommendations and reminding the family that the situations previously identified as high risk are likely to be associated with symptom exacerbations in the future. The clinician should ensure that the parent and child are familiar with treatment procedures. Given the natural changes in tic repertoire that occur in TS, clinicians should ensure that the client is capable of developing competing responses for new tics that may emerge.

9.7   Expert Competencies of the Clinician

Expert clinician competencies in HRT generally involve the ability to treat more complex cases and adapt or modify treatment procedures when particular treatment components are problematic for a client.

9.7.1　Dealing with Complex Cases

Children with severe comorbid conditions or considerable diagnostic overlap are often more difficult to treat. A clinician working with these children needs to be well versed in diagnostic assessment and the subtle differences that distinguish one disorder for another.

OCD. A common example is the overlap with TS and OCD (Mansueto & Keuler, 2005). Some children with TS have repetitive behaviors that are difficult to categorize either as a complex tic or a compulsion, such as repeatedly tapping or touching objects, rewriting words, or stating particular phrases repeatedly. To distinguish between compulsive behavior and complex tics, it is important to keep in mind that tics and compulsions are distinguished not on the basis of their topography, but on the basis of their function. Compulsions often function to alleviate the worry or anxiety associated with an obsession and tend to be associated with cognitions about specific feared consequences. Tics, on the other hand, often function to alleviate a premonitory urge, which is a vague or transient somatic sensation. Expert clinicians should be able to make these diagnostic distinctions and plan treatment accordingly. Given that repetitive behaviors classified as compulsions rather than tics are likely to be more amenable to an ERP treatment approach than to an HRT approach, expert clinicians should also be competent in ERP.

ADHD. ADHD is also prevalent among children with TS and may warrant changes in the HRT protocol. For example, it is typically recommended that a child hold a competing response for at least 1 min. However, a child with ADHD, or even a young child, may find it difficult to hold the competing response for this duration. Therefore, it may be appropriate to ask the child to hold a competing response for a shorter duration. Although the effect of this modification on the outcome has not yet been studied empirically, it may at least help to bolster compliance by making the treatment more manageable for the child. A child with ADHD may also have difficulty staying on task during the session or completing homework as assigned. Clinicians may also implement a behavioral reward system to reward the child for staying on task during smaller intervals of the session or for approximations of homework completion. Behavior modification techniques that have been shown to be effective for children with ADHD (Chronis, Jones, & Raggi, 2006) could also be used by the therapist in session, as well as taught to the parents for home use. For example, desired behavior could be increased using praise or positive attention, and undesired behavior could be reduced using planned ignoring or time out (for a more complete description of these techniques, see Barkley, 1998).

Oppositional behavior. Children who are oppositional or noncompliant, such as those with comorbid oppositional defiant disorder (ODD), may also have difficulties with HRT. In particular, these children may refuse to use competing responses as directed, participate poorly during sessions, or argue when their parents try to implement social support procedures. Expert clinicians could address these behaviors by incorporating behavioral treatment for noncompliance into the treatment plan (e.g., McMahon & Forehand, 2003). Clinicians may also address treatment resistance using motivational interviewing (Miller & Rollnick, 2002), which is designed to address ambivalence toward treatment and enhance the client's desire to initiate and maintain behavior change.

Developmental disorders. When treating a child with a co-occurring pervasive developmental disability (PDD), expert clinicians should be able to distinguish tics and habits from stereotypic movements and be able to adapt HRT procedures for this population. Woods, Piacentini, and Himle (2007) suggested that three symptom features can aid a clinician

differentially diagnosing tics from stereotypies. First, although tics do occur in this population, it is more likely for a repetitive behavior to be a stereotypy when there is also a diagnosis of a developmental disability. This is especially true for complex repetitive movements such as body rocking. Second, a single stereotypic movement that does not vary in location or severity is more likely to be a stereotypy. Third, stereotypic movement disorder is a more appropriate diagnosis if the child has a limited number of complex movements in the absence of a history of simple head or facial tics.

Although some literature supports use of HRT for tics and BFRBs in persons with a PDD (Richman & Lindauer, 2002; Roane, Piazza, Cercone, & Grados, 2002), an empirical evaluation of how a PDD diagnosis moderates HRT efficacy has not yet been conducted. Children with PDDs may have difficulty with treatment compliance, may have limited awareness of the target behavior, and may demonstrate a limited ability to independently implement a competing response. Given these possible limitations, expert clinicians may choose to focus primarily on function-based interventions. In the case of a self-injurious habit, clinicians may also want to teach the use of a competing response using discrete-trial training or shaping procedures (Sigafoos et al., 2006).

A case may also be complicated when difficulties arise for some children during particular components of HRT. Some of these difficulties are highlighted and discussed as follows.

Urge does not diminish or patient cannot tolerate urge. Ideally, children can use the competing response contingent upon the experience of an urge, so that habituation to the urge can occur. However, the child may have an intense or particularly strong urge that is difficult to endure.

When children have an urge that is particularly difficult for them to endure, clinicians may want to devote entire sessions toward competing response practice to provide additional support and encouragement. As mentioned previously, clinicians can also graph the child's subjective urge ratings during practice, to help the child notice any reductions in urge intensity.

Urge difficulties might also be addressed by the expert clinicians using a combined ACT/HRT approach to enhance the client's ability to willingly experience the urge. This approach is generally recommended for older adolescents and adults. A treatment manual for ACT-enhanced behavior therapy for TTM by Woods and Twohig (2008) is available for clinical use. It is likely that this treatment approach could be easily adapted for other habit behaviors, such as skin picking. It is recommended that clinicians using this approach understand the competencies thought to be associated with successful application of ACT, which have been described elsewhere (Strosahl, Hayes, & Wilson, 2005).

Difficulty in establishing awareness. Another treatment challenge that may arise during awareness training is the difficulty in establishing awareness. Occasionally, instances of the target behavior and/or its preceding sensations do not occur naturally during the session. In this case, it can be beneficial for the clinician to elicit occurrences of the behavior by creating high-risk situations that were identified in the functional assessment. For example, a clinician could ask the child to describe a stressful event, sit with the child in front of a mirror, or center conversation around a topic related to the target behavior, such as hair or skin. If this strategy does not work, clinicians could ask the child to model instances of the behavior to at least allow him/her the opportunity to practice identifying it in the session. Clinicians could also ask the child's parent to videotape the child during a high-risk situation that occurs outside of session. The clinician could then review the tape with the child and ask the child to point out instances of the target behavior as they occur on the video.

In the case of TTM or oral-digital habits, clinicians may also recommend the use of an electronic awareness-enhancement device, which is designed to emit sound whenever the

client's hand is raised above his/her neck (Rapp, Miltenberger, & Long, 1998). Alternatively, for females, a set of bracelets that make a sound when the arm is moved may serve a similar function. Another treatment idea comes from Risvedt and Christenson (1996), who found that a woman's awareness of hair pulling was enhanced when a topical cream called capsaicin, which increases skin sensitivity, was applied to her scalp.

Difficulties in implementing the competing response. Difficulties that an expert clinician should be able to troubleshoot often arise during competing response training. Children may be dissatisfied with a competing response for a host of reasons. They may find that the competing response is too conspicuous, painful, difficult to hold for a long period of time, or disruptive of other activities.

Clinicians should thoroughly assess the reasons for a child's dissatisfaction. In some cases, alternative competing behaviors can be selected if they are available. For example, if a child finds that doing controlled breathing for 1 min interferes too much with his/her ability to hold a conversation, a clinician might suggest a slight modification, in which the child pauses speech upon experience of an urge, takes a breath in, and speaks on exhale (Conelea, Rice, & Woods, 2006). Research also suggests that competing responses may still be effective even if they are compatible with the tic (Woods et al., 1999). For example, if a client experiences neck pain while tightening neck muscles, he/she could be told to tighten the leg muscles contingent upon the urge for the head tic.

Children may be worried that the competing response will be too distracting, and make it more difficult to attend to concurrent activities. Preliminary experimental data suggest that some children with TS may experience decrement in the accuracy of a concurrent task while they are suppressing tics (Conelea & Woods, 2008b). However, the authors of this study suggest that increased practice of the competing response will probably increase automaticity of the behavior, making it easier for the child to implement in a distracting environment. Therefore, if a child presents with this concern, the clinician may suggest that the child initially practice the competing response in an "easy" setting with few concurrent demands. Once competing response use has been mastered in this setting, the child can be encouraged to implement it in more complex or demanding settings.

A thorough assessment of competing response dissatisfaction may also reveal areas of difficulty that necessitate additional treatment procedures. For example, a child with a BFRB may think that the competing response is too embarrassing and may fear using it in front of his/her classmates. Cognitions related to this fear could be explored and addressed using cognitive restructuring. In the case of children with overlapping TS and OCD symptoms, the competing response may be ineffective for a compulsion incorrectly classified as a tic. For example, the child might engage in another compulsive behavior to alleviate obsession-related anxiety or simply be unable to hold the competing response for a sufficient amount of time. Therefore, when children with TS and OCD present with competing response difficulties, it is recommended that clinicians conduct additional assessment of the child's premonitory experience and include questions specifically designed to reveal possible obsessions. Clinicians should keep in mind that children who are embarrassed or uncomfortable talking about their obsessions may not have discussed them at the outset of therapy, but may be more likely to discuss them later in the treatment. If the assessment suggests that the "tic" might be better classified as a compulsion, a shift to ERP is likely warranted.

Addressing complex tics. Complex tics may present a challenge during competing response training. For example, a child may have a series of tics that occur in a particular pattern and last for a long duration. In this case, the clinician should focus on helping the child implement

a competing response for the first tic in the sequence. Competing responses should also be selected for each distinguishable movement within the complex tic sequence, as well as enable the child to suppress the tic at any point in the sequence. Therefore, if a child forgets or is unable to implement the competing response for the first tic in the sequence, he/she can still benefit from implementing a competing response to prevent the full complex tic from occurring. As has been mentioned elsewhere in this chapter, complex tics may also be difficult to treat because of their similarity with compulsions or stereotypies. If a clinician decides to treat the target behavior as a tic using the traditional HRT approach but encounters limited success, it may be beneficial to re-assess the behavior to ensure that it has been accurately categorized.

BFRBs occurring at night or during sleep. Night-time oral-digital habits, such as thumb sucking, may be difficult to treat using standard HRT procedures. It has been recommended that function-based interventions be used to address these habits. First, a safe but aversive substance could be applied to the child's digits prior to bedtime (Friman, Barone, & Christopherson, 1986). Second, the child can wear gloves or bandages during sleep (Ellingson et al., 2000). The second intervention option may also work well for children who pull their hair while they are trying to fall asleep.

Establishing generalization. Expert clinicians should understand how to ensure that generalization of treatment gains occurs. One potential generalization problem that may arise is that the child only uses the competing response in the presence of the support person or the therapist. Remote detection procedures, in which the support person covertly monitors the child and rewards independent use of the competing response, may be helpful in this case. It may also be beneficial to recruit other people in the child's life to help praise the child for correct implementation of the competing response, such as the child's siblings or other family members, coaches, teachers, babysitters, or peers. Similarly, the child may have trouble using the competing response in places other than home or the therapy room. Again, providing reinforcement across multiple settings, situations, and events may probably increase competing response use globally and enhance generalization.

One area in which children may have difficulty using competing responses is in the school setting. Clinicians can help to create situations that simulate the school experience so that the child is able to practice the competing response in a similar setting. For example, a clinician may ask the child to sit at a desk during a portion of the session or ask him/her to take notes while watching an educational video or listening to the therapist talk. It may also be beneficial to recruit the child's teacher as a social support person. For older children with multiple teachers, a close peer who is with them for multiple portions of the day may also serve as a social support person. When social support procedures are used in the school setting or any other public setting, it may be beneficial for communication between the client and their social support person to be inconspicuous, so as not to draw attention to the child or his/her problem behavior. Hand signals or code words may be used as subtle reminders for the child to use a competing response.

9.8   Transition from Basic Competence to Expert Competence

Although there are no data to help define the distinction between basic and expert HRT competencies, it is likely that the variables that best distinguish these competency levels are related

to a clinician's ability to treat cases of varying complexity and to adapt treatment procedures to best serve the needs of a particular client. There are several strategies that can help a clinician develop the competencies that probably capture the abilities of an expert.

One of the most important steps in the transition from basic to expert involves having exposure to multiple cases that cover a wide breath of symptom presentations. Although TS and habit disorders share key features, the distinct features associated with each diagnosis call for slightly different variations of the HRT procedure. Even HRT for one disorder, such as TS, may differ depending on several case variables, such as the number, complexity, and severity of tics; degree of tic awareness and premonitory urge experience; comorbidity profile; and social support network. By seeing a variety of children with TS and habit disorders, clinicians are more likely to be exposed to the types of clinical issues discussed in this chapter and to have the opportunity to practice adapting the basic principles of HRT across an array of individually nuanced cases.

Another step in developing expert competencies involves seeking out training and, if possible, supervision from another clinician who is already an HRT expert. Interaction with an expert gives clinicians the opportunity to ask questions about a typical case presentation, to receive personalized guidance and feedback about their own skills, and the potential to learn by observing the expert deliver the treatment. In order to establish contact with an expert, clinicians can seek out training opportunities at research conferences or workshops, which are occasionally sponsored by patient support organizations such as the Tourette Syndrome Association and the Trichotillomania Learning Center. These organizations also offer clinician referral services that clinicians can use to find experts in their geographic area.

Finally, reading the existing treatment literature on TS and habit disorders, as well as staying up to date on recent research, can greatly enhance a clinician's knowledge base. Knowing the literature on TS/habit disorders benefits a clinician in various ways. First, clinicians who are well versed in the literature can share their knowledge with clients during psychoeducation. Second, staying up to date on the literature ensures that clinicians are using empirically supported variants of HRT. Although the core principles of HRT have remained similar since the initial treatment outcome study by Azrin and Nunn (1973), empirically based modifications to the treatment have occurred over the years, culminating in recent adaptations of the treatment (e.g., Woods & Twohig, 2008; Woods et al., 2008). In addition, it is likely that the future research will begin to examine the differential benefit of these approaches. It is possible that the data garnered from this research will lead to differences in the way the treatment for TS and habit disorders is currently practiced. Staying abreast of the literature will help the clinicians to make empirically sound and informed treatment decisions, currently and in the future.

9.9   Summary

Treatment of tic and habit disorders in children and adolescents requires familiarity with the symptoms of these disorders and their assessment. In addition, understanding the principles and techniques associated with efficacious treatments is likely to contribute to treatment success.

Although outcome research has demonstrated the efficacy of some TS and habit disorder treatments, particularly HRT, no research has yet examined the role of therapist competency in client outcome. This chapter provides information on competencies that likely contribute

to outcome variance, such as treatment compliance, acceptability, and maintenance. Where possible, data were used to substantiate suggestions regarding therapist competencies; however, it is important to note that many of the recommendations provided in this chapter are yet to be explored empirically. For example, no research has yet examined if or how outcome is impacted when clinicians make modifications to the HRT protocol, such as changing the duration of the competing response or using cognitive restructuring to address a child's thoughts about his/her symptoms. Similarly, the distinction between basic and expert competency with respect to the treatment of these disorders has not been empirically delineated.

Future research will likely help to guide our understanding of therapist competency as it relates to the successful treatment of tic and habit disorders. For example, effectiveness studies could be a first step in examining the impact of protocol deviations on outcome. This research could also provide insight into understanding whether the outcome differs between those categorized as basic and those categorized as expert clinicians. However, until these data are available, it is likely that the recommendations provided here will serve, at the least, as a starting point to guide clinicians interested in treating patients with these disorders.

10 Anorexia and Bulimia

David M. Garner · Christopher D. Keiper

Abstract: Therapist competency is fundamental to the success in treating most psychological disorders. However, the skills required to effectively treat eating disorders may be more demanding than for many other psychological disorders because achieving competency requires familiarity with a body of scientific knowledge covering areas that are not generally a part of clinical training. Information on nutrition, dieting, biology of weight regulation, physical complications, and culture must be added to an understanding of more general psychological themes pertinent to eating disorders. Various theoretical approaches have been developed against which therapist competency can be evaluated in the treatment of eating disorders; however, this chapter describes the cognitive behavioral framework because it is the most popular and best researched. Prominent themes from the cognitive perspective include: 1) idiosyncratic beliefs related to food and weight; 2) specific reasoning errors and disturbed information processing related to the significance given to weight and shape; 3) the role of cultural ideals for feminine beauty that place a premium on dieting and weight control as a marker for self-worth; 4) positive and negative cognitive reinforcement contingencies that maintain symptoms; 5) the operation of underlying assumptions, dysfunctional self-schemas and core beliefs (e.g., low self-esteem, self-identity, perfectionism, pursuit of asceticism, need for self-control, fears of maturity, "anorexic identity," and interoceptive deficits); and, 6) the physiological consequences of starvation that tend to aggravate pre-existing emotional disturbance and maintain disordered beliefs and behavior. The distinguishing feature of the expert clinician is the ability to identify the relevant themes and then creatively implement effective interventions that address the complex determinants of behavior. As described in this chapter, perhaps the most important element in the transition from basic to expert skills as a therapist is acquiring state-of-the-art training and supervision from a skilled and experienced therapist.

10.1 Overview

10.1.1 Prevalence and Associated Problems

Eating disorders have been part of the psychiatric nomenclature for many years; however, only in the past 2 decades have they commanded widespread interest in psychology, psychiatry, and allied professions (Theander, 2004). Part of the reason for this interest has been the recognition of the severe health consequences of the disorders; anorexia nervosa (AN) has a long and established history of high mortality, having an estimated average standardized mortality ratio (the ratio of observed to expected deaths) of 10.5, with the leading cause of these deaths being suicide (Birmingham, Su, Hlynsky, Goldner, & Gao, 2005; Franko & Keel, 2006). AN mortality rates are consistently ranked the highest of any other psychiatric disorder (Millar et al., 2005; Sullivan, 1995). Although mortality rates for bulimia nervosa (BN) are much lower, they are still notable (Nielsen, 2003). The prevalence rates of eating disorders in Western cultures are the topic of some debate; however, most epidemiological

studies point to the prevalence of 0.3% for AN and 1% for BN among young women (Hoek & van Hoeken, 2003).

Medical complications are typical during the acute phase of an eating disorder (Becker, Grinspoon, Klibanski, & Herzog, 1999) and persist among those who are unsuccessfully treated (Keel, Mitchell, Davis, & Crow, 2002). In addition, eating disorders are associated with a wide range of physical and emotional disorders through early adulthood, including major depression, obsessive compulsive disorder (OCD), substance abuse, and anxiety disorders (Johnson, Cohen, Kotler, Kasen, & Brook, 2002; O'Brien & Vincent, 2003). The complex interplay between the psychological and physical symptoms contends against defining eating disorders as exclusively "psychiatric" or "medical," as effective treatment must target both domains.

10.1.2 Diagnostic Classification

The prevailing diagnostic systems, the *Diagnostic and Statistical Manual of Mental Disorders* (4th ed. [*DSM–IV*]; American Psychiatric Association [APA], 1994) and the *International Classification of Diseases* (World Health Organization, 1992) have limited the current classifications of eating disorders to one of three diagnostic categories: that of AN, BN, and a third category of disorders not matching stringent criteria for either, which is labeled eating disorders not otherwise specified (EDNOS). AN individuals have further been classified into subtypes of those who simply restrict caloric intake (AN-R) and those who have symptoms of bingeing and/or purging (AN-B/P). Binge-eating disorder (BED), characterized by binge-eating episodes and lack of compensatory behaviors for caloric intake, is currently classified under EDNOS; however, it is likely to be addressed in more detail in the forthcoming edition of the *DSM* (Wilfley, Bishop, Wilson, & Agras, 2007).

Despite the requisite nature of diagnostic classifications, the clinical stability of eating-disorder diagnoses have been questioned in the long-term owing to significant crossover between both the full diagnostic categories and subtypes (Eddy et al., 2008; Fichter & Quadflieg, 2007; Wonderlich, Joiner, Keel, Williamson, & Crosby, 2007). While there is some established distinctiveness between the categories of AN and BN diagnoses (e.g., Eddy et al.), the remarkable heterogeneity in psychological features within the diagnostic subgroups underscores the clinical utility of evaluating patients on a broad spectrum of meaningful psychosocial variables. For clinical purposes, there is far greater heuristic value in directly assessing the psychological domains that are conceptually relevant across all eating-disorder subgroups rather than simply drawing inferences from *DSM-IV* (1994) diagnostic categories.

10.1.3 Risk and Maintenance Factors

The understanding of factors that contribute to the etiology and maintenance of eating disorders has advanced substantially in recent decades. Most models assume that eating disorders are multidetermined and heterogeneous in nature deriving from the interplay of three broad classes of predisposing or risk factors: cultural, individual, and familial (Garner, 1993). However, cumulative evidence has begun to specify the respective roles of these categories in greater detail (Jacobi, Hayward, de Zwaan, Kraemer, & Agras, 2004; Stice, 2002; Striegel-Moore & Bulik, 2007).

Jacobi et al. (2004) have recommended conceptualizing factors in terms of clinical evidence and potency of association. Important high-potency factors that predispose the disorders are being female, in adolescence or early adulthood, having weight concerns, dieting, and ideating a negative body image. Medium-potency factors are having experienced sexual abuse and physical neglect in adolescence. Lower potency and non-specific variables that predispose eating disorders are temperament factors, frequent alcohol consumption, low social support, low self-esteem, and general psychiatric morbidity. The key maintaining or perpetuating factors are the psychological, emotional, and physical effects of starvation and semi-starvation.

10.1.4 Evidence-Based Treatment

The recommended evidence-based treatments for eating disorders generally include weight restoration/maintenance incorporated with psychotherapy. Outpatient service is possible for a large portion of patients with BN, while more acute manifestations of BN and many AN cases (owing to the clinical severity of AN behaviors and maintenance effects of emaciated state) may require a more protracted and intensive treatment to reach a desirable level of functioning (Haliburn, 2005; Garner, Vitousek, & Pike, 1992; Wilson, Grilo, & Vitousek, 2007). Pharmacotherapy treatment alone for the primary diagnoses of eating disorders is contraindicated and ineffective for weight maintenance (Castro-Fornieles et al., 2007; Wilson et al., 2007).

10.2   Recognition of Symptoms and Their Assessment

10.2.1 Screening and Initial Assessment

Initial assessment of the presence of an eating disorder should follow professional referral or a patient's volitional search for the treatment. A difficulty in assessing eating disorders, especially AN, is that often patients view their symptoms as functional, necessary, or even desirable, and may be ambivalent about seeking treatment (Garner, Vitousek, & Pike, 1997; Vitousek, Watson, & Wilson, 1998). It is, therefore, paramount that the initial interview be fostered to develop a sense of openness and trust between the clinician and patient in hopes of establishing a therapeutic alliance. In cases of denial or minimization of the symptoms, the clinician should avoid making value judgments of the patient's condition and provide empathic support in an effort to motivate the patient toward treatment (Vitousek et al., 1998). A number of standardized and non-standardized measures have been created to supplement an individual's clinical background; the conventional assessments used for screening of eating disorders will be briefly discussed.

10.2.2 Medical Assessment

Medical complications are common in those with eating disorders; therefore, patients should be assessed by a physician familiar with physical byproducts of starvation and eating-disorder symptoms such as binge-eating and vomiting. A complete medical examination should include

a medical history, review of presenting physical symptoms, laboratory tests, and careful consideration of medical conditions other than an eating disorder that could account for the patient's current state (Becker et al., 1999). Choosing a physician with experience in evaluating those with eating disorders cannot be overemphasized in the light of the complex interplay between the physical and psychological symptoms' presentation.

10.2.3 The Structured Interview

Four structured interviews have specifically been created for assessing and screening eating disorders (Grilo, 2005). These include the Eating Disorder Examination (EDE; Cooper & Fairburn, 1987), Clinical Eating Disorder Rating Instrument (CEDRI; Palmer, Christie, Cordle, Davies, & Kenrick, 1987), the Interview for the Diagnosis of Eating Disorders (IDED; Williamson, 1990), and the Structured Interview for Anorexic and Bulimic Disorders (SIAB-EX; Fichter, Herpertz, Quadflieg, & Herpertz-Dahlmann, 1998). Of these, the EDE is the most sophisticated and detailed (Grilo, 2005), and is regarded as the most established for assessing eating disorders (Wilfley, Schwartz, Spurell, & Fairburn, 2000). In addition, the EDE has been adapted for use with children and adolescent patients (ChEDE; Bryant-Waugh, Cooper, Taylor, & Lask, 1996). The latest revision of the IDED focuses exclusively on providing differential diagnosis using *DSM-IV* (1994) criteria. The SIAB-EX differs from other interviews in providing information on general and familial psychopathology linked to eating disorders (Grilo, 2005).

Although there is an agreement that interview assessments have good potential to provide accurate information owing their probing utility (Pike, 2005), their disadvantages include their lengthy time to administer, the necessity of a trained interviewer, and the potential to be viewed as overly intrusive. Additionally, some have suggested that self-report measures may provide more accurate information of eating-disorder symptomatology based on the willingness of the patients to be more honest in the absence of an interviewer (Keel, Crow, Davis, & Mitchell, 2002; Wolk, Loeb, & Walsh, 2005).

10.2.4 Self-Report Measures

Self-report measures provide an efficient means of obtaining information for clinical purposes. While these measures should not be used as the sole basis for diagnostic and treatment decisions, they provide advantages of economical administration and scoring. Among the measures that test for general eating pathology, the Eating Disorder Inventory (EDI; Garner, 1991, 2004; Garner, Olmstead, & Polivy, 1983) has created a substantial body of supporting research (Peterson & Mitchell, 2005). The EDI was developed to assess the symptoms of eating disorders as well as related psychological variables. It has undergone several revisions; the second revision (EDI-2) is a widely used test with easy administration and scoring that attains information on eight subscales, all of which seem to be generalizable across cultures (Podor & Allik, 2009). The most recent revision (EDI-3; Garner, 2004), reorganizes items from the 1991 version (EDI-2) into three "eating-disorder risk" scales (Drive for Thinness, Bulimia, and Body Dissatisfaction), nine psychological scales, six composite scores, and three response-style indicators.

An adaptation of the EDE structured interview, the Eating Disorder Examination-Questionnaire (EDE-Q; Fairburn & Bèglin, 1994) focuses on eating-disorder symptoms and attitudes over a 28-day history. While the EDI is useful for general eating pathology, the EDE-Q is a valid instrument for making *DSM-IV* diagnoses and is considered accurate for assessing binge-eating (Pike, 2005). The EDE-Q contains four subscales: Restraint, Eating Concern, Shape Concern, and Weight Concern. It has produced levels of reliability and validity to support its use (Fairburn & Cooper, 1993) and has acceptable levels of internal consistency (Peterson et al., 2007). Also, reports finding higher levels of disturbance on EDE-Q than its EDE-interview counterpart have led to suggestions that it may be a more accurate indicator of severity of symptoms (Wolk et al., 2005).

In addition to the above mentioned assessments, the Eating Attitudes Test (EAT; Garner & Garfinkel, 1979; Garner, Olmsted, Bohr, & Garfinkel, 1982) is a useful screening instrument of severity in clinical and non-clinical samples. Other instruments, such as the Eating Disorder Questionnaire (EDQ; Mitchell, Hatsukami, Eckert, & Pyle, 1985) are useful as database tools for tracking an array of demographic information and symptoms over time (Peterson & Mitchell, 2005).

10.2.5 General Measures of Psychopathology and Medical Assessment

Complete psychiatric assessment of patients with eating disorders should also include measures of personality, psychological distress, self-esteem, depression, anxiety, family functioning, history of sexual abuse, social and vocational adaptation, and impulse-related features. Careful assessment of these related areas is important in confirming Axis II diagnoses and treatment planning.

10.3 Factors Maintaining Eating Disorders

10.3.1 Conceptualization of Risk and Maintenance Factors

A discussion on the perpetuating factors of a psychiatric disorder is necessarily based on the understanding of etiology; however, there are few models that integrate putative factors of association or causality into a developed framework for eating disorders (Tylka & Subich, 2004). Moreover, certain risk factors do not easily fit into the classes of predisposing, precipitating, or maintenance regarding the course of the disorders (Garner & Magana, 2006). Furthermore, although many associations and links have been identified, knowledge surrounding the risk factors for eating disorders is frustratingly incomplete (Strieglel-Moore & Bulik, 2007). For brevity, this discussion will limit itself to describing factors profoundly associated with eating-disordered populations, and will avoid exploring a framework that would include an etiological timeline. Additionally, factors are included for eating disorders, in general, rather than deferring to specific diagnostic classifications. This is based on the clinical utility of assessing a potential patient across conceptually associated variables that overlap the disorders. For a detailed discussion on these factors specific to their classifications, see the comprehensive review by Jacobi et al. (2004).

10.3.2 Putative Factors of Risk for Eating Disorders

There have been several large-scale reviews of the risk factors of eating disorders in recent years which have been the primary sources for our discussion (Jacobi et al., 2004; Stice, 2002; Striegel-Moore & Bulik, 2007). Jacobi et al. recommended conceptualizing a factor in terms of the magnitude of association, called its potency. Putative factors may also be broken down into their larger domains of context – whether they are derived from culture, family/biology, or are specific to the individual.

10.3.3 Cultural Factors

Cultural risk factors were originally posited to account for the high prevalence of eating disorders among women in Western countries, conceptualized as a response to pressures to achieve an ultra-thin representation of feminine beauty (Garner & Garfinkel, 1980). They are considered high-potency contributing factors; however, it is now well-established that eating disorders also occur in non-Western cultures and in minority populations (Wildes & Emery, 2001). Participating in sports or professions emphasizing thinness (e.g., gymnastics, dancing, or wrestling) is considered as another high-potency factor. Being of a minority culture while in the process of acculturation to a dominant culture is an additional factor with unspecified potency.

10.3.4 Familial and Biological Factors

Biological. One very consistent finding in the literature is the preponderance of females with eating disorders when compared with males, estimated up to ten times for both the disorders, and is a highly potent risk factor. Factors specific to genetics are also considered to be of high potency however, most studies point to a polygenic risk (involving multiple gene sites) probably conferring the risk through a predisposition to personality traits (perfectionism and obsessionality) in a Gene–Environment interaction. Some of the key biological factors of unspecified potency which are likely to contribute to maintenance are the physical effects of emaciated state (Garner, 1997).

Parental. Having a mother with an eating disorder is the highest potency familial indicator of risk for an eating disorder. Other medium-potency factors include having a parent who diets and parents making critical comments about a child's weight. Additional low and nonspecific potency factors of parents and parenting involve high-performance expectations, low contact or neglect, over-concern or hypervigilance, a parental history of obesity, high levels of exercise, and presence of an affective disorder.

10.3.5 Individual Factors

Adverse life events. Physical abuse, physical neglect, and sexual abuse are all low-to-medium potency factors of risk for developing an eating disorder. Other general stressful life events (such as loss as the result of death), have been conceptualized as a factor of low potency.

Behavioral. Major factors of extremely high potency for risk are the presence of restrictive dieting, concern/fear of gaining weight, and ideating a negative body image. Involvement in

high levels of exercise is also regarded as a high-potency factor. A final nonspecific risk factor is the abuse of substances (drugs and alcohol).

Cognitive processes and core beliefs. Central to cognitive theory of eating disorders are idiosyncratic beliefs, self-statements, automatic thoughts, and underlying assumptions about food, eating, weight, and shape that can interact with more core beliefs about the self (Garner & Magana, 2006). Constructs that have manifested valid risk for eating disorders are consistent with EDI-3 subscales (Garner, 2004). High-potency factors include having a drive for thinness, body dissatisfaction and weight concerns, low self-esteem or ineffectiveness (low self-efficacy), perfectionism, interpersonal insecurity and/or alienation/attachment deficits, and errors in reasoning. Medium-potency factors are depression, anxiety, low interoceptive awareness (difficulty in recognizing and responding to affective states), and poor emotional regulation. Cognitive factors of low and nonspecific potency are body misperception, obsessive compulsive traits, asceticism (pursuit of virtue through sacrifice), fears of reaching psychobiological maturity, and neuropsychological deficits (e.g., altered serotonin levels).

Developmental. A major factor specific to an individual's development of high potency for risk is being in adolescence. Other factors of low and unspecified potency include having childhood eating problems, pregnancy complications/premature birth, childhood anxiety, and early onset of puberty.

10.4 Evidence-Based Treatment Approaches

10.4.1 Pharmacological Treatment

Many psychiatric disorders are treated primarily by pharmacological intervention. Pharmacotherapy as a primary treatment for eating disorders has little empirical support; however, it may be useful as an adjunct to other forms of therapy for the treatment of co-occurent conditions, such as affective disorders and psychosis (Bulik, Berkman, Brownley, Sedway, & Lohr, 2007; Castro-Fornieles et al., 2007; Wilson et al., 2007).

10.4.2 Weight as a Consideration in Treatment

In contrast to the earlier decades, there is now a milieu of options for treating eating disorders, most of which have been ill-researched (Fairburn, 2005). Some emerging facilities and approaches to treatment do not require weight gain as part of therapy for patients. As mentioned earlier in this chapter, eating disorders inevitably affect both psychological and medical domains of functioning. It should be mentioned that, irrespective of the intervention being considered, the factors of weight gain and weight maintenance are inexorably linked to the course and outcome of the disorder (Garner, 1997). Clinical practice that advises against or neglects these variables is in contradiction with a wide body of clinical research; evidence that weight gain should be considered in the treatment can be observed from the use of weight gain in definitions of recovery for individuals with AN (Couturier & Lock, 2006), that weight gain is predictive of remission (Lock, Couturier, Bryson, & Agras, 2006), low weight at presentation is predictive of death in AN (Berkman, Lohr, & Bulik, 2007), and weight suppression for BN patients has a direct relationship with the frequency of bingeing and is a predictor of the outcome (Butryn, Lowe, Safer, & Agras, 2006).

10.4.3 Psychological Treatment for Eating Disorders

Although eating disorders have been recognized in modern psychotherapeutic practice for several years, only a few models of psychological treatment for eating disorders have received controlled-trial or clinical support (Wilson et al., 2007). Most trials for the treatment of AN have additionally used considerably small samples (Fairburn, 2005). As there are many approaches still in question, this chapter will reserve discussion to three approaches that have been most investigated in the context of eating disorders: interpersonal psychotherapy (IPT), family-based therapy (FBT; specifically the Maudsley approach), and cognitive-behavioral therapy (CBT).

10.4.4 Interpersonal Psychotherapy

Interpersonal psychotherapy was originally developed as a time-limited outpatient therapy for depression (Klerman, Weissman, Rounsaville, & Chevron, 1984) and was adapted for treatment of BN by Fairburn and colleagues (Fairburn, Jones, Peveler, Hope, & O'Connor, 1993). The basic tenants of the theory focus on non-directive and non-interpretive intervention, attempting to resolve relational conflicts discovered within the patient's life. The clinician focuses on one of the four problem areas: interpersonal disputes, role transitions, abnormal grief, or interpersonal deficits (Weissman & Markowitz, 2002). Clinicians and theorists advocating the use of IPT for the treatment of eating disorders cite dysfunctional interpersonal functioning found in families of the eating disordered, such as closed and rigid family structures, overprotective parenting styles, and high expectation of achievement, as well as the argument that while in adolescence these individuals are ill-equipped to deal with interpersonal demands (McIntosh, Bulik, McKenzie, Luty, & Jordan, 2000).

Efficacy of treatment. Although there have been few trials investigating the efficacy of IPT for the treatment of eating disorders, at least two studies have compared the outcomes of BN with treatments using CBT (Agras, Walsh, Fairburn, Wilson, & Kraemer, 2000; Fairburn et al., 1991). The results suggest that IPT is inferior to CBT at post-treatment, though equally effective at long-term follow-up. To our knowledge, there have been no large-scale randomized control trials of nearly any treatment modality for AN. IPT is not an exception, even though some have made theoretical arguments for its use in eating-disordered populations as mentioned earlier (McIntosh et al., 2000); however, IPT has been rated as mid-level methodologically for the treatment of BN, because it does not directly address the core dysfunction and symptomatology, and is recommended as an alternative to CBT (National Institute for Clinical Excellence [NICE], 2004).

10.4.5 Family-Based Therapy

Family-based therapy is the most investigated form of treatment for AN (Wilson et al., 2007). The best researched of these therapies is the Maudsley approach, described in detail by Lock, le Grange, Agras, and Dare (2001). Lock et al. suggested FBT for adolescent patients specifically, because adolescents are generally embedded within a family system that provides necessary nurturance and support for development. Best construed as an intensive outpatient treatment, parents and immediate family members play an active role in recovery in the

context of clinician–family meetings incorporated with weight gain. Lock et al. (2001) outlined a three-phased therapy.

The first phase of treatment involves *refeeding the patient*, and focuses almost exclusively on the eating disorder and related symptoms. It includes a family mealtime, with the clinician acting as observer and working toward absolving the parents from blame for the disorder. The second phase of treatment involves *negotiating a new pattern of relationships* for the patient, in which the patient surrenders to the will of the parents to increase the food intake. In this phase, the parents take the main control of the treatment to return their child to physical health. The third phase of treatment involves *issues of adolescence and termination of treatment*. During this last phase, the patient achieves and maintains a stable weight, which Lock et al. (2001) stated should be above 95% of ideal body weight. The core themes of this phase are embedded within establishing a healthy adolescent identity and maintaining appropriate parental–adolescent boundaries.

Efficacy of treatment. Although FBT has a widely known precedence of treatment for AN, the conception that it has strong body of empirical support is unsubstantiated, and the mechanisms of action are not well understood (Fairburn, 2005). The Maudsley approach seems to be more efficacious with younger adolescents (Fairburn, 2005; Russell, Szmukler, Dare, & Eisler, 1987; Vitousek & Gray, 2005), though there is a lack of evidence that it is better than individual therapy (Wilson et al., 2007). For AN, FBT has been awarded a mid-level rating for practice with adolescents (NICE, 2004). FBT for adolescent patients with BN has recently been investigated and is possibly efficacious (le Grange, Crosby, Rathouz, & Leventhal, 2007; Schmidt et al., 2007), though results are limited owing to small sample sizes and lack of blind assessment in the study by le Grange et al.

10.4.6 Cognitive-Behavioral Therapy

CBT is the most frequently tested individual therapy for AN (Wilson et al., 2007) and has the longest established framework of the treatments presently discussed. CBT, as a treatment for AN, was first described by Garner and Vitousek (Garner & Bemis, 1982; Garner et al., 1997). However, an alternative perspective has been presented for treating BN (Fairburn, 1985; Fairburn, Marcus, & Wilson, 1993); the treatments are largely consonant. However, it is noted that there are important treatment differences according to the diagnostic group that the patient belongs. These are based on the differing characteristics of the disorders and manifest in areas such as treatment motivation, weight gain, and introducing self-monitoring behaviors (Garner et al.).

CBT as a treatment for AN and BN is largely based on cognitive theory in which patients are collaborators in their recovery with the clinician. Using a variety of strategies, the clinician addresses dysfunctional thinking patterns, schemas, and beliefs, and guides the patient through creating new, appropriate methods of thinking. It is also noted that the framework of the intervention is sufficiently broad to address specific clinical issues by incorporating IPT or Family Therapy into treatment (Garner et al. 1997). Garner et al. have outlined a three-phased intervention.

Phase I of the treatment involves *building trust with the patient and setting treatment parameters*, and includes outlining and building a positive therapeutic alliance, fostering motivation for treatment, and assessing key features of the patient's manifestation of the disorder. As many eating-disordered patients are ambivalent about the treatment, much of this phase is dedicated to establishing this therapeutic bond. Phase II of the treatment involves *changing patient beliefs*

related to food and weight, and subsequently broadening the scope of therapy to address specific clinical issues and dysfunctional thought patterns. The core issues addressed within this phase are emphasis on weight gain and normalized eating, as well as identifying and developing cognitive skill sets for restructuring dysfunctional thoughts and schemas. Phase III of the treatment is driven toward *preventing relapse and preparing the patient for treatment termination*, and includes summarizing therapeutic progress, reviewing areas of vulnerability and continuing progress, and making the patient aware of when to return to treatment.

Efficacy of treatment. Manually-driven CBT has been rated as the treatment of choice for adults with BN and is superior to other interventions at least in the short-term, eliminating between 30% and 50% of bingeing and purging symptoms in all the cases (NICE, 2004; Wilson & Fairburn, 2002; Wilson et al., 2007). However, along with other forms of therapy, there is a desire for further empirical support for treating AN (Wilson et al., 2007). To date, there have been at least three studies comparing CBT with other forms of psychotherapy, in which no differences were found between the modalities (Ball & Mitchell, 2004; Channon, de Silva, Hemsley, & Perkins, 1989; McIntosh et al., 2005). However, the length of the treatment was truncated against the recommendations of the CBT format currently discussed. Other trials have compared CBT with the nutritional counseling in which CBT was found to be superior, but the comparison has been deemed weak (Pike, Walsh, Vitousek, Wilson, & Bauer, 2003; Serfaty, Turkington, Heap, Ledsham, & Jolley, 1999).

10.5 Mechanisms of Change Underlying the Intervention

10.5.1 The Cognitive Model of Change

Eating disorders continue to have elusive etiologies, and therefore, any discussion on the underlying actions of therapeutic change is derived from a limited understanding of how they occur. A review of the various theoretical models for the mechanisms of change in eating disorders is a daunting task and is well beyond the purpose of this chapter. We have chosen to limit the brief discussion of mechanisms of change to a cognitive framework, as it is the most popular and best researched model to date.

The essence of the cognitive theory of eating disorders is that the symptoms are maintained by a characteristic set of over-valued ideas about the personal significance of body shape and weight. Early cognitive conceptualizations were derived from clinical observations and adapted to address certain distinctive features of AN (Garner & Bemis, 1982) and BN (Fairburn, 1985) which have been increasingly applied to all eating-disorder diagnostic subgroups (Cooper, 2005; Vitousek, 1996). Relevant variables include: (1) idiosyncratic beliefs related to food and weight; (2) specific reasoning errors and disturbed information processing related to the significance given to weight and shape; (3) the role of cultural ideals for feminine beauty which have placed a premium on dieting and weight control as a marker for self-worth; (4) positive and negative cognitive reinforcement contingencies that maintain the symptoms; (5) the operation of underlying assumptions, dysfunctional self-schemas, and core beliefs (e.g., low self-esteem, self-identity, perfectionism, pursuit of asceticism, need for self-control, fears of maturity, "anorexic identity," and interoceptive deficits); and, (6) the physiological consequences of starvation that tend to maintain disordered beliefs and behavior, and aggravate pre-existing emotional disturbance. A detailed discussion on the cognitive mechanisms of

change is well beyond the scope of this chapter; however, the relevant theoretical principles can be found elsewhere in comprehensive reviews (Cooper, 1997, 2005; Garner, Vitousek, & Pike, 1997; Vitousek, 1996; Wilson et al., 2007).

Of relevance in a practical chapter on competence in the treatment of eating disorders is an understanding of stereotypic beliefs and attitudes about food, shape, and weight characteristic of eating disorders. Body dissatisfaction and the desire to lose weight (drive for thinness) are two of the most well-recognized cognitive precursors to dieting and development of eating-disorder symptoms in community samples of preadolescents, adolescents, and adult females (Jacobi et al., 2004; Stice, 2002). It is important for the novice clinician to be familiar with the "proximal" (versus remote) causes of eating-disorder behavior as being derived from the supreme importance given to weight or shape in maintaining the vast array of thoughts and behaviors displayed by those with eating disorders. The cognitive-behavioral model does not disavow the role of remote etiological variables (i.e., biological, genetic, constitutional, developmental, and personality), but "declines to take a strong position on the contribution [of these factors]" (Vitousek & Ewald, 1993). The cognitive approach to eating disorders can be distinguished not by the specific content or timing of the presumed etiologic variables, but rather by the methods used in evaluating their relevance, as well as the general sequence followed in exploring the historical material. The cognitive approach does not make *a priori* assumptions regarding the relevance of historical variables; however, their relevance is dictated by the degree of confidence with which they can be linked to current eating-disorder symptoms and current overall functioning. By their nature, some variables or constructs (e.g., early feeding patterns) defy the credible linkage or proof. Moreover, the sequence in exploring historical material distinguishes the cognitive approach by focusing "on proximal factors which maintain the disorder while gradually working back to explore distal belief systems which may have played a role in the actual development" (Garner & Bemis, 1985, p. 108). This model allows the exploration of historical themes relevant to the meaning system of a particular patient, without compelling all the cases to fit into one explanatory system.

10.6   Basic Competencies of the Clinician

Eating disorders have a reputation of being difficult to treat; however, experienced clinicians following current guidelines for care can have a very positive impact on the outcome. Although therapist competency is fundamental to the treatment of all psychological disorders, proficiency in treating eating disorders requires a familiarity with a body of scientific knowledge covering areas that are not generally a part of clinical training. Information on nutrition, dieting, biology of weight regulation, physical complications, and culture must be included to understand the more general psychological themes pertinent to eating disorders.

10.6.1 General Therapist Qualities

There is broad agreement that trust in the therapeutic relationship is a key to success with most patients and is fundamental in promoting change in diffident and often resistant eating-disorder patients. Being able to trust one's therapist is judged by the patients and former patients as the most important component of treatment quality (de la Rei, Noordenbos, Donker, & van Furth, 2008). Basic skills are required for the therapist to convey warmth, accurate empathy,

genuineness, trust, and a collaborative relationship. Particularly, in light of the eating-disorder patient's ambivalence about the goals of treatment, it is vital that the therapist be cognizant of the patient's ongoing appraisal of the quality of the relationship. The therapist must strive to convey qualities of appropriate warmth, sensitivity, compassion, genuineness, honesty, flexibility, engagement, acceptance, positive regard, and be acutely attuned to how the patient is feeling about the treatment progress, as well as the therapist's role in this process. The patient's confidence in the therapist's trustworthiness, emotional fortitude, and technical skills are pivotal in establishing a therapeutic connection.

10.6.2 Duration and Structure of Cognitive Therapy

The duration of treatment for BN is typically about 20 weeks (Fairburn, Marcus et al., 1993); however, it is well recognized that difficult patients may require a longer period of care (Wilson et al., 2007). In contrast, treatment for AN often lasts more than a year (Garner et al., 1997). The longer duration of treatment is required in most cases of AN, because of the time required to overcome motivational obstacles, achieve appropriate weight gain, and occasionally implement inpatient or partial hospitalization.

The structure of individual cognitive-therapy sessions is similar for BN (Fairburn, Marcus et al., 1993) and AN (Garner et al., 1997). Each session involves: (1) setting an agenda; (2) self-monitoring is reviewed; (3) dysfunctional behaviors, schemas, and core beliefs are identified and changed; (4) the session is summarized, and homework assignments are specified. For AN, additional components are added for addressing poor motivation, checking the patient's weight, discussing weight within the context of goals, reviewing physical complications, and meal planning (Garner et al.). Also, in AN, therapy format must be adapted with respect to the age of the patient and clinical circumstances. Meeting format may be individual, family, or a mix of both formats, according to the clinical needs.

10.6.3 Two-Track Approach to Treatment

Throughout all the stages of treatment, there are "two tracks" to treatment. The first track pertains to symptom control in areas related to eating, weight, bingeing, vomiting, strenuous dieting, and other behaviors aimed at extreme weight control. The second track addresses the psychological context of the disorder, including beliefs and thematic underlying assumptions that are relevant to the development or maintenance of the disorder. In practice, there is considerable switching back and forth between the two tracks during the therapy. Greater emphasis is placed on track 1 early in the therapy, emphasizing on the interdependence between the mental and physiological functioning. Subsequently, the treatment shifts to track-2 issues, as progress is made in the areas of eating behavior and body weight.

10.6.4 Motivation for Treatment: Addressing Resistance in a Constructive Manner

Eating-disorder patients have been labeled as resistant, stubborn, defiant, and unmotivated to change. This overgeneralization is unwarranted for many patients whose veneer of

non-compliance is overshadowed by the awareness of their fragile physical and emotional state and wish to change. However, resistance to change is a common clinical obstacle for many, particularly, when they are directed to focus on behavioral change of eating-disorder symptoms. Thus, the clinician should expect that some patients will lack motivation or, at the very least, experience ambivalence at the beginning of therapy and at certain points thereafter. One of the key roles of the therapist is to assist in cultivating and sustaining motivation for change. Methods have been suggested for minimizing therapist anger that can result from the lack of patient progress as well as improving motivation (Vitousek et al., 1998). Motivation partly depends on the goals of the treatment; if the degree to which the therapist and the patient have shared goals is greater, then the cooperation will also be greater. From the earliest stages of treatment, goals need to be negotiated, which balance the need to focus on behavioral change while focusing on the underlying psychological issues. Educating patients about the starvation symptoms and the long-term effects of dietary restriction can play a valuable role in helping the them move toward behavioral change, as failure to correct these problem areas precludes the understanding and changes underlying psychological issues.

10.6.5 Content Domains for Competency in the Treatment of Eating Disorders

Content domains of therapy which reflect competency in the treatment of eating disorders have received very limited research attention in the field, other than empirically derived practice guidelines for eating-disorders treatment (APA, 2006; NICE, 2004). However, practice guidelines do not directly address the issue of competency. Thus, the remainder of this chapter comprises these practice guidelines and is supplemented by our own clinical experience pertaining to treatment competency. In one of the few studies to examine content domains associated with quality of treatment, de la Rie, Noordenbos, Donker, and van Furth (2008) surveyed therapists, current patients, and former patients to determine the factors that contribute to the quality of treatment from both therapist's and patient's perspective. ❯ Table 10.1 provides the ranking of the top ten items with respect to therapist and patient perception of factors contributing to quality of treatment. All the items from the questionnaire were factor-analyzed, and the results revealed seven interpretable factors explaining 33% of the variance. The factors were: "mastery," "treatment modalities," "information," "focus on underlying problems," "bond with the therapist," "acceptance," and "focus on eating behavior." In general, therapists most often stressed the focus on eating-disorder symptoms and behavioral change, whereas current and former eating-disorder patients most often stressed the importance of the therapeutic relationship and the need to address problems underlying the eating disorder. Despite these differences, the main finding was that the therapists and patients shared many values on the factors associated with the quality of treatment.

10.6.6 Basic Competence in Assessment of Eating Disorder Symptoms

Assessment of key clinical features of eating disorders is a basic skill-set required of the clinician. A detailed weight history should be taken to gather information regarding the nature and temporal sequence of events in the development of eating disorder. The assessment should include careful questioning regarding the duration and frequency of binge-eating and vomiting, as well as abuse of laxatives, diuretics, and diet pills. It should also cover other

◉ **Table 10.1**

Ranking of weighted criteria on the quality of treatment of eating disorders by therapists and eating disorder patients (Adapted from de la Rie et al., 2008. *International Journal of Eating Disorders, 41*, 307–317)

Therapists rank	Patients rank	Ten most-important weighted criterion items
1	6	Being respected
2		Learning take your own responsibility
3		Learning how to eat normally
4		Focus on recovering weight
5		Focus on improving your body image
6	2	Being taken seriously
7	1	Trust in therapist
8		Explanation or information on EDs
9		Keeping a(n) (eating) diary
10	9	Being able to talk about eating behaviors
	3	Treatment that addresses the person
	4	Being able to talk about feelings
	5	Focus on self-esteem
	7	Being able to talk about thoughts
	8	Addressing underlying problems
	10	Being accepted as you are

weight-controlling behaviors, such as other drug or alcohol use to control appetite, chewing and spitting food out before swallowing, prolonged fasting, and vigorous exercise for the purpose of controlling body weight. As mentioned earlier, there are numerous standardized self-report measures and structured interviews to assess eating pathology that can be used to supplement the clinical assessment (Peterson & Mitchell, 2005).

10.6.7 Educational Topics to Achieve Basic Competence

Most would agree that "generalist" skills are insufficient in the treatment of eating disorders. The competent clinician requires familiarity with specific scientific information about physical and psychological complications that perpetuate eating disorders, and this information needs to be conveyed to the patient to encourage self-responsibility and collaboration in the recovery process. "Psycho-education" has become a standard component of CBT (Garner, 1997; Garner, Rockert, Olmstead, Johnson, & Coscina, 1985) and is based on the assumption that eating-disorder patients often suffer from misconceptions about the factors that both cause and maintain symptoms. Patients are less likely to persist in self-defeating symptoms if they are made truly aware of the scientific evidence regarding the factors that perpetuate eating disorders. The educational approach conveys the message that the responsibility for change rests with the patient; this is aimed at increasing motivation and reducing defensiveness. Psycho-educational

topics will be briefly summarized and the reader should consult primary references to gain a more complete understanding of the content areas.

10.6.8 Weight Suppression and Eating-Disorder Symptoms

Eating-disorder patients typically do not appreciate the extent to which their food preoccupations, binge-eating, emotional distress, cognitive impairment, and social withdrawal are secondary to their extreme attempts to reduce or control their weight. As mentioned earlier, symptoms that once were thought to be primary features of those with eating disorders are actually better understood as consequences of semi-starvation observed in normal volunteers exposed to periods of sustained weight loss (Garner, 1997). The description of the "starvation state" as normal physiological consequences of weight suppression can mitigate guilt or defensiveness about the symptoms that may have been perceived as "primary psychopathology." It also introduces the notion that the current starved-state seriously impedes the reliable assessment of personality features, and also implies that restoring biological equilibrium is necessary to address fundamental emotional problems. Finally, the patient may be motivated through an understanding that increased food intake and the inevitable weight gain will possibly act as a method of diminishing some negative affective experiences of the disorder. Following on this thought, we have recommended that patients should think of food as "medicine" (Garner, 1997). Education must be presented sensitively to avoid minimizing the patient's current experiences that may be influenced by distorted perceptions resulting from starvation.

10.6.9 Education Indicating that Dieting Does Not Work

Long-term follow-up studies of obesity treatment consistently indicate that 90–95% of those who lose weight will regain it within several years (Garner & Wooley, 1991; Mann et al., 2007). Patients can benefit from understanding that the failure of restrictive dieting in permanently lowering body weight is not related to a lapse of will-power; rather, it is logically consistent with the biology of weight regulation that shows that weight loss leads to metabolic adaptations designed to return body weight to levels normally maintained. It is also important to emphasize that restrictive dieting may lead to weight gain in normal adolescents. Prospective studies on adolescents indicate that dieting to lose weight may actually result in weight gain and binge-eating over the course of 3–5 years (Field et al., 2003; Neumark-Sztainer, Wall, Haines, Story, & Eisenberg, 2007).

10.6.10 Education Indicating that Restrictive Dieting Increases the Risk of Bingeing

Therapists should understand the literature on dieting as a risk factor for binge-eating (Jacobi et al., 2004; Polivy & Herman, 2002) as well as the development of full-blown eating disorders (Jacobi et al.; Patton, Selzer, Caffey, Carlin, & Wolfe 1999). Severe calorie restriction breaks down into binge-eating over time, even among the most dedicated dieters – those with the "pure" restricting AN. Over an 8-year follow-up, 88% of pure restricting patients reported

regular binge/purge behaviors (Eddy et al., 2002). The fact that binge-eating can occur in the absence of primary psychopathology is surprising to many patients and can serve as a springboard to a new understanding of the need to restore normal eating patterns.

10.6.11 Education About the Self-Perpetuating Cycle of Binge-Eating and Vomiting

Self-induced vomiting and laxative abuse usually begin as methods of preventing weight gain by "undoing" the caloric effects of normal eating or binge-eating. It becomes self-perpetuating, because it allows the patient to acquiesce to the urge to eat but eliminates the feedback loop that would stem underlying hunger and food cravings.

10.6.12 Education Regarding Laxative Abuse

Laxative abuse is dangerous because it contributes to electrolyte imbalance and other physical complications. Perhaps, the most compelling argument for discontinuing their use is that they are an ineffective method of trying to prevent the absorption of calories (Garner, 1997).

10.6.13 Education Regarding Physical Complications

Eating-disorder patients should have a medical evaluation to determine the overall physical status and to identify or rule out the physical complications associated with starvation and certain extreme weight-loss behaviors (Becker et al., 1999). However, all clinicians should be aware of the range of physical complications that can be expected in those with eating disorders.

10.6.14 Education About Eating Disorders

Attention should be given to clarifying myths resulting from inaccurate or conflicting reports regarding etiology and complications of eating disorders (Garner et al., 1997).

10.6.15 Assessment and the Rationale Regarding Body Weight

Therapists without specialized training in treating eating disorders may conclude that weighing patients is either outside of their role or that it can interfere with the therapeutic relationship. Some patients may resist the idea of being weighed as part of outpatient management. However, there are practical and theoretical reasons regarding why every therapist offering specialized eating-disorder treatment should routinely assess the body weight of patients who are underweight. At a practical level, it would be irresponsible to ignore self-harming behaviors in a suicidal patient, as it would be inappropriate to ignore a precipitous drop in

body weight in an eating-disorder patient. Clearly, it is advisable for all seriously ill patients to be monitored by medical specialists; however, there is an added layer of protection when the therapist also weighs the patient. At a theoretical level, assessing body weight emphasizes the interdependence between physical and psychological functioning.

The clinician must be sensitive to the patient's current level of understanding and motivation when formulating body weight and eating goals. If body weight is below a BMI of 17.5 or if weight loss has been precipitous, then a partial hospitalization or inpatient treatment may offer sufficient structure to facilitate weight gain and is highly recommended. However, at the very beginning of the therapy, informing the patient about a precise weight goal may not be practical until there has been the opportunity to gather detailed information on the patient's personal weight history. Moreover, early in therapy, it may be prudent to avoid non-productive battles about "target" weight, and instead, can focus on educating the patient about the factors that must be considered in establishing a healthy body. Once the patient understands the range of factors that must go into recommendations about the body weight, there is more opportunity for thoughtful discussions and ultimate agreement on this difficult topic. Another way to address the issue of weight and eating-disorder symptoms is to keep a short-term focus. In the absence of formal agreement to change the eating-disorder symptoms, it is still possible to proceed with "experiments" aimed at stabilizing the body weight, normalizing eating, and controlling bingeing, vomiting, and laxative abuse.

Delineation of all the factors that must be considered in establishing a target body-weight range is beyond the current discussion; however, the APA Practice Guidelines for eating disorders (APA, 2006) provides a good source. As a general rule, favorable outcome with both anorexia and BN is associated with achieving a body weight that may be closer to 90% of premorbid weight (or extrapolations from pediatric growth charts), rather than attaining some percentage of population norms for body weight. In adolescent onset of AN, pediatric growth charts available through the Center for Disease Control provide valuable information about the trajectory of weight gain prior to the onset of the eating disorder. This concept can be alarming for patients with a higher premorbid body weight. Timing and sensitivity are essential in relating this information to patients, as prematurely recommending a higher weight that is terrifying may drive the patient from the treatment, while avoiding the topic entirely fails to address a primary treatment issue and is likely to lead to a therapeutic impasse.

10.6.16 Meal Planning and Self-Monitoring

Self-monitoring and meal planning are specific strategies to impose structure and regularity to dietary intake in those with eating disorders. Meal planning consists of specifying the details of eating in advance. It involves prescribing specific foods and amounts to be consumed, and describing the context, such as place and time. The structure imposed by meal planning allows most patients to relax rigid rules about food, and assures them that they will not be allowed to go too far in the direction of either overeating or under-eating. Self-monitoring involves recording all food and liquid ingested shortly after consumption. Therapists should feel comfortable with both the procedures and should review the meal planning or self-monitoring forms in each meeting as well as associated problematic eating behavior and dysfunctional thoughts.

10.6.17 Interrupt Bingeing and Vomiting

Basic competency in treating eating disorders involves familiarity with different strategies for interrupting binge-eating and self-induced vomiting, as well as other eating-disorder symptoms designed to lose weight. A detailed presentation of these techniques is beyond the scope of this chapter, though they have been reviewed elsewhere (Fairburn et al., 1993; Garner, 1986). Practical strategies for changing cognitive focus include: (1) delaying acting on urges to binge and purge, (2) distracting away from troublesome thoughts and urges, and (3) engaging in alternative behaviors that can break the thought chain, such as abruptly leaving the house to go for a walk, making telephone calls to friends, listening to loud music, or watching television.

10.6.18 Early Cognitive Implementations

Early treatment areas targeted with the patient largely revolve around increasing motivation for change. As indicated earlier, while some eating-disorder patients enter therapy "ready" to face the challenges of weight gain and losing the functionality of their eating disorder, many do not (Geller, 2006). Issues and beliefs often addressed early in therapy are the fear of weight gain and shape change, losing control surrounding food, and false beliefs concerning food and dietary health. Helping the patient to understand the often fluctuating path of symptoms toward recovery, allowing the patient to analyze the pros and cons of the disorder, aiding the patient in cognitively projecting into their future lives with and without the disorder, and reframing the ego-syntonic eating-disorder symptoms as incompatible with long-term goals may also be addressed at the beginning stages of the therapy.

10.6.19 Develop Cognitive Restructuring Skills

Cognitive restructuring is a method of examining and modifying dysfunctional thinking. Automatic thoughts, beliefs, and assumptions can be pinpointed by increasing awareness of the thinking process. They may also be accessed by observing behavioral patterns. For example, restricting eating to "fat free" foods implies certain beliefs. The automatic thought may also be identified by focusing on particular situations and replaying the thinking and feeling associated with that situation. Then, the patient is encouraged to generate and examine the evidence for and against a particular dysfunctional belief. Most of the following cognitive strategies have been described in connection with the treatment of other emotional disorders; however, the content and style must be adapted with regard to eating disorders. Throughout the course of therapy, the therapist needs to assist the patient in learning to identify the dysfunctional thoughts and the processing errors that influence his or her perceptions, thoughts, feelings, and symptomatic behavior. The clinician also must take particular care to avoid allowing interventions to deteriorate into an inquisition or argument over points of logic. There is a delicate balance between being persuasive on one hand, and avoiding any hint of personal attack on the other. Probes and suggestions must occur in an atmosphere of acceptance. Beliefs and behaviors that direct symptomatic behavior need to be connected to more general and often implicit schemas referred to as underlying assumptions (Beck, 1976), higher-order implicit meaning (Cooper, 1997), or schematic models (Garner et al., 1997).

Although different therapeutic orientations have been recommended in the treatment of eating disorders, empirical evidence for the utility of cognitive-behavioral methods compel the competent clinician to have mastery of the basic techniques. The clinician should be familiar with cognitive interventions, such as *decentering, challenging dichotomous reasoning, and decatastrophizing* that have been adapted to deal with the thought content of those with eating disorders (Garner & Bemis, 1982; Garner et al., 1997).

Decentering involves the process of evaluating a particular belief from a different per-spective to appraise its validity more objectively. It is particularly useful in combating ego-centric interpretations that the patient is central to other people's attention. For example, one patient reported "I can't eat in front of others in the residence cafeteria because others will be watching me." First, it needs to be established that the eating behavior is not indeed unusual. If not, then the therapist might inquire: "How much do you really think about others' eating? Even if you are sensitized to their eating, how much do you really care about it except in the sense that it reflects back to your own eating? Even if your behavior was unusual, do others *really* care?" In examples like this, decentering can be useful in reducing worry and anxiety.

Dichotomous reasoning (all-or-none or absolutistic thinking) is a common problem applied to food, eating, and body weight by those with eating disorders. For example, it is common for patients to believe that foods containing sugar are bad, eating food after a certain time of the day will lead to weight gain, or gaining a pound is a sign of complete loss of control. This style of thinking is applied to topics beyond food and weight. Patients commonly report extreme attitudes in the pursuit of sports, school, careers, and acceptance from others. This type of reasoning is particularly evident in the beliefs about self-control. Common examples include: "If I am not in complete control, I will lose all control;" "if I become angry, I will lose control of my emotions;" "if I experience pleasure, I will be dominated by hedonism;" "if I relax, I will become lazy." A major therapeutic task is to teach the patient to recognize this style of thinking, examine the evidence against it, evaluate its maladaptive consequences, and subsequently, practice adopting a more balanced lifestyle.

Decatastrophizing was originally described by Albert Ellis (1962) as a strategy for challeng-ing anxiety that stems from magnifying negative outcomes. It involves asking the patient to clarify vague and implicit predictions of calamity by probing with questions such as: "What if the feared situation did occur? Would it really be as devastating as imagined? How would you cope if the feared outcome does occur?" Ironically, catastrophizing can actually produce the feared outcome. In an attempt to avoid social rejection and isolation, patients may withdraw from all social interactions, thus becoming isolated. Fear of failure can lead to the scrupulous avoidance of risk which results in failure. Moreover, there is no relief from catastrophic think-ing. If a patient believes gaining weight would be a catastrophe, it is clear why they would be fearful and anxious when they experience weight gain. What is less obvious to the patient is that even when the fears are avoided in the short-term, it does not completely eliminate anxiety as there is a risk for the perceived calamity to develop in the future. In addition to helping the patient temper dire forecasts about the future, the therapist can facilitate the development of coping plans for mastering feared situations if they were to occur.

10.7 Expert Competencies of the Clinician

The categorical distinction between basic and expert clinician competencies is somewhat artificial, as nuance and complexity can be applied to even the most basic topics areas. For

example, meal planning may seem quite straightforward in its basic form; however, a patient's objections to meal planning may be related to a myriad of underlying or core self-concept deficits, cognitive vulnerabilities, or interpersonal themes rather than a simple lack of information. For example, describing or implementing meal planning can lead to resistance that reflects complex family dynamics related to control, and simply providing information without awareness of the underlying interpersonal themes would only intensify the conflict and subterfuge therapeutic recommendations. The distinguishing feature of the expert clinician is the ability to identify the relevant themes and then creatively implement effective interventions that address the complex determinants of behavior.

10.7.1 Understanding the Multiple Functions of Eating-Disorder Symptoms

Regardless of the conceptual framework used in therapy, there is a general agreement that eating disorders and their symptoms can serve multi-level adaptive functions across the heterogeneous patient population (Cooper, 2005; Garner et al., 1997; Vitousek, 1996). At the most basic level, these can be understood in reinforcement terminology. One factor responsible for the intransigence of eating-disorder symptoms is that they are maintained by positive internal and social contingencies. They have been described as eliciting feelings of accomplishment, pleasure, power, and pride (Bemis, 1983; Vitousek et al., 1998). It is not uncommon for patients to strive for and then cling to an "anorexic identity," because the disorder or symptoms of the disorder such as dietary restraint and exercise have acquired such a positive connotation in Western society. The strength of the positive connotation that has been placed on eating-disorder symptoms by some is reflected by the popularity of the so called "pro-anorexic" websites that brazenly extol the virtues of eating disorders as a "lifestyle" rather than a serious illness. Eating-disorder symptoms can also have a negatively reinforcing function, in that they allow the patient to prevent, avoid, or diminish unpleasant feelings. Examples include negative emotions, conflict, and anxiety, as well as a mature body shape that may be associated with fears or developmental expectations for which the patient feels unprepared. Self-starvation can also serve as an "organizing" function, particularly in obsessive patients. Starvation tends to direct thinking toward specific cognitive content domains related to food. This may not only have a positively reinforcing effect on an individual with obsessive preference for order, exactness, and sameness, but it may also accommodate a rigid information-processing style by narrowing focus in a predictable manner.

10.7.2 Advanced Cognitive Interventions

The therapist tends to take the lead in early cognitive interventions by probing the implications of specific behaviors and then gently countering them with information within pertinent arguments. This strategy quickly reveals the content and intensity of dysfunctional beliefs and thinking patterns that pertain to more fundamental underlying assumptions, schemas, and core beliefs that drive maladaptive behaviors. These cognitive schemas (relatively stable cognitive structures that organize and interpret new information) are by nature resistant to change often reflecting information biases (e.g., selective abstraction, overgeneralization, magnification

of negative events, dichotomous reasoning, or personalization) that may be biologically and genetically determined, as in the case of perfectionism reviewed in the following section. Shifts in the fundamental information-processing styles and the core beliefs that they support depend heavily on the development of a positive therapeutic relationship as well as a high level of therapeutic skill. Movement away from familiar but dysfunctional thought patterns is a gradual process that may require months or even years practicing the application of new modes of thinking in many different situations. It is essential to remain mindful of the inherent links between cognitions and behavior. Putative shifts in beliefs that are not accompanied by associated behavioral change may be viewed with skepticism. Advanced cognitive interventions involve behavioral experiments and exercises that are molded to reinforce as well as corroborate cognitive shifts in emergent belief structures. Behavioral exercises molded to reinforce new models of thinking are gradual and are often performed with trepidation on the part of the patient; therefore, the clinician must play a vital role in encouraging and reinforcing the pursuit of adaptive and healthful goals throughout the course of treatment.

10.7.3 Anxiety, Obessionality, and Perfectionism

Those with eating disorders have been shown to have an elevated lifetime prevalence of several anxiety disorders, including simple phobia, social phobia, panic, and OCD (Halmi et al., 1991; Perdereai, Faucher, Wallier, Vibert, & Godart, 2008; Toner, Garfinkel, & Garner, 1988). These reviews have led to the conclusion that anxiety disorders may represent a genetically mediated pathway to the development of eating disorders. Those with eating disorders tend to display only some obsessional target symptoms, such as need for order, symmetry, exactness, and arrangement, rather than obsessive checking or sexual obsessions common among others with OCD (Perdereai et al., 2008).

Perfectionism has been found to precede the onset of eating disorders, is present during the acute phase, persists well after recovery, and runs in families (Bulik et al., 2003; Franco-Paredes, Mancilla-Diaz, Vasquez-Arevalo, Lopez-Aguilar, & Alvarez-Rayon, 2005). There is considerable debate about the definition and structure of perfectionism as it relates to eating disorders; however, "high personal standards," "doubts about actions," and "concern over mistakes" have been identified as core constructs in a multi-conceptualization of perfectionism (Tozzi et al., 2004).

The central role that anxiety and worry plays in the development and maintenance of eating disorders has practical implications on clinicians aspiring to achieve expert competence in the treatment of these patients. In addition to understanding the idiosyncratic fears and worries experienced by those with eating disorders, it is also important for the clinician to be well-versed in both the theory and practice of treating those with severe anxiety disorders.

Behavioral methods of desensitization and graded exposure as well as their cognitive foundations are central elements of therapy. In the area of behavioral change, patients experience intense and sometimes debilitating fear with attempts to change eating patterns and gain weight. If patients are to recover, they must begin making behavioral changes in these areas. The experienced therapist is able to provide support and encouragement, as well as generate persuasive arguments for making behavioral change in the presence of extraordinary anxiety. This is one area in which specialized training is essential. The "irrational" nature of the danger or threat experienced by most anxious or phobic patients (e.g., fear of flying, social phobia, panic, agoraphobia, hand washing) may be evident to even the untrained health professional,

although the techniques for ameliorating the problem usually require technical expertise. However, the erroneous thinking behind many of the fears expressed by those with eating disorders is not always obvious and may even be shared by a therapist who has not had specific training (e.g., "dietary fat is bad – if I eat dietary fat, I will gain weight;" "I cannot allow myself to eat certain foods or I will lose control;" "I must take laxative so the food is not absorbed;" "I cannot eat more than 1,000 Calories or I will gain weight and become obese;" "if I eat 100 extra calories a day, I will gain 10 pounds a year;" "my body will get used to restricting to fewer calories;" "I am terrified of eating any sweets because they make me binge-eat;" I am frightened to eat after 6:00 pm because the food will turn to fat;" I must exercise an hour a day or I will gain weight"). As mentioned earlier, psychoeducation can be used to challenge certain irrational beliefs and assumptions associated with idiosyncratic eating behaviors (Garner, 1997). However, exposure through behavioral change is necessary to probe, challenge, and provide "evidence" to correct faulty assumptions regarding eating, weight, and related self-attributions. For example, it is probably more difficult to maintain the belief that you cannot eat dietary fat or sugar without binge-eating if you indeed consume these substances without losing control. Similarly, behavioral change can have a profound effect on the beliefs in other areas that are not directly related to food and weight. Successful social interaction can attenuate the view of self as socially incompetent. Independent and self-reliant behavior interferes with personal and family schemas that foster over-protectiveness and excessive dependence. However, it should be noted that with more fundamental belief systems, such as those related to negative self-evaluation, it is possible for well-established beliefs to remain intact, despite undeniably contradictory behavior. Again, it is important for the therapist to make sure that the implications of the behavioral change are integrated at the cognitive level.

10.7.4 Body Image: Reattribution Techniques

Misperceptions related to weight and shape do not characterize all patients with eating disorders; however, a significant proportion of patients appear unable to accurately appraise their body. There are no reliable methods for directly modifying body-size misperception in eating disorders. Rather than correcting size misperception reported by some patients, it is useful to reframe the interpretation of the experience (Garner et al., 1997). This involves interrupting and overriding self-perceptions of fatness with higher-order interpretations, such as "I know that those with eating disorders cannot trust their own size perceptions" or "I expect to feel fat during my recovery, so I must consult the scale to get an accurate reading of my size." The therapist can ask the patient to attribute these body self-perceptions to the disorder, and to refrain from acting upon intrusive thoughts, images, or body experiences. This approach is contrary to the general therapeutic goal of encouraging self-trust in the validity and reliability of internal experiences.

10.7.5 Modifying Self-Concept

Self-concept is a multidimensional construct involving at least two sub-components: self-esteem and self-awareness. Self-esteem constitutes the appraisal or evaluation of personal value, including attitudes, feelings, and perceptions. In contrast, self-awareness relates to the perception

and understanding of the internal processes that guide the experience. Vitousek and Ewald (1993) have organized self-concept deficits that are characteristic of eating disorders into three broad clusters of variables: the unworthy self, the perfectible self, and the overwhelmed self. The *unworthy self* is characterized by (1) low self-esteem, (2) feelings of helplessness, (3) a poorly developed sense of identity, (4) a tendency to seek external verification, (5) extreme sensitivity to criticism, and (6) conflicts over autonomy/dependence. The second cluster, the *perfectible self*, includes (1) perfectionism, (2) grandiosity, (3) asceticism, and (4) a "New Year's resolution" cognitive style. The third cluster, the *overwhelmed self*, is characterized by (1) a preference for simplicity, (2) a preference for certainty, and (3) a tendency to retreat from complex or intense social environments. The expert clinician should have a good working knowledge on self-concept deficits and methods of modifying it in those with eating disorders.

10.7.6 Improving Self-Esteem

As mentioned earlier, it is well recognized that poor self-esteem often predates the appearance of eating-disorder symptoms (Jacobi et al., 2004; Stice, 2002). The pride and accomplishment of weight control seem to temporarily alleviate low self-esteem, particularly in adolescents coming from families that place greater emphasis on appearance (Senra, Sanchez-Cao, Seoane, & Leung, 2007). Correction of low self-esteem, particularly, if pervasive and long-standing, is a time-consuming process. At the beginning of the therapy, it may be expressed in vague terms such as general feeling of ineffectiveness, helplessness, or lack of inner direction. Over time, the therapist needs to help the patient distill vague assumptions about self-worth into a clear and simple statement such as "I feel like a failure," "I do not feel like a worthwhile person," or "I must be liked by others in order to feel good about myself." Once the patient has expressed the view that he or she has low self-worth, it is useful to engage in a more general discussion about the basis for self-worth, later applying what has been learnt back to particular index situations identified by the patient. It is often useful to begin by noting how much time and energy most people devote in trying to evaluate their self-worth. For most patients, weight or shape has become the predominant gauge for inferring self-worth. It is possible to determine the pros and cons of this frame of reference and then to extend this to other behaviors, traits, or characteristics employed in the process of self-evaluation following the procedures described by Burns (1993).

10.7.7 Difficulties in Labeling and Expressing Emotions

Cognitive theorists have attributed this tendency to idiosyncratic beliefs, assumptions, or schemas that eating-disorder patients use in evaluating inner state (Garner & Bemis, 1985). These beliefs commonly center on attitudes about the *legitimacy*, *desirability*, *acceptability*, or *justification* of inner experiences. The following comments by patients are clues to the operation of this process: "I do not know how I feel; how should I feel?," "I do not experience pleasure; I never feel angry," "I am always energetic and never get tired," "I admire others who don't show their feelings," "I can't stand these feelings – they are too strong," "I don't feel anything – I just binge." Asked about feelings in a family interview, one patient appeared confused and responded by pointing to her mother stating: "ask her, she knows me better than I do." Similar mislabeling can be applied to other sensations like pleasure, relaxation, or sexual feelings. Patients

commonly interpret these sensations as "wrong," frivolous, or threatening. One patient reported: "If I give in to the urge to relax, I will become a degenerate." Once distorted meanings are revised, it is important for the therapist to encourage behavioral exercises to reinforce and legitimize the new interpretations.

10.7.8 Interpersonal Focus in Therapy

Interpersonal concerns are inevitably expressed by eating-disorder patients during the course of therapy. The prominence of interpersonal schemas has been the basis for their inclusion in earlier cognitive approaches to the disorder (Garner & Bemis, 1985; Garner et al., 1997). Self-schemas and interpersonal schemas both influence and are influenced by interactions with others. Although the interpersonal focus to therapy requires a shift in therapy content, the systematic reliance on standard cognitive procedures continues. Patients tend to apply the same types of schematic processing errors and dysfunctional assumptions to interpersonal relationships as those displayed in other areas (Cooper, 2005).

Cognitive therapy generally eschews the exploration of historical individual material; however, this approach can also be therapeutic in examining interpersonal schemas. First, it is sometimes necessary to examine historical relationships to find recurrent interpersonal patterns. Second, it can be useful for patients to develop some understanding of the historical events and relationships that may have made particular interpersonal schemas "adaptive." Understanding the earlier adaptive context can allow the patient to make sense of the current dysfunctional interpersonal schemas. Therapy sessions provide in vivo opportunities to assess dysfunctional interpersonal schemas that may generalize outside the therapy. For example, the patient might be encouraged to examine beliefs that interfere with assertiveness and then practice assertiveness in the therapy session. The therapist and the patient then need to plan out-of-session opportunities to apply this newly-acquired skill.

10.7.9 Family Therapy

Support for involving the family in the treatment of eating disorders comes from a number of sources. First, there are ethical, financial, and practical grounds for including the parents in the treatment of younger patients with eating disorders. Second, recovered patients consider resolution of family and interpersonal problems as pivotal to recovery (Rorty, Yager, & Rossotto, 1993). Third, this mode of intervention has received empirical support in controlled trials (le Grange et al., 2007; Russell et al., 1987).

Practical factors are sufficiently compelling to justify the family approach with some patients; however, our primary impetus for integrating family and cognitive approaches to eating disorders is the conceptual harmony that can be achieved in integrating these two treatment models (Garner & Bemis, 1985; Garner et al., 1997). At a fundamental level, there is agreement between both the models for which "meaning" is the primary locus of clinical concern. Also, both the models assume that the symptoms are adaptive at one level of meaning and dysfunctional at another. The clinician should not assume the specific meaning behind interactional patterns, but should try to assist the patient and the family in identifying dysfunctional assumptions through questioning and the prescription of behavioral change.

The following example illustrates multi-level beliefs. One patient did not understand why she was so angry at her mother's cheerful and congenial manner until she realized that it was really insincere. This patient communicated her anger in her conflict-avoidant family by vomiting, claiming that her behavior was involuntary. The clue to the meaning of her behavior was that she always left the bathroom door open and retched so that all could hear. By defining her vomiting as involuntary, she denied its hostile intent and avoided reprisals.

10.8   Transition from Basic to Expert Competence

There are several important factors to consider in facilitating the transition from basic to expert competency in treating eating disorders. Expert competency requires knowledge of the theory and the application of therapeutic model being used. One of the advantages of the cognitive model of therapy is that there have been detailed manuals providing the structure, stages, content, and methods used (Cooper, Todd, & Wells, 2008; Fairburn, 2008; Garner, Vitousek, & Pike, 1997; Lock et al., 2001). Clear specification of the treatment methods allows better evaluation of how closely therapists adhere to treatment protocols. There are several other areas that are important focal points to consider in this brief discussion of transition to expert competence such as: (1) therapy skills; (2) mastery of content; (3) case conceptualization; (4) relationship factors; and (5) supervision.

10.8.1 Therapy Skills

Cognitive therapy emphasizes on collaboration, guided discovery, and structure (Beck, Rush, Shaw, & Emery, 1979), and these key elements apply to the treatment of eating disorders.

As has been mentioned repeatedly in this chapter, eating disorders are a heterogeneous group, and the competent clinician must have the ability to select the most appropriate approach that fits each patient's needs. One approach to varied patient needs has been "stepped-care," "decision-tree," or "integration" models which rely on fixed or variable rules for the delivery of the various treatment options (Garner & Needleman, 1997). According to the stepped-care model, a patient is provided with the lowest step intervention, one that is least intrusive, dangerous, and costly, even if the lowest step intervention does not have the highest probability of success. In contrast, a decision-tree approach provides numerous choice points resulting in different paths for treatment, depending on the clinical features of the patient as well as the response to each treatment delivered. The use of a combined decision-tree and integration model recommends an educational approach as the initial intervention for the least disturbed BN patients, and forms of treatment need to be integrated for more severe patients such as those with AN. Family therapy is recommended as the primary treatment modality if patients are young, living at home, or highly dependent on parents. Until recently, inpatient hospitalization was the standard treatment for patients who needed to gain substantial body weight; however, most of these patients can now be managed effectively and at substantially lower cost at the partial hospitalization program (PHP) level of care. Selecting the correct form of treatment, applying specialized content, formulating a viable conceptualization of each case, and developing a strong therapeutic relationship are necessary ingredients to achieving competency. Mastery of different therapy formats (individual, group, or family) is highly desirable depending on the work setting.

10.8.2 Mastery of Content

There has been enormous growth of the knowledge base on eating disorders in the past 20 years, and mastery of the key content domains and their clinical application is a daunting task. Moreover, the compiling of research evidence in the eating-disorder area continues to accelerate, making it challenging to stay abreast of current developments. As has been emphasized throughout this chapter, many of the educational content areas in therapy with eating-disorder patients, such as the biology of weight regulation, are not part of the standard preparation of the "generalist" therapist. Basic educational principles must be learnt; however, achieving competency involves conceptualizing the most important targets for change and then artfully interweaving educational and core cognitive content domains in an effective manner.

10.8.3 Case Conceptualization

A cornerstone of therapist competency is the ability to formulate a useful conceptualization of the core problems that apply to the patient. Understanding the specific meaning that the eating-disorder symptoms have acquired for the individual and how this meaning has changed over time is vital. This involves understanding of the present meaning that body weight, shape, and appearance has for the patient as well as the historical derivations of the meaning. For many patients, the historical source may be very different from the factors maintaining the symptoms in the present. For example, a patient may develop the eating disorder in response to being teased about weight as a child, but the current symptom picture may be driven by feelings of control and mastery. It is desirable to move beyond more generic conceptualizations to a more individualized understanding that takes into account the patient's developmental and interpersonal history as well as the key assumptions, core beliefs, and functional aspects that symptoms have acquired over time. Therapists should be encouraged to discuss tentative conceptualizations early in supervision and make refinements based on new information. It is important to determine the patient's conceptualization of the functional aspects of the eating disorder, as a shared understanding of the fundamental problems can be expected to lead to greater progress.

10.8.4 Relationship Factors

As mentioned earlier, trust in the therapeutic relationship is rated by patients as the most important component of treatment quality (de la Rei et al., 2008). Maintaining a positive therapeutic relationship can be challenging, as some patients are very resistant to making behavioral change and seem intent on sabotaging progress. However, it is beneficial to develop a good understanding of the functional aspects of the disorder and to convey this along with empathy and compassion to the patient. In a classic work on motivation for change, Vitousek et al. (1998) provided practical suggestions for understanding resistance to change, and developing empathy and validation of the patient's experience without undermining the arguments for recovery.

10.8.5 Supervision

Perhaps, the most important element in the transition from basic to expert skills as a therapist is acquiring state-of-the-art training from a skilled and experienced therapist. It is ideal to be part of a team in a multidisciplinary setting that permits live observation of the delivery of high-quality treatment as well as discussion of the rational for specific interventions. Supervision usually begins with didactic discussions and specifically designed reading material. The focus is on mastery of the therapy methods, educational content, and developing case conceptualization skills. As therapy skills develop, more attention is focused on the therapy relationship and understanding more advanced topics, such as the integration of individual and family interventions. Group therapy can be a useful training format, as it allows the less experienced therapist to benefit from real-time learning from a more skilled therapist. It is important to encourage the novice therapist to participate in the group therapy process and build on the supervisee's strengths. Another key function of supervision is to provide the less experienced therapist with an opportunity to share reactions to patients and the process of the therapy. Role playing can be effective in illustrating specific therapy skills. Videotapes can have the advantage of capturing particular themes or learning points that can be discussed in relation to specific theoretical principles. Supervision should pinpoint problem areas, identify the specific skills needed to advance competency, and provide a clear roadmap for continued training.

10.9 Summary

Therapist competency is fundamental to the success in treating most psychological disorders. However, the skills required to effectively treat eating disorders may be more demanding than many other problems, because competency requires mastery of considerable educational information about physical complications associated with eating-disorder symptoms and chronic weight suppression. The cognitive-behavioral model of treatment has become well-defined in recent years; however, the mark for therapist competency continues to rise as the knowledge base has expanded with the high level of clinical and research interest in eating disorders. The guidelines provided in this chapter are intended to provide a springboard for the training and supervision to improve patient care.

11 Substance Use Disorders

Brad Donohue · Kendra Tracy · Ashli J. Sheidow

Abstract: Although adolescent substance abuse has decreased during the past decade, its consequences to family, society and youth who abuse substances are devastatingly problematic. Youth afflicted with this disorder are often highly resistant to treatment and pose unique challenges to therapists, including difficulties achieving diagnostic accuracy, rapport, and development of social support networking. To address these difficulties clinical research involving adolescent substance abuse has become increasingly sophisticated during the past decade, resulting in a growing body of knowledge and skill sets in mental health professionals treating this disorder. Therefore, this chapter begins with a full description of the disorder, including various co-occurring problem behaviors, prevalence and important issues leading to its development and maintenance. We then underscore evidence-based methods that have been found to effectively identify, formally diagnose, and functionally assess substance abuse in adolescents. We also describe factors that often complicate treatment planning, as well as solutions to these problems. Evidence-based treatments for adolescent substance use are reviewed, particularly family- and behavioral-treatments, due to their efficacy. Finally, clinical and administrative competency is extensively reviewed, both in the degree to which mental health professionals progress from novices to experts, as well as the progression that naturally and empirically occurs from the point of intake to treatment termination. Given the emphasis on empirical skill development in this chapter, we review several training models that have demonstrated effectiveness in competency at the novice and expert level.

11.1 Substance Abuse and Dependence

11.1.1 Overview

This chapter underscores the scientific literature of Substance Abuse and Dependence, as relevant to clinical competence. We begin with a brief review of the diagnostic criteria for these disorders, and outline their prevalence, course, risk factors, and useful strategies in the assessment of their clinical symptoms. Given the inherent bias of participants to conceal substance use, we emphasize on the assessment strategies that are relevant to its identification, including biological testing and self-report screening instruments. We also provide a brief review of the underlying mechanisms involved in maintenance of substance-abusive patterns of behavior, and evidence-supported psychological methods used to treat these problem behaviors. In conclusion, the recent developments in the assessment and training of clinical competence allow a broad range of issues to be described that are relevant to clinical competence as applicable to substance abuse and dependence.

11.2   Overview

11.2.1 Diagnostic Features

As defined by the *Diagnostic and Statistical Manual of Mental Disorders* (*DSM*; American Psychiatric Association, 2000), substance abuse and dependence are the two most frequently occurring substance disorders. Substance abuse is less severe, and includes a maladaptive pattern of substance use leading to clinically significant impairment. Such problems include fulfilling major role obligations owing to substances, using substances in dangerous situations, legal problems, or continued use despite persistent or recurrent social or interpersonal problems. Substance dependence is more severe, and is often indicated when physiological symptoms are experienced, such as tolerance and withdrawal. Symptoms of dependence include unsuccessful efforts to lower or control the frequency of use, spending excessive amounts of time in activities necessary to obtain, use, or recover from substance use, withdrawal from important social, occupational, or recreational activities, and continued use despite having persistent physical or psychological problems.

11.2.2 Prevalence, Course, and Risk Factors

Overall, adolescent substance abuse has been declining gradually since 1999. However, lifetime prevalence of illicit substance use among adolescents is still relatively high at 47% (Johnston, O'Malley, Bachman, & Schulenberg, 2008). Marijuana is the most prevalent and easily accessible drug, and thus is most resistant to trends of declining use. High levels of marijuana use in adolescence are related to poor academic achievement and degree attainment, higher rates of unemployment and dependence on welfare, and poorer relationship quality (Fergusson & Boden, 2008a, b). Misuse of prescription pills or other medications, such as cough syrup, has been on the rise among adolescents since 1999, although recent reports have shown that this rate is decreasing or holding steady (see Johnston et al., 2008 for a review). With nearly 20% of the eighth graders reporting drug use at some point in their lifetime, the problem of adolescent substance abuse remains a major concern.

Early onset of substance abuse is related to higher rates of mental-health problems (e.g., depression, anxiety, Attention Deficit Hyperactivity Disorder), and higher rates of drug use in late adolescence and young adulthood (Fergusson & Boden, 2008a, b; Teesson, Degenhardt, Toumbourou, & Loxley, 2005). Adolescents who use substances have a higher mortality rate and are more likely to engage in risky behaviors, such as unprotected sex, which puts them at risk of pregnancy and contracting HIV and other sexually transmitted diseases. In addition, adolescents' brains may be more susceptible to the effects of substances than adults, with early use resulting in brain abnormalities, structural damage, and cognitive impairments (Lubman, Yucel, & Hall, 2007). Though some of the effects of substance use are temporary, with chronic use, the effects of substance use may be irreversible.

Effects of substance abuse can be severe. Therefore, it is important to recognize adolescents who may be at particular risk for substance use, so that prevention measures can be initiated early in the developmental process. Risk factors may be manifested in the adolescent's community, peer group, family, or in the adolescent's own characteristics, such as a preference for novelty or sensation seeking. Poverty or living in a poverty-stricken area is often associated with drug use. Along a different vein, substance-using peers have consistently been identified

as one of the strongest predictors of adolescent substance abuse. In addition, a history of substance abuse in the family puts the adolescents at risk. This effect is not simply owing to modeling or social learning, as a genetic component has been indicated demonstrating that patterns of substance abuse in families can be transmitted up to three generations (Fergusson, Boden, & Horwood, 2008). Children who have been physically or sexually abused are at risk of developing substance-use problems. Indeed, many adolescents report that they begin using substances to help them cope with mistreatment, and continue to use substances for many of the same reasons (Titus, Godley, & White, 2007).

11.3 Recognition of Symptoms and Their Assessment

Elimination of problem behaviors associated with substance abuse and dependence generally follows a consistent course of action. First, it is necessary to recognize when substance use is problematic, or conservatively speaking, when it has the potential to become problematic. Among other reasons, recognition of the symptoms of substance disorders in adolescents is often difficult to assess, because societal punishments are usually initiated when substance use is discovered (e.g., fines, arrests, antipathy), the symptomatic presentation varies across drugs, and there is sometimes poor recall of events owing to memory impairments influenced by substance use. Physical effects of drug use are perhaps the most recognizable, such as dilated pupils, poor motoric coordination, or slurred voice. However, these indicators are often caused by factors that are not associated with substance use, and often vary according to the type of substance ingested. For example, cocaine, a stimulant drug, is known to enhance euphoric feelings and thereby increase the activity levels, whereas depressant drugs (e.g., benzodiazepines) are often used for their relaxing effects, resulting in decreased levels of activity. The immediate physical symptoms of drug use are also relatively short-lived and usually have an abrupt onset. As such, it can be difficult to verify the presence of symptoms because they can be easily disguised or hidden. For instance, bloodshot eyes can be masked by wearing sunglasses or avoiding going home until the drug effects wear off. Therefore, professionals and family members working with adolescents who are suspected of substance abuse should become familiar with symptoms of specific types of drugs. Professionals may gather this information from research-supported manuscripts (e.g., Physician's Desk Reference, 2009), whereas family members may find reputable Internet websites particularly valuable. Along this vein, the National Institute on Drug Abuse has an interactive website that underscores factual information about illicit drugs, reports testimonials from youth who have experienced drug abuse, and includes electronic quizzes relevant to knowledge of drug symptoms (see NIDA for Teens; teens.drugabuse.gov).

Changes in behavior and relationships may be indicative of problematic substance use. These include changes in appearance (e.g., decrease in hygiene), delinquency, difficulty remembering recent events, changes in appetite (which may lead to marked weight gain/loss), changes in sleep patterns, bizarre behavior or speech (i.e., paranoia), and inappropriate affect. Substance abuse also negatively affects the academic performance, as school may be missed to recover from the effects of substance use or school may be avoided to use substances. Drug use also indirectly exacerbates school performance by negatively influencing motivation for self-improvement, and causing difficulties with memory and concentration. Indeed, drug use may be prioritized over school, with increasing time spent on drug-related activities and less time

for schoolwork. Therefore, a sudden drop in grades or an increase in absenteeism is common among adolescents who abuse substances. An abrupt increase in behavior problems may also occur, particularly at home and school where adolescents spend much of their time. Drug abuse may influence adolescents to change their peer structure, spend more time engaged in activities with other drug uses, and perhaps become delinquent youth. There may be a noticeable lack of motivation or loss of interest in activities that were once enjoyed, resulting in stressed relationships with family members and friends who do not approve of drug use. When adolescents who have not evidenced family problems begin isolating themselves from their family or make new friends who are not introduced to the family, this may be indicative of substance abuse.

Adolescents who abuse substances also evidence emotional or attitudinal changes, including feelings of being disconnected from others, emotional lability, or marked changes in mood. Indeed, drug abuse may influence adolescents to engage in frequent angry outbursts in response to ordinary events. Some may show signs of depression, cry often or without warning, report feeling of sadness or hopelessness, or experience worrisome thoughts that are excessive.

Symptoms of substance abuse are similar to those of other psychological disorders, and hence differential diagnosis is difficult, albeit essential. There are several comorbid conditions frequently associated with substance abuse and dependence in adolescents. These include disorders of conduct, depression, impulsivity, and anxiety (Azrin et al., 2001). Indeed, between 30% and 60% of drug users are estimated to evidence a coexisting mental-health condition (Leshner, 1999). It is important to assess how these conditions interact to influence the onset, course, and severity of substance use. As peer relationships and school-related pressures are salient to adolescents, it is useful to adopt a systemic and thorough assessment of developmental, family, and academic histories, current social and psychological functioning, and the sociocultural milieu to obtain a clear picture of the presenting problem. Along these lines, it is recommended to use a variety of assessments from a variety of informants, whenever possible.

The assessor should be familiar with commonly used psychoactive substances, their street names, and their effects. The National Institute of Drug Abuse [NIDA] has compiled a comprehensive list of illicit substances, their street names, methods of ingestion, and their associated intoxicating effects and health consequences that is available on their website (NIDA, 2008). With nearly 25% of eighth graders reporting use of an illicit substance, it is important that screening for substance use begin early. The American Medical Association (AMA) recommends screening for substance use in elementary school with continued assessment on a yearly basis (AMA, 1997). Another approach involves screening youth who are particularly at risk for substance disorders, including those identified to use alcohol and drugs. Primary psychometric methods of identifying youth who may be using or abusing substances include biological testing of urine, saliva, blood, and hair follicles (also breath in the case of alcohol), and self-report screening measures. Biological tests yield rapid results, and are relatively easy to administer. However, they are sometimes considered invasive by those being tested, and are often unable to detect when the use has occurred owing to the time of test administration being too far from the time of substance use or because of the use of adulterants (some of which are undetectable). Biological testing is limited in its ability to indicate the extent and circumstances of substance use, as well as when the detected substances were used. However, it is the gold standard objective measure of substance use, particularly in adolescents.

Self-report screening instruments are often developed to identify risk and protective factors relevant to substance abuse and dependence. Psychometrically-validated screening instruments include the Problem-Oriented Screening Instrument for Teenagers (POSIT; Latimer,

Winters, & Stinchfield, 1997); the Drug Use Screening Inventory (DUSI; Kirisci, Tarter, & Hsu, 1994; Thomas, 1990); the Personal Experience Screening Questionnaire (PESQ; Winters, 1992); and the Drug and Alcohol Problem – Quick Screen (DAP; Schwartz & Wirtz, 1990). The afore-mentioned scales are relatively brief (e.g., requiring from 10 to 40 min to complete), and most provide subscales that may be used to assist in the assessment of co-morbid constructs that are relevant to treatment planning. The Time-Line Follow-Back procedure (Sobell & Sobell, 1996) may be used to obtain an estimate of the frequency of substance use. In this method, a month-by-month calendar for the time period of interest (i.e., usually 4–6 months prior to the day of assessment) is utilized. Significant memory anchor points (e.g., birthdays, family activi-ties) are recorded on the calendar to facilitate recall of the days on which the substances were used. Adolescents are asked to indicate on the calendar the days on which illicit drugs and alcohol were used. Additionally, reports of frequency of substance use are obtained from col-lateral sources, typically a parent, thus, greatly enhancing the sensitivity of this measure to detect substance use. Psychometric properties of this scale are very good, as it has been found to significantly correlate with urinalysis testing and measures of behavior problems that have been negatively influenced by substance abuse in adolescents (Donohue, Hill, Azrin, Cross, & Strada, 2007).

Although self-report screening instruments have been shown to be relatively reliable and valid in determining adolescents who are likely to evidence substance abuse and dependence, most provide limited information that is directly relevant to treatment. Therefore, when substance abuse is suspected, clinical interviews may be used that have established psychometric support. For instance, the Structured Clinical Interview for Adolescents (SCI; Brown, Vik, & Creamer, 1989) is a psychometrically-validated semi-structured interview that yields information relevant to diagnosis and treatment planning. As it is directly relevant to substance use, this interview may be utilized to assess the desire to eliminate substance use and family history of substance use. Other topics include interpersonal relationships, academia, psychological functioning, and peer behavior. The Structured Clinical Interview for DSM-IV diagnosis (SCID-IV; First, Spitzer, Gibbon, & Williams, 1997) is more diagnostically focused than the SCI, and may be utilized to assess the major AXIS I mental disorders in the DSM-IV-TR, including substance abuse and dependence that are important to consider in treatment planning. The SCID-IV has good validity and reliability (Williams et al., 1992), but requires substantial training, and is relatively less flexible than the SCI. Nevertheless, structured (e.g., SCID) and semi-structured (e.g., SCI) clinical interviews may be used to assist in determining areas warranting comprehensive assessment (e.g., pathological symptoms that co-exist or over-lap with substance abuse and dependence), particularly when these methods are combined with other self-report measures and unstructured interviews.

11.4 Maintenance Factors of Substance Abuse and Dependence

Substance abuse and dependence in adolescents are often maintained by antecedent stimuli that precede drug use and positive consequences occurring after drug use. Stimuli may influ-ence drug use explicitly through reinforcement, or indirectly owing to their past associations with drug use. Direct or explicit influences are usually more obvious, and include modeling by adolescent peers, encouraging and praising drug use, providing drugs, and mandating drug use as a right of passage or initiation (e.g., gang involvement). Indirect influences contribute to

drug use through classical and higher-order conditioning, and are particularly difficult to assess because the extent of their influence is often unknown. For example, mere presence of peers may stimulate drug urges owing to their previous positive associations with drug use at parties. Specific places (e.g., street signs, bathrooms) and objects (e.g., drug paraphernalia, cash) that have become associated with drug use are notorious "triggers" for future drug use, as are situation-specific antecedents (e.g., being expelled from school, boredom, excitement, various celebrations). Adolescents may also use illicit drugs and alcohol when they encounter aversive stimuli (e.g., arguments, death of a loved one, physical pain, and illness), thereby removing aversive states and maintaining future drug use through the process of negative reinforcement. Conversely, people who are associated with abstinence from drugs usually act to buffer against drug use, as these individuals are more likely to engage in non-drug associated activities (e.g., sport activities, homework) at places that are incompatible with drug use (e.g., school, family home).

There are various contextual factors that act to facilitate or inhibit drug use. For instance, community factors may include culture, neighborhood characteristics, presence of violence, and availability of drugs in the community. When drugs are readily available, it becomes much more difficult to achieve or maintain sobriety. In support of this finding, Schiffman (2004) found that one of the strongest predictors of marijuana use was the availability of drugs. Indeed, adolescents were seven times more likely to have used marijuana in the past year if they had been given the opportunity to buy drugs. When availability is combined with other risk factors, adolescents may be particularly vulnerable to drug use. For example, many adolescents who have been found to abuse drugs lack assertiveness skills in refusing substances, including difficulties generating alternative actions to drug use (Donohue, Van Hasselt, Hersen, & Perrin, 1999). Thus, neighborhoods and schools in which drug users and drug dealers are part of the culture are likely to maintain substance abuse.

Social factors are also very important in the maintenance of adolescent drug use. For example, arguments occurring between family members may distract parents from focusing on the problems of their youth. Permissive parenting styles may lead to inadequate monitoring of youth, which appears to be associated with greater rates of marijuana use (Lockman, 2003). Parental modeling of substance use also acts to trigger drug use in their children (Fergusson, Boden, & Horwood, 2008). Conversely, rewarding youth for non-drug associated behavior appears to be an effective parenting strategy in the reduction of substance use in adolescents (e.g., Azrin, Donohue, Besalel, Kogan, & Acierno, 1994). Peers may assist in maintaining substance use through acceptance of drug use, modeling of drug use, making drugs easily available, or may interfere with the implementation of social consequences for drug use by authority figures (e.g., hiding drug use paraphernalia). In understanding the role that adolescent peers play in maintaining adolescent substance use, it is important to understand that these youth often fail to recognize the severity of drug-use problems (Sheidow & Henggeler, 2008). Thus, it makes sense that family and friends should be involved in the treatment plan when working with adolescents who have been identified to abuse drugs.

11.5   Evidence-Based Treatment Approaches

The evidence base for the treatment of adolescent substance abuse includes family-, individual-, and group-based models (see reviews by Austin, Macgowan, & Wagner, 2005; Bender, Springer,

& Kim, 2006; Deas, 2008; Muck et al., 2001; Strada, Donohue, & Lefforge, 2006). A recent comprehensive report by Waldron and Turner (2008) reviews the research findings for evidence-based treatments for adolescent substance abuse. The report provides a thorough summary of the "state of the field" and a useful framework for discussing the evidence-based treatment approaches for this population. Thus, the following is a brief synopsis of various evidence-based treatment approaches for adolescent substance abuse. Specific information about many of these treatment programs is available through the National Registry of Evidence-based Programs and Practices (NREPP), which is a service of the Substance Abuse and Mental Health Services Administration (SAMHSA), or the National Institute on Drug Abuse, both of which can be found online (www.nrepp.samhsa.gov and www.nida.nih.gov, respectively). These searchable databases are continually updated with new research findings.

The majority of clinical trials for adolescent substance abuse has evaluated family-based treatments, and in their meta-analysis of family treatments for drug abuse, Stanton and Shadish (1997) suggested that such approaches may be more efficacious than individual and group therapies for both adults and adolescents. Family-based approaches with clinical trial findings highlighted in the Waldron and Turner (2008) review, for instance, include Family Behavior Therapy (FBT), Brief Strategic Family Therapy (BSFT), Functional Family Therapy (FFT), Integrated Behavioral and Family Therapy (IBFT), Multidimensional Family Therapy (MDFT), and Multisystemic Therapy (MST). Delivery for these treatment models range from intensive, home-based treatments preventing out-of-home placement (e.g., in inpatient or detention facilities) to office-based approaches, and they may include both family and individual sessions. Although each of these models is too complex to describe here, some of their features are reviewed as follows.

A noteworthy characteristic of most of these family-based treatments is an emphasis on engaging families into treatment. For nearly all of these treatment models, therapists are active when it comes to engagement, compared with passive strategies often employed in community practice. Some of the models have a phase of treatment dedicated to building client engagement, while other models maintain engagement as an underpinning aspect of treatment which must be present for the remaining aspects of treatment to be successful. Therapists are taught skills and techniques for obtaining and increasing engagement, which may include verbal and nonverbal therapist behaviors, as well as pragmatic strategies like home visits, telephone enlistment and engagement calls, pre-treatment engagement meetings at public locations, and convenient scheduling.

Also common among most of these research-based family approaches is the use of a family system's perspective to conceptualize adolescent substance abuse. That is, members within the family, including the adolescent substance abuser, should interact with one another to potentially influence and sustain substance-abuse problems. Some of the family-based treatments extend this even further by taking an ecological perspective, with individual factors (e.g., coping, motivation), family factors (e.g., relationships, communication patterns, discipline practices), and external systems (e.g., peer, community) combining to produce and sustain the adolescent's substance-abuse problems. Such approaches to conceptualization and treatment planning are consistent with the developmental research on the correlates and causes of adolescent behavior problems, whereby the risk and protective factors have been identified across individual, family, peer, school, and community contexts. Thus, considering factors from multiple areas of the youth's ecology, and developing treatment plans to target various areas appears to be a useful component of family-based treatments for adolescent substance abuse.

Approaches to treating adolescent substance abuse usually rely on a combination of specific interventions implemented by the therapist or treatment team. However, the specific interventions employed vary. Nevertheless, there do appear to be some commonalities. Many of the family-based approaches rely on structural and strategic family therapy techniques. Detailed descriptions of these techniques are presented in studies such as Minuchin (1974) and Haley (1987), and generally are learnt through extensive training and supervision. These techniques aim to alter maladaptive family interactions, such as dysfunctional family boundaries, hierarchies, and alliances. In some of these family-based models, poor communication sequences among family members are targeted. Thus, training families to communicate more effectively and frequently is a common target for some evidence-based family models.

Some ecologically-focused models attempt to increase the instrumental and emotional support for the adolescent's caregivers through leveraging key participants in the family's lives, thereby alleviating stressors that might prevent caregivers from effective parenting. Generally, the family-based models with empirical support view each family as unique and attempt to individualize treatment to capitalize on family strengths and reduce family weaknesses. For example, a family with a supportive grandparent, but one who is undermining a parent's limit-setting with the adolescent would be leveraged without eliminating the supportive role that the grandparent could continue to play. The essence of most of these models is that there is no "one size fits all" family or ecology. Thus, treatments generally follow sets of coherent principles and utilize a prescribed set of interventions without taking a cookbook approach to therapy.

Often, the family-based treatments include training caregivers to implement behavior modification techniques. For some of the family-based models highlighted in the Waldron and Turner (2008) review, behavioral interventions are the primary focus. In general, behavioral interventions for family-based approaches to adolescent substance abuse include (a) the family setting clear expectations (e.g., the youth will eliminate substance use); (b) the family setting clear contingencies for behaviors that are relevant to substance use that they can apply consistently and as temporally close to the behavior as possible; and (c) accurate monitoring of behavior (e.g., using urine drug tests in addition to self-reports from adolescent clients and significant others whenever possible). Expansions of these behavioral interventions may include variants of a functional analysis (for instances of drug use) that aims to identify the antecedents and consequences of use, thereby providing the family and therapist with additional contextual variables to target, such as improving supervision through contingency management systems, family communications skills training, management of stimuli that place youth "at-risk" to use substances, and teaching drug refusal skills. Thus, many of these family-based models incorporate both behavioral and cognitive-behavioral strategies for treating adolescent substance abuse.

Effectiveness of these cognitive-behavioral techniques also has been supported for use in individual- and group-treatment approaches for adolescent substance abuse. The cognitive-behavioral therapy (CBT) approaches that had empirical support generally include 12–16 h of therapy, and are highly structured treatments. These interventions often include contingency management, enlistment of family support, and utilization of skills training designed to teach adolescents to effectively manage drug relapse, and recognize and avoid antecedents to drug use. There is great variability in the researched treatment programs, and with regard to the family-based approaches, the readers can seek detailed information on specific treatment approaches at the NREPP website or through the respective treatment manuals and articles cited in the Waldron and Turner review. Waldron and Turner indicated that group cognitive-behavioral interventions are well-established, and in fact, appear to be as effective as

the family-based treatments in reducing adolescent substance abuse and related problem behaviors. Other promising therapies include Seven Challenges, Strength Oriented Family Therapy (SOFT), and the 12-Step Minnesota Model. Thus, these treatment approaches may be appropriate targets for future research investigations.

There appears to be a number of noteworthy treatment approaches that can produce positive outcomes for adolescent substance abuse, as indicated earlier. Further, research is being carried out investigating additional treatment approaches and improvements on existing approaches. In particular, existing treatments are seeking to improve effectiveness, as rates of relapse are relatively high. Indeed, although active interventions consistently demonstrate improved outcomes in clinical trials, these state-of-the-art treatments generally produce only average effects. Thus, there is always room for improvement. Along a slightly different vein, very few outcome studies have been conducted with adolescent substance abusers who are formally diagnosed with co-occurring disorders, and co-occurrence tends to generate worse outcomes (see Bender et al., 2006). Therefore, specialized treatment approaches or modifications of the existing approaches may be necessary, with some currently under investigation.

Dissemination of evidence-based treatment approaches for adolescent substance abuse plagues the services field, as it does for the general mental-health services field. The NIDA, SAMHSA, and other groups targeted the translation of research findings into clinical practice as a priority. Services research regarding cost evaluations, organizational readiness, and therapist training has greatly advanced the knowledge for bridging the "science to service" gap, but barriers continue to arise. Based on the findings of successful treatment approaches till date, individuals preparing for a career in treating adolescent substance abusers would be fairly secure in considering the apparent commonalities among research-based treatments. That is, preparation in actively engaging families and adolescents in treatment, family systems, and ecological conceptualization and treatment planning, family therapy techniques from the structural and strategic family therapy approaches, and behavior modification and cognitive-behavioral interventions would provide an optimal background for those pursuing careers in evidence-based treatment models for adolescent substance abuse.

11.6   Mechanisms of Change Underlying the Intervention

Similar to other treatment areas, little research has been conducted regarding the mechanisms of action for treatments of adolescent substance abuse. In fact, a review by Waldron and Turner (2008) reports that: "No studies published to date have been able to provide clear links between mediators of change and outcome for adolescent substance abuse treatment" (p. 254). Further, these authors point out that there could be a single pathway through which change occurs or multiple paths within or between treatment approaches. However, there are numerous questions of interest yet to be answered. A related literature can be found in the process research for specific family therapies for delinquent youth (i.e., MST, FFT, Multidimensional Treatment Foster Care), but only a few studies have been conducted and these findings for delinquent youth may or may not be generalized to adolescent substance abusers. There exists preliminary support to suggest that adolescents formally diagnosed with both conduct and substance abuse disorders are responsive to FBT (Azrin et al., 2001).

Thus, discussion on the mechanisms of change underlying interventions, is based on hypothesized relationships. That is, the evidence-based treatments discussed previously were

developed, for the most part, upon developmental research findings. Developmental research during the past few decades has improved our understanding of the correlates and causes of adolescent behavior problems, which has directed treatment developers to target the variables and risk factors that appear to be linked to adolescent substance abuse. For instance, peer influence is a known risk factor for adolescent substance abuse. Based on the developmental research conducted to date, this influence can occur through paths, such as peer attitudes, beliefs, norms, attachment, access to drugs, modeling, and status. As peer substance abuse consistently has been identified as one of the strongest predictors of adolescent substance use, improving things such as drug refusal skills and parental supervision seems logical as a mechanism for sustaining adolescents' abstinence from substance use, and is, in fact, a component of most CBT programs for adolescent substance abuse.

Likewise, direct effects on adolescent substance use have been found for family management characteristics. Such characteristics include supervision, discipline strategies, consistency in parenting, parental support, and parent–child relationship quality. Therefore, many treatment approaches target these variables as they are hypothesized to be mechanisms of change for reducing adolescent substance abuse. Developmental research also provides evidence for a relatively complex, multidetermined conceptualization of adolescent substance abuse. Thus, family systems and ecological models for treatment utilize the background literature in hypothesizing with regard to the mechanisms of change for their approach to deal with adolescent substance abuse. However, most of these models utilize a family-based approach to engage the family in changing the ecology, given the expense and difficulty in implementing a community-wide intervention.

As may be obvious, cognitive-behavioral models of treatment hypothesize that altering the adolescent's cognitions generates change in substance-use behavior. Improvement in coping skills and cognitive distortions is the goal of such treatments, based on the assumption that these are the primary mechanisms for changing adolescent substance abuse. Further, these models would lend themselves to hypotheses regarding alterations in cognitions that might subsequently cause adolescents to change their own ecology. For example, youth might decide to alter their peer affiliations based on the cognitive-behavioral interventions applied. Thus, even though the initial mechanism of change may be the altered cognitions, the pathway to reducing substance use could include altering the ecological variables and risk factors.

An important but often overlooked mechanism of change may be more foundational in nature. Engagement is a notable factor for all mental-health treatments, regardless of the approach or even the presenting problem. For adolescent substance-abuse treatment, the research shows that failure to engage is common and may have a direct link to treatment outcomes. In national studies, half of all the adolescents dropped out prematurely from treatment for substance-use problems (Office of Applied Studies, 2002), and those who drop out have worse outcomes than those who complete treatment (e.g., Stark, 1992). Thus, engagement is hypothesized to be a mechanism for change and, as described previously, is a focus for many of the evidence-based approaches to adolescent substance-abuse treatment.

11.7 Basic Competencies of the Clinician

Skills sets, with which clinical competency is evaluated, vary widely in substance-abuse settings. Nevertheless, competence is generally considered adequate when providers are able to implement substance-abuse services that are beneficial to patient care. Of course, the extent of

competency in mental-health professionals dynamically changes across client characteristics and experience (Hogue et al., 2008). In this way, a therapist's desire to actively seek out and learn a variety of evidence-based models and theories relevant to addiction is a chief therapeutic competency when treating adolescents who evidence substance disorders. As indicated in the American Psychological Association's *Ethical Principles of Psychologists and Code of Conduct* (American Psychological Association, 2002), psychologists are expected to learn and successfully implement evidence-based practices, which are becoming increasingly available through various training programs and government-sponsored initiatives. Indeed, support of government officials in utilizing evidence-based practices in adolescent substance abuse has shifted the field to improve service delivery in community settings.

As indicated earlier in this paper, research indicates that there are now many evidence-based treatments available. However, no active treatment for drug abuse has clearly outperformed any other active treatment (see Waldron & Turner, 2008). Moreover, there is accumulating evidence that effective utilization of specific and non-specific therapeutic factors improves the treatment outcome. Non-specific factors are often considered skills that are relevant to establishing positive therapeutic relationships (e.g., being genuine, empathy), whereas specific factors are relevant to explicit procedures involved in the implementation of prescribed treatments (i.e., maintaining treatment integrity). Contemporary therapists are challenged to adopt evidence-based treatments while developing their clinical competencies. As might be expected, with experience and effective training in evidence-based methodologies, mental-health professionals are likely to transition from basic to expert competencies. In the remaining sections, we review some of the major processes underlying basic and expert competencies as relevant to the administration of evidence-supported programming for adolescent substance abuse.

11.7.1 Basic Competencies

As underscored in SAMHSA's Technical Assistance Publication Series 21 (TAP 21; www.nattc.org), having a basic understanding of the addictions is essential to treatment service delivery. Thus, it is important that service providers seek out evidence-supported training opportunities in addictions, and learn methods of accessing addiction-related materials from reputable organizations, such as the National Institutes of Health (NIH) and SAMHSA. Prior to clinical training, therapists should establish a foundation of basic knowledge in the addictions, such as prevalence rates for substance abuse within the general adolescent population, substance withdrawal and overdose symptoms that frequently occur across major drug classes, and the primary pharmacological effects of psychoactive substances. Evidencing knowledge of various etiological influences that are responsible for the development of substance disorders, as well as major theories that act to maintain substance disorders (e.g., operant and associative learning, systems theory) are also basic competencies. This information permits service providers to implement treatment planning that is well-conceptualized, and therefore, likely to target key problem areas in these adolescents.

Basic competency must be demonstrated upon the youth and primary caregiver's first contact with the substance abuse clinic, which is usually during an initial telephone call. As Lefforge, Donohue, and Strada (2007) indicated in their extensive review of the intervention outcome studies relevant to therapeutic session attendance, it is important to discuss treatment

prior to scheduling outpatient and home-based therapeutic sessions in substance-abuse populations that are known to evidence poor session attendance rates. The concept of "teletherapy" or nonoffice-based engagement meetings with clients and their significant others is unfamiliar to many substance service providers. Nevertheless, therapists need to know the research literature regarding these pre-intervention strategies indicates that they are clearly effective in the improvement of therapy-session attendance and retention.

During initial contacts, it is important to listen to the concerns of both the youth and youth's parents, empathize with expressed concerns, and provide an orientation of the program (e.g., potential services offered, solicitation of obstacles that may interfere with session attendance, generation of solutions to solicited problems). When praising commitments to enter treatment, the provider needs to appear confident, sincere, and supportive. However, unconventional telephone calls performed a few days prior to on-going treatment sessions also appear to assist in managing problems that may occur between the sessions (e.g., completion of therapy assignments, arguments) and improve treatment retention.

High ratings of rapport have been associated with greater retention and lower levels of drug use and criminality, after treatment termination (Joe, Simpson, Dansereau, & Rowan-Szal, 2001). Therefore, it is very important that substance-abuse service providers utilize clinical skills that have been found to be associated with the establishment of rapport, such as being objective, empathic, and praiseworthy (Bohart & Greenberg, 1997). An objective style focused on maintaining neutrality when conducting therapy sessions is important because youth who have abused illicit drugs and alcohol are often critiqued, and usually find it reinforcing when others listen to their concerns unconditionally and later express concern for their welfare. Other important basic competencies relevant to interviewing style include utilization of open-ended questions, reflective statements, affirmations, and pointing out discrepancies in a supportive and reassuring manner.

Competent substance-abuse providers value the importance of prompting family members to be reinforcing, rather than permitting them to dwell on undesired behaviors. They are able to be enthusiastic, and instill hope when reviewing the treatment plan, presenting therapeutic options and collaboratively guiding the family in appropriate decision-making.

Other basic competencies are relevant to understanding which psychometrically-validated instruments are available for use in the identification and assessment of substance use and its associated problems. This includes understanding how to evaluate the utility and psychometric merit of these methods, determining the measures that are most appropriate in various settings, and how best to implement the assessment batteries to measure the treatment outcome. Knowledge of the fundamental areas of assessment cannot be underestimated. These include, but are not limited to, a thorough assessment of substance use, social skills, family functioning, psychopathology, medical and medication concerns, previous treatments, stimuli that facilitate and inhibit substance use, and spirituality. The provider must be adequately trained to summarize and interpret the results to assist in determining an effective treatment plan.

There are various safety issues that must be assessed and effectively managed, if present. These include child maltreatment, substance overdose, suicidal ideation, and home hazards. Indeed, safety management is a primary basic competency, including a sincere understanding of the seriousness of both immediate and long-term consequences of violence. The substance abuse provider with basic competence is aware of generic safety plans that may be customized to address idiosyncratic concerns. These include flowcharts guiding implementation of safety skills, and generic lists of appropriate resources to assist in expeditiously making appropriate

referrals to shelters, family service agencies, or legal counsel when indicated. When conducting home-based interventions, it is important for the competent therapists to tour the home for hazards, and assist families in the prevention of accidental injury and assault.

Along a different vein, substance-abuse providers must be familiar with factors that place adolescents at risk to abuse substances, and similarly, understand how various factors act to buffer against substance abuse. Indeed, such knowledge is more important in establishing an effective treatment plan than being aware of the severity of substance use (Latimer, Newcomb, Winters, & Stinchfield, 2000), probably because this information may be utilized to develop accurate case conceptualization and treatment planning.

Substance-abuse providers with basic competency are able to create goals for therapy that are desired by the youth, caregiver, and referral agent (e.g., judge, probation officer), although they may have difficulty integrating these goals to address common desires. Developed goals include treatment target dates in which the behaviors are to be accomplished, and the rewards that will be associated with goal accomplishment. Providers with basic competence understand that it is necessary to include at least one goal that is relevant to the prevention of substance use, either directly targeting the abstinence or lowering the frequency of days used, or indirectly targeting stimuli that are incompatible with substance use (e.g., coming home on time for curfew, attending school).

Knowledge of evidence-based substance-abuse treatment options, including methods of evaluating the appropriateness of intervention models, has historically not occurred in community treatment settings. However, this has significantly changed in recent years. Today, for instance, various "best practice" treatment models for use in adolescent substance abuse are being sought after by administrators of community substance-abuse programs. Some of these treatments are more empirically established than others. Therefore, it is especially important that treatment providers understand the basic research methodologies, so that they can effectively examine the treatment outcome studies to assist in determining those interventions that are most appropriate. In addition, with regard to basic competencies, professionals need to understand how to ensure that the treatment is working, which may be difficult because adolescents who abuse illicit drugs and alcohol are often unmotivated to indicate when they fail to accomplish their treatment goals.

Competent service providers are able to manage behavior problems that co-exist with substance disorders. At the basic level of competency, service providers should at least be vaguely familiar with the Diagnostic and Statistical Manual for Mental Health Disorders IV-TR (American Psychiatric Association, 1994) to assist them in identifying mental-health symptoms that trigger substance use (e.g., depressive thoughts in Dysthymia, anxiety at a party in Social Phobia, guilt consequent to purging food in Bulimia Nervosa, fist fight in Conduct Disorder). With regard to protection of patients, mental-health professionals should be cognizant of co-morbid mental-health disorders, and appreciate medical disorders that may influence, or be influenced by, addictive disorders. The substance-abuse provider is ethically responsible for researching theoretical models involved in the inter-disciplinary provision of care. This permits them to make appropriate referrals expeditiously, when indicated. Medical professionals should be especially considered in the treatment of addictions, as they may prescribe drugs that lower relapse potential. For instance, anti-depressant medications may lower depressed thoughts that often act to trigger drug use. Although evidence-based treatments for substance abuse are beginning to demonstrate efficacy with comorbid behavioral disorders, professionals must be competent in realizing their professional limitations.

Adolescent substance-abuse service providers are expected to appreciate and show interest in clients of diverse backgrounds (see Strada, Donohue, & Lefforge, 2006). Similarly, treatment providers need to be familiar with adolescent development and differences in application of treatment between adults and adolescents. For instance, CBTs for drug abuse emphasize greater contingency management and family support in adolescents than in adults. Furthermore, an understanding of the legal and ethical differences that differentially affect these age groups is also a basic competency. Youth, for instance, require parental consent for treatment in most situations, and if the service provider feels it is appropriate to do so, parents may legally obtain information about the substance-abuse treatment of their children without their consent.

When working with youth who are severely dependent on substances, cravings may influence relapse. Therefore, it is essential that service providers with a basic level of competence are familiar with commonly encountered antecedent stimuli in the environment that are likely to bring about cravings for substance intoxication. Providers also need to be adept in helping patients manage these cues before the cravings intensify to bring about substance use.

Competent substance-abuse providers should be familiar with the consequences of adolescent substance abuse and abstinence. Negative consequences associated with substance abuse include family anguish, lack of interest in school, withdrawal of support from significant others, physical and psychological harm, and poor relationships with others. However, service providers at the basic level of competence are also familiar with various positive consequences of substance use, including feelings of euphoria, acceptance of peers, and elimination of anxious feelings and aversive thoughts. Being aware of such consequences may help the substance-abuse providers understand the factors that act to motivate youth to attempt abstinence from substances.

Traditionally, community-based substance-abuse treatment programs have excluded family members from participation in the therapy. However, studies have indicated significant benefits when family members are involved in the treatment plan. Indeed, as indicated earlier, family-based treatment for adolescent substance abuse is at least as effective as group and individually-based behavioral therapies. Thus, it is important that substance-abuse providers understand how the family members may influence both substance abuse and abstinence.

11.8 Expert Competencies of the Clinician

Substance-abuse providers who have reached expert status evidence all of the aforementioned basic competencies. However, they are also capable of demonstrating adherence to prescribed protocols while effectively incorporating their own style and adjunctive intervention modalities. Indeed, experts are able to demonstrate innovative applications, as they not only seek out evidence-supported treatments, but integrate these methods to address problems that have been insufficiently addressed in the research literature. Experts are able to identify prevalence rates of substance abuse and dependence in particular demographic groups, and understand why the prevalence rate differs among these sub-groups. With regard to patient safety, experts are able to both recognize and effectively manage substance withdrawal and overdose symptoms. They are familiar with the pharmacological effects of psychoactive substances, as well as their effective management. In addition to being familiar with

etiological influences responsible for the development of substance disorders, experts are intimately familiar with the contextual factors that maintain and inhibit substance disorders (e.g., economic and cultural environment). Along these lines, they can develop and modify treatment planning spontaneously based on the needs of the clientele and their responsiveness to treatment.

Experts are particularly good at recognizing non-verbal and indirect signals that indicate that the patients are insufficiently engaged in therapy (e.g., avoidance of eye contact, repeated attempts to refute therapist directives, smirks, stating, "I guess…"), and upon first indication of these signals, are able to motivate individuals to do well in therapy. Experts are also able to assess the influences that underlie poor therapy-session attendance, and quickly implement strategies that are likely to encourage future participation. For instance, an expert might very neutrally ask a caregiver to indicate potential "cons" about the therapy, empathize with expressed concerns, and solicit solutions to poor session attendance. Experts are also adept at non-aversively challenging patients to discontinue noncompliant therapeutic behaviors, and can easily identify, encourage, and implement consequences that increase participation in therapy. For instance, a treatment provider with basic competence might recognize the importance of letting a noncompliant youth know that there are negative judicial consequences for missing therapy sessions. However, an expert might first let this adolescent know that he or she has done well in the therapy, and subsequently disclose the consequence of missed attendance in an empathic manner (i.e., "I think it would be terrible if your children were removed from your home because you weren't able to attend your sessions with me. What can I do to help you make your sessions?"). In the aforementioned example, the therapist with basic competence is likely to increase therapy attendance, but perhaps, at the risk of decreasing rapport, whereas the expert provides the same message, but as an advocate to the adolescent.

As indicated previously, basic competencies is indicated when service providers are objective, empathic, and praiseworthy. However, non-experts, when compared with experts, may get flustered in certain therapeutic situations, leading them to evidence difficulties maintaining these skills. Indeed, adolescents may rudely and repeatedly talk to others during group sessions, yell at their parents during family sessions, or refuse to initiate behavioral rehearsal exercises. Experts are able to recognize the antecedent stimuli leading to these problem behaviors early in the response chain, and soon after calmly and confidently reinforce successive approximations towards the desired behavior. For instance, while basic competence would be demonstrated if a treatment provider was able to immediately separate an arguing parent and youth to prevent further escalation and potential for violence, an expert might terminate the argument by waving hands as a distraction technique, blame underpinnings of the argument on some external factor, and utilize the problem situation as an opportunity to instruct both parties to practice anger management and communication skills training in vivo (see Azrin et al., 2001). Throughout this experience, expert competence would be demonstrated if the service provider was able to model calm and empathic behavior.

While basic competence is noted when service providers are able to administer screening and assessment tools for adolescent substance abuse according to standardized methods, experts are able to administer these tools more quickly and with greater accuracy owing to years of practice. They are also knowledgeable about the methods of influencing youth and their significant others to respond accurately to these measures. For instance, they provide rationales prior to administering each measure that indicate how exactly the results will inform treatment planning, what the measure is intended to assess, the limits of confidentiality,

high likelihood of having to re-administer inaccurate tests, and that validity measures are being administered to assist in demonstrating their candid responses. Experts may also be aware of the signals that indicate that responses are inaccurate or deceptive, and are able to take immediate steps to correct these problems to protect the validity of testing. For instance, answer-key patterns resembling conspicuous shapes or peculiar designs reflecting a lack of effort (e.g., filled in bubbles resemble a Christmas tree), urine samples as clear as water, all endorsed items reflecting denial of problem behavior, or excessively quick responses.

Experts are proficient at parsimoniously selecting relevant psychometrically-validated assessment measures based on responses to their clinical interview and screening instruments. Indeed, given the limitations of administration time, they are able to effectively determine when to solicit additional information during standardized test administrations, and when it is important to maintain strict adherence to pre-determined assessment protocols.

Most substance-abuse treatment providers evidencing basic competencies are capable of recognizing environmental ecosystems and stimuli that make substance use more and less likely to occur. They are capable of conceptualizing how these factors act to maintain substance-abusive patterns of behavior for their clients in a manner that they can appreciate. Moreover, they motivate adolescents to critically examine the importance of eliminating risk factors, and to discover people and events with whom they can associate with to enhance their quality of life, while decreasing substance use.

Expert providers are able to create goals for therapy that integrate what is specifically desired by the youth, caregiver, and referral agent (e.g., judge, probation officer). Along these lines, they are able to diplomatically determine the mutually agreed upon target behaviors and incentives, and effectively negotiate the target dates in which mutual satisfaction will occur in the event of accomplishment of goals within these time periods. When legal goals appear to be unreasonable, expert providers establish meetings to express apparent concerns and attempt to persuasively generate alternative goals that are likely to build enthusiasm and self-efficacy in adolescent clients. However, experts are also able to recognize when adolescents need to set more ambitious goals, and similarly, when significant others need to provide more encouragement for the completion of effective goal setting. When these situations occur, experts confidently motivate family members to realize their potential. If motivation is low, experts are able to effectively utilize motivational techniques to raise awareness of problem behavior and incite desire for goal accomplishment. This may be done by soliciting unpleasant consequences associated with substance abuse, and empathizing with these concerns. Another expert-laden strategy involves soliciting both unpleasant and pleasant consequences, and pointing out discrepancies to motivate goal-oriented behavior. For instance, an expert therapist might state, "You indicated that you hate it when your mother always nags you when you're high, but find drug use helps you relax. Help me to understand how this is relaxing to you?" Another motivational technique involves breaking difficult-to-accomplish goals into easier-to-accomplish sub-goals that are more achievable, and bring about immediate reinforcement.

Although experts are aware of the major processes underlying various evidence-based treatment options, they are intimately familiar with at least one evidence-based intervention approach for substance abuse, and capable of training and supervising others in the administration of this treatment. When problem behaviors appear in therapy that co-exist with substance disorders, experts are familiar with evidence-based substance-abuse treatment programs that have shown improved outcomes with these co-existing problem behaviors.

They are prepared to implement multiple intervention approaches in complicated cases, and be flexible to adjust the treatment to accommodate various motivational levels of patients (which frequently change for better or worse). Experts understand that evidence-based treatments often do not exist for some problem behaviors, but are prepared to integrate ancillary treatments that have demonstrated outcomes with similar problem behaviors. Experts appear to know when it is most important to implement non-prescribed interventions. Along these lines, some studies indicate enhanced treatment outcomes when therapists demonstrate a high degree of competence and moderate degree of adherence to substance-abuse treatments (Barber et al., 2006). For instance, if an adolescent client was diagnosed with Trichotillomania, an evidenced-supported therapy specific to this disorder (e.g., Habit Reversal; Azrin & Nunn, 1973) would be utilized to complement the respective substance-abuse therapy. Along a different vein, experts are able to manage crises that interfere with treatment planning. Sources of potential crises include extenuating life stressors (e.g., running away from home, being expelled from school, being arrested) that interfere with the development of daily living. However, experts appreciate their limitations, and make appropriate referrals when they are unfamiliar in the treatment of co-morbid problems or crises. After making referrals, experts regularly inquire about how their clients are progressing with the referral agent's treatment plan. They encourage their clients to actively participate in ancillary programs, and diplomatically indicate alternative courses of treatment when they feel these treatments are inappropriate or ineffective.

11.9   Transition from Basic to Expert Competence

Transition from basic to expert clinical competence in substance abuse is a continuous and sometimes unpredictable learning process shaped by both professional and non-professional experiences. Professional training is directly relevant to clinical competence (Kaslow, 2004), whereas non-professional "life experiences" are also likely to have an impact on the rate and extent of the development of clinical competence. For instance, particular therapeutic skill sets, enthusiasm and skill level of the trainer, motivation of the participants, and intelligence, among many other factors, all act to shape receptivity to training, which in turn influences the development of clinical competence in various contexts. Further complicating the transition from basic to expert competence are experiential circumstances, such as those mentioned earlier, which interact with one another. Thus, an unenthusiastic trainer may be perceived by his trainees to be uninterested in the respective training workshop, resulting in the trainees being non-responsive to the trainer's requests, which in turn leads the trainer to be increasingly reserved. Of course, some life experiences are not good for substance-abuse treatment, whereas others may lead to greater acquisition and skill. Along these lines, non-directive therapies have been found to be relatively ineffective in adolescent substance abuse when compared with other treatments (e.g., Azrin et al., 2001). Therefore, persons who espouse these therapy approaches for substance abuse may evidence difficulties adjusting their therapeutic style to evidence-based treatments.

Of course, clinical supervisors and trainers are unlikely to control life experiences of attendees. However, they are capable of adjusting their own behavior to increase the likelihood of trainees to get motivated to learn the various clinical tasks that are the focus of the training. For instance, they can be enthusiastic about the intervention approach, conduct

behavioral role-playing, emphasize flexibility, and frequently solicit feedback (Fraser & Greenhalgh, 2001). Similarly, supervisors should be knowledgeable about State and Federal laws governing administration of the therapy, incorporate a supervision model that utilizes evidence-based strategies (e.g., structured case presentations, modeling, behavioral rehearsal, assigned readings), and encourage evaluation of the treatment's integrity. Although focused on treatment integrity, supervisors will likely increase receptivity to protocol adherence if they encourage participants to develop their own personal style when doing so. For instance, in our own method of improving protocol adherence (e.g., Azrin et al., 2001; Sheidow, Donohue, Hill, Henggeler, & Ford, 2008), therapists are encouraged to choose to implement substance-abuse therapies from a list of behavioral therapy options. Each therapy is guided by a protocol checklist of various therapeutic steps to be performed by the therapist. The therapist must implement the therapeutic behaviors that are indicated in the respective checklist to achieve adherence. However, the therapist is free to initiate whatever ancillary treatments or actions are desired without negatively affecting adherence to the prescribed treatment model. Although this method of assessing treatment is only recently developing psychometric support (see Sheidow et al., 2008), it is quite promising as it effectively integrates enhanced therapeutic flexibility within a standardized behavior therapy model. There are great benefits to conducting standardized training initiatives to support the transition from basic to expert competencies (Belar, 1992). For instance, standardized materials (e.g., manuals, protocol checklists summarizing the information in manuals) may be cost-effectively produced, role-play scenarios and other components of training can be systematically enhanced based on experiences over time, and treatment implementation can be easily monitored and adjusted. Recently, research has commenced to determine the relationship between treatment adherence and competence. Indeed, the few studies that have addressed this relationship have yielded mixed results (see Hogue et al., 2008). Similarly, the evaluation of supervision and training strategies in adolescent substance abuse is also in its infancy, although relatively more advanced than the association between competence and adherence. Future studies must be conducted to determine viable training strategies that balance treatment integrity with enhanced therapist flexibility in the transition from basic to expert competencies within community settings.

11.10 Summary

A basic overview of basic and expert competencies involved in the treatment of adolescent substance abuse and dependence was provided, including relevant background information about the primary substance disorders (i.e., abuse and dependence). Furthermore, diagnostic features, prevalence rates, developmental course, and risk factors were highlighted to provide a context in which to examine professional clinical competencies. In addition, methods of recognizing substance abuse and factors that act to increase its likelihood were also emphasized. Family and behavior therapies appear to demonstrate greatest relative efficacy in the treatment outcome literature, and some of the common characteristics of these interventions were presented. Lastly, the transition from basic to expert competencies appears to be an unpredictable and often difficult process to measure. Some of the complications that act to facilitate and impede clinical competency were presented. Advancements in training technology may be useful in making this process more efficient.

12 Child Sexual Abuse

Elaine K. Martin · Christopher Campbell · David J. Hansen

Abstract: Child sexual abuse (CSA) is a pervasive problem that significantly impacts many youth and their families. CSA has been associated with a variety of internalizing and externalizing problems for sexually abused youth. However, the effects of CSA are rarely limited to victims, and nonoffending caregivers and siblings often experience distress following the disclosure of abuse. Due to the heterogeneous symptom presentation exhibited by victims of CSA, and the potential impact of CSA on the entire family, it is important for clinicians to use assessment strategies that are multi-method, multi-symptom, and multi-informant. Similarly, treatment planning for sexually abused youth is complicated by the diverse impact of CSA on families, and psychosocial interventions often include victims of CSA as well as nonoffending family members. While several psychosocial interventions exist for CSA, most have not been rigorously examined. However, CSA treatments typically include similar mechanisms for change, such as psychoeducation, anxiety management, exposure, cognitive coping, behavior management, and social support. Due to the complex nature and potential long-term consequences of CSA, it is important for clinicians who work with sexually abused youth to understand and demonstrate mastery levels of clinical competencies in this area. This chapter examines CSA-related clinical issues and describes competencies for addressing the heterogeneous impact of CSA on youth at both the basic and expert level. Competencies discussed include using an evidence-based approach, possessing scientific knowledge of CSA and treatments, case conceptualization skills, building rapport and the therapeutic alliance, treatment planning and monitoring, understanding client characteristics, monitoring legal and ethical issues, evaluating risk for harm to self and others, working with interdisciplinary teams, and understanding the effects of medication on treatment. Methods of mastering these competencies through education, training, experience, supervision, and self-assessment are discussed.

12.1 Overview

Child sexual abuse (CSA) is a serious problem that impacts the lives of many youth and their families. Although CSA is sometimes described differently across clinical, legal, and research contexts, it is commonly defined as sexual acts between a youth and an older person (e.g., 5 or more years older) in which the dominance of the older person is used to exploit or coerce the youth for sexual stimulation. Despite the lack of consensus on the definition of CSA, most professionals agree that abusive behaviors may include *contact offenses*, such as genital touching, oral sex, and digital, object, or penile penetration (vaginal or anal), as well as *noncontact offenses* (e.g., genital exposure, voyeurism, exposure to pornographic material, having a child undress or masturbate, etc.).

Sexual acts between individuals with age differences of 5 or more years are generally seen as abusive because younger children are not considered capable of consenting to sexual activities with older persons. In clinical and research contexts, CSA is sometimes used to describe youth

who were victimized by similar age peers, though in legal contexts these may be viewed as "assault." Similarly, perpetration by an adult stranger or nonfamily member may be considered sexual abuse in clinical contexts, but within the legal system it may be treated as sexual assault.

Challenges in defining CSA contribute to the difficulty in identifying its incidence and prevalence. Child protective services (CPS) records indicate that approximately 1.1 children per 1,000 experience sexual abuse in the USA each year (US DHHS, 2008). Research utilizing retrospective reports indicates that as many as 20% of women and 5–10% of men experienced sexual abuse as a youth (Finkelhor, 1994; Wolfe, 2006). However, it should be noted that the number of CSA cases substantiated by CPS dropped by approximately 40% during the 1990s (Finkelhor & Jones, 2004; US DHHS). While some of this decrease may reflect a real decline in incidence, it is likely due to a combination of factors, including increasing conservatism on what is substantiated as abuse, exclusion of cases that do not involve caretakers, changes in data collection methods, and less reporting due to concerns about backlash from families (Finkelhor & Jones).

All 50 states have laws requiring specific individuals to report cases of suspected child abuse and neglect. These statutes take precedence over professional confidentiality requirements, and commonly include physicians, nurses, psychologists, social workers, teachers, day care workers, and law enforcement personnel. In fact, many state laws require "all persons" to report suspicions of maltreatment, though many people are unlikely to be aware of the mandate. Statutes provide immunity from criminal and civil liabilities when reports are made in good faith and without malice, whereas failure to report suspicions can lead to criminal or civil penalties, as well as malpractice and licensure problems. Unfortunately, research has consistently shown that despite these reporting requirements, many cases of abuse go unreported, even by professionals; this can be due to the failure to recognize that the situation may be abusive or because they choose not to report (Kalichman, 1999).

CSA may come to the attention of caregivers, authorities, or others via child self-disclosure, medical or physical evidence (e.g., sexually transmitted disease), changes in behavior that prompt concern and inquiry, and investigations with other abused youth. Generally, there are no physical indications of CSA at the time of evaluation; however, when present, medical findings are extremely valuable for substantiation. After initial identification that CSA may have occurred, forensic interviews are often conducted to carefully document the abuse, make decisions about protecting the children, and prosecute perpetrators (Cronch, Viljoen, & Hansen, 2006). Once the occurrence of CSA has been determined, a detailed clinical assessment of abuse-related symptomatology can begin.

Over the past 4 decades, a growing body of empirical literature has linked childhood sexual abuse to a myriad of short- and long-term psychological problems, including internalizing (e.g., anxiety, depression, etc.) and externalizing (e.g., substance abuse, sexual behavior, etc.) problems (Beitchman, Zucker, Hood, DaCosta, & Akman, 1991; Kendall-Tackett, Williams, & Finkelhor, 1993; Tyler, 2002). Although posttraumatic stress symptomatology is the most common clinical syndrome (Kendall-Tackett et al., 1993), sexually abused children are a heterogeneous group, and victimization does not necessarily have an inevitable pattern or a unified presentation of symptoms (Saywitz, Mannarino, Berliner, & Cohen, 2000). In fact, some individuals exhibit little to no symptoms following the abuse (Kendall-Tackett et al.; Wolfe, 2006). While the research on CSA symptomatology is extensive, it is largely correlational and without experimental control. Thus, findings are challenged

by the presence of many potential confounding variables, such as the co-occurrence of other forms of maltreatment, domestic violence and marital dysfunction, and poverty (Hecht & Hansen, 2001).

Understandably, effects of CSA are rarely limited to the victim, and often impact the entire family, including nonoffending caregivers and siblings. For example, caregivers may experience a variety of stressors associated with the disclosure of abuse such as partner separation/divorce, moving, financial loss, and participation in criminal and/or civil legal litigations (Corcoran, 2004). These stressors are often accompanied by psychological distress including anger, depression, guilt, embarrassment, grief, and secondary trauma (Deblinger, Hathaway, Lipmann, & Steer, 1993; Manion et al., 1996). Siblings may also struggle with problems such as confusion, fear, shame, helplessness, guilt, anger, and resentment toward the victim (Baker, Tanis, & Rice, 2001; Swenson & Hanson, 1998). Given these difficulties, varied interventions may be necessary not only for the victims of CSA, but also for their nonoffending family members.

This chapter examines clinical issues and competencies for addressing the heterogeneous impact of CSA on youth. Although the primary focus will be on child victims, this chapter also addresses issues associated with the impact on their parents and siblings, to increase the chances of successful treatment of CSA youth and their families.

12.2 Recognition of Symptoms and Their Assessment

12.2.1 Symptomatology to Assess

As stated above, victimization does not have a fixed pattern or a unified presentation for youth. Rather, sexually abused youth display various patterns of behavioral and emotional symptoms at different levels of severity. CSA has been linked to a variety of internalizing problems, including anxiety, depression, poor self-esteem, sleep disturbances, and somatic complaints (Beitchman et al., 1991; Kendall-Tackett et al., 1993; Paolucci, Genuis, & Violato, 2001; Tyler, 2002). Posttraumatic stress disorder (PTSD) is the most commonly identified clinical syndrome; research indicates that more than 50% of the CSA youth meet full or partial criteria for PTSD (Saywitz et al., 2000).

Research has also linked CSA to a variety of externalizing problems, including conduct problems and delinquency, substance abuse, poor academic performance, interpersonal relationship difficulties, and self-injurious and suicidal behaviors (Beitchman et al., 1991; Kendall-Tackett et al., 1993; Paolucci et al., 2001; Tyler, 2002). In addition, some youth may exhibit increased interest with sex and genital areas, as well as heightened sexual activity in the form of increased masturbation, compulsive sexual play, and/or inappropriate sexual behavior toward peers and adults (Kendall-Tackett et al.).

While some CSA victims display a variety of symptoms, other individuals – as many as 21–49% of sexually abused children – exhibit little to no symptoms following the abuse (Hecht & Hansen, 1999; Kendall-Tackett et al., 1993; Sawyer & Hansen, 2009). Many of these youth may remain symptom-free across their lifespan, but there is some evidence for a "sleeper effect," in which symptoms manifest months or years later (Finkelhor & Berliner, 1995; Mannarino, Cohen, Smith, & Moore-Motily, 1991). Research suggests that as many as 10–20% of asymptomatic children may experience increased symptomatology over a 12–18-month

period following disclosure (Finkelhor & Berliner; Mannarino et al., 1991) or experience symptoms during critical periods of life such as puberty, entry into sexual relationships, and child bearing (Olafson & Boat, 2000). It is important to note that the high number of asymptomatic youth may also be explained, at least in part, by methodological issues, such as the possibility that measures utilized in CSA research do not assess the entirety of symptoms or lack the sensitivity to capture symptoms experienced by these youth.

Heterogeneity of consequences is not surprising, given the varied nature and extent of sexual abuse and the contexts in which it occurs. Research indicates that the impact may be more severe when abuse occurs over a longer duration, with greater frequency, involves force or violence, more serious sexual acts are committed, and the perpetrator has a closer relationship to the victim (e.g., father or father figure; Kendall-Tackett et al., 1993; Tyler, 2002). However, results remain inconsistent across studies suggesting that other factors (or combinations of factors) may impact outcomes of CSA, including premorbid child characteristics, family functioning (e.g., marital conflict, finances, etc.), environmental stressors, and school and community support (Tyler; Wolfe, 2006). Additional risk factors include poor caregiver support following disclosure, distorted cognitions, negative attributional style (by the victim or parents), problematic coping strategies, and additional forms of maltreatment (Mannarino & Cohen, 1996).

As previously noted, disclosure of childhood sexual abuse is a disruptive experience that often impacts the entire family, including nonoffending caregivers, siblings, or even extended family members. Caregivers are expected to support their children as they attempt to cope with the abuse and related consequences, but caregivers also experience substantial emotional distress, conflict, and trauma after their child's disclosure, and may be viewed as secondary victims (Deblinger et al., 1993; Elliott & Carnes, 2001; Lewin & Bergin, 2001; Olafson & Boat, 2000). Nonoffending caregivers may experience heightened levels of depression, anxiety, and diminished maternal attachment behaviors (e.g., sensitivity, cooperation, acceptance, and accessibility during interactions with their children; Lewin & Bergin), as well as symptoms of PTSD (Davies, 1995). Further, empirical literature suggests that, although an abuse history for mothers is not associated with diminished support (Deblinger et al.), nonoffending mothers with a history of CSA experience significantly more PTSD symptoms (Timmons-Mitchell, Chandler-Holtz, & Semple, 1997) and general psychological distress (Hiebert-Murphy, 1998; Timmons-Mitchell et al., 1997) than do mothers without such history.

12.2.2 Assessment of Abuse-Related Symptoms

When a sexual abuse allegation occurs, a forensic assessment may be needed to determine whether the child was abused, collect information for prosecuting the perpetrator, and protect the youth. A detailed description of the forensic assessment process is beyond the scope of this chapter (for additional information, Cronch et al., 2006; Friedrich, 2006; Hubel, Flood, & Hansen, in press). Similarly, a comprehensive list and thorough description of the wide variety of assessment measures used in CSA treatment are also beyond the scope of this chapter (for additional information, see Friedrich; Hansen, Hecht, & Futa, 1998; Swenson & Hanson, 1998). Instead, the following section will provide a brief description of commonly used, empirically supported clinical instruments that assess the social, emotional, and behavioral functioning of the youth and their family following sexual abuse. Across the variety of symptoms areas noted

below, clinical interviews are essential for identifying problems and selecting measures and treatment approaches (Hubel et al., in press). Given the wide array of potential symptomatology linked to sexual abuse, pretreatment assessment should be multi-method, multi-symptom, as well as multi-informant.

Sexual Abuse History. It is imperative for clinicians to have an understanding of the abusive experiences, which is generally ascertained from the caregiver(s) or referral sources. The History of Victimization Form (Wolfe & Gentile, 1992) can be used to obtain detailed information from the child's social worker (or other professionals) so that the youth is not subjected to further investigative questioning. The Parent Impact Questionnaire (Wolfe & Gentile) is a structured interview for obtaining the youth's physical and sexual abuse experiences, as well as historical information such as family problems (e.g., separations or divorce, parental conflict, etc.).

Abuse-Specific Symptoms. A fundamental aspect of the evaluation process is the assessment of symptoms specific to the sexual abuse experience. Two commonly used empirically supported measures for youth between the ages of 8 and 16 are the Children's Impact of Traumatic Events – Revised (CITES-R; Wolfe, Gentile, Michienzi, Sas, & Wolfe, 1991; Chaffin & Schultz, 2001) and the Trauma-Symptom Checklist for Children (TSC-C; Briere, 1996). The 78-item CITES-R measures the impact of sexual abuse from the child's perspective (i.e., thoughts and feelings about what happened to them) across four dimensions: posttraumatic stress (intrusive thoughts, avoidance, hyper-arousal, sexual anxiety), abuse attributions (self-blame/guilt, vulnerability, dangerous world, empowerment), social reactions (negative reactions, social support), and eroticism. The TSC-C is 54-item measure that assesses symptoms related to abuse experiences, but is not limited to only experiences of sexual abuse, making it particularly useful for youth who experienced multiple types of abuse. The TSC-C has scales assessing trauma-specific symptoms of anger, anxiety, depression, posttraumatic stress, dissociation, and sexual concerns. A version for children between the ages of 3 and 12, the Trauma-Symptom Checklist for Young Children, is also available (Briere et al., 2001).

Some sexually abused youth may exhibit inappropriate sexual behaviors. The Child Sexual Behavior Inventory (CSBI; Friedrich et al., 2001) is a 38-item inventory completed by parents (or caregivers) to assess the frequency of various sexual behaviors pertaining to sexual aggression, self-stimulation, gender-role behavior, and personal boundary violations observed in their children from ages 2–12 years. For older youth (ages 12–18 years), the Adolescent Clinical Sexual Behavior Inventory (ACSBI; Friedrich, Lysne, Sim, & Shamos, 2004) is a 45-item self-report measure used to assess sex-related behaviors, including sexual risk taking, nonconforming sexual behaviors, sexual interest, and sexual avoidance/discomfort. A parent report version of the ACSBI is also available, though caregivers may lack sufficient information to accurately report adolescent sexual behavior.

The Weekly Problems Scale-Child Version (WPS-C) and the Weekly Problems Scale-Parent Version (WPS-P) were developed for use as brief repeated measures that assess multiple domains of symptoms during the treatment of CSA youth (Sawyer, Tsao, Hansen, & Flood, 2006). The WPS-C (11 items) and the WPS-P (15 items) assess emotions, behavior, and relationships that occur over the past week. The WPS-C subscales measure negative mood and behaviors, problematic peer and parental interactions, and self-esteem problems. The WPS-P measures problematic behaviors, parenting and family problems, negative mood, and sex and sexual abuse communication issues.

Child Emotional and Behavioral Symptoms. Child self-report measures of internalizing problems are often an essential component for treatment planning and ongoing assessment.

Examples include: (a) the Children's Depression Inventory (CDI; Kovacs, 1992), a 27-item assessment measure of depressive symptomatology across affective, cognitive, and behavioral dimensions; (b) the Multidimensional Anxiety Scale for Children (MASC; March, 1997), a 39-item measure of clinically significant domains of anxiety, including physical symptoms, social anxiety, harm avoidance, and separation/panic; (c) the Revised Children's Manifest Anxiety Scale (RCMAS; Reynolds & Richmond, 1985), a 37-item assessment of general anxiety in children and adolescents; (d) the Children's Fears Related to Victimization (CFRV), a 27-item subscale of the Fear Survey Schedule for Children – Revised (FSSC-R; Ollendick, 1983) used to assess situations sexually abused youth may find distressing (e.g., people not believing me); (e) the Children's Loneliness Questionnaire (CLQ; Asher & Wheeler, 1985), a 24-item questionnaire of children's feelings of loneliness, social adequacy, and subjective estimations of peer status; and (f) the Self-Esteem Inventory (SEI; Coopersmith, 1981), a 58-item measure of children's attitudes about themselves in social, academic, family, and personal areas of experience.

Utilization of multiple informants, such as the child, caregivers, and professionals (e.g., teachers), is a crucial element in all behavioral assessments of children, especially in relation to externalizing problems. Most commonly, broad-spectrum measures are incorporated to assess a variety of emotional and behavior problems. Widely used measures with substantial empirical support include: (a) the Child Behavior Checklist – Parent Report Form (CBCL; Achenbach & Rescorla, 2001), with versions for ages 2–18 years; and (b) the Behavior Assessment System for Children – Second Edition (BASC-2; Reynolds & Kamphaus, 2004), with versions for ages 2–21 years.

Caregiver Symptoms. A comprehensive evaluation should also include the assessment of caregiver mental health that may influence the youth's adjustment. Depending on the nature of the presenting problems and intervention, a broad-spectrum assessment for mental health may be useful. For example, the Symptom Checklist-90-Revised (SCL-90-R; Derogatis, 1983) is a 90-item multidimensional symptom inventory on which respondents rate the degree of distress experienced across a variety of symptoms of psychological distress. Targeted assessment measures, such as the Beck Depression Inventory II (BDI-II; Beck, Steer, Brown, 1996) or Beck Anxiety Inventory (BAI; Beck & Steer, 1993), may also be useful. Additional assessments may include the Parenting Stress Index (PSI; Abidin, 1986), the Dyadic Adjustment Scale (DAS; Spanier, 1976), and the Quality of Marriage Index (QMI; Norton, 1983). The PSI is a 120-item self-report measure of stress associated with parenting and identification of dysfunctional parent–child relationships. The DAS is a 32-item scale designed to measure adjustment in relationships, whereas the six-item QMI measures overall marital satisfaction. The caregivers own maltreatment history can be assessed using the Childhood Trauma Questionnaire (CTQ; Bernstein & Fink, 1997). The CTQ is a 28-item measure that retrospectively assesses five types of childhood maltreatment: sexual abuse, physical abuse, emotional abuse, emotional neglect, and physical neglect.

It is also important to assess caregiver reactions and responses to children's disclosure of abuse. For example, the Parent Emotional Response Questionnaire (Mannarino & Cohen, 1996) is a 15-item questionnaire used for assessing parental emotional reactions to their child's sexual abuse, including reactions such as sadness, guilt, anger, and embarrassment. Another measure, the Parent Support Questionnaire (Mannarino & Cohen) is a 19-item measure for evaluating parent's perceptions of their response to their child's sexual abuse.

Family Functioning and Coping. As stated above, CSA will likely impact broader family dynamics, making the assessment of overall family functioning an important aspect of any

evaluation. The Family Adaptability and Cohesion Evaluation Scales (FACES-III; Olson, 1986) is a 20-item self-report measure that assesses the respondent's perceptions of the current and ideal family systems across three categories: adaptability, cohesion, and family satisfaction. Also, the Family Crisis-Oriented Personal Evaluation Scales (F-COPES; McCubbin, Olson, & Larsen, 1987) is a 30-item assessment of effective problem-solving, coping attitudes, and behaviors used by families in response to problems or difficulties.

12.3 Maintenance Factors for CSA

12.3.1 Abuse-Related Factors

While it is important to acknowledge that findings have been inconsistent, several abuse characteristics have been repeatedly linked to more severe outcomes in sexually abused youth. First, the victim's relationship to the perpetrator, in particular, a close relationship with the perpetrator (e.g., father or father figure), has been associated with more severe symptomatology (Beitchman et al., 1992; Noll, Trickett, & Putnam, 2003). However, the relationship to the perpetrator has been inconsistently defined, and it might be more beneficial to assess the degree of the victim's emotional attachment to the perpetrator (Heflin & Deblinger, 2007; Kendall-Tackett et al., 1993). Second, victimization by multiple perpetrators has also been associated with increased psychological distress (Steel, Sanna, Hammond, Whipple, & Cross, 2004). Third, several studies have found use of force or threat of force to be related to increased symptomatology for sexually abused youth (Beitchman et al.; Briere & Elliott, 1994; Steel et al., 2004). Fourth, increased severity of abuse (i.e., more invasive or intimate sexual contact), such as vaginal, anal, or oral penetration, has been associated with more negative outcomes (Beitchman et al.; Kendall-Tackett et al.). Lastly, there is some empirical support for an association between longer duration and greater frequency of abuse and more negative outcomes (Kendall-Tackett et al.; Steel et al.). However, single-episode violent assaults are also associated with greater symptomatology (Beitchman et al.).

12.3.2 Familial Response to Disclosure

A growing body of empirical literature suggests that nonoffending caregivers' support following disclosure significantly influences adjustment and functioning of sexually abused youth, including overall level of distress and psychological symptoms (Elliott & Carnes, 2001; Mannarino & Cohen, 1996). In fact, some research indicates that parental support may be a better predictor of psychological adjustment than the abuse-related factors described above (Tremblay, Hebert, & Piche, 1999). However, it is not clear whether abuse-specific support or overall support in the parent–child relationship is a better predictor of short- and long-term adjustment (Elliott & Carnes). It is important to note that, according to Bolen and Lamb (2004), as many as one third of nonoffending caregivers oscillate in their level of support of their sexually abused child following disclosure. Thus, clinicians should encourage caregiver participation in the treatment process, which will provide parents (or guardians) opportunities to process their reactions, so that they can be available to support their child in an effective and consistent manner (Heflin & Deblinger, 2007).

12.3.3 Cognitive Attributions

Research suggests that certain patterns of cognitions are more common among sexually abused youth, including self-blame for negative events, the impression that the world is a dangerous place, and problematic attitudes (preoccupation with and/or aversion) toward sexuality (Cohen, Deblinger, Maedel, & Stauffer, 1999). Negative cognitive attributions, particularly those related to the abuse involving shame, powerlessness, and stigmatization, have shown a strong and persistent relationship with PTSD, depression, and low self-esteem (Feiring, Taska, & Lewis, 2002; Kallstrom-Fuqua, Weston, & Marshall, 2004). Moreover, internalization of childhood abuse, including a sense of powerlessness and stigmatization, has been associated with psychological distress in adulthood (Kallstrom-Fuqua et al., 2004; Steel et al., 2004).

12.4 Evidence-Based Treatment Approaches

The treatment of sexually abused youth is unique in that many children are referred for services due to the sexual abuse experience, and not necessarily because they are exhibiting clinical levels of emotional or behavioral symptoms. Parents often seek services based on concerns that the abuse will psychologically damage their child and/or to diminish the risk of future difficulties and revictimization (Finkelhor & Berliner, 1995; Wolfe, 2006). While several interventions have been used for victims of CSA, few have been systematically evaluated in controlled treatment outcome studies (Cohen, Berliner, & Mannarino, 2000). Methodological difficulties in CSA treatment research are also amplified by the fact that victimization does not have an inevitable pattern or a unified presentation of symptoms (Kendall-Tackett et al., 1993; Saywitz et al., 2000). In fact, sexual abuse itself is a heterogeneous act, consisting of numerous possibilities and experiences ranging from a single act of exhibitionism to sexual intercourse, and perpetrators varying from close family members to complete strangers.

Several types of psychosocial interventions are currently available to sexual abuse victims (Chaffin & Freidrich, 2004; Putnam, 2003; Saunders, Berliner, & Hanson, 2004), and recent research has produced enormous growth in our knowledge about effective treatments for traumatized youth (Cohen, 2005). Overall, meta-analytic results show a moderate effect size for psychosocial treatments reducing the effects of sexual and physical abuse (Skowron & Reinemann, 2005), with one treatment – Trauma-Focused Cognitive Behavioral Therapy (TF-CBT) – accumulating the most empirical support. TF-CBT has been evaluated in multiple randomized clinical trials and is currently the only treatment for youth exposed to trauma to meet the well-established treatment criteria from the APA Division 12 Society of Clinical Psychology Task Force (Chambless & Hollon, 1998). Treatment components of TF-CBT include parenting skills, psychoeducation, cognitive processing, trauma narration, in vivo desensitization, and enhancing safety (Deblinger & Heflin, 1996). TF-CBT also includes a non-offending parent component designed to enhance parental support of the child, decrease the parent's own emotional distress following the abuse, and improve positive parenting practices. TF-CBT was designed to decrease PTSD symptoms, reduce negative emotional and behavioral responses, and correct maladaptive beliefs and attributions related to the abusive experiences in youth 3–18 years of age (Cohen; Cohen, Deblinger, Mannarino, & Steer, 2004; for more information on TF-CBT, Cohen, Mannarino, & Deblinger, 2006; Deblinger & Heflin; Deblinger, Mannarino, Cohen, & Steer, 2006). Moreover, TF-CBT has also been shown to be effective at

reducing PTSD symptomatology and maintaining treatment gains 6-months and 12-months posttreatment (Deblinger, Mannarino et al., 2006).

Although several treatment approaches exist, with the exception of TF-CBT, most lack well-controlled methodological research. Nevertheless, specific programs and techniques have been developed to address heterogeneous needs and abuse-specific sequelae (e.g., PTSD symptoms, sexual behaviors, depression, anxiety) of sexually abused youth and their families (Wolfe, 2006). More importantly, these programs have demonstrated increasing empirical support within an evidence-based framework. For instance, Bonner, Walker, and Berliner (1999) have developed a cognitive-behavioral group treatment designed to reduce the occurrence of inappropriate and/or aggressive sexual behavior in children. Another example, CBT for Sexually Abused Preschool Children (CBT-SAP; Cohen & Mannarino, 1996), showed significant improvements when compared to Nondirective Support Therapy. CBT-SAP contains strategies to address ambivalence toward the perpetrator, attributions regarding sexual abuse, inappropriate sexual behavior, and safety/assertiveness skills. Similarly, King et al. (2000), utilizing a CBT framework, found a reduction in PTSD symptoms in school-aged CSA survivors regardless of parental involvement in the therapeutic process. Lastly, Project SAFE (Sexual Abuse Family Education; Hansen et al., 1998) – a 12-week, cognitive-behavioral group treatment for sexually abused youth and their nonoffending caregivers – has demonstrated positive outcomes (e.g., increased self-esteem, less anxiety, fewer fears related to sex and victimization, and reduced feelings of loneliness and isolation) at posttreatment and again 3-months posttreatment (Campbell, Martin, Hubel, Flood, & Hansen, 2009; Hansen et al.; Hsu, Sedlar, Flood, & Hansen, 2002). Overall, the available research on the treatment of sexually abused youth is promising as shown by better outcomes for individuals who received trauma-focused CBT or abuse-specific CBT (Saywitz et al., 2000).

Traumatized children are increasingly receiving psychopharmacological interventions, despite the lack of randomized control trials of medication for CSA victims (Cohen, 2005). Psychopharmacological treatments have been used both independently and as adjuncts to psychosocial treatment approaches for PTSD (Wolfe, 2006). However, findings suggest that children often display a high rate of placebo response, such that many psychotropic medications that appear to be effective in open treatment trials are subsequently found to have equal efficacy as the placebo when subjected to double-blind randomized clinical trials (RCTs; Cohen). Thus, a lack of empirical research, concern about the effects of medications on developing brains, and family preferences for psychosocial interventions for youth have limited the use of pharmacological interventions for trauma (Cohen, Berliner, & Mannarino, 2003).

Treatment approaches for CSA also vary in a number of ways, including length, theoretical orientation, setting, and treatment participants. Services are often delivered in individual, group, or family formats (or some combination). Group interventions provide an opportunity for youth to share similar life-changing experiences with peers. Groups also provide an environment where support, normalization, and validation of experiences are readily available (Hecht, Chaffin, Bonner, Worley, & Lawson, 2002). Group interventions have been shown to be an effective form of treatment for CSA, including reducing PTSD symptoms, decreasing behavioral problems, and improving self-esteem and internalizing symptomatology (Avinger & Jones, 2007; Hetzel-Riggin, Brausch, & Montgomery, 2007).

Over the past 20 years, an expansive body of literature indicates that parental support following CSA disclosure is positively and significantly related to better emotional and behavioral adjustment in sexually abused youth (Elliott & Carnes, 2001). More specifically, several studies

have found that maternal support is critical to mediating the negative effects of CSA (Corcoran, 2004; Deblinger, Steer, & Lippman, 1999). Thus, the majority of rigorous studies have included parents in their treatment protocol (Deblinger et al., 1999; King et al., 2000). Nonoffending caregiver treatment is often conducted either in a parallel individual/group format (i.e., caregiver and child meeting concurrently but separately) or in conjoint sessions with the victim. Parental treatment usually contains abuse-related elements similar to treatment for abused youth, as well as additional components designed to reduce parental distress and teach behavior management strategies (Hecht et al., 2002). Available research suggests that parental involvement in CSA treatment effectively decreases externalizing behaviors and sexual behaviors, while improving adjustment in families after CSA has occurred (Corcoran; Saywitz et al., 2000).

As the research continues to grow, other issues will need to be addressed, including the replication and refinement of promising treatments, dissemination of effective interventions, and increased examination and inclusion of family members in treatment. For example, although nonoffending sibling treatment has not yet received significant research attention, sexual abuse impacts the entire family, and siblings may benefit from treatment (Campbell et al., 2009; Swenson & Hanson, 1998). For instance, in some cases, siblings may continue to be in direct contact with the perpetrator (e.g., perpetrator has partial custody and/or visitation privileges), placing them at risk in the future. Including nonoffending siblings in treatment provides siblings with the opportunity to discuss their thoughts and emotional reactions, address misinformation/misconceptions, and increase their understanding of their sibling's abusive experiences. Thus, sibling interventions may incorporate components designed to (a) address good and bad touches, (b) teach and practice assertiveness, (c) increase communication with the nonoffending caregiver, (d) discuss personal space, (e) differentiate between positive surprises and negative secrets, and (f) teach problem-solving techniques for risky situations (Campbell et al.).

12.5 Mechanisms of Change Underlying Interventions

Abuse-specific interventions are generally based on cognitive-behavioral principles that have proven effective for a variety of conditions (Berliner & Elliott, 2002). There are several common components across CSA treatments that are believed to embody the underlying mechanisms responsible for positive treatment outcomes with sexually abused youth, including psychoeducation, anxiety management, exposure, and cognitive coping (Berliner & Elliott), as well as behavior management and social support. To date, however, no dismantling studies have been conducted to examine the relative efficacy of treatment components.

12.5.1 Psychoeducation

Psychoeducation is often a starting point for many CSA interventions, particularly with youth who are uncomfortable talking about their abuse experience (Deblinger, Behl, & Glickman, 2006). Psychoeducation helps youth normalize their feelings related to the sexual abuse experience by addressing how their feelings and beliefs are similar to those of other sexually abused children (Swenson & Hanson, 1998). Information provided during psychoeducation typically includes a definition of CSA, prevalence of CSA, description of victims and perpetrators, why perpetrators offend, and how children respond to abuse (Deblinger, Behl et al., 2006;

Hansen et al., 1998). Providing normative information about CSA helps to introduce the topic of CSA for discussion and prepares children for future discussion of their own abuse experiences. Normative sexual development information is often included in the psychoeducation portion of CSA treatment. According to Deblinger and Heflin (1996), sex education is particularly important for sexually abused children for four reasons: (a) it is critical that youth receive accurate information to correct any misconceptions that may have developed as a result of their abusive experience; (b) sex education may reduce a victim's vulnerability to revictimization, premature sexual activity, and/or adult sexual dysfunction; (c) sex education may be incorporated into the gradual exposure process for youth who avoid discussions of sexual issues because it precipitates memories of the experience; and (d) through the sexual education process, adults have the opportunity to model appropriate conversations related to sexual issues. Sexual education can also facilitate discussions about body ownership, appropriate personal space, as well as good and bad touches.

12.5.2 Anxiety Management

Anxiety management refers to teaching youth how to utilize various relaxation and emotional/cognitive coping strategies to reduce fearful and anxious responses to abuse-related memories (Berliner & Elliott, 2002). Most treatments employ and/or adapt some form of relaxation training to help youth cope with their psychological distress. Techniques include breathing retraining, progressive muscle relaxation, and guided imagery. Children are also encouraged to identify personal means of relaxation such as listening to music, reading, journaling, participating in sports, and so forth. Relaxation skills should work to reduce anxious and avoidant behavior by helping children to control their emotions and providing them with a sense of control over their emotions.

12.5.3 Exposure

Gradual exposure is often regarded as the central and critical component of many CSA treatments. Utilizing this technique, youth are gradually exposed to thoughts, memories, and other reminders of the abusive experience until they are able to tolerate those memories without significant emotional distress, thereby eliminating the avoidance of abuse-related cognitions (Deblinger & Heflin, 1996). Techniques may involve direct discussions, narratives, drawings, imagination, or visualizations of the traumatic event in a graduated manner (Cohen et al., 2000). After becoming more comfortable discussing the abuse, youth will be better able to pursue cognitive and affective processing of their experiences (Deblinger & Heflin). Processing the experience then provides opportunities to correct misconceptions, enhance their cognitive understanding of the abuse, and clarify their emotional response to their abusive experiences.

12.5.4 Cognitive Coping

Cognitive coping techniques are often used in CSA interventions to challenge and replace cognitive distortions about the abusive experience and/or generalized negative attributions about themselves or others (Berliner & Elliott, 2002). Techniques used to correct negative

automatic thoughts and maladaptive thinking errors include cognitive restructuring, guided self-dialogue, and thought stopping (Deblinger, McLeer, & Henry, 1990). Cognitive coping can diminish/eliminate cognitive attribution difficulties such as self-blame for negative events, the impression that the world is a dangerous place, and problematic attitudes (preoccupation with and/or aversion) toward sexuality.

12.5.5 Behavior Management

As previously noted, CBT approaches for CSA treatment often include nonoffending caregiver components conducted either in a parallel individual or group format or in conjoint sessions with the victim. These parental interventions typically entail comparable components to those described above (e.g., psychoeducation, cognitive coping), although at a different developmentally appropriate level. In addition, maltreated youth may display disruptive behaviors that could result from maltreatment or stem from disordered family interactions – possibly placing them at risk for future maltreatment (Lutzker, Van Hasselt, Bigelow, Greene, & Kessler, 1998). Therefore, behavior management strategies may also be incorporated into nonoffending caregiver treatment (Cohen et al., 2000). A detailed description of behavior management strategies is beyond the scope of this chapter, but a number of evidence-based interventions are available (Barkley, 1997; Barkley, Edwards, & Robin, 1999; Hembree-Kigin & McNeil, 1995; McMahon & Forehand, 2003).

12.5.6 Social Support

Both theoretical and empirical literature suggest that children's emotional and behavioral adjustment following abuse is linked to the reactions and support they receive from caregivers (Elliott & Carnes, 2001). Empirical research suggests that sexually abused youth who have a supportive caregiver exhibit fewer symptoms of distress (Esparza, 1993; Morrison & Clavenna-Valleroy, 1998), as well as fewer abuse-specific symptoms (Leifer, Shapiro, & Kassem, 1993) when compared to youth without social support. Moreover, research suggests that the association between higher social support and better adjustment is evident regardless of whether the level of supportiveness and psychological adjustment is rated by the youth, caregiver, or mental health professional (Elliott & Carnes; Esparza; Mannarino & Cohen, 1996). Notably, empirical research also suggests that social support is beneficial for the nonoffending caregiver following the disclosure of abuse. Studies suggest that parents with less social/environmental support are more distressed (Hiebert-Murphy, 1998) and less supportive of their children (Leifer et al., 1993). Thus, the inclusion of nonoffending caregivers in the therapeutic process may be a critical component.

12.6 Basic Competencies of the Clinician

The American Psychological Association (APA, 2002) requires that psychologists provide services that are within the limits of their competency based on education, training, supervision, consultation, study, and clinical experience. However, the APA ethical guidelines do not provide information on what constitutes clinical competencies or what criteria need to be met in

order to be considered competent. Thus, difficulties exist for clinicians working with special populations wherein unique skills often go undefined. Recently, professional agencies have been developing guidelines and practice parameters to clarify the skills that constitute clinical competencies with specialized populations.

In 1988, the APA's Interdivisional Task Force on Child Abuse Training suggested that mental health professionals within the field of child maltreatment have competencies in child development, parent–child interactions, assessment and treatment of child maltreatment, and forensic issues (Garbarino, 1988). In 1996, an APA Task Force on Child Abuse and Neglect developed guidelines for mental health professionals that emphasized competencies in defining and recognizing child maltreatment, theories of abuse, working with interdisciplinary teams, ethical issues, assessment, and treatment related to child maltreatment (APA Child Abuse and Neglect Working Group, 1996; Haugaard et al., 1995). Clinicians specializing in CSA should further broaden their clinical competencies across a variety of realms. These competencies can be thought of at both basic (i.e., minimal competency that all practitioners must have in order to practice) and expert levels (i.e., demonstrating skills beyond the fundamental standards necessary – possessing knowledge deemed adequate to provide clinical supervision and/or scientific contribution to the field). An expansive and comprehensive guide to clinical competencies in working with children is beyond the scope of this chapter. However, more information can be found in the *Handbook of Clinical Psychology Competencies* (see ❯ volume 1, chapter 1).

12.6.1 Using an Evidence-Based Practice Approach for Treatment of CSA

Practitioners working with sexually abused youth should apply an evidenced-based practice (EBP) approach, which the APA has defined as "the integration of the best available research with clinical expertise in the context of patient characteristics, culture, and preferences" (APA, 2006, p. 273). The first component suggests that, when making treatment decisions for youth, clinicians must be guided by the strongest empirical evidence available, with evidence viewed hierarchically (i.e., clinical anecdote and uncontrolled case studies at the bottom, and randomized controlled trials at the top). Clinical expertise, the second component, refers to the skills needed to assess, diagnose, and implement a treatment following disclosure (APA, 2006). The final component considers not only ethnic diversity, but also a variety of values and individual differences that exist (APA), such as developmental issues, diversity considerations, and familial stressors related to CSA. Moreover, clients should also be informed about the probability that they will benefit from the evidence-based approaches, as well as the relative efficacy of any alternate empirically supported treatments. Application of the EBP standard to CSA suggests that clinicians offering services to sexually abused youth need the following basic competencies.

12.6.2 Fundamental Scientific Knowledge of CSA Symptoms and Treatment

Scientific knowledge of CSA involves a general understanding of traumatic stress and the impact of CSA on children and families. For example, clinicians should be familiar with the definitional and prevalence issues related to CSA (described previously in this chapter), since psychoeducation is an introductory component of most treatments. In addition, professionals

should have a basic understanding of the research on theoretical models of CSA impact (Freeman & Morris, 2001; Spaccarelli, 1994) and the consequences and correlates of maltreatment, including factors that may mediate or moderate the heterogeneous effects of CSA (Kendall-Tackett et al., 1993; Tyler, 2002).

Clinicians should also be aware of evidence-based treatments, such as those described earlier, and related effectiveness in symptom reduction for children who have experienced CSA. It is also important for clinicians to be aware of current trends in the scientific literature and growing concerns or controversies in the field of maltreatment. For instance, while there has been increased awareness of the possibility of false allegations and false "recovered" memories (Loftus & Davis, 2006), there has also been concern that fears regarding the suggestibility of children have gone too far and may prevent some children from being believed and/or questions to not be asked for fear of producing false allegations (Everson & Boat, 1989; Lawson & Chaffin, 1992).

Resources for staying current on research findings include professional journals, books, conferences, and workshops. In addition, valuable information is available via government agencies, professional organizations, and research centers, including the Office of Victims of Crime, the American Professional Society on the Abuse of Children (APSAC), and the National Child Traumatic Stress Network. Increasingly, these organizations make information available via the Internet, including training programs (e.g., the TF-CBT web site, tfcbt.musc.edu).

12.6.3 Fundamental Case Conceptualization Skills

According to Persons and Davidson (2001), a case conceptualization provides a systematic method for developing a working hypothesis (formulation) about the mechanisms underlying client symptomatology, developing a treatment plan based on the formulation, and evaluating the outcome of the treatment plan. Case conceptualizations should inform treatment decisions related to appropriateness of various CSA treatments, modifications that may be needed to increase the effectiveness of treatment, and evaluation of the ability to treat the case. Case conceptualization in CSA requires that the clinician considers a myriad of factors, including but not limited to, the following: (a) age and developmental level of the child, (b) severity and chronicity of current symptom presentation, (c) preexisiting psychopathology or comorbid disorders, (d) psychosocial stressors, (e) parental psychopathology and distress, (f) family support and functioning, and (g) abuse characteristics and prior/multiple trauma.

A thorough understanding of the case should also guide assessment-related decisions (i.e., the assessment of initial CSA symptomatology as well as ongoing and posttreatment evaluations). As noted above, sexually abused youth are often referred for services because of the experience and not necessarily due to clinically significant symptom presentation. Therefore, practitioners should take into account the heterogeneous symptom presentation (with as many as 21–49% sexually abused youth presenting as subclinical; Kendall-Tackett et al., 1993), and incorporate a variety of measures that assess for internalizing and externalizing symptomatology.

12.6.4 Establishing Rapport and Therapeutic Alliance

According to Rogers (1992), *rapport*, the warm relationship between the therapist and the client must be established if any progress is to be made. Rapport requires a genuine interest in the

individual, and successful rapport constitutes a personal bond whereby the therapist helps build client confidence and trust, which makes subsequent elements in the treatment process possible (Rogers). The *therapeutic alliance* is a complex interaction between the clinician and the client, each of whom brings to treatment his or her own characteristics, personality, and history (Gelso & Carter, 1994). Youth who develop emotional bonds and alliance with their therapist are more likely to be active in treatment-related tasks, increasing the likelihood of positive treatment outcomes (Karver, Handelsman, Fields, & Bickman, 2006).

The clinician's ability to establish rapport and therapeutic alliance may be especially relevant to sexually abused youth who could be experiencing difficulties with trust. Relatedly, the importance of rapport and alliance is increased by the fact that exposure to the distressing memories is a core component of most CSA treatments. Preferably, exposure should include client-directed verbal descriptions of important trauma details, but most children experience difficulties discussing their abusive experience and skillfully avoid activities that require them to remember or discuss abuse-related topics (Wolfe, 2006). It is important to note that pushing children to talk, having a formal interpersonal style, and sharing similar experiences may hinder the development of the therapeutic alliance (Creed & Kendall, 2005). Therefore, avoidant youth (after becoming comfortable with their therapist through rapport building exercises) may benefit from gradually discussing their abusive experience and clinicians may include both verbal and nonverbal means to express trauma-related feelings and thoughts (e.g., play, art, drama; Wolfe). Additionally, key factors linked to strong therapeutic alliance and improved symptom outcomes and family functioning include (a) developing and using a collaborative approach to therapy; (b) establishing treatment goals together; and (c) presenting treatment as focused on family relationships (Creed & Kendall).

Clinicians might expect initial difficulties forming an alliance with sexually abused youth, although they should be able to develop and maintain a strong alliance over time. A strong therapeutic alliance with children who have experienced CSA should involve empathy, tolerance of affect and emotional responses, and a collaborative nature. Children may express a variety of cognitive and emotional reactions following disclosure such as embarrassment, anger, and/or guilt and the clinician must remain supportive while gently correcting any misconceptions (e.g., they are to blame for what happened, sexual abuse is limited to their family). In many cases, a strong therapeutic alliance may also be necessary between the clinician and the caregiver(s) who may be experiencing stressors associated with disclosure (e.g., separation from a partner, moving, finances, decreased social support; Corcoran, 2004). Additionally, caregivers with their own abuse history report higher levels of psychological distress following the disclosure of abuse which may impede their ability to provide support to their child (Bergin, 2001). Moreover, in some circumstances, caregivers may be experiencing increased distress related to their own CPS investigation for failure to protect their children from sexual abuse. Thus, it is important that the clinician be empathetic and understanding of the emotional reaction of the entire family.

12.6.5 Treatment Planning

Heterogeneity of symptom presentation in sexually abused youth can present a challenge when making treatment decisions. Potential factors to consider when developing a treatment plan include, but are not limited to, the following: (a) chronological age of the child; (b) developmental

level; (c) risk factors for revictimization; (d) abuse-related characteristics (e.g., noncontact, fondling, penetration); (e) current symptomatology, severity, and psychosocial impairments; (f) comorbid disorders; (g) family functioning and support; and (h) other psychosocial stressors for the family.

Clinicians must also identify the treatment modalities that best meet the needs of the youth and family (e.g., individual, family, group). More individualized treatment approaches have the advantage of being able to be adjusted to the specific needs of the client. Group treatments can provide a valuable opportunity to learn from peers, may provide asymptomatic children with education on boundaries, and allow the clinician to further assess functioning without having them participate in intense exposures (Olafson & Boat, 2000). Contrarily, group treatment may not be appropriate for children exhibiting severe internalizing or externalizing behaviors, or with serious developmental delays (Hecht et al., 2002).

As described earlier, caregiver distress and support can significantly impact a youth's symptom presentation. Thus, clinicians should incorporate nonoffending caregivers into treatment when possible. It is also important to consider both the child and family's attitudes and acceptance of the intervention to maximize treatment compliance. For instance, if a caregiver or child is uncomfortable with exposure, a strong rationale for the treatment must be presented to encourage client commitment and treatment adherence.

Practitioners must also consider applicability of various treatments for CSA. For example, the clinician needs to ascertain the availability of the treatment, such as access to necessary manuals or resources, and the affordability of the treatment for the client. Most importantly, the clinician must consider his/her level of training and expertise. According the APA (2002) ethical guidelines, psychologists can only provide services within their scope of practice and for which they have established competency through training, education, experience, or consultation. It is important that clinicians evaluate their skill level and seek out training opportunities in treatments for CSA due to the discomfort some clinicians may feel when using exposure and cognitive restructuring techniques (Cohen et al., 2006). Practitioners who are unfamiliar with conducting exposure techniques for other anxiety disorders may not be prepared to address problems presented by PTSD clients (Becker, Zayfert, & Anderson, 2004). Thus, inexperienced clinicians should either seek out supervision or consultation when implementing treatments for CSA in which they do not feel proficient. In some cases, referrals to professionals with more specialized training and experience with CSA may be the ethically appropriate solution.

12.6.6 Monitoring Treatment Progress

Mental health professionals should monitor progress throughout treatment, rather than limiting assessment to pretreatment and posttreatment, in order to examine the effectiveness of the intervention. This continuous examination and evaluation can also guide necessary modifications to the case conceptualization and/or treatment plan, if symptom reduction is not achieved or additional symptoms emerge. In most cases, empirically validated assessment measures should be used to monitor treatment progress and changes in client symptomatology (e.g., CITES, WPS-C, WPS-P). However, the development of idiographic measures may be necessary to assess for symptomatology or factors that are unique to the client or population of youth served.

Clinicians should also identify factors that may impede treatment adherence and monitor such factors throughout treatment. For example, abuse-related distress may interfere with treatment commitment, compliance, and positive outcomes for youth. In addition, caregivers with their own maltreatment history may experience PTSD symptoms and general psychological distress following the disclosure of abuse (Timmons-Mitchell et al., 1997). Clinicians should address avoidance (e.g., openly discuss the temptations to cancel prior to exposures) and utilize a variety of techniques (e.g., psychoeducation, normalizing) to reduce abuse-related distress that occurs within the family during initial sessions. Other common challenges to CSA treatment adherence include unclear rationale for treatment and parental devaluation of the importance of treatment (Lane, Dubowitz, & Harrington, 2002). Lastly, practitioners should assess and address physical barriers (e.g., lack of transportation, lack of childcare, financial difficulties) at the outset of treatment to increase adherence and success.

12.6.7 Modifying Treatments

When therapists are novices and unfamiliar with CSA treatment approaches, they may feel uncomfortable adapting or individualizing treatment components, potentially leading to temptations to apply a "one size fits all" model or a "cookbook" approach to therapy. However, clients (and clinicians) do not necessarily conform to the strict expectations of manualized treatments, which are the standard in rigorous treatment outcome studies. Due to the heterogeneous nature of the CSA experience, the varied symptomatology, and the unique experiences that families encounter following the disclosure, it is critically important for practitioners to possess the ability to modify treatments if and when necessary to match client characteristics. Following the EBP framework, clinicians should base modifications on the best research evidence available, as well as prior data gathered from continuously monitoring treatment to inform treatment modification decisions. Modifications include, but are not limited to, the following: (a) lengthening or adding sessions, (b) eliminating components that are not relevant for the client, (c) modifying or adding components to address particularly difficult issues, and (d) modifying treatment to address developmental or cultural concerns. As one might expect, the modification of treatment generally requires a higher level of expertise, and beginning practitioners should seek consultation/supervision prior to modifying treatment plans.

12.6.8 Understanding Developmental Considerations Involved in Assessment and Treatment for CSA

Not surprisingly, practitioners working with children in general, and specialized populations such as sexually abused youth in particular, must be knowledgeable in developmental psychopathology and consider developmental issues throughout the assessment and treatment planning/implementation process. Empirical research indicates that the impact of abuse may manifest differently at varying developmental stages. As summarized in recent literature reviews (Kendall-Tackett et al., 1993; Tyler, 2002), common symptoms for each developmental period include:

- *Early childhood* – anxiety, nightmares, PTSD symptoms, inappropriate sexual behavior, as well as other internalizing and externalizing behaviors
- *Middle childhood* – anxiety, depression, anger or aggression, nightmares, hyperactivity, regressive behavior, inappropriate sexual behavior, sexual anxiety, suicidal ideation, and difficulties with school
- *Adolescence* – depression, withdrawal, low self-esteem, self-injurious and suicidal behaviors, illegal acts, substance abuse, risky sexual behavior, and pregnancy

Developmental theories of CSA suggest that abuse interferes with the development of the child with regard to social and self-functioning and may later manifest in psychopathology (Spaccarelli, 1994). In general, clinicians should consider the child's reading level, writing abilities, language comprehension, and cognitive abilities in comparison to those required by the assessment or treatment. Practitioners working with adolescents are more likely to utilize both cognitive and behavioral strategies (e.g., cognitive coping), whereas younger children may benefit more from behavioral skill-building exercises through the use of games (e.g., feelings charades).

12.6.9 Understanding Diversity Consideration Involved in Assessment and Treatment for CSA

Practitioners utilizing an evidence-based approach should always take into account a variety of client factors when planning and implementing treatment including, but not limited to, gender, culture, ethnicity, sexual orientation, and the client's personal preferences. Cultural influences may impact symptom expression in sexually abused youth (Mennen, 1995; Shaw, Lewis, Loeb, Rosado, & Rodriguez, 2001), and expectations for development (e.g., what is considered adaptive behaviors, appropriate parenting practices, family patterns, etc.) may vary according to cultural contexts (Pumariega, 2003). Clinicians should be culturally sensitive and should continually adapt and incorporate strategies in the assessment and treatment process to match unique cultural needs. Thus, clinicians need to understand, recognize, and address diversity issues that might impact treatment progress. Common factors clinicians should consider when working with diverse families include: (a) the primary language of the client, the client's proficiency in the clinician's primary language, and the appropriateness of an interpreter; (b) socioeconomic status; (c) education level; (d) incorporation of culturally relevant information into treatment; (e) adaptability of items and activities to client's culture; and (f) availability of supports and resources, including extended family.

12.6.10 Understanding Life Stressors and Challenges in Assessment and Treatment of CSA

Professionals must anticipate and recognize a variety of challenges that contribute to difficulties in implementing treatments for families who have experienced CSA. Factors that may impede treatment include poverty, lack of transportation, unstable home environment, family stressors (e.g., childcare, legal system), social isolation, and lack of family/community resources. Following disclosure, parents may experience a variety of stressors such as separation/divorce, moving, reduced social support network, and participation in criminal and/or civil legal

litigations (Corcoran, 2004). Families in which the perpetrator was a parent or spouse may face added financial burdens due to a loss of the perpetrator's income, and may have difficulties affording treatment. Clinicians working with financially challenged families may provide services on a sliding scale, offer a payment schedule, or refer clients to other CSA competent agencies/professionals with more flexible payment plans. Clinicians should also refer families to community resources (e.g., Child Advocacy Centers, community action programs) that may connect them with needs, such as housing and transportation assistance, interpreters, and material resources. Overall, practitioners should have an understanding of the stressors related to CSA disclosure and the ability to recognize unique factors that might impact treatment. More importantly, clinicians should possess the ability to generate strategies to address such challenges to increase treatment adherence and effectiveness.

12.6.11 Evaluating and Monitoring Legal, Ethical, and CPS Concerns

Clinicians working with sexually abused youth must be able to assess, monitor, and act on ethical issues that arise throughout assessment and treatment. This requires them to have a basic knowledge of ethical principles, standards of professional conduct, as well as legal and forensic issues. For example, the APA ethical guidelines and code of conduct (APA, 2002) are the basic standards by which all psychologists must abide. In addition, work with CSA involves the application of additional practice standards. Organizations such as the American Professional Society on the Abuse of Children (APSAC) and the American Academy of Child and Adolescent Psychiatry (AACAP) have developed guidelines and practice parameters for mental health professionals conducting forensic interviews with children who have experienced CSA (AACAP, 1997; APSAC, 1995, 1997).

On a basic level, mental health professionals working with CSA will face legal and ethical issues involving confidentiality, multiple roles, mandated reporting, third parties, and court involvement (Kalichman, 1999). As with any client, clinicians working with CSA are required to protect the youth's privacy, maintain appropriate documentation of client's records while maintaining confidentiality (APA). While all records are deemed confidential, regulations regarding appropriate documentation (and who is privy to these records) vary across states (Myers, 2002), and it is generally the practitioner's responsibility to remain current on regulations related to files and documentation. Although the child's legal guardian has the right to know detailed information on what is discussed during session, this can cause youth who have experienced sexual abuse to hesitantly participate in therapy. Therefore, it may be beneficial to advise parents to allow youth to share as much or as little about the contents of each session in order for them to feel more comfortable in treatment, with a detailed understanding (with both the parent and the client) that safety concerns (e.g., self-harm, suicidal ideation, promiscuity, unprotected sex) must be reported. This allows youth to discuss and process a variety of topics including family issues, parental reactions to disclosure of abuse, parental support, as well as dating and sexual relationships.

Treatment for sexually abused youth often entails working with the entire nuclear family, and clinicians must be cognizant of ethical situations that may arise from having multiple roles within the family. The APA (2002) ethics code requires that clinicians working with families identify the primary client and the relationship that the clinician will have with each family member. Although treatment may include parents and siblings of sexually abused youth, the

primary client is almost always the abused youth, and all components of the assessment and treatment process should reflect that fact.

Psychologists and other mental health practitioners are mandated reporters and required to report suspected child abuse, elder abuse, and/or harm to self or others (Kalichman, 1999). Clinicians working with families who have experienced CSA should be prepared to report disclosures of abuse from other family members such as siblings who previously denied abuse. Clinicians must also report incidents when parents violate court orders, such as when the parent allows the perpetrator to be alone with the child. Further, clinicians often have to work with third parties such as CPS or attorneys due to the legal processes involved in reporting and prosecuting CSA. Clinicians should make sure they know the appropriate rules and regulations governing subpoenaed records. When releasing information to third parties, clinicians should discuss this process with the client and keep them informed of progress.

In cases with court involvement, the clinician should work with the family to provide support and guidance while their case proceeds through the legal system. Clinicians may also be called upon to discuss the effects of CSA on the child, or in cases in which a forensic interview was conducted by the clinician, he or she may be asked to describe the veracity of the reported abuse. However, treating clinicians typically do not play a role in the forensic interview process and should therefore avoid providing testimony with regard to the veracity of abuse allegations (Mannarino & Cohen, 2001). Clinicians should always seek consultation in legal matters for which they are inexperienced.

12.6.12 Evaluating and Monitoring Risk of Harm to Self and/or Others

Mental health professionals are required by law to act when there is a threat of self-harm or harm to others (APA, 2002). This is particularly salient for clinicians working with sexually abused youth since CSA has been associated with an increased risk self-harm and suicidal ideation (Glassman, Weierich, Hooley, Deliberto, & Nock, 2007; Nock & Kessler, 2006). Clinicians must have an understanding of what constitutes a significant risk (e.g., cutting, self-burning, suicidal plans) and what behaviors require continuous monitoring and follow-up (e.g., suicidal thoughts). If there is risk for self-harm or suicidal behaviors, the clinician must be able to develop a safety plan up to and including inpatient hospitalization. If confidentiality must be broken based on client's disclosure of self-harm or suicidal behaviors, it is often beneficial to discuss concerns with the youth first and encourage them to disclose to their caregivers with the clinician's supervision and support. If the client refuses to discuss the topic with their caregiver(s), it is the clinician's responsibility to immediately communicate concerns with the caregivers who are often critical in implementing a safety plan. Use of clinical skills, such as interpersonal sensitivity and developing a therapeutic alliance, are paramount when assessing for risk. For more information on assessing and treating children with suicidal behaviors, please refer to the guidelines available through the American Academy of Child and Adolescent Psychiatry (AACAP, 2001). In general, all mental health professionals should seek consultation when faced with complex issues of self-harm and suicidal behaviors.

Clinicians must also be able to recognize and assess risk of harm to others (APA, 2002). As mandated reporters, clinicians have a duty to warn the individual in danger and should be aware of any relevant state laws regarding their duty to warn (*Tarasoff* v. *Regents of the University of California*, 1974/1976). This issue may arise in the context of therapy with parents expressing

anger towards the perpetrator. Parents often express intense anger with the perpetrator, and clinicians must differentiate between comments that allow the parents to vent their emotions and comments that express actual intent to seek revenge on the perpetrator. Clinicians may also face duty to warn issues when working with sexually abused youth exhibiting externalizing or sexual behavior problems. For example, a large number of abused youth subsequently display inappropriate sexual behaviors, potentially placing them at risk for perpetrating on other children (Friedrich et al., 2001; Kendall-Tackett et al., 1993). The type of sexual behaviors displayed should be assessed, and clinicians must determine the likelihood of these children sexually assaulting others. Overall, when examining risk to others clinicians should start by assessing for (a) a detailed plan; (b) access to weapons; (c) contact with the individual in danger; and (d) whether the individual in question would act on the plan. Again, practitioners should seek supervision or consultation when faced with issues related to the duty to warn.

12.6.13 Working in an Interdisciplinary Context

Thus far, the focus of the basic competencies has been on tailored individualized care; however, clinicians working with children who have experienced CSA must recognize that children are embedded within multiple systems and often need coordinated care (Wolfe, 2006). Practitioners working with children frequently interact with outside agencies, in addition to legal, school, family, medical, and other mental health professionals during the course of treatment. At the most basic level, clinicians must be able to interact with other agencies and professionals in a variety of contexts (e.g., referrals, retrieve records, communicate progress, etc.). For this reason, it is often beneficial for clinicians to conceptualize treatment within a social ecological framework (Bronfenbrenner, 1979). Children may already be receiving services from multiple agencies (e.g., school, primary care, child welfare, juvenile justice, etc.), and establishing a working relationship with professionals from different agencies is paramount in coordinating and enhancing treatment outcomes. Just as clinicians would work to develop a therapeutic alliance with a client, clinicians must also be able to develop a working alliance with individuals from interdisciplinary teams. Clinicians must be effective at communicating the needs of the child as well as what services the agency is expected to provide. This may require the clinician to address and define problems, negotiate a goal with the agency, correct discrepancies over expectations, provide solutions to problems, and implement a plan that addresses the needs of all parties involved.

12.6.14 Understanding the Effects of Medication on Treatment for CSA

As noted above, increasingly more traumatized youth are receiving pharmacological interventions, particularly for PTSD symptomatology. However, to date, no medication has been approved by the US Food and Drug Administration (FDA) for PTSD with children and adolescents (Wolfe, 2006). Thus, clinicians must consider reasons why a medication consultation might be valid. For example, medication may be valuable for improving outcomes for sexually abused youth with an unmedicated comorbid diagnosis of ADHD, who are exhibiting behavior problems and having difficulty staying on task during treatment. Also, in extreme cases of childhood anxiety, children may find it hard to talk about the abuse or may be reluctant to

participate in exposures. It may be beneficial for these children to receive combined treatments, which will allow them to focus more during treatment and participate in important aspects of treatment.

Due to increased attention related to medication treatment for trauma, depression, and PTSD symptomatology, clinicians must be knowledgeable about not only pharmacological interventions, but also alternatives to medications and, more importantly, have the ability to communicate options to caregivers. For instance, practitioners may want to inform clients that TF-CBT has also been shown to be effective at reducing PTSD symptomatology and maintaining treatment gains at 6-months and 12-months posttreatment without the use of medications (Deblinger, Mannarino, et al., 2006). Clinicians should always seek collaboration with families and primary care physicians when making abuse-related treatment decisions that may involve medication.

Lastly, although physicians and psychiatrists have traditionally been the professionals responsible for prescribing psychotropic medication, there is a growing movement in the field advocating for psychologists' prescription privileges. In fact, some states have successfully passed legislation that enables psychologists to prescribe psychotropic medications (Lavoie & Barone, 2006). If this trend continues, medically trained psychologists would possess additional training and expert competencies in psychopharmacology. Such psychologists would be able to determine whether to prescribe (or unprescribe) medications for sexually abused youth and provide medication consultation to other professionals not trained in psychopharmacology.

12.7   Expert Competencies of the Clinician

The purpose of the previous section was to provide practitioners with detailed suggestions for the basic standards necessary to demonstrate clinical competency when working with sexually abused youth. Expanding upon this foundational framework, the following section describes expert competencies in the realm of CSA. The competencies listed below build upon the basic competencies detailed in the previous section, highlighting skills advanced clinicians possess, and utilize when working with abused youth. Expert competencies should be thought of as the highest level a clinician can achieve, with an understanding that expertise in an expansive field requires continuous effort and energy. Therefore, development of expert competencies should be viewed as the ongoing integration of a collection of skills requiring a systematic approach to accomplish and maintain.

12.7.1 Advanced Scientific Knowledge of CSA Symptoms and Treatment

Advanced clinicians with CSA expertise not only possess a thorough knowledge of the research literature, but they also have the ability to apply their knowledge to the assessment and treatment process. For example, expert clinicians (a) have theoretical perspectives on the impact of CSA and selection of treatments, (b) understand the influence of the maintenance factors described above (e.g., abuse characteristics, familial response to disclosure, and cognitive attributions), (c) have an in-depth understanding of the mechanisms for change, and (d) have extensive knowledge of evidence-based CSA-related therapeutic techniques.

Due to the ever-changing and expansive nature of CSA literature, clinicians must take active steps to remain current within the field. Advanced practitioners benefit from, and likely contribute back, to the field via journal articles, conference presentations and workshops, and professional organizations (e.g., APSAC; APA Division 37, Section on Child Maltreatment). These contributions are critical to the development of the field and build a better understanding of the short- and long-term sequelae associated with CSA. Contributions should come from both academic researchers as well as practicing clinicians who provide invaluable information on the implementation and effectiveness of CSA treatment in "real world" clinical settings.

However, a thorough knowledge of CSA alone is not enough, and expert clinicians often incorporate information from other areas of psychology and outside fields to effectively treat families. Practitioners should remain current in the scientific literature of related fields that potentially impact the assessment and treatment of sexually abused youth (e.g., research on anxiety or other forms of trauma). For instance, there is increased use of psychopharmacological treatments for disorders commonly experienced by maltreated youth. Advanced clinicians with knowledge in a variety of scientific realms are better able to provide evidence-based rationale for or against different treatment approaches.

12.7.2 Advanced Case Conceptualization

As previously mentioned, sexually abused youth have a heterogeneous emotional and behavioral response following the traumatic event(s) resulting in a wide range of symptomatology (including asymptomatic or subclinical presentation). Expert clinicians are able to (a) differentiate between developmentally normal and abnormal behavior, (b) assess for comorbid diagnoses, and (c) make differential diagnoses. Furthermore, experienced clinicians take a systematic approach to develop a comprehensive case conceptualization, oftentimes combining and integrating several competencies in the area of CSA (e.g., diversity considerations, developmental considerations, scientific knowledge of CSA, parental factors). Moreover, advanced clinicians utilize a systemic and/or ecological framework in their case conceptualization. Expert clinicians readily adjust and adapt to new information disclosed by the family and other agencies; refining their case conceptualization and modifying their treatment plan based on the new material presented. Expert clinicians are also able to clearly communicate the conceptualization and treatment options to parents and children.

12.7.3 Advanced Rapport Building and Therapeutic Alliance

Developing rapport and a strong therapeutic alliance with the client is necessary but not solely sufficient for the effective treatment of CSA. Before treatment can be implemented the family must "buy in" to the treatment approach, and expert clinicians can enhance rapport and alliance in a number of ways, including (a) normalize feelings related to the sexual abuse experience, (b) address any reluctance to participate in treatment, (c) collaboratively develop treatment goals; (d) comfortably explain the different components and options for treatment, (e) describe how the selected treatment specifically addresses the families' needs, and (f) address confusion, questions, and concerns that arise. A collaborative approach may improve the family's

commitment to treatment, whereas disagreements on goals and approach may result in resistance from the family, impede treatment, and hinder the therapeutic relationships.

Expert competencies in this area also involve recognizing issues immediately after (if not before) they arise and addressing issues in an expeditious manner that maintains rapport. Experienced clinicians demonstrate problem-solving skills when factors emerge that may impede treatment adherence and outcomes. Resistance is associated with dropout and can take the form of arguing, interrupting, negating, and ignoring (Miller & Rollnick, 2002). For resistant clients, expert clinicians are likely to employ additional techniques such as motivational interviewing skills (e.g., shifting focus, reframing, emphasizing personal choice and control; Miller & Rollnick).

12.7.4 Expertise in Planning, Monitoring, and Modifying Treatment

In general, practitioners should take an evidence-based approach to treatment of CSA (i.e., combining the best available research with clinical expertise in the context of patient characteristics, culture, and preferences). However, more advanced CSA clinicians have the ability to more efficiently and effectively integrate client information and current empirical research into the treatment process. Moreover, experienced clinicians oftentimes can predict when change is expected or when a reemergence of symptoms may occur and incorporate this information into their treatment plan. For example, a clinician may plan a booster session after court proceedings to address any concerns or reemergence of symptoms that may have emerged during the trial. Beyond applying scientific knowledge to treatment, advanced clinicians also take a systematic approach to evaluating their own clinical work. One common way of evaluating treatment progress is to use a single-case design to monitor the effectiveness of treatment (Barlow, Nock, & Hersen, 2009). At a basic level, empirically supported measures are utilized at pretreatment and posttreatment, whereas more advanced clinicians implement ongoing assessment methods throughout treatment. More importantly, expert practitioners use the data to evaluate progress, inform treatment decisions, and make modifications to the case conceptualization and treatment process.

12.7.5 Advanced Understanding of Client Characteristics and Context in Treatment for CSA

Client characteristics represent one component of the tripartite evidence-based practice model, and advanced clinicians are responsible for integrating and addressing individual characteristics to ensure clients receive the best possible services. Advanced clinicians are able to adjust procedures as needed to match the developmental level of the child. They also recognize family stressors that may impede treatment and, through a collaborative effort with everyone involved in the treatment process, adapt services to meet the needs of the client and their family. Experienced clinicians also actively seek out resources for clients/families, and establish contacts and professional relationships with community agencies in the area in which they practice. Additionally, expert clinicians more readily recognize cultural misunderstandings or distrust by the client/family and immediately address these issues to build rapport and increase treatment compliance. The incorporation of a diverse treatment

team may provide invaluable consultation for clinicians to gain additional perspective and knowledge of both the client's circumstances and cultural resources in the community. Ethnic minorities are a diverse group, and it is important that clinicians are flexible in their applications of recommendations because they likely do not apply to all members of the minority groups. Unfortunately, a detailed description of cultural considerations for each minority group is beyond the scope of this chapter (Fontes, 1995; Futa, Hsu, & Hansen, 2001). Expert clinicians are able to identify the role and importance of a number of issues that can be important for individuals across a variety of cultural groups, such as kinship bonds and extended family, religion and spirituality, willingness to seeking treatment for psychological issues, comfort in sharing problems and expressing emotions, views on sexuality and homosexuality, gender stereotypes, and respect for adults and authority (Fontes; Futa et al., 2001).

12.7.6 Contributing Expertise in Ethical and Legal Situations

Contrary to other competencies described in this chapter, being an ethical practitioner is not on a continuum. However, with years of practice comes an increased recognition of the gray areas associated with ethical dilemmas for which clinicians should seek consultation. While beginning clinicians may focus on understanding professional guidelines and laws regulating clinical services, more advanced clinicians have expertise that provide guidance in dealing with challenging ethical dilemmas and legal issues. In fact, more advanced and experienced clinicians could serve as resources or consultants for other professionals, thereby contributing back to the field in the form of professional service.

Advanced clinicians are able to serve as a valuable resource for families, providing them with information on what they can expect from the legal process, as well as addressing the impact the legal process may have on the youth and their family. It is not uncommon for sexually abused youth to be called to testify in front of their perpetrator. Not surprisingly, this experience may be frightening for the client and a natural response may be to avoid court proceedings altogether. Clinicians may conduct "court school," whereby children become acquainted with the courtroom and the judicial proceedings prior to testifying, which is often beneficial in reducing court-related distress.

More advanced, and forensically trained, clinicians in the area of CSA may frequently provide expert testimony in regards to the veracity of the abuse and the accuracy of the child's testimony (Mason, 1991; Sagatun, 1991). Advanced clinicians serving as expert witnesses should be well-versed with historical rulings (e.g., *Frye* v. *United States*, 1923; *Daubert* v. *Merrell Dow Pharmaceuticals, Inc.,* 1993; *Kumho Tire* et al. v. *Carmichael,* 1999), as well as standards for expert testimony in their jurisdictions. However, as previously noted, treating clinicians lacking a role in the forensic interview process should avoid testimony with regards to the veracity of abuse allegations (Mannarino & Cohen, 2001).

12.7.7 Addressing and Treating Risk of Harm to Self and/or Others

As noted above, sexually abused youth are at an increased risk for self-harm and suicidal ideation (Glassman et al., 2007; Nock & Kessler, 2006). Therefore, expert competencies in this area

go beyond simple risk recognition and assessment of self-harm behaviors, and focus on prevention and treatment. Advanced clinicians are readily able to recognize subtle cues of self-injury (e.g., visible scratches, long sleeves in warm weather). In addition, experts possess knowledge of how circumstances and responses associated with CSA relate to common contextual (e.g., loss of a relationship, social isolation) and emotional (e.g., sadness, shame, guilt) antecedents of self-harm. Further, advanced practitioners assess and address behaviors that place clients at increased risk for other safety and health concerns (e.g., promiscuity, unprotected sex). Expert clinicians should be able to provide consultation as well as valuable resources.

12.7.8 Working with Interdisciplinary Teams

Youth who experience CSA are likely to receive services from a wide variety of agencies, placing them at risk for fragmented care that may not address their overall needs. Advanced clinicians possess the ability to utilize both their knowledge and relationships with outside agencies to coordinate services in a systematic manner. Expert clinicians are able to provide service coordination at the case, program (e.g., involvement in clinical and policy decision making), and larger system levels (e.g., interagency structure and agreements). Multidisciplinary teams often incorporate professionals from the schools, Child Advocacy Centers, CPS, law enforcement, legal, and mental health agencies in order to coordinate services and address multiple areas of functioning. Advanced clinicians will likely be active members of multidisciplinary teams working to facilitate communication/services across providers and providing ongoing consultation to a variety of organizations. Advanced practitioners understand the role and function of each team member, including the shared and unique contributions of the other professionals.

Further, clinicians with expert competencies in CSA often serve as sources of information for other practitioners and professionals. Thus, expert-level clinicians are able to provide in-depth information on empirically supported research and treatment for CSA to a variety of professionals within their community, region, state, and possibly around the globe. Moreover, the continuous dissemination of CSA-related information (e.g., common symptomatology, heterogeneous emotional/behavioral responses, treatment programs, expert advice) will likely encourage collaborative efforts between agencies; thereby increasing the likelihood that sexually abused youth will receive the best services available.

12.8 Transition from Basic Competence to Expert

The transition from basic to expert competencies is a gradual developmental process that requires continuous (a) education and training, (b) experience, (c) supervision, and (d) self-assessment. Although basic and expert competencies have been presented separately in this chapter, clinical competency in CSA should be conceptualized along a continuum rather than dichotomous approaches. Through the process of ongoing training, experience, and self-evaluation, clinicians progress along the continuum to possess more advanced proficiencies in CSA competencies. In order to reach the level of expert competency, professionals must be able to efficiently and effectively integrate the competencies previously discussed.

Understandably, the development of more advanced CSA skills requires significant personal commitment, investment, and time.

12.8.1 Continued Education and Training

An understanding of historical literature can provide a foundational background to the beginning practitioner, but the active consumption of the rapidly advancing and expanding CSA literature is critical for advanced clinicians seeking to remain current with the field (e.g., current theories, prevalence rates, psychological outcomes, and the efficacy of different treatment options). Additionally, the beginning clinicians can enhance their current knowledge and therapeutic skills by actively seeking continued CSA-specific education and training. For instance, conferences and workshops specializing in maltreatment (e.g., the APSAC Annual Colloquium, the San Diego International Conference on Child and Family Maltreatment) provide valuable educational opportunities and instruction on conducting certain techniques (e.g., gradual exposure) from experts in the field.

In addition, professional organizations and research centers (e.g., APSAC; APA Division 37, Section on Child Maltreatment; National Child Traumatic Stress Network; National Crime Victims Research and Treatment Center) that address CSA are important sources of education and training available to clinicians looking to gain more advanced skills. Moreover, some organizations now provide online information and/or continuing education credits for clinicians completing online tutorials (e.g., http://tfcbt.musc.edu/). Practitioners striving to advance their CSA clinical competency will likely build a library of materials relevant to CSA such as journals, manuals, and measures. This allows more advanced clinicians to easily access relevant information, keep up to date on the current state of the field, and serve as helpful resources when providing consultation to beginning clinicians.

12.8.2 Continued Experience

In an EBP framework, continued experience with sexually abused youth and their families provides invaluable opportunities for clinicians to strengthen and refine their skills. With continued experience, clinicians are able to confidently address a variety of issues that may influence treatment effectiveness such as necessary modifications based on client characteristics (e.g., addressing "familismo" in Latino clients by incorporating extended family members into treatment) and potential barriers to treatment (e.g., transportation, financial concerns, lack of resources, social isolation).

12.8.3 Supervision and Consultation

Continuously seeking supervision and consultation from CSA experts is often critical to the transition from basic- to expert-level competencies. In fact, the APA (2002) Code of Ethics states that clinicians using new therapeutic techniques and providing services to populations with which they do not have expertise should seek supervision and consultation to ensure that

the client receives appropriate services. Supervision can provide support and guidance with case conceptualization, therapeutic techniques, and modifications to the treatment plan. While practitioners with increased expertise may require less direct supervision, even expert clinicians may benefit from ongoing consultation with colleagues to discuss treatment challenges and ethical issues (e.g., testifying as an expert witness).

12.8.4 Self-Assessment of Clinical Competencies Involved in Treating CSA

Arguably, nothing could be more critical in the transitioning process than the ongoing self-evaluation of your own clinical skills. Clinicians should monitor their clinical skills throughout their entire career in all realms, including rapport and therapeutic alliance, assessment and treatment techniques, and the implementation/modification of treatment plans. Self-assessment allows clinicians to identify weaknesses, which can be improved through continued education, experience, and supervision.

Clinicians working with CSA victims may experience secondary traumatic stress or compassion fatigue (Figley, 1995) and burnout (Azar, 2000). Self-assessment can be valuable for recognizing and acting on these problems. In these situations, it may be useful for professionals to decrease the number of CSA cases in their caseload, maintain a healthy balance between personal life and work, employ self-care strategies such as stress management, and seek peer support and supervision.

12.9   Summary

CSA significantly impacts many youth and their families. Effects of CSA vary considerably, and consequences may include internalizing (e.g., anxiety, depression, etc.) and externalizing (e.g., substance abuse, sexual behavior, etc.) problems. Posttraumatic stress disorder (PTSD) is the most commonly identified clinical syndrome. A substantial number of youth do not show measurable clinical symptoms, although problems may appear later in life for some youth. Nonoffending parents and siblings may also experience significant distress and need treatment as well. Given diversity of problems that may be present, assessments should be multi-method, multi-symptom, as well as multi-informant.

Intervention for CSA is complicated by heterogeneity of symptom presentation and the fact that many children are referred for services due to the sexual abuse experience, and not necessarily because of exhibiting clinical levels of emotional or behavioral symptoms. Caregivers may seek services for the CSA victim to address questions and concerns, and reduce the likelihood of negative consequences. Treatment for sexually abused youth commonly includes psychoeducation, anxiety management, exposure, cognitive coping, and social support. Behavior management strategies may be valuable for conduct and sexual behavior problems.

Basic-level competencies for clinicians working with CSA include the following inter-related skills: (a) using an evidence-based practice approach for treatment; (b) possessing fundamental scientific knowledge of CSA symptoms and treatment; (c) using fundamental case conceptualization skills; (d) building rapport and therapeutic alliance; (e) treatment planning; (f) monitoring treatment progress; (g) modifying treatments as needed; (h) understanding

the impact of developmental issues, diversity considerations, and life stressors and challenges in assessment and treatment; (i) evaluating and monitoring legal, ethical, and CPS concerns; (j) evaluating and monitoring risk of harm to self and/or others; (k) working in an interdisciplinary context; and (l) understanding the effects of medication on treatment for CSA.

Expert-level competencies, which build upon the foundational skills, include the following: (a) possessing advanced scientific knowledge of CSA symptoms and treatment; (b) using advanced case conceptualization skills; (c) using advanced rapport building and therapeutic alliance skills; (d) having expertise in planning, monitoring, and modifying treatment; (e) having advanced understanding of the impact of client characteristics and context; (f) contributing expertise in ethical and legal situations; (g) addressing and treating risk of harm to self and/or others; and (h) working with interdisciplinary teams. The transition from basic to expert competencies requires integration of different competencies and the development of more advanced clinical skills through additional education and training, experience, supervision, and self-assessment.

13 Child Physical Abuse and Neglect

Lenore E. Walker

Abstract: Child abuse exists everywhere in the world, in all cultures and ethnic groups, resulting in huge economic and personal costs. Legal and health professionals have studied the causes and treatment methods to try to prevent and mitigate the harm done by abuse, especially from parents or other caregivers. This chapter provides the legal issues and definitions in physical abuse and neglect, maltreatment, and psychological abuse looking at the recent history and current laws. Information is given about the child protection system in the USA and other countries. Psychological theories of why parents abuse their children are discussed and the psychological harm such abuse has on their children using a developmental perspective and emphasizing the learned behavior from one generation to the next. Basic and special competencies needed by health professionals to work in this area are also described including psychological assessment of children and abusers. Standardized psychological tests and assessment inventories commonly used by psychologists are reviewed. Various psychotherapy interventions with children and parents are listed including offender-specific treatment for abusers, cognitive behavioral therapy, dialectic behavior therapy, family systems therapy, EMDR, and supportive therapy. Prevention strategies following a public health model of decreasing risks and strengthening resiliencies is discussed. Expert competencies are described for clinicians providing forensic evaluations and serving as expert witnesses. Numerous references are available for further information.

13.1 Overview

► *Jill lay on the floor of the playground appearing to be writhing in pain. She clutched her stomach and moaned from time to time. Her father was chasing after her little brother, Billie, who was trying to climb up the slide and did not pay much attention to her. The boy started screaming as his father pulled him up by the arm, leaving him dangling. It was summer and other bruises could be seen on the young boy by any casual observer. But observers did not think twice about what they saw given the high activity level of the child and the difficulty the well-dressed man seemed to be having in controlling his children. He seemed like any other father who had the responsibility of two young children. In fact, later one observer stated that she felt sorry for the father and wondered where the children's mother was. At no time did she even suspect that the father who had been granted shared parental responsibility of the two children whom he abused would eventually kill them and himself.*

Unfortunately, the above scene is becoming more familiar as courts are granting shared parental responsibility or joint custody when parents get divorced. As discussed later in this chapter, the standard for granting joint custody is not adequate in protecting children, especially when their father has also committed domestic violence against their mother (see www.theleadershipcouncil.org). Although protective mothers attempt to provide evidence to the family

court that their children are in danger from fathers who have not had any prior, major responsibility for child care, it often falls on deaf ears. Even worse yet, court-appointed mental health professionals with no competency in child abuse evaluations opine that these mothers are trying to keep their soon to be ex-husbands away from the children using a nonscientific theory, Parental Alienation Syndrome (PAS), proposed by Gardner (1992), to justify their recommendations to the court to not to give sole custody to fathers who are unprepared for the rigors of single parenting young children. Although most of these fathers do not kill their children or themselves, the damage done to children is apparent as they battle for control with these abusive parents.

Despite the efforts of the child protection system around the world, children are still being killed after physical assault and severe neglect from a parent or caretaker. Studies demonstrate that more males than females and more father's or mother's paramours are responsible for these fatalities from physical abuse and more mothers are responsible for those fatalities from severe neglect (US Advisory Board on Child Abuse and Neglect, 1995). This is usually because mothers spend more time with children and therefore have more opportunity to engage in maltreatment. In some cases, mothers are under the power and control of an abusive partner and unable to protect their children as well as themselves. The US National Child Abuse and Neglect Data System (NCANDS) statistics indicate that an estimated 1,530 children died from an injury resulting from child abuse or neglect in 2005, while over one quarter million reports of abuse were made. Other studies suggest that this represents less than one fifth of all the child fatalities due to poor reporting standards (Crume, DiGuiseppi, Byers, Sirotnak, & Garrett, 2002; Herman-Giddens et al., 1999). NCANDS data indicates that the highest risk for fatality is for children under 1 year of age (44.2% in 2006) and over three quarters (78% in 2006) are children under 4 years of age. Although most child fatalities come from injuries after repeated child abuse (22.4%) or such as in shaken-baby syndrome (Altimkier, 2008), or such us in shanken-beby syndrome (Altimkier, 2008), or severe maltreatment (41.1%), another 31.4% of fatalities were the result of multiple types of maltreatment (Child Welfare Information Gateway, www.childwelfare.gov/pubs/factsheets/fatality.cfm, downloaded April 23, 2008).

Why are these cases so difficult to identify? Neither physical and mental health professionals, nor legal professionals want to believe that well-dressed and well-spoken parents can inflict such serious harm to their own children. Although the statistics indicate that approximately 60% of those men who batter their intimate partner will also abuse their child, professionals are more willing to believe that it is not possible in the case in front of them. These cases are not identified easily by family court mental health professionals who make the assumption that the child custody guidelines from various professional associations deal with high conflict but not necessarily abusive families. Obviously, the rise in cases of domestic violence and family homicides proves them wrong. Although the USHHS Administration for Children and Families produces numerous materials to assist professionals in identification, most mental health professionals are unaware of them (http://www.dhs.state.il.us/page.aspx?item = 9262 retrieved June 2009).

▶ *The 3-year old child brought into the emergency room seemed lifeless to mental health professional who was assigned to the pediatric ER. He was so thin and appeared malnourished. His little belly was distended and his body had bruises of all different colors indicating different stages of healing. The standard protocol was to separate the mother from the child and interview her while the pediatrician was examining the child who barely moved as he was being touched. The mother sat there stunned, barely able to talk. She had gone to work and came home to find the child lying in his crib. She had*

asked a neighbor to watch him as no one else was available and she simply had to work or there would be no money to pay the rent or buy the child and her food. She believed the boy would stay asleep through the night like he usually did and all the neighbor had to do was look in on him every so often. How could she know that he would get up in the middle of the night and cry so hard that he was inconsolable. Life was difficult for them and she tried to do the best she could.

This is another familiar scene to those who work with children who are abused. Here the mother may have been negligent in not providing adequate child care while she went to work. Was she abusive? Did the child accidentally swallow something toxic or touch something that harmed him? Did the babysitter shake him because she could not get him to stop crying? Could this mother continue to care for her son if she had assistance from the local agency that provided Child Protective Services (CPS)? Could this have happened even if she had an expensive nanny in the house to care for him?

This scenario becomes even more common when the economy worsens. Child abuse authorities report a dramatic increase in cases of abuse and neglect especially in children with poor nutrition. Both mothers and fathers who have lost their jobs will be home spending more time with their children rather than keeping them in day care they no longer can afford. While there is no specific profile of an abuser, high-risk situations include stressful environmental situations and parental depression (US Advisory Board on Child Abuse and Neglect, 1995). Mental health professionals who work in hospitals see this scene repeated over and over despite their wish to believe that the concerned parent had not really caused the abuse to the child.

► *Shauna and Tyrone were 13 year old twins who were referred for a psychological evaluation by the court to assist in placement. Both children were currently in a foster home placed by the local state Child Protective Services Agency. They had been in and out of foster care for most of their lives as their mother was a known crack addict who was unable to care for them and their father, also a known polysubstance abuser, was in and out of prison. They have an 18-year-old brother who no longer is eligible for services and a 16-year-old sister who just had her first baby. Their records indicated the multiple types of abuse each of them had experienced throughout their lives. Although they were diagnosed with communication and language difficulties that impacted their learning in school and were already placed in special education programs, their behavior had taken a turn for the worse. Shauna was beginning to act out sexually with other boys her age and Tyrone was acting like a bully to the other children in the foster home. The court wanted to know what was happening with them that may have caused this recent behavior change.*

Shauna and Tyrone are from the typical type of family that most people think of when child abuse and neglect is discussed. Their parents were unavailable and they were in and out of the state foster care system due to abuse and neglect. Their learning problems were diagnosed and they were being given some remediation in school. Yet, they were not doing well and in fact, were actually deteriorating. The job of trying to tease out the cause of the current deterioration in their behavior is a challenge for any psychologist given the twins' extensive history of trauma and probable cocaine-exposure in utero during their mother's pregnancy. Stability in the foster home system is almost impossible for most of these children as other children are coming in and out of the homes even if they were able to be in one foster home for an extended period of time. Their developmental age must also be examined as entering into adolescence with the hormonal and other biological changes can add to the multi-determination of why they are in need of further

assistance especially since they are aware of their brother's problems supporting himself having aged-out of the system and their sister is repeating the generational cycle with no means of support for herself and her baby. What type of assessment and intervention will help these twins?

In this chapter, the requisite competencies that are needed by psychologists who work with children who are abused and neglected are explored. In particular, the history of the protection of children from child abuse and neglect and relevant laws and agencies is discussed as it is important for mental health professionals to understand their role in relation to others in the system. Although the theories of intervention that are most successful for working with abused children and their families have not been carefully evaluated, there are some that appear to be standard in the field and therefore are described here. Methods of assessment including the knowledge of the developmental issues as they interact with impact from child abuse and especially how they relate to risk and resiliency factors in families are presented. Where there are differences for children who have been neglected and maltreated and those who have also been physically abused, these differences are clarified. This is also true in the discussion on therapy and prevention strategies for mental health professionals. Finally, a section on training needs and continuing education for psychologists and other health care professionals concludes the chapter.

13.2 History

It may seem difficult to believe it, but the mandatory reporting of child abuse and neglect only began in the mid-1970s with pediatricians Henry Kempe (Kempe & Helfer, 1972; Kempe et al., 1962) at the University of Colorado and David Gil (1970) at Brandeis University each writing a book detailing their research results and found far more incidents of child abuse and neglect than had ever before been suspected. By the early 1970s, most states passed child abuse reporting laws and began to collect data of reported cases and the National Center on Child Abuse and Neglect (NCAN) and its statistics branch National Center on Child Abuse and Neglect Data System (NCANDS) were established within the executive branch of the US government at the Health and Human Services Department for Children and Families in 1974 with the *Child Abuse Prevention and Treatment Act (CAPTA) (PL-93–247)* that provided for uniform definition of the different forms of child maltreatment as described below (Hurt, 1975). By 2003, there were 2.9 million referrals regarding over 1 million children made to child protective services around the USA with approximately one third subsequently being substantiated. During that year 1,500 children reportedly died from child abuse or neglect. Most of the reports made to CPS agencies are for neglect rather than physical abuse. Reports that cannot be substantiated but still might be legitimate abuse are called "unfounded" and the rest are considered as not being reportable abuse (US Department of Health and Human Services [USDHHS], 2005). Psychologists and other mental health professionals are asked to work closely with the judicial and executive branches of government in order to properly assess and treat many of these children and their families.

Interestingly, child abuse and neglect is treated as a serious problem all over the world although there are cross-cultural differences in definitions of abuse and neglect that are most likely related to the amount of resources a particular country can provide to children in general as well as when identified as at-risk (Bottoms & Goodman, 1996; Corcorcan & Chaudry, 1997; Evans-Campbell, 2008). The Convention on the Rights of the Child (CRC) was developed by

the United Nations over a 10-year period to protect the human rights of the child by banning discrimination against children and affirming special protection and rights appropriate to minors. Specifically, children have the right to survival, develop to their fullest, be protected from harm including abuse and exploitation, and participate fully in family, cultural, and social life. Guidelines also govern health care, education, legal, civil, and social services. All member nations have signed the document except for the USA and Somalia (UNICEF, 1989; UNICEF, 2004). The USA claims it will ratify the document as soon as it determines it is not in conflict with any of the myriad of laws that impact on children (McCauley & Schwartz, 2007).

Today, mental health professionals are all trained to know that they are in a mandatory report category requiring them to make a report upon suspicion of child abuse to the appropriate state authority. They must inform clients that their privilege of confidentiality does not extend to disclosures of child abuse. The only other area that permits a breach of confidentiality in therapy is if clients give indications they will hurt themselves or someone else. Failure to report child abuse can cause disciplinary actions and even criminal charges in some states.

The goal is for the state to protect children, but the system is so overloaded with cases that identification and provision of limited services do not often provide the necessary protection. At the same time, if a mental health professional makes the mandatory report, many families drop out of treatment, as they no longer trust the professional to be helpful to them. However, most states do not permit the psychologist to make this determination. Further, the legal standards for state intervention in the family demand a high evidentiary burden for the state to meet leaving the child with no treatment and no protection from the state. Even if the state does take control of the child and prepares a reunification plan for the parent(s) to complete, services to both the child and the parent(s) are often inadequate or nonexistent. If the child is removed from the home and placed in the foster care system, other problems are rampant such as abuse in the foster home, lack of attachment to adult caretakers, and adjustment to new schools, friends, and quasi-family members. If a child custody dispute is also taking place at the same time, an abused child refusing to see the abusive parent may be forced into a reunification plan that does not provide for psychological or physical safety but rather, shared parental responsibility, the new name for "joint custody" in most states.

13.2.1 Legal Issues and Definitions

The legal standard for family court matters calls for "the best interests of the child" as the way to make decisions impacting on the child's life (Child Abuse Prevention & Treatment Act, 1974, 1999). However, there are few legal definitions of what that means and those that do exist do not take into account the psychological development of the child. One of the major problems is that children do not have legal standing in the US courts and cannot be represented by a lawyer who looks out for what they want and not just their best interests. Rather, they can and often do have a Guardian ad Litem (GAL) appointed to represent their "best interests," but again, the definition of what exactly that means is often vague and difficult to assess. In Florida, for example, children are permitted to have legal representation in two situations: (1) if they are about to be sent to a residential placement and (2) if their parent's legal parental rights are about to be terminated. Cases like these often demonstrate the extreme differences between what is thought to be in a child's best interests by the GAL and what the child really wants and may actually need. Laws in other countries, such as Australia and Israel, have been changed to

permit a child's own legal standing in the court, which is especially useful for older children and adolescents. Children's own legal standing seems to be encouraged by the CRC document explained above.

For example, in the case of *Gregory K* (Russ, 1993), a 12-year-old child who was in and out of the foster care system for most of his life wanted to be adopted by his foster parents who also wanted to adopt him. However, the state CPS system insisted that he was not eligible for adoption because his parents were still working on their treatment plan and, therefore, could not be forced to have their parental rights terminated. Initially, the court concurred with Gregory and his foster parents who wanted to adopt him. The appellate court then ruled that this was not possible due to the presumption of reunification in the state laws and overturned the decision. However, had the court been legally able to take Gregory's wishes into consideration and not just his parents' or the CPS rules, the adoption could have taken place. For Gregory, it would have meant a lot to have a real family. He had never been able to live with his parents for more than a short time due to their problems. But, without legal standing, the court was unable to take his wishes into consideration. These types of legal restrictions often put the mental health professional in conflict with the requirements of the law and make it difficult to protect the child (Kalichman, 1993; Russ; Silver, 1967).

This also occurs in child custody cases, especially when children have made allegations of physical or sexual abuse of one parent towards them. These types of allegations are extremely difficult to prove especially since courts do not have to listen to the children themselves. To perform a custody evaluation, many cases are referred to mental health professionals who are not trained in the assessment of child abuse or even domestic violence between parents, which frightens some children into not wanting to spend time with their abusive parent. However, the presumption in the law is that shared parental responsibility is in the best interests of the child even though there is no empirical research to support such a presumption in all cases. So these children are forced into contact with the parent he or she has accused of abuse, often without any protection, causing the child major psychological and sometimes physical harm. This occurs most frequently when the allegedly abusive parent does not fit the stereotype of a child abuser (Walker, 2009).

The second area in addition to NCAN where definitions of child abuse and neglect can be found are in the International Society for the Prevention of Child Abuse and Neglect (ISPCAN) where research has been done throughout the world to behaviorally define abuse and neglect (ISPCAN, 2004). Although most countries define child physical abuse as any nonaccidental injuries inflicted upon the child or placing the child in harm such as allowing children to live on the streets or be forced into prostitution, the definition of neglect may have more differences based on regional, cultural, and religious values. McCauley and Schwartz (2007) suggest that more developed countries with resources for services for children may have broader definitions of neglect than those countries with fewer availability of services.

In 1974, in the original CAPTA law, child abuse and neglect was defined in broad terms that described injuries to the child and harm to their welfare. Over the years the definitions have been clarified and in 1996, the US Congress changed the definitions to:

► (T)he term "child abuse and neglect" means, at a minimum, any recent act or failure to act on the part of a parent or caretaker, which results in death, serious physical or emotional harm, sexual abuse or exploitation, or an act or failure to act which presents an imminent risk of serious harm (42 U.S.C. p 5206g(2)(1999)).

13.2.2 Characteristics of Abusive Parents

Although there has been a great deal of research on characteristics of abusive parents, in fact, most modern research suggest that it is a combination of high-risk situations including high-risk child characteristics that mix together with parents at a high risk to abuse. Kempe & Helfer (1972) suggest that these three variables are needed: parent + child + situation = abuse and/or neglect. Delsordo (1963) proposed that there are five categories of abusers: (1) mentally ill, (2) overflow abuse (unable to cope and abuse others also when under stress), (3) batter child because seen as a competitor or special burden, (4) disciplinary abuse relying on physical punishment, and (5) misplaced abuse by someone who is angry, in general.

The mentally ill abusive mother often confuses the child with herself as she is unable to differentiate and separate. This mother is at high risk for committing child abuse and filicide especially if she has developed postpartum depression (McKee, 2006). High publicity cases such as Andrea Yates who drowned her five children often leave the impression that this occurs more frequently than it actually does. Statistics indicate that fewer than 1,500 children per year are killed by both mothers and fathers with the largest percent being father's and mother's paramours killing children during attempts to discipline them (US Advisory Board on Child Abuse & Neglect, 1995).

Holter and Friedman (1968) found that parents of abused children were impulsive, dependent, immature, impulsive, rigid, self-centered, and rejecting. Others have found parents of abused children are predominantly from a lower socioeconomic group and have less knowledge about developmental skills of children (Gregg & Elmer, 1969) and have personality inadequacies, impulsive behavior, and display sadistic aggression (Bennie & Sclare, 1969). These parents are said to have few "mothering skills" so their expectations of what a child can do is at odds with the child's actual developmental level.

Today, most agree that these early suggested characteristics of abusive parents are not conclusive by themselves. Rather, like domestic violence and elder abuse, child abuse is multidetermined and other factors such as environmental stress and the caretaker parent's substance abuse are more likely to raise the potential of abuse in high-risk families. Newberger (1973) was among the first researchers to study the contribution of characteristics of children who were at high risk to be abused in addition to the abuser's characteristics. Early on it was found that one of the highest risks for abuse are infants who are prematurely born, probably because of the extra special care they need to survive. The same is true for children with disabilities. Terr (1970), who has been studying the impact of trauma on children, found that abused children often retaliate against parents with behavior that will definitely bring them more abuse, but also relieves some of their feelings of powerlessness by waging a full-scale counterattack. Some examples include children who refuse to eat, those who deliberately tell others lies about what is going on in their family, those who violate norms like defecating in a public place or breaking a parent's possessions, and those who demonstrate direct anger in the parent's face. Others have looked at the mismatch of temperaments between parents and child which may cause sufficient daily stress in caring for them. An example is the easy-going parent with a hyperactive child or the opposite. For some parents, certain behaviors at a particular developmental stage may present a challenge that is seen as provocative, although Gregg and Elmer (1969) found that this was more often associated with bonafide accidents that harm children.

Situational factors that raise the stress level in a family also produce higher risk for child abuse. These factors include social, economic, and psychological issues. Living in poverty has

been found to be one of the more important contributory factors over time (Brooks-Gunn & Duncan, 1997). The sharp decline in the family's living economic living conditions, such as that which occurs when a parent loses his or her job, also may cause severe stress that makes it difficult to properly parent a child. Studies have found that a parent who is depressed has a high risk of neglecting the needs of a child. Homes in which children are exposed to domestic violence not only raise the risk of child abuse (some studies have found a 40–60% overlap) but also may raise the risk that boys will be more likely to use violence in their own homes when they are adults (Walker, 2009). Alcohol and other drug abuse also make it difficult to adequately parent children and in homes where family money goes to support the parent's drug habit rather than food for the children, neglect is often the result. Although these situations do place children at higher risk for being abused or neglected, in fact, most researchers today believe that for abuse to actually occur, it is necessary for there to be the potential for the parent to be abusive together with a special kind of child and a crisis or series of crises in the family.

Not all parents who have situational crises and have the potential to be child abusers actually do use abuse. Research has found protective factors that give clues to what types of interventions might help provide safety for children. Some of these protective factors include supportive family and friends, ability to ask for and utilize help, a supportive spouse/partner, and an affinity for the child. Some studies have found that only one child in a family with other children are abused suggesting that the parent–child bond is not well established. The presence of a step-parent in the home may also be a trigger for abuse of a particular child or in some cases, all the children in the home including his or her biological children. Domestic violence perpetrators are more likely to abuse more than one child as has been found with fathers who sexually abuse children. Many of them have outward appearances of being a stable community member often volunteering for leadership positions that successfully hide their abuse in the home to outsiders. These families have very tight borders where very little interaction takes place that the father does not control and the children as well as their mothers are frightened into silence. It is typically physical or physiological symptoms that expose them or the abuse is revealed during the pendency of a divorce.

13.3 Psychological Theories of Child Abuse

13.3.1 Theories About Abusers

The early researchers and clinicians who published in the area of child abuse and neglect were mostly reporting what they observed without much theory to help better understand either the abuser or the abused child. As more children were reported to the NCAN register, patterns were analyzed, still without much theory to hold them together. Some of the earliest attempts at theory about why abusers acted as they did included psychoanalytic premises that placed blame on mothers for loving their children too little or too much. Overpossessive and overbearing mothers, schizophrenic-genic mothers, narcissistic, rejecting, and frigid mothers who used their daughters to substitute for themselves all appeared in the literature. Alcoholic mothers who were inconsistent in the attention paid to their children were also blamed for their children's problems.

Despite the inaccurate portrayal of mothers, the psychodynamic theories did provide information about the difficulty in all interpersonal relationships that appeared to be common in some types of abusers. Some of those theories are still useful in cases where mothers with

postpartum depression kill their infants or in those who are unable to form attachments to others to help them care for their children.

However, by the time the 1980s were over, the women's movement attempted to take the blame for child abuse away from the mother using the supportive statistics that demonstrated the violence that father's used against children (Chesler, 1991, 1972). The research about the impact of trauma on children and women also helped put many of the psychoanalytic theories to rest as rarely relevant in understanding why abuse occurred or how to rehabilitate the various family members. New data about nonoffending mothers began to demonstrate the strong relationship between the different forms of violence in the family and trauma theories seemed to be a more useful way to conceptualize some forms of child abuse especially when domestic violence was also present (APA, 1996a). The analysis included some understanding of mothers who were under pressure from controlling husbands to discipline children or ignore children and therefore, in their attempt to protect children from an abusive father, over- or under-disciplined them (Walker, 2009). Boundary violations are often commonly seen in domestic violence families which may also account for the high risk of other forms of violence in addition to intimate partner abuse.

Neglect of a child may also be multi-determined as was illustrated in the earlier case vignettes. More mothers are accused of neglecting children than fathers but that may be an artifact of how much time mothers spend together with children as compared to fathers. It also may be due to external circumstances that perpetuate neglect such as poverty (Corcorcan & Chaudry, 1997) lack of education, religious beliefs that prevent seeking necessary medical attention, and coercion from fathers who also commit domestic violence (Johnston & Roseby, 1977; Jones, Finkelhor, & Halter, 2007; Peterson, 1994; Peterson & Brown, 1994; Polaha et al., 2004). Stress theories proposed by Lazarus et al. attempt to account for the situational impact that influences abusive behavior in parents (Lazarus & Folkman, 1984). Speilberger et al. have examined the impact of stress on state and trait anger in cross-cultural studies (Speilberger, Sarason, Kules, & Van Heck, 1991).

Theories abound about why men use violence in their relationships but most agree that although violence is multi-determined, it continues to be used for power and control in relationships as violence works to get what the abuser wants immediately and no one is able to stop them (APA, 1996a). Straus has linked child abuse and domestic violence together finding that the overlap between men who abuse women and those who abuse children may be as high as 60% (Straus & Gelles, 1990). Gil (1970) was one of the first professionals to suggest that there is a generational transmission of violence from father to son which is supported by the Straus and Gelles model from their data. Stark (2007) proposed that application of a learning theory model to the experiences of those who live with family violence presents the best fit for understanding why men use violence. Further, Stark describes how ongoing patterns of coercive control link various acts of family violence together. Bancroft (2002) takes these theories further and applies it to understanding the minds of angry and controlling men and how it impacts on their parenting within the family (Bancroft & Silverman, 2002). Interestingly, Kalmuss (1984) extrapolated from the original Straus data and found that boys who were exposed to their fathers' abuse of their mothers were 700 times more likely to use violence in their own lives and if they also were abused, the risk factor rose to 1,000 times the nonabused child. Given the high numbers of children at risk for exposure to domestic violence every year, estimated at 10–20% of all American children (Carlson, 2000), and the propensity of the family courts to enforce shared parental custody despite reports of family abuse, it is important to understand the modeling of children who are exposed to violence and coercive control in their families.

Family systems theories also have been used to explain child abuse and how to change the dynamics so as to better protect children. While most theorists today believe that family systems theories should not be utilized when there is domestic violence, this admonition does not hold for child abuse. Gil (1996), for example, provides a treatment plan based upon the systemic view that the family itself has a relational disorder and only treatment with all members can make each of them whole again. Kaslow (1996) and other psychology colleagues who work with families rather than individuals have proposed a new diagnostic category of relational disorders to account for dysfunctional family patterns reportedly being considered by the DSM-V work groups.

13.3.2 Theories About Impact of Abuse on Children

Child abuse and neglect has been seen as the cause of most of the problems in childhood. For example, the high rate of abuse and neglect in children in the foster care system or charged with delinquency is often blamed for children's bad behavior (Rapp-Paglicci & Loeber, 2007).

Pathways from child abuse victim to juvenile delinquent are theorized using a social-control, social-learning model suggesting that children learn behaviors and attitudes towards violence at an early age, usually at home, and then find like-minded individuals and groups to associate with who influence them to act aggressively without concern for consequences. Others suggest that the severity and frequency of the abuse experienced in the family will have a greater impact on the future behavior of the child. In research from battered women, it has been suggested that children who are unable to form attachments to either one or both parents or to society in general are also at high risk of antisocial and sometimes violent behavior (Walker, 2009). Still others suggest that children with oppositional and conduct disorders have a higher risk of developing antisocial disorders including psychopathy, yet there are still others who believe that psychopaths have brain chemistry disorders that may also be genetically influenced (Hare, 1996). However, although the exact balance of prosocial and negative influences on a child's life in order to choose one or the other is not known, it is thought to often depend upon the interaction of the child's situation and the influence of both family and peers (Rapp-Paglicci & Loeber, 2007).

Garbarino has contributed important psychological understanding to the issue of impact of child abuse and neglect on boys (1999) and girls (2002). His findings also support a learning theory model of behavior although his most recent work has provided more suggestions and less blame for parents of aggressive children (Garbarino, 2003, 2006; Garbarino & Bedard, 2002). Newberger (2000) a pediatrician who devoted his career to helping abused children also has theorized that the socialization of boys promotes more violent behavior than in girls. This theory is also subscribed to by psychologists including Pollack (1998) and like Garbarino, psychiatrists Prothrow-Stith and Spivak (2005) indicate concerns about the rising amount of violent behavior in adolescent girls. The APA Task Force on Violence and Youth (1993) however found that the process called "maturing-out" may also account for the reduction of aggressive and violent behavior throughout the lifetime of an adolescent whose brain has not yet matured sufficiently to control impulsive behavior.

A concise empirically based theory of the transmission of violence from father to son was developed by Patterson (1982) in his studies of aggressive boys. Patterson and his colleagues went into the homes of these aggressive boys, aged 9–11 years old, and observed their behaviors

with their parents. Interestingly, he found that cross-gender aggressive behaviors were often found in these families with fathers and sons demonstrating coercive behaviors to mothers and daughters. In addition, he found that the coercive behaviors occurred in a pattern that is similar to the cycle of violence found in studies of domestic violence families (Walker, 2009). That is to say, there were clusters of aggressive behaviors followed by clusters of positive behaviors, in what Patterson called "haining and fogging" behaviors which prevented the recipient of these behaviors from making appropriate responses. Stark's (2007) work on coercive control in the domestic violence family supports Patterson's earlier results with aggressive boy's families. Typically, observations in normal families find more positive than negative interactions between family members. In dysfunctional families which do not have aggressive children, Patterson found more negative than positive behaviors towards each other, but they were more equally distributed across all family members. Thus, a careful analysis of coercion among family members may give important clues to whether or not a family may be engaging in abusive behaviors even without direct observation.

Research on trauma theory may provide the link between biological, situational, and psychological theories about impact from, and transmission of, physical child abuse and neglect.

Charney, Deutch, Krystal, Southwick, and Davis (1993) studying the neurotransmitters and hormones associated with posttraumatic stress disorder (PTSD) have found changes in the elevations of adrenalin and norepiniphrine that are responsible for increases in blood flow and heart rate. This may also be associated with panic attacks. The typical "fight" or "flight" response known to occur in trauma reactions are also mediated by the cortisol releasing factor (CRF) which prepares the organism to deal with perceived danger. The body uses the flow of glucocorticoids to deal with the pain from physical attack along with the endorphins that are opiates that the brain also releases. Cognitive memory may also be interfered with as the frontal cortex responds to the higher levels of dopamine that also stimulates thought processes and perhaps assists the intrusive memories of the trauma in the midbrain area that are then reexperienced with or without associations to parts of the trauma event.

In repeated traumas such as child abuse, parts of prior abusive events get reexperienced each time a new one occurs. While most of the studies of psychoneuroimmunology (PNI) have been on adults, Goleman (1996) and others suggest that structure as well as function of the child's nervous system that is still in the process of developing may be damaged by trauma. Although children's cognitive areas have been studied more than their emotional areas of the brain, there are those who believe that the most critical area impacted by trauma is in the midbrain area that controls the autonomic nervous system and its emotions, leaving the child's ability for social interaction and feelings of empathy for others damaged (Stahl, 2000).

13.4 Basic Competencies

13.4.1 Psychological Assessment

It is important for mental health professionals who work in the specialized area of child abuse and neglect to understand assessment methods that are appropriate for various developmental ages and abilities of the children, and other members of the family. Often physical signs of child abuse make assessment easier when there is a question of whether or not abuse has occurred.

Neglect and other forms of maltreatment are more difficult to assess as most mental health professionals are not trained to perform forensic evaluations. It is often critical to make sure that assessments do not compromise the legal issues involved. For children this means interviews and questions around the allegations of abuse and neglect must be done in an open-ended manner so that there is no danger of the evaluator biasing the child's information. The most benign interviews may create a bias by causing the child to give erroneous information that he or she thinks will please the interviewer. Sometimes when such bias is created it is difficult for the child not to continue repeating it, especially if the reaction of the adults is positive. On the other hand, it is also common for children to recant the information they have given about abuse once they realize that they are getting a parent or other adult they may also love in trouble.

Over the past 20 years, there has been a great deal of controversy over the stability of children's memory of abuse (Loftus, 1993). The American Psychological Association appointed a task force composed of clinicians and cognitive researchers to study the controversy and attempt to come to a reconciliation of their differences. They were unable to do so and wrote two separate reports explaining that the clinician's experiences with the clients who both remember and forget memories of child abuse were not consistent with what the knowledge from the research about cognitive memories would support. However, this debate spurred further research into the emotional experience of trauma and the storage of these memories, often nonverbal, in the hippocampus area of the brain, which helped explain the difficulty in consistent retrieval and storage into the cognitive memory areas (APA, 1996b).

13.4.1.1 Children

Assessment of children who are allegedly abused is complex as it is important to learn about the child's biopsychosocial development as well as current functioning without creating bias as described above (Briere, Berliner, Buckley, Jenny, & Reid, 1996). The biological integrity of the child may be inferred by studying the developmental milestones such as walking, talking, and cognitive abilities displayed in school or other settings. This information may come from interviews of family members, teachers and other school personnel, doctors, and others in the child's life. The same people may also assist in understanding the child's social environment. Children with disabilities are known to be at a high risk of child abuse and neglect (APA, 1993, 1996a). It is incumbent upon the evaluator to understand the impact of violence in the media and violence in the community on youth as well as other societal conditions. Exposure to weapons, alcohol, and other drugs, and prior violence all are high risk of both future victimization as well as violent behavior on the part of the child (APA, 1993, 1996a).

The psychological integrity of the child is assessed through clinical interviews, observations, and standardized tests where appropriate. Cognitive, emotional, and behavioral issues should be assessed and compared to age-mate and developmental expectations. Often abused and neglected children display both physical and psychological symptoms that should be part of the evaluation as it may help identify abusive experiences, especially in young children with difficulty in verbal reports. For example, children with physiological symptoms that indicate anxiety such as hair loss, headaches, stomachaches, vaginitis, frequent physical illnesses, and unexplained bruises may all come from abuse and neglect although these symptoms may also come from other reasons (Danese, Pariante, Caspi, Taylor, & Poulton, 2007; Kendall-Tackett,

2008). In particular, Kendall-Tackett has proposed that the immunological system of an abused child is compromised resulting in a variety of physical illnesses.

The American Professional Society on the Abuse of Children (APSAC) provides guidelines that assist in developing a protocol to question children at various ages (Briere et al., 1996) as does the Society for Research on Child Development (SRCD) (Steward et al., 1996). APA (*www.apa.org*) provides guidelines that can assist in understanding the process of the clinical and forensic evaluation of children as well as record keeping and ethical standards. These guidelines may be helpful both in preparing for an evaluation as well as through the entire process. Clinical interviewing may be unstructured or structured depending on the information needed to develop either a treatment plan or for legal purposes as discussed below. Greenspan (2003) provides a developmental framework within which to evaluate the information gained from the clinical interview. He emphasizes the need to understand the content of the child's statements during the interview through both developmental and clinical knowledge of the hypotheses set up before and during the examination.

Others also provide protocols that assist in obtaining information especially those that are frequently used in child custody evaluations such as the *Child Behavior Checklist for Children* (Achenbach & Edelbrock, 1983) which has forms for parents, teachers, and other caretakers as well as adolescent children to complete. Comparisons can be made for each person who completes a form per child using the child behavior and emotion profile that can be obtained from the scoring program recommended. Cognitive testing is usually done using the *Weschler Intelligence Scale for Children (WISC-IV)* although young children often perform better on the *Stanford-Binet* test because there are less failures until their age level is reached. Subjective as well as objective personality testing can also be utilized for children, most of which are available through various test companies such as *Personality Assessment Resources, Pearson, and Western Psychological Services* to name a few. Children's drawings and interview props such as stuffed animals, dolls, sandtray figures, cars, and the like are often used diagnostically as well as in play therapy, especially for those who have difficulty verbalizing their feelings about what happened to them (Bottoms & Goodman, 1996; Gitlin-Weiner, Sandgrund, & Schaefer, 2000).

One of the major areas to assess in children who have been abused and neglected is whether or not they have developed PTSD or other psychological diagnoses from the abuse. Sometimes the presence of these symptoms can assist in determining whether or not the abuse or neglect actually occurred in children unable to give a good verbal history. Even when the children do not meet the entire criteria for childhood PTSD assessment may be helpful to develop a trauma treatment plan. There are standardized tests that can assist in making the diagnosis of PTSD including the *Trauma Symptom Checklist for Children* (Briere & Scott, 2007) that has a version with and without allegations of sexual abuse for children 8 years old to 16 and the *Trauma Symptom Youth Checklist* (Briere & Scott, 2007) for parents to complete for children younger than 8 years. Interestingly, in research with adolescent girls who were being held in a youth detention center for either delinquency or status charges, it was found that although they denied any overt child abuse, 85% had significant scores on the Trauma Symptom Inventory (TSI) and Trauma Symptom Checklist for Children (TSCC) administered (Walker, 2009).

Many of the childhood signs and symptoms of PTSD are similar to those seen in children with attention deficit disorders and major depressive disorders. Therefore, it is important to be able to assess children through a developmental and clinical model as the signs and symptoms of PTSD change as the child gets older. Briere and Scott (2007) provide a comprehensive review

of PTSD signs and symptoms, evaluation methods and treatment of trauma for both adults and children. As children move into adolescence, it is important to assess for possible substance abuse given that the use of alcohol and other drugs is a popular way to self-medicate mental health symptoms.

13.4.1.2 Assessment of Parents and Others Suspected of Abuse

It is important to understand that the protection of the legal rights of those accused of child abuse or neglect is paramount in the manner in which they are questioned by nonlegal professionals. They may be charged with a criminal act as well as a civil dependency court charge, either or both of which can mean major losses and changes in their lives. They have much to lose and therefore it is critical to be aware of the need for informed consent to proceed with questions about the abuse or neglect allegations. On the other hand, it is often important to be able to conduct a clinical forensic assessment of the mental state of the alleged perpetrators to assist the court or for treatment planning purposes if the perpetrator had admitted to the charges.

Psychological interviewing gathering a detailed psychosocial history and abuse history is usually the initial step when performing a psychological evaluation for treatment planning. If the assessment is done from a family systems perspective, then genograms and other systems assessment tools may be used by the clinician. Whether or not a family systems approach is utilized, it is important to learn as much information about the person's family background especially since child abuse is known to be passed down from one generation to the next. Gold (2000) has delineated a number of areas to assess as it is known that family support can increase or decrease the psychological impact from child abuse. Assessing for strengths as well as deficits is recommended. Neuropsychological screening and other neurological tests may be needed depending upon information gained about possible head injuries or other similar nervous system factors including simple saliva testing of the cortical releasing factor when PTSD is thought to be present.

If the evaluation is for forensic purposes, then a complete battery of psychological tests are usually administered to assess for cognitive, emotional, and behavioral functioning of the individuals involved. Cognitive testing may be helpful in understanding lapses of good judgment when emotions are not well regulated. The *Weschler Adult Intelligence Scale* (*WAIS-IV*) is currently the most popular standardized psychological test used by psychologists. If the parent is being held in a detention center where time for evaluations is limited, the abbreviated version (*WASI*) may also be used. The most often used standardized personality tests are the *Minnesota Multiphasic Personality Inventory* (MMPI-2), the *Personality Assessment Inventory* (PAI), and in some cases where personality disorders may be suspected, the *Millon Clinical Multiaxial Inventory* (MCMI-3). As with children, it is important to assess adults for trauma symptoms and standardized tests by Briere (1995), Myers et al. (2002) such as the *Trauma Symptom Inventory* (TSI) and the *Detailed Assessment of Posttraumatic Stress* (DAPS). Assessment for substance abuse is also appropriate when performing both clinical and forensic evaluations.

Risk assessment to determine the likelihood of further violence has been a recent development. Most of the assessment instruments are actuarials which measure an individual against what is known about violence recidivism. Although the adage that the best predictor of future violence is past violence still has some truth, the MacArthur Foundation studies have identified other factors that contribute to the probability of further violence. These include static

variables such as the age at the time of the commission of the first violent act, family status, types of violence exposure; biological variables such as neurological signs and symptoms; psychological variables such as severe mental illness diagnosis and psychopathy and for some of the available assessment instruments such as the *HCR-20*, any treatment that the individual received. The *Hare PCL-R* is being used more frequently with accused perpetrators to attempt to assess for psychopathic behavior and antisocial personality disorder traits. The *Child Abuse Potential* test is also utilized with suspected abusive parents although these norms have not yet been standardized and are based mostly on mothers rather than fathers. There are several assessment instruments in the beta testing stage specific for danger from domestic violence and child abuse, but only the *Spousal Assault Risk Assessment* (SARA), which is really a protocol for the risk assessment, is in use at this time.

13.4.2 Psychological Interventions and Psychotherapy

Interventions and psychotherapy for victims and perpetrators of family violence need special training and expertise in trauma. Effective intervention programs are said to share two specific characteristics: (1) they draw on the understanding of developmental and sociocultural risk factors leading to antisocial behavior and (2) they use theory-based intervention strategies that are based on outcome evidence that they are effective in changing behavior (APA, 1993).

Although for most clinicians, their theoretical orientation will inform their conceptualization of a case and their treatment plans and techniques, most will need to add certain trauma-specific methods to their treatment. This will include reduction of anxiety and avoidance symptoms together with teaching emotional re-regulation and control over intrusive reexperiencing of the traumatic abuse events. However, prior to any treatment it is of critical importance to make sure that the clients are safe from further abuse. Often creating a safety plan with the adults or even older children helps prevent further abuse. Safety from being overwhelmed by their own internal thoughts, feelings, and behavior is as important as safety from another person's abuse or exploitation. Although it is not completely understood, the research shows that abuse victims are vulnerable to more victimization, perhaps because their resiliency is compromised (Walker, 2009). This risk is similar to children who are vulnerable due to other disabilities. Risk assessment methods as described above may be helpful.

13.4.2.1 Abused Children

Child psychotherapy. It is one of the most often recommended interventions for children who have been abused or neglected. Therapy needs to be tailored to the child's developmental age and wishes. Often there are differences in gender with boys more likely to engage in play that gives them a chance to talk and girls being more receptive to verbal psychotherapy. Veltkamp and Miller (1994) provide succinct behaviors that help identify abused and neglected children. These are helpful to know what areas need improvement through psychotherapy.

Successful intervention programs for children should begin as soon as possible upon discovery of the abuse to interrupt the impact from the violence. The psychotherapy should directly address any aggressive or other antisocial behavior on the part of the child especially paying attention to all the areas of the child's life that reinforces such behavior. Treatment also

needs to take advantage of what are called "windows of opportunity" that may naturally occur as transition periods in the child's life or are created by consultation with important others in the child's life. Programs that help children move into adolescence are particularly helpful in building resilience in youth and helping them make good choices that will impact on their later lives (APA, 1993). Although various techniques such as CBT and DBT are discussed below, many child therapists believe that it is the relationship between the child and the therapist that helps these children model good attachment and interpersonal skills.

Play therapy. This utilizes various forms of play and is particularly useful for young children or those older children who have difficulty expressing themselves with language. Gitlin-Weiner et al. (2000) and O'Connor (2000) have provided a variety of treatment approaches to play therapy depending upon the child's age, cultural background, and development. Sand-tray play with various figures and other materials can also be therapeutic for both children and adults who have been abused. Drawings and other forms of art therapy, music therapy, and movement therapy are also adjuncts to play therapy and have a similar effect on children to help them relax, become desensitized to abuse triggers, less angry, and rebuild interpersonal relationships in the family and with peers.

Eye Movement Desensitization Reprocessing (EMDR). It is an adjunctive therapy that has a good deal of research demonstrating its effectiveness with children and adults. A tapping procedure is often used once trauma triggers are identified so that the intensity of the child's reaction to the reexperienced memories of trauma is reduced and often eliminated (Greenwald, 1998). The therapist is expected to help the child remember details that may have been discussed in the assessment phase and utilize the EMDR technique to reduce the psychological impact that these memories have on the child's functioning.

Trauma-Specific Treatment. This treatment for children is similar to trauma treatment for adults exposed to abuse although the issues to be dealt with need to be age-appropriate to children. Identification of trauma triggers as suggested by Briere and Scott (2007) and assistance in stripping them of their power to control the child's emotional response directly is an important addition to psychotherapy with abused and neglected children. Relaxation training and desensitization methods are then used to help the child stop responding to the trauma trigger and gain better control over their intrusive memories. Some Dialectical Behavioral Therapy techniques such as mindfulness where the child is trained to concentrate on the present may assist in this area (Hayes, Follette, & Linehan, 2003).

Treatment for Bullying Behavior. It is another specific area of focus as the damage to children who have been victims and sometimes also aggressors of bullying behavior has been found to be significant in development of antisocial traits. Espelage (2003) describes the link between bullying and school violence which is another reason for the addition of this treatment area for child abuse experts. She suggests that bullying behavior occurs on a continuum and will be reduced by getting the community to come to an agreed upon definition of what it consists of and what will and will not be tolerated. Thus, bullies who are identified by peers or teachers may also be victims of other violence toward them. CBT and family systems therapy are both suggested as effective ways to intervene.

13.4.2.2 Adults in the Child's Family

Providing psychotherapy for different members of the family where abuse has occurred calls for a focus on the individual and where he or she fits into the family system. The family member's

treatment of the child must also receive focus during treatment. At the same time, it is important to respect the legal rights of abusers who may not admit to the abuse because of legal reasons. Obviously this is not a major issue when the abuser has admitted and is ordered into treatment by the court. Some treatment programs for abusers deal directly with their offending behavior and require admission of their acts, taking responsibility for the abuse or neglect, and for changing their behavior using methods such as relapse prevention and other techniques. Other treatment programs focus on the psychological stability and personality changes that need to be made by the abuser and nonoffending family members. Various adjuncts to psychotherapy are often used such as acupuncture, meditation, and other nonWestern techniques to stay calm and feel better. Choosing the right method often depends upon a combination of what is best for the child, what is best for the abuser, and what is best for the family. The following are some of the more popular treatment modalities that have some evidence-based effectiveness:

Offender Specific Treatment. This is a cognitive-behavioral treatment program for abusers that focuses on the abusers anger management and attitudes toward women and toward violence. Some of the programs deal with child abuse but not all. When first designed over 30 years ago, batterers' intervention programs provided battered women the option of cooperating with law enforcement and having an alternative to sending the batterer to jail or prison. However, as these group programs began to be conducted by the criminal justice system, they became more psychoeducational than psychotherapeutic, and men (or in some cases, women) who had a diagnosable mental illness were not getting appropriate treatment, especially as many of the programs only lasted for 6–12 weeks. Early models such as AMEND in Denver which utilized licensed therapists and kept batterers in treatment from 2 to 5 years still provide a more inclusive protocol (Walker, 2009).

Cognitive Behavior Therapy (CBT). These programs provide both conceptualization and treatment protocols for working with child abusers and nonabusing family members. Many of the skills that are taught in the various CBT programs are useful for helping them think about the targeted child and the situation in a different way. Most CBT protocols work with the individual in treatment although it may still be a cost-effective choice because behaviors to be changed are often targeted on a short-term basis rather than permitting them to come up in a more long-term person-centered treatment model. This treatment is particularly useful in getting the abuser to take responsibility for behavior rather than rationalization or blaming the victim. CBT can also assist neglectful parents by focusing on the issues that prevent them from dealing appropriately with their lives. However, the relationship issues that often need to be addressed in therapy may not get the attention needed to make major changes.

Dialectic Behavior Therapy (DBT). It is a newer treatment modality that has had success with adults who have a variety of cognitive and emotional problems, many of which may be traced back to their own childhood experiences (Hayes et al., 2003). Some of the areas that are addressed in DBT that have proven successful with difficult to treat clients include the concept of "mindfulness" which helps the person stay on task and face important issues such as the proper care of a child and the exercises in "emotional re-regulation," which assist the person to learn how to control and express emotions in a more appropriate way. Dealing with emotions before they build up and explode is important for many child abusers who cannot deal will with stress as they do not feel it until it is more difficult to control their reactions. This is especially important when working with adults who were abused as children.

Family Systems Therapy. It has provided many models of working with families where abuse has occurred (Gil, 1996; Kaslow, 1996). The goal is to avoid blaming each of the family members for the abuse and rather help them change the dysfunctional family system that permitted child

abuse or neglect to occur. Following a systems theory model, the therapist helps change in one area of family life which will then cause a shift in other areas because the family system that maintained the inappropriate behavior has changed. This model is particularly useful when the family stays together and each member needs to learn to pay attention to his or her own needs as well as the needs of other members in the family. When relational issues are the focus, family therapy can be useful as an adjunct to individual treatment using other modalities especially if empathy-building is an issue. In complex cases, especially when the child's needs may not get the attention needed, family members have been given their own therapists and when the family gets together, all the therapists are present.

Eye Movement Desensitization Reprocessing. It is useful in working with individuals who are dealing with their own trauma memories that are negatively impacting on their cognitions, emotions, and behavior. It is often used as an adjunct to other therapies although research indicates it may also be a stand-alone treatment. It is especially useful in teaching the abuser to control his or her emotional responses to the child's behavior that triggers their anger and abuse.

Supportive Therapy for the Non-Abusing Parent. It may be appropriate especially when that parent blames himself or herself for not knowing what was happening to the child or feels guilty for not being able to better protect the child. Some are genuinely shocked when they learn what has occurred and need support in uncovering their own use of denial or other psychological mechanisms that helped them not recognize the child's needs. In fairness, many children who have been abused reveal the extent to which they have gone to cover up the abuse for fear that the nonoffending parent may not be able to handle it and they might lose that parent's love and whatever support that is available.

Substance Abuse Treatment. It is a necessary adjunct to psychotherapy when the abuser or the nonabusive parent used alcohol or other drugs to cope with emotional issues. For many, the over use of substances also has caused problems in work productivity and in other relationships which need to be addressed. There are different theories and therefore models of substance abuse treatment that range from the belief that addiction is a disease often passed down genetically to models that stress the learned behavior in families. Most treatment is done in groups as it has been found that others in the same situation are more likely to confront the frequent manipulation and lies that substance abusers tell themselves as well as others. Usually substance abuse treatment programs utilize random drug testing as a method of helping keep track of clients' use. As abuse of a variety of substances, both legally prescribed and illegally obtained, is a frequent way of self-medication and many of these people also need medication for stabilization.

13.4.3 Prevention

Conceptualizing child abuse and neglect as a form of family violence that occurs within a family system, a local community, and a cultural community enhanced by exposure to media and street violence requires social prevention. As violence is more visible in crowded urban areas that are often inhabited by people living in poverty and feelings of hopeless, these conditions in the community need to be addressed as well as individual interventions with high-risk populations. Rural areas present their own difficulties especially since the isolation is able to cover up both child abuse and domestic violence.

The risk and resiliency model that public health systems adopt are particularly useful here (Mersky, 2009; Stith et al., 2009).

13.4.3.1 Primary Prevention

Primary prevention programs are those that educate the entire community through use of the media, religious institutions, schools, and other agencies frequented by the people who live in a particular community. Special risk groups may also be targeted by primary prevention programs such as improving prosocial competence and reducing at-risk behavior among youth. Promotion of nonviolent norms and addressing the spurt of violent behavior that often develops in at-risk adolescents is part of primary prevention. The APA Task Force on Violence and Youth (1993) stated that one of the most helpful prevention responses is the improvement in at-risk youth's cognitive skills. Learning to read and write at the appropriate developmental level builds competence and resiliency in children. Learning to control emotions, change attitudes towards violence, and building better interpersonal skills has been found to prevent antisocial behavior from continuing to develop in children from high-violence neighborhoods.

13.4.3.2 Secondary Prevention

Secondary prevention programs are directly aimed at children who are known to have been abused or neglected. Again, programs that build cognitive skills, improve emotional control, and encourage prosocial behavior with those selected youth have been found to increase their confidence, competence, and efficacy, which then interrupts the cycle of violence (Aronson et al., 2003; Kotch et al., 2008; McCurdy, 1994). Family systems therapy with families that are willing to get help may also interrupt further abuse and neglect.

The most important variable that prevented further delinquency in studies was the support of family members. Thus, helping the parents learn how to support the child through teaching positive affirming interactions may assist children in changing their dysfunctional and difficult to control behavior. The difficulty is in identifying those families that can be helped to change their dysfunctional patterns through therapy, those who need to redefine the family constellation in order to change, and those who can be strengthened so that the patterns change when the situation changes. In the latter group are welfare parents who enter into a job-training program where they learn new skills, feel better about themselves and their children, and change their dysfunctional and abusive behavior patterns without even working on them directly (Ascione & Arkow, 1999). In this group also are those parents who know what to do but are so overwhelmed by life that they cannot apply their knowledge to their behavior. Sometimes the addition of a family helper in this type of family will provide relief for all members. These are often called "wrap-around" services in community groups (Slattery & Knapp, 2003). For others, attending a parenting class may help teach a parent new methods of addressing family problems that then interrupts the abuse cycle in that family. These are particularly effective strategies for families where there is child neglect due to lack of resources.

13.4.3.3 Tertiary Prevention

The tertiary level of prevention are for those children and families where they need some type of time-out from their life patterns to try to heal and adopt new ones. The Child Protective System may be helpful in giving parents or children some time alone so that the family

dysfunctional patterns are broken. In some cases, child protection workers are sent into hospitals when new babies are born into families where abuse has been identified in other children. Cooperation with infant protection programs as well as removal of the infant may be the choice here. Reunification then can take place only if all members of the family are ready and willing to rebuild the family in a new way. Women who go into battered women shelters with their children are helped to use that time to rebuild their family, usually without the batterer being in the home full-time although sometimes the women do try to make their marriage work again. Batterers in intervention programs may also learn new skills that help them reunite with their families although that is a complex and difficult task. The children may gain strength from the children's programs in shelter and so they too are stronger and less susceptible to the effects of being bullied, intimidated, and abused (Espelage, 2003).

13.5 Expert Competencies

13.5.1 Legal Issues

The legal issues that arise in working with children who have been abused and neglected are both numerous and complex. In the USA there are at least three or four different courts that may take jurisdiction over these children: criminal court, if the abuser is prosecuted, juvenile court, if there is a dependency petition by the state against the parents, juvenile court, if there is a charge of delinquency against the minor, and family court, if there are custody disputes after a divorce is filed by the parents. Sometimes there are cases simultaneously in one or more of these courts, all of which will have an impact upon the mental health or forensic evaluator. Both legal and ethical issues are of great importance in these cases as the mental health needs of the child and family may be in conflict with the legal needs. Even when there are no conflicts, the requirements for working in the two different arenas may require different skills so both a forensic evaluator and a treating therapist for each member of the family may be involved. Issues include designation of who is the client – the court, the lawyer, the child and/or the parent, or a state agency; informed consent from adults and minors; legal rights especially the right not to incriminate oneself in criminal cases; competency issues for children around telling the truth; when, if ever, to use suggestive questioning or interview aids; and how to deal with recantations either before, during or after the examination.

13.5.1.1 Competency to Testify

The issue of a child's mental competency to testify at a trial with reliable information has been an area that psychologists may provide information to assist the court. Young children need to demonstrate that they know the difference between truth and lies, but asking them directly is insufficient. Bottoms, Perona, Sorenson, and Najdowski (2007) suggest that asking children facts that are verifiable, such as their teachers' names or details about how a particular place looks may be a better way to determine their competency. Older children may be asked the Grisso (1988) competency questions to make sure that any mental health issues that are present will not prevent the youth from giving reliable and valid testimony (Grisso, Borum, & Edens,

2002). Each state has requirements for age and competency to give testimony and in many states the child may be declared unavailable to testify if a mental health expert testifies that it will cause the child harm. Obviously, every case must be evaluated separately, as testifying is therapeutic for some children and harmful for others.

13.5.1.2 Forensic Versus Clinical Evaluations

Psychologists have been attempting to provide guidelines to assist in differentiating a forensic from a clinical psychological evaluation. Although in some cases, a psychologist may act as both a forensic examiner and a psychotherapist, this may cause a loss of objectivity that then harms the client, and so it is discouraged (APA Forensic Guidelines, www.apa.org; APSAC Guidelines, 2002). Others have set forth protocols that assist the mental health professionals in performing a forensic evaluation that utilizes review of documents as well as psychological interviewing and standardized tests upon which their opinions must be based (Bottoms & Goodman, 1996; Myers, 1997). Psychologists who perform emergency treatment for children who are in emotional distress as well as those who provide ongoing therapy may also be admitted as an expert witness to testify about their opinions of the child. However, they base their opinion on different information from the forensic expert.

13.5.1.3 Best Interests of the Child and Burden of Proof

The expert witness's opinion must meet the legal standard within that particular type of case. All cases involving children must be decided on what the judge finds is in the "best interests of the child" at different standards of proof. For example, criminal cases must be proven by the state prosecutor "beyond a reasonable doubt" which is often operationalized as 99.9%. Obviously this is a very high burden of proof to meet and few cases are sent to criminal court by prosecutors unless there is strong evidence. On the other hand, cases in dependency court usually require "clear and convincing evidence" that is usually operationalized at around 75% or "a preponderance of the evidence" that usually means 50.1% are more likely than not that the abuse occurred and the judges' findings are in the best interests of the child. Given these guidelines, the judge must weigh the evidence, taking into account that some evidence is stronger than other evidences. Judges also must eliminate evidence that is more prejudicial to the alleged abuser than "probative," which is defined as that which is helpful in meeting the best interests of the child.

13.5.1.4 Child Custody Cases

Judges sitting on child custody cases in family court usually do not have the expertise to determine what is in the best interests of the child even though that is their job. This is especially true when there are allegations of domestic violence and child abuse and neglect. Sometimes these allegations are not revealed until the family begins to separate. Therefore, they depend upon mental health experts to assist them in determining the child's needs and the parent's ability to meet them. Sexual abuse allegations often occur together with physical

abuse and psychological maltreatment. They need special interview techniques that will meet the legal standards set in various jurisdictions (Faller, 1996; Kuehnle, 1996; Kuehnle & Walker, 2003).

Cases that deal with domestic violence and child abuse are the most difficult for the court to protect children when divorce and custody issues are pending (Edelson, 1999; Jaffe & Geffner, 1998; Jaffe, Lemon, & Poisson, 2003; Jaffe, Wolfe, & Wilson, 1990). Most state custody laws have presumptions that are considered to be in the best interests of the child even though these presumptions have not been scientifically proven. To overturn a presumption in the law, the burden of proof must be met by the person who wants to change it. One presumption is that it is in the best interests of the child to have equal access to both parents even if the father has committed domestic violence against the mother. It is the mother's burden to prove that it is "detrimental to the child" or some version similar to this such as it "will cause irreparable harm to the child" for the parents to share parental responsibility.

Another presumption in some states is that the parent who is the friendliest to the other parent will make other decisions that are in the best interests of the child. Obviously, it is difficult if not impossible, for a mother who has been battered by the child's father, to be friendly to him. In some cases, when the child's mother believes the child is in danger from physical or sexual abuse or maltreatment by the father, she may attempt to protect the child. This may bring her into conflict with the court's orders to make sure the father has access to the child. Father's may retaliate by claiming the mother is alienating the child from him rather than try to understand what he has done to frighten and alienate the child. Mental health professionals who are not trained in understanding the impact of domestic violence on children may unintentionally reinforce the PAS claims. Courts that do not believe the mother's claim of danger to the child may place the child in the father's custody without regard for the child's safety.

13.5.1.5 Memory and Suggestibility of Children

Memory and suggestibility of children (Eisen, Quas, & Goodman, 2002; Bottoms & Goodman, 1996) is a major issue when conducting forensic evaluations of children. As was stated earlier, trauma memory may be different than cognitive memory, but until they are integrated, it may be difficult to rely upon the stability of young children's reports of abuse. Older children may recant their initial allegations of abuse if they get frightened that the disclosure will disrupt the family. It is important not to accept recantation of testimony without a thorough investigation.

13.5.1.6 Preparing Children to Testify

Forensic psychologists may be called upon to prepare children to testify (Eisen et al., 2002; Goodman, Pyle-Taub, Hones, England, Port, Rudy, & Prado, 1992; Myers, 1997; Myers et al., 2002). Attempts have been made for special accommodation for children so that they do not get frightened by sterile courtrooms or hostile cross-examination. For some children, the first time they see the abuser since the arrest will be in the courtroom and they may be intimidated and frightened. Preparation and support may help overcome these potential problems.

13.5.1.7 Legal Issues for Parents

The legal issues that arise for mental health professionals working with parents of children who have been physically abused or neglected are similar to those reported above when working with children. If one or both parents have been accused of perpetrating the abuse then informed consent from the parent and any lawyers involved must be obtained, especially if criminal or civil charges are still pending. They must be informed that the usual privilege of confidentiality that is afforded to psychotherapy patients does not apply in these cases and the evaluator has a special duty to report any danger to children, others, or themselves that is reported. Often the alleged perpetrator is ordered into a psychological evaluation without clarification about what are the legal questions that need to be answered. It is a very different evaluation if the legal question is whether someone is mentally competent, if that person is at risk to commit further violence or if that person should be treated in an in-patient or out-patient facility. Forensic evaluators must understand the legal issues before the court in order to conduct an appropriate evaluation. The APA Guidelines on these issues (www.apa.org) would help guide the clinician as would APSAC (2002) guidelines in addition to references discussed in the legal section on children.

It may be necessary to evaluate the parents separately rather than together, especially when issues of access to children or possible custody disputes are raised in the future. When criminal charges are pending, the nonoffending parent should not be interviewed together with the alleged offender, so as to avoid the appearance or actual bias in their later reports. If the clinician is the first interviewer to uncover child abuse, it is often best to focus on the child's needs and the parents' ability to meet those needs rather than go into further depth that might place the parents in legal jeopardy, spoil evidence, and create bias for the court later. Clinicians who are asked to perform emergency services but have no forensic training should immediately secure the safety of the clients, refer them to an attorney, and obtain legal consultation for themselves as it is difficult to know how to move through the myriad of legal issues surrounding these issues (Myers, 1997).

13.6   Summary

In conclusion, the field of child abuse and neglect has grown and matured since its beginnings over 30 years ago with the introduction of "battered child syndrome" into the health care literature. Medical doctors now specialize in the recognition of child abuse through behavior and confirm physical abuse through X-rays and other imaging techniques available today. Child abuse reporting is now mandatory, statistics are kept by nations, children's rights have become a global concern, and states intervene taking over as parents when necessary.

Psychologists and other mental health professionals are an integral part of the child protection system by assisting in the identification, assessment, treatment, and prevention of child abuse and neglect. However, competencies in the assessment, treatment, prevention, and legal issues must be developed when mental health professionals attempt to be helpful to children who have suffered from physical abuse and maltreatment and their families.

14 Adolescent Sexual Offending

Barry R. Burkhart · Patrick K. Cook

Abstract: Adolescents who sexually offend present difficult and complicated demands for clinicians. The gravity of sex offending cannot be ignored, however, because adolescent offending does not necessarily presage adult offending, intervention must not preclude normal developmental opportunities. However, most adult persistent offenders begin offending during adolescence. Thus, clinicians have to provide effective treatment for the potentially serious adult offender while preventing negative second order effects that might create iatrogenic developmental consequences. The essential conclusions about the etiology of juvenile sex offending are that the processes are multi-factorial, complex and developmentally organized. Based on this analysis, assessment of the individual adolescent is critical to establishing an articulated treatment plan and five domains are identified as critical areas for the clinical picture. These are: (1) offender's victimization and abuse history; (2) social skills deficits, social isolation, and attachment difficulties; (3) deviant sex arousal and/or sexual preoccupation; (4) aggression and general delinquency; and (5) an exaggeration of "normal" adolescent sexual curiosity or exploration in a context of opportunism and weak supervision. Given the complexity of developmental pathways, no single model for intervention provides a sufficiently comprehensive approach for the treatment for juvenile sex offenders. Instead, treatment should be organized by a risk-need-responsivity paradigm that provides a useful algorithm for clinical treatment formulation. Additionally, the intervention must eventuate in the development of a non-stigmatized identity for the developing adolescent. Based on the notion that a risk-need-responsivity analysis should inform treatment, clinicians need to have a strong grasp of developmentally sensitive assessment, competency in navigating the social and legal contexts in which adolescent offenders are found, and be able to serve as a social and legal advocate based on a solid understanding of the empirical findings about adolescents who have sexually offended.

14.1 Overview

Barbaree and Marshall (2006) define a juvenile sex offender as "[a] person who has been convicted of a sexual offense and who is considered by law to be old enough to be held criminally responsible for the crime, but not so old as to be subject to the full range of adult criminal sanctions" (p. 3). While concise, this definition brings into focus a number of critical practical and conceptual issues having clear implications for professionals who work in this area. The first implication being that the cardinal criterion for identifying the client is not a specific behavior; it is an interaction between the client's behavior and the actions of the juvenile and criminal justice system. Given the difficulties of defining what is, or is not, a deviant sexual behavior for adolescence (Barbaree & Marshall, 2006; Bancroft, 2006) combined with the vagaries of the justice system, which vary by national and state jurisdiction and even to the level of the local court, what is defined as juvenile sex offense is so unreliable and elastic that it defies description. Moreover, this is not a context where clients can be counted on to provide veridical information.

Juveniles with markedly dissimilar behaviors often will have the same legal charge and those with the same behavioral event will have different legal charges. Moreover, the consequence of this variability is that clinicians may be working under profoundly different psychological and legal contexts depending on the charge applied to the client. For example, in the state of Alabama, if the charge is Sex Abuse 1st degree, then the client, even if only 12-years old, may be incarcerated for treatment, forced to go back to court after treatment, and be registered as a sex offender and placed on the notification register which would be available to anyone who had access to the Internet. If the charge is Sexual Misconduct (a misdemeanor charge), even if it is for the same behavior, then none of these sanctions may apply.

In different jurisdictions, even the same age child may be exposed to a profoundly different legal, correctional, and treatment process depending on the definitions in the law and the availability of treatment options. In some states, adolescent offenders may be treated on an outpatient basis, whereas in other states, with the same level of risk and offense, they will be incarcerated for treatment.

Moreover, the juvenile justice system has undergone large swings in philosophical stance with relation to how juvenile sexual crimes should be defined. The traditional philosophy of seeing adolescents, as a group, distinctly different from adults and, thus, requiring a very different judicial and correctional policy is now being threatened by the conservative movement to define all sex offenders as more alike than different, including obscuring or even obviating the distinction between juveniles and adults. Particularly with the passage, at the federal level, of the Adam Walsh Act, treatment providers are seeing the historic protection of juveniles from many of the adverse effects of the criminal justice system being eroded (Caldwell, Ziemke, & Vitacco, 2008). The developmental implications of being registered and subjected to adult notification in the life of an adolescent can hardly be imagined, though there is already some empirical evaluation of these pernicious outcomes (Letourneau & Armstrong, 2008).

Recently, Calley (2009) has demonstrated that one of the unintended consequences of the Adam Walsh act is that local judges are attempting to circumvent the notification consequences of the law by altering usual dispositional decision making to avoid charges that compel compliance with the registration requirements of the Adam Walsh act. In so doing, juveniles often are precluded from access to otherwise mandated treatment programs. Thus, the unintended consequence of the attempt to protect juveniles from an onerous and developmentally inappropriate community notification processes, is that juveniles who could benefit from treatment, are denied critical treatment opportunities. This outcome, in the context of the empirical demonstrations that treated juvenile sex offenders are at significantly lower risk for reoffending (Reitzel & Carbonell, 2006; Walker, McGovern, Poey, & Otis, 2004), is worrisome and illustrative of the negative, though unintended, second-order effects of poorly constructed policies and laws.

These legal and definitional issues are too extensive to be covered in this chapter, but, in the long run, may have more to do with defining and shaping the field than our evidenced-based judgments. The cardinal implication of this analysis of these social and legal processes is that clinicians may be required to be involved in political and social debates, if the opportunity for the best practices approach is even to be possible. In the remainder of this chapter, the focus will be on defining and describing what, currently, is seen as best practices for assessment and treatment of juveniles with sex offending behaviors; however, the recognition that the possibility

and opportunity to provide these practices is inextricably bound up with what happens in national and state legislatures should be part of the awareness of all providers who work with these children.

14.2   Recognition of Symptoms and their Assessment

The "symptoms" of adolescent sex offending are the behaviors which bring them to the attention of the court. What is required for professionals is a solid understanding of the epidemiology of these behaviors. Perhaps the most important core facts to appreciate about the epidemiology of juvenile sex offending are that: (1) juveniles commit a substantial proportion of sex crimes, particularly with children as victims (Pastore & Maguire, 2007); (2) by far the majority of adolescents who commit sex offenses do not continue to offend as adults (Worling & Curwin, 2000). In addition, a corollary of this fact is that treated adolescents have a significantly lower likelihood of committing another offense than untreated adolescent offenders (Hanson et al., 2002; Reitzel & Carbonell, 2006); and (3) a majority of adult sex offenders acknowledge that their first offenses began during adolescence (Gray & Pithers, 1993), and, for some of these offenders, the lifetime prevalence of victims they create is astounding (Abel et al., 1987).

These facts, taken together, have several important assessment and treatment implications. However, when considered separately, these facts can lead to very different and contradictory conclusions. Thus, conclusions must be drawn, carefully, and in relationship to each of the other facts. As these facts are reviewed, some of these contradictions and the important conclusions will be outlined.

The first fact, that adolescents are directly responsible for a large number of the sexual crimes committed, has clear implications for the necessity of preventing or treating juveniles who offend. According to Pithers and Gray (1998), 40% of the perpetrators of sexual crimes against children are children or adolescents. This fact represents a substantial sum of suffering and harm to innocent children and the implications to be drawn are that: (1) much more work needs to be done in the area of primary prevention and (2) early intervention is important, adolescents who offend should be promptly identified and provided appropriate treatment. The old judicial and clinical style of denying or downplaying sexual crimes against children when committed by other children/adolescents is not a good idea.

The second fact that most adolescent offenders discontinue sexual offending and do not persist as adult offenders, likewise is important to appreciate, particularly as it leavens the first fact. The modal number of reported victims of male adolescents adjudicated as juvenile sex offenders and placed in a large state residential treatment program is one and the mean is two (Burkhart, Cook, & Sumrall, 2008). Moreover, even though these boys were placed in a secure setting based on this conviction, over 50% had no previous commitment in the juvenile system. Additionally, though strong decreases in many of the identified areas of need were found as a function of exposure to treatment, particularly with internalizing symptoms, an increase in dimensions related to delinquency predisposition was noted (Burkhart et al., 2008). These findings parallel those of Bonta, Wallace-Capretta, and Rooney (2000), in which they found that low-risk, untreated offenders recidivated at lower rates than low-risk offenders exposed to a high-intensity treatment. This is a finding well recognized by other researchers (Dishion, McCord, & Poulin, 1999). Adolescents are learning machines who learn from adults and their peers, and, in fact, peers may well be more efficient teachers.

What this means is that treatment, though important, must not otherwise disrupt the normal developmental trajectory of juveniles who have offended sexually against children. Specifically, we must be alert to the possibility of iatrogenic effects which increase the social and psychological burdens for boys who are being treated for their offenses, most of whom are likely to spontaneously desist. Directly stated, the unintended side effects of treatment must be measured and considered as part of the decision making in evaluating the impact of treatment. Langton and Barbaree (2006) drawing on the work of Andrews and Bonta (2003) have outlined a useful conceptual algorithm in which initial risk levels, area of treatment needs, and responsive treatment form the crucible within which treatment for any specific offender can be organized. Langton and Barbaree further suggest that the recognition of treatment by need interactions should drive the research enterprise and that interaction designs, even on a post hoc basis, must be the prototype for effective and useful research. Thus, though treatment might be necessary to ensure that juveniles who sexually offend discontinue their sexual misconduct, the intervention must be sensitive and nondisruptive to a normal developmental trajectory. The least burdensome and restrictive treatment necessary to effectively treat the early adolescent offender is the model course.

There is an additional consideration which has been highlighted by the findings from longitudinal recidivism studies. Although the rate of sexual offending recidivism is relatively low, particularly in treated groups of offenders, the rate of general delinquent offending is high. For example, Reitzel and Carbonell (2006), across both treated and untreated samples, found that recidivism rates for nonsexual violent offending were 24.73%, for nonsexual nonviolent crimes, it was 28.51%, and for unspecified nonsexual crimes, it was 20.40%. These finding were based on an average follow-up length of 59 months. It should be noted that the rate of recidivism for sexual crimes was 12.53%. These data are typical of other follow-up studies which show a high rate of general delinquency in groups of adolescents who were originally identified as sex offenders. Smallbone (2006) reported that, in fact, juvenile sex offenders were two to four times more likely to recidivate for nonsexual crimes than for sexual crimes. Moreover, up to 10% of juveniles who were originally convicted of nonsexual crimes end up being reconvicted for sexual offenses (Rubenstein, Yeager, Goodstein, & Lewis, 1993).

Thus, if we adhere to the model explicated by Langton and Barbaree (2006), treatment of adolescent sex offenders must accommodate to the fact that there are far more likely to recidivate for nonsexual delinquency. Thus, the risk of such delinquent offending should be identified prior to treatment so that treatment components can be articulated to this identified risk. In our treatment facility, adolescents with sex offending problems have been separated from the general delinquent population based on the recognition that the general delinquents were quite a bit more antisocial and delinquent, qualities which negatively impacted the sex offending adolescents with modest delinquent histories (Burkhart, Peaton, & Sumrall, 2009; Burkhart et al., 2008).

However, fact number three moderates the above discussion. By the sheer number of victims created those few adolescent offenders who continue as adult offenders can have the impact of a typhoid-infected well on the public health. Abel, Mittleman, and Becker (1985) reported that the majority of adult sex offenders indicated that the onset of their sexual offending occurred prior to age 18. In addition, the lifetime prevalence rates reported by adult offenders who were guaranteed confidentiality are astounding and alarming. Moreover, even more alarming is the finding of a 25:1 ratio of self-reported sexual offenses to actual arrests among adult sex offenders (Elliott, Huizinga, & Morse, 1985). This fact has to be a part of policy and practices in the management and treatment of adolescents who sexually offend against children.

Given these data, the consequences of failing to effectively treat adolescent sex offenders, specifically those at high risk for adult persistent offending, are potentially disastrous.

The compelling implication of these facts, considered conjointly, is that we must be able to make empirically valid distinctions which "carve nature at her joint." We must be able to identify adolescents who are at risk of sexual offending and, for those who have begun to offend, we must then be able to inhibit their beginning trajectory, but not so bluntly that we cause other harm. Also, we must be able to capture in our risk analyses those who are likely to persist as adult offenders so that we can prevent the further development of an adult persistent offense cycle. The recognition that many adult offenders began as adolescents makes it necessary that those adolescents who are at risk for life course persistent offending be identified and that their pernicious developmental trajectory must be aborted.

The problem is that our current state of knowledge does not provide a scientific base to be successful at making these critical distinctions. Though there are no validated risk assessment procedures currently available (Rich, 2009), there is some recent evidence that experienced clinicians can identify, with a moderate level of accuracy, those high-risk adolescents who reoffend (Hagan, Anderson, Caldwell, & Kemper, 2008).

One additional critical general observation must be emphasized: adolescents who have sex offending problems are not alike (Rich, 2009). Thus, recognition of the heterogeneity of this population is one of the key starting points and guiding precepts of treatment. The exception to this observation is gender; boys are, by a factor of 20 to 1 or more, the more likely offenders in sexual misconduct. The practical implication of this fact is that the usual client will be a teen-aged boy. Moreover, though there are some data relevant for evaluation and treatment of girls (Hunter, Becker, & Lexier, 2006), the bulk of the research is addressed to the functioning and status of boys.

A global, comprehensive, post-adjudication assessment, therefore, should be the essential starting point for treatment professionals working with adolescents with sexual behavior problems (American Academy of Child and Adolescent Psychiatry, 2000). Rich (2003), also, provides an excellent outline of assessment domains and a guideline to organizing the relevant clinical data. To inform case conceptualizations, formulate treatment plans, and assess treatment progress (or lack thereof), the numerous strengths that standardized assessment measures provide including their comparative and predictive abilities must be used to the clinicians' advantage. Furthermore, an accurate assessment establishes an individualized baseline point in which change can be tracked throughout and following treatment. Finally, a solid foundation utilizing empirical assessment measures allows treatment professionals the ability to empirically test factors for which there may be a differential response in treatment (Langton & Barbaree, 2006). This ability to "test" hypotheses at both the individual and group level provides data that can be fed back into the treatment process to better improve treatment interventions. (Burkhart et al., 2008; Rich, 2009).

Working with juvenile sexual offenders in a forensic context presents additional unique concerns worth considering (Rich, 2003). Forensic assessments are unique in that those being assessed have an increased motivation to engage in deceptive behaviors (e.g., denial, minimization, malingering) in order to achieve some desired outcome. Juvenile sexual offenders are commonly mandated to complete treatment, are frequently resistant to be an active participant throughout treatment, and thus, typically cannot be considered to be collaborative agents throughout the assessment and treatment process. In fact, their motivations to obscure the "truth" regarding their offense behaviors may be considered to be both a natural and

self-protective response, given the negative outcomes associated with full and complete disclosure. Despite being relatively unsophisticated, many of these individuals report a great degree of shame and embarrassment related to their behaviors. The likelihood for adjudicated juvenile offenders to engage in some type of deceptive behavior is quite common, yet little empirical evidence exists examining the prevalence of such behaviors prior to the onset of treatment. For example, over 90% of juvenile sexual offenders who were interviewed following the completion of treatment reported being deceptive when initially describing their adjudicating offense (Burkhart et al., 2008). Offenders were most likely to underreport the total number of sexual offenses that occurred, the duration in which the offending behaviors occurred, and the total number of victims.

14.3 Maintenance Factors of Adolescent Sex Offending

Data from assessments of juvenile sex offenders have served as the empirical foundation for addressing etiological and maintenance issues regarding this population of offenders (Becker, 1998; Calder, 2001). The broad conclusions are: (1) that etiology is complex, multidetermined, and developmentally based and (2) no single model or factor has been definitively linked to the onset or maintenance of this behavior. Rich (2003), in an effort to provide a comprehensive account of this complexity, has listed 46 motivating and maintaining factors for juvenile sex offending. These 46 factors, he suggests, can be clustered into ten categories representing core domains in the etiology and maintenance of the behavior. These hypothetical categories represent a good conceptual summary of those domains to be studied; however, little specific research has been devoted to examining, in a theoretically driven process, the contributions of each these domains to the development or maintenance of adolescent sex offending.

At this point in the literature development, there are five areas which are consistently identified as high-probability predicates to juvenile sex offending. These are: (1) offender's victimization and abuse history; (2) social skills deficits, social isolation, and attachment difficulties; (3) deviant sex arousal and/or sexual preoccupation; (4) aggression and general delinquency; and (5) an exaggeration of "normal" adolescent sexual curiosity or exploration in a context of opportunism and weak supervision.

14.3.1 Offender's Victimization and Abuse History

A significant history of prior victimization is often found among individuals who go on to abuse others (Jonson-Reid, 1998). Thus, the notion of a "cycle of violence" or "victim to victimizer" has been applied to juvenile sex offenders as research clearly indicates that many juvenile sex offenders have been victims of abuse; however, the causal role in the etiology of subsequent offending behaviors has not been delineated.

Victimization as a child is related to subsequent delinquent acts during adolescence and adulthood. For example, Widom (1995) using a matched-sample design examined arrest rates during adolescence and adulthood for 908 children who were abused or neglected prior to age 11. Using official records documenting substantiated cases of physical and sexual abuse and neglect during childhood, 26% of those who experienced maltreatment were later arrested as juveniles compared to 16.8% of those not abused, with 28.6% of abused and neglected children arrested

as adults compared to 21.0% for those in the control group (Widom, 1995). Furthermore, sexually abused children, compared to nonabused control subjects, were 4.7 times more likely to be arrested as adults for a sex crime. In addition, physically abused boys were more likely than sexually abused and neglected children, as well as nonabused children, to be arrested as adults for rape or sodomy. As Widom highlights, an adult rapist may be motivated by violence rather than sexual gratification alone.

Sexual victimization during childhood, also, has been associated with subsequent acts of sexual perpetration. For example, Ryan, Miyoshi, Metzner, Krugman, and Fryer (1996) reported on a sample of juvenile sex offenders consisting of 1616 youth whose data were provided by treatment professionals from 90 members of the National Adolescent Perpetrator Network (NAPN) located across 30 states. Of these youth, ranging in age from 5 to 21 years of age (mean age 14-years old), 41.8% were victims of physical abuse, 39.1% were sexually abused, and 25.9% of the sample experienced neglect as reported at intake.

Worling (1995) compiled data on 1268 male juvenile sex offenders from eight studies that reported pretreatment and posttreatment accounts of sexual abuse. Across studies, histories of sexual abuse varied considerably as 19–55% of juveniles reported a history of sexual abuse. Of note, the rate of sexual abuse reported following treatment (52%) was significantly greater to the rate reported prior to the onset of treatment (21%). Worling (1995), citing clinical observations (e.g., Becker, 1988; Kahn & Lafond, 1988), postulated that the increase may be the result of a trusting therapeutic relationship allowing a greater level of disclosure or that the increase report of sexual abuse may be a treatment-learned justification/minimization behavior. Further-more, Worling reported that juvenile sex offenders with child victims reported being twice as likely to be sexually abused compared to juvenile sex offenders with peer-aged or adult victims (29.90% versus 14.94%, respectively). In addition, Worling grouped 87 juvenile sex offenders according to victim age and gender and examined the rate of sexual abuse according to groups. In total, 43% of the sample reported a history of sexual abuse; however, rates varied considerably according to the group with male, child victims reporting the greatest rate of abuse (75%), followed by those with male and female, child victims (74%), those with female child victims (24%), and finally, those who offended against peer-aged or adult, female victims (26%).

Burton, Miller, and Shill (2002) reported that 79.4% of 272 institutionalized juvenile sex offenders (mean age = 16.9-years old; SD = 1.47) were sexually victimized based upon self-reported responses on the Sexual Abuse Exposure Questionnaire. Of note, subjects were described to be mid-treatment when abuse information was collected. Of those who reported being sexually abused, the average age of onset was 8.8 years (SD = 3.97) with the average duration of sexual victimization lasting 5.6 years. Here, researchers speculated that high rate of sexual victimization (79.4%) compared to other empirical investigations with abuse prevalence rates of approximately 40% (e.g., Cooper, Murphy, & Haynes, 1996; Hunter & Figueredo, 2000) may be a function of the anonymous data collection process or that the data were collected after a treatment relationship had been formed; thus subjects may have been more willing to report abuse.

A history of abuse has been consistently linked to juvenile sex offenders; however, it is important to reiterate that most sexually abused juveniles do not go onto sexually abuse others and that the majority of male, juvenile sex offenders do not have a history of abuse. Nonetheless, victimization and the burden of other forms of abuse and neglect are clearly part of the treatment needs of juvenile sex offenders.

14.3.2 Social Skills Deficits

A significant portion of male, adolescent juvenile sex offenders has been described as lacking appropriate social skills (Davis & Leitenberg, 1987; Becker & Kaplan, 1988). These social deficits are believed to potentiate poor peer relationships, contribute to a burden of social apprehension, and, in some instances, lead to isolation. In fact, commonly used instruments designed to measure risk of reoffending with juvenile sex offenders address social support when determining level of risk. Furthermore, the observed deficits with adult sex offenders have been extended downward to juvenile sex offenders. For example, adult sex offender literature has identified, among a portion of these offenders, difficulty relating with peers and an inability to form and engage in consenting heterosexual relationships (Marshall, 1996). Therefore, adolescent sex offender researchers and treatment providers have attempted to empirically ascertain the relationship between social skill deficits and sex offending behavior during adolescence.

For example, Fehrenbach, Smith, Monastersky, and Deisher (1986) examined 256 male juvenile sex offenders and observed that a significant portion of these offenders (65%) were described as being seriously socially isolated. When male, adolescent child molesters ($n = 31$) were compared to delinquent, nonsex offending peers ($n = 34$) and nondelinquent adolescents ($n = 71$), child molesters endorsed feeling alone and socially isolated to a greater degree than nondelinquent subjects. Furthermore, results indicated that child molesters reported less assertion, greater anxiety and distress when in a social situations, lower self-esteem, and greater social maladjustment compared to nondelinquent subjects and less confidence regarding adequacy in hetero-social situations when compared to delinquents. Awad and Saunders (1991) reported that 33% of those male juveniles who committed hands-on, sexually assaultive offenses and 62% of child molesters were described as socially isolated, compared to 22% of delinquent control subjects, Furthermore, Miner and Crimmins (1995) reported that juvenile sex offenders had fewer peer attachments to that of delinquent, nonsex offender peers and nondelinquent subjects.

In regards to sexual recidivism by male, juvenile offenders, Kenny, Keogh, and Seidler (2001) reported data on 40 first-time offenders (mean age = 15.86 years; SD = 1.64) and 30 recidivists (mean age = 15.40 years; SD = 1.40). Here, researchers measured a greater frequency of "poor social skills" among recidivists (50%) when compared to newly adjudicated offenders (15%). Therefore, poor social skills is not only a construct of interest related to the etiology of juvenile sexual offending, it, also, may be related to subsequent acts of sexual offending by recidivists; thus, potentially having a significant role in maintenance of nonoffending status.

The aggregate of these results indicate that a significant portion of male, juvenile sex offenders experience deficits in social functioning. Additionally, the greater social deficits measured among juvenile sex offenders with child victims may be a function of their failed attempts to "connect" with peer-aged individuals. However, these results are not universal as several studies reported no differences in social competency skills relative to other delinquent and nondelinquent adolescents (e.g., Rowe-Lonczynski, 1992; Ford & Linney, 1995). These discrepancies suggest that poor social skills may be related to general adolescent delinquency and antisocial behaviors rather than specific to male, juvenile sex offenders alone. Therefore, causal relationships between social deficits among offenders and subsequent sex offending behaviors may exist; however, research has not established strong, direct causal links. Whether there is such a direct link, the bulk of the evidence suggests that, particularly for child target adolescent

offenders, some quality of social or attachment deficit is likely and remediation of these deficits should be a part of any comprehensive treatment evaluation. Thus, most treatment programs include treatment modules or components aimed at addressing and remedying measured socialization deficits.

14.3.3 Deviant Sex Arousal and/or Sexual Preoccupation

Cognitive-behavioral theorists, utilizing associative learning principles, hypothesize that deviant sexual arousal can be developed with the pairing of previously innocuous stimuli and stimuli that produce a sexual response (Alford, Morin, Atkins, & Schoen, 1987). Frequent parings of deviant sexual fantasies along with sexual arousal, including masturbation and orgasm, are hypothesized to contribute to the maintenance and strengthening of deviant sexual interests (Hunter & Becker, 1994). The pathway of deviant sexual arousal leading to action is poorly articulated within juvenile sex offender literature; however, deviant arousal patterns are considered to be one of the mechanisms by which problematic sexual behavior can be established and maintained which is a clinical focus when working with this population (Hunter & Becker, 1994), especially given the downward extrapolation from adult offenders. For example, a significant portion of 561 adult sex offenders reported their deviant sexual interest was established during adolescence (Abel & Rouleau, 1990) and deviant sexual fantasies were found among 29% of an outpatient sample of child molesters prior to age 20 (Marshall, Barbaree, & Eccles, 1991). However, a significant portion of males among a general population sample (31.1%) reported deviant sexual fantasies of forced sexual contact (Leitenberg & Henning, 1995) making the specificity of these fantasies difficult to establish with sex offenders. Further complicating the role regarding deviant sex fantasies are findings by Daleiden, Kaufman, Hilliker, and O'Neil (1998) who measured similar levels of deviant fantasy among juvenile sex offenders when compared to controls. Furthermore, Worling (2004) examined studies that relied on physiological measures of deviance (e.g., penile plethysmograph) and reported that only a fraction (25–36%) of juvenile sex offenders responded to sexual stimuli. Therefore, the emphasis on deviant sexual arousal as a "concrete" etiological factor of juvenile sex offending behavior has abated to some degree since first applied to juvenile sex offenders during the 1980s.

In an attempt to better understand the relationship between deviant sexual arousal and behaviors, researchers have relied upon self-report data regarding deviant sexual thoughts and fantasies given the ethical concerns of using physiological measures of deviancy with juveniles (e.g., Veneziano & Veneziano, 2002; Fanniff & Becker, 2006). Thus, the ability for treatment professionals to accurately identify deviant arousal patterns reliably among juvenile sex offenders is a current challenge given the questionable veracity of self-report data. Yet, identifying deviant arousal remains an important goal given the paraphilic interests of some juvenile offenders (Fanniff & Becker, 2006). For example, DiGiorgio-Miller (2007) compared 66 inpatient and outpatient male, juvenile sex offenders (mean age 15.2 years; SD = 1.45) on the Sexual Fantasy Questionnaire with inpatient residents reporting a greater number of deviant fantasies compared to outpatient offenders. Furthermore, positive correlations between deviant sexual fantasies and the number of victims, offenses, and measure of hostility were reported suggesting that more deviant fantasies were related to greater victimizing behaviors and offenses.

Using another distinction, Kenny et al. (2001) compared 40 male, first-time juvenile sex offenders with 30 recidivists. Group comparisons revealed that those offenders charged with more than one sex offense reported deviant sexual fantasies as a major offense feature (60.7%) versus those charged with a single sex offense (29.4%). Furthermore, of the recidivists, 60% were rated by their therapist as having deviant sexual fantasies, whereas only 32.5% of the first-time juvenile sex offenders were seen as having such fantasies. Lastly, significant, positive correlations were measured between rearrest for a sexual offense and deviant sexual fantasies.

Daleiden et al. (1998) reported that youthful sexual offenders endorsed more typical/nonconsenting sexual experiences than nonsexual offenders and college males. Furthermore, sexual offenders reported fewer typical/consenting sexual experiences when compared to delinquent, nonsex offending peers. Next, juvenile sex offenders reported more frequent paraphilic interests compared to delinquent, nonsex offenders and college males. It may well be that paraphilic interests are one of the mediators of adult persistent offending and, therefore, may require new research attention as the transition from adolescent offender to adult offender becomes more closely tracked in research.

14.3.4 Delinquency and Aggressive Behavior

A significant portion of juvenile sex offenders have a history of prior delinquent, nonsex offending criminal behavior. Estimates of criminal behaviors preceding a sex offense have been reported to range from 40% to 63% for these offenders (e.g., Fehrenbach et al., 1986; Kahn & Chambers, 1991; Ryan et al., 1996; Smith & Monastersky, 1986). Furthermore, the severity of these prior delinquent criminal behaviors varies considerably from minor offenses (e.g., misdemeanors) to violent acts against others (e.g., felony assault). In addition, a significant portion of juvenile sex offenders have had numerous prior arrests. Of the 1661 juvenile sex offenders examined by Ryan et al. (1996), 27.8% were measured to have committed four or more nonsex offenses. Thus, in addition to committing a sexual offense, a sizable portion of these offenders have a significant history of antisocial behavior.

Not only do many of these offenders have a history of previous delinquency, of those who recidivate following adjudication or treatment for a sexual offense, the majority will also commit crimes of a nonsexual nature. Measured recidivism rates for nonsex offenses range considerably as sample estimates of 35–54% have been reported (e.g., Rasmussen, 1999; Miner, 2000; Schram, Milloy, & Rowe, 1991; Vandiver, 2006). Of note, the rate for nonsex offending rearrest greatly eclipses the likelihood of rearrest for an additional sex offense as sex offense recidivism rates range between 8% and 14% (e.g., Kahn & Chambers, 1991; Miner, 2002; Rasmussen, 1999). The rate of rearrest and severity of crimes committed also ranged considerably. For example, Vandiver (2006) reported that the majority of 300 juvenile sex offenders followed into adulthood (52.7%) were rearrested ranging between 1 and 11 arrests. Furthermore, of this sample, the majority of rearrests were for property offenses (36.7%) followed by drug offenses (32.3%), but ranged in severity including one arrest for capital murder.

As a significant portion of juvenile sex offenders commonly have a history of general delinquency as well, they are at an increased risk at posttreatment for nonsex offending delinquency, these findings increase the complexity of treatment concerns to include general delinquency

issues, as well as sex offending specific components. The necessity of individual risk-needs analysis is highlighted by these findings.

14.3.5 Situational or Opportunistic Offending

One of the findings evident to many researchers is that the relatively high frequency of adolescents who were caught, having initiated sexual contact with a younger child, presents with little evidence of significant co-morbid psychopathology and no previous delinquent history. In our large sample representing most of the adjudicated adolescents in the state of Alabama (Burkhart et al., 2008), one of the largest groups were boys with one offense, no previous charges, and relatively benign psychometric test results. This group represents a subtype of the population of adolescent sex offenders who appear to be primarily situational or opportunistic offenders. When deconstructing their offenses, the modal pattern is that, having had some type of exposure to adult forms of sexuality, often video pornography, they are left with little supervision and access to a younger, vulnerable child. They attempt some kind of sexual contact, are discovered, and, as the Alabama state code requires treatment for adjudicated juvenile sex offenders, they are referred to treatment.

It is important to consider these offenders in light of the slowly accumulating knowledge about normative sexual experiences among children and adolescents (Bancroft, 2006). Even given the significant gaps and limitations in reliable information about sexual behaviors in childhood and adolescence, it is clear that children and adolescents have considerable sexual exposure and experience. Consider the findings of Reynolds, Herbenick, and Bancroft (2003), in which a sample of university students provided retrospective accounts of childhood sexual experiences with peers; 87% of the males and 84% of the females reported such an experience during childhood. These were most common during elementary school years and the subjects reported that the usual motivation was curiosity. Moreover, it should be noted that these experiences more frequently involved genital touching as the age of the child increased. With such a high base rate of childhood sexual experiences, it is not surprising that a subset of these boys and girls trespass legal boundaries and end up being caught up in the legal system.

The implications of these data have been not extensively considered in the literature. The necessity for a careful risk–need analysis, and crafting of a adequate, but not overdone, response to these adolescents seems clear, but there is so little information available about what are the specific development trajectories of the different types of adolescents with sexual offenses that it is difficult to draw the apparently clear implication that a policy of benign neglect might be appropriate for some of these cases.

14.4 Evidenced-Based Treatment Approaches

In his seminal book on juvenile sex offenders, Phil Rich (2003) makes the point that treatment of juveniles with sex offending problems is unlikely to be accomplished with limited, focused models of treatment. Instead, he argues that a limited treatment model focused on symptoms is not sufficient to effectively intervene and substantially assist the positive development of these adolescents. Based on his analysis of the complexity and magnitude of pathology found

in populations of juveniles with sex offending presentations (e.g., Ronis & Borduin, 2007; van Wijk, van Horn, Bullens, Bijleveld, & Doreleijers, 2005), having to deal with a developmentally dynamic population, and the fact that treatment is often confounded with criminal justice system involvement, Rich argues that treatment processes and rehabilitation with these adolescents most likely will be multifaceted, intensive, and complex. As he summarizes:

▶ Many juvenile sex offenders have never been in good health, emotionally or behaviorally, so rehabilitation is more a process of creation that renewal or restoration. Either way, the broadest purpose of treatment is increased functional ability and enhanced sense of well being, and, in the case of sexual aggression, public safety. This is no simple task, however. In fact, as complex and critical as evaluation is, it is far easier to evaluate, formulate, and diagnose individuals than to treat them effectively. (Rich, 2003, p. 218)

Moreover, at this point in the development of the literature, few, if any of the basic clinical questions about how sex offending adolescents should be treated have been asked or answered. There is a very modest foundational evidence for most treatment decisions. In fact, what once was thought to be a core and validated foundation for treatment, the relapse prevention model, has failed to be supported in two large treatment trials with adult sex offenders (Marques, Wiereranders, Day, Nelson, & van Ommeran, 2005). As a consequence, this model of treatment, though once considered the only standard form of treatment for both adults and adolescents, is now questioned with sex offending adolescents, given the lack of empirical support in adult populations and the absence of cohesive and coherent conceptual match with contemporary analyses of treatment needs of adolescents (Thakker, Ward, & Tidmarsh, 2006). Thus, there is no overarching or foundational conceptual model for treating sex offending problems. Unlike some areas, like anxiety problems, where there is reasonably solid understanding that exposure, however accomplished, must be a part of the treatment, there is no foundational conceptual principle which has solid theoretical and empirical support in the treatment of juvenile sex offenders. This leaves providers with little in the way of solid support for treatment decisions. We do not know what modes of treatment are best (groups, individual, or family) or even what methods (relapse prevention, empathy training, victim clarification, etc.) should be used, based on empirical foundations. Moreover, the ability to match juvenile offenders to specific treatments by clinically relevant dimensions (Langton & Barbaree, 2006) is, despite the clear need for such, simply not available. So, while there are numerous shibboleths about how treatment should be provided, there are few empirical validated guidelines for treatment.

Despite the absence of strong support for specific treatment approaches, there is a reasonably strong support that treated adolescent sex offenders typically fare much better than untreated adolescents in terms of sexual offending recidivism (Walker et al., 2004). In a recent meta-analysis of all the comparative outcome studies by Reitzel and Carbonell (2006), adolescents who had been treated had a sexual offense recidivism rate of 7.37%, whereas untreated controls had a sexual recidivism rate of 18.98%. These findings support the general value of treatment, even if little is known about specific treatment by aptitude interactions. Particularly, given public safety and public relations considerations, it is important that evidence supporting the effectiveness of treatment exists. Of course, these findings are weakened by the recognition that general delinquent recidivism is relatively high for treated sex offending adolescents. It is clear that all research must examine both sexual and nonsexual delinquency to provide a true estimate of positive clinical and social effects.

A significant exception exists to this summary, however. Two randomized clinical trial studies have found Multisystemic Therapy (MST) to be considerably more efficacious than comparison treatment of individual therapy (Borduin, Henggeler, Blaske, & Stein, 1990) or cognitive behavioral group and individual treatment provided in typical outpatient contexts (Borduin, Schaefer, & Heiblum, 2009). Although two studies cannot define a field, these findings deserve careful consideration. First, the current zeitgeist of the field is such that group-based cognitive behavioral treatment organized by relapse prevention concepts is ubiquitous and almost the standard method of treatment. For example, McGrath, Cumming, and Burchard (2003), in a survey of community programs, found that a large majority (91%) based their treatment on relapse prevention informed, cognitive behavioral treatment. Such a monolithic approach in the absence of any compelling empirical support for differential and enhanced efficacy represents a prescription for failure, particularly if there are few data supporting the paradigmatic treatment. Borduin et al.'s (2009) results combined with the absence of support for the conventional relapse prevention model of treatment with adults suggests that, at least, there should be an open approach to determining what kinds of treatment fits best with this population. In addition, MST has considerable conceptual appeal which will be reviewed in the following section.

A second new treatment approach, also, with considerable conceptual appeal is the Good lives model (Word & Mann, 2004). More a theoretical orientation than a discrete set of techniques, the Good lives model rests on the several theoretical, empirical, and developmental observations about adolescents who offend sexually. First, numerous writers have opposed the downward extension of treatment methods developed for adult offenders to adolescents (Miner, 2002; Thakker et al., 2006; Trivits & Reppucci, 2002). Arguing that there are profound and deep differences between the psychological characteristics of adult and adolescent offenders, that these differences are exacerbated by the developmental differences between adolescents and adults, and that the initiating and maintaining factors between adult and adolescent offending demonstrate little overlap (Miner, 2002), Ward and others (Ward, 2002; Ward & Mann, 2004; Thakker et al.) have argued that a fundamentally different approach must be developed for adolescents.

For example, a core component of the adult approaches to treatment is based on the concept of overcoming offender denial to enable the adult offender to take responsibility for identifying and controlling the essential cognitive and behavior patterns which characterize the offense cycle (Pithers, 1990; Pithers, Marques, Gibat, & Marlatt, 1983). Thus, the adult offender must accept and acknowledge that his or her behavior is the result of an ingrained and repetitive pattern in order to learn to disrupt and prevent the execution of the offense. Ward et al. argue that what defines adolescence is the opposite of a fixed pattern. Instead, adolescents are characterized by change, transformation, and, fundamentally, the absence of fixed or ingrained patterns. Instead, Ward argues that the core task of adolescence is to develop a set of core guiding assumptions about the world and, eventually, as a result of the cumulative effect of the adolescents' developmental experiences, a theory of self. Thus, Ward suggests that the fluidity and openness of the adolescent to developmental input create a developmental opening within which a positive model of the self must be created. In effect, one of the central tasks in treatment is to assist the "adolescent to change his conception of himself from that of a developing sex offender to someone trying to live a different life" (Ward, Polaschek, & Beech, 2006, p. 315). What must not happen is that the treatments have the effect of fixing in the adolescent that he is indeed a sex offender who is caught up in an addictive, lifelong process which he will have to guard against for the rest of his life.

14.5   Mechanisms of Change Underlying the Intervention

For MST, Borduin, et al. (2009) suggest that the positive results:

▶ may be due in part to its explicit focus on ameliorating key social-ecological risk factors that are related to problem sexual behaviors and place youths on a developmental pathway (or pathways) for sexual offending. Specifically, MST interventions (a) targeted important socialization processes that contributed to or maintained problem sexual behaviors and (b) promoted healthier (i.e., prosocial, strength focused, and age appropriate) interpersonal transactions in family, peer, and school contexts. (p. 35)

Additionally, they hypothesize that:

▶ improved family support, peer relations, and academic performance allowed MST participants to experience increased success in accomplishing educational, occupational, and other important developmental tasks (e.g., the formation of healthy romantic relationships) during the late adolescence and early adulthood. We suggest that a major limitation of typical treatments for juvenile sex offending is their relatively narrow focus and failure to account for the multidetermined nature of problem sexual behaviors and other serious antisocial behaviors. (p. 35)

Thus, treatment success depends on the ability of the therapist to intervene in multiple contexts in the lives of adolescent offenders and successfully promote alternative ways to meet the developmental demands associated within each of the critical life domains.

At this point in the development of the literature, there is an insufficient empirical base to declare any winners or losers. However, a sufficient nomological net of empirical and conceptual development does support a framework of treatment that is based on the principles of risk, needs, and responsivity (Langton & Barbaree, 2006), and that is responsive to the developmental, social, family, and environmental contexts of adolescents.

Thus, what appears to be critical in the treatment of adolescents is not a particular technique, but the ability to address complex, multi-factor problems through comprehensive, developmentally sensitive, and ecologically responsive methods. Thus, given the core finding of hetero-geneity among juvenile offenders, it is reasonable to expect that a complex and dynamically responsive model of treatment such as MST would be a strong candidate for effectiveness.

Moreover, the conceptual articulation between the precepts of MST and the Good lives model is impressive. Both approaches coalesce around a common set of principles founded on an awareness of the complex, multidetermined etiology and maintenance of the problem behaviors and a flexible, developmentally sensitive, growth-oriented treatment and intervention procedure. Thus, future development of a rapprochement between the technological strengths of MST and the conceptual framework and promise of the Good lives model may well be the next important conceptual paradigm. In addition, Koss, Bachar, and Hopkins (2006) have suggested that there is possible rapprochement between MST and concepts drawn from restorative justice theory.

An informed summary of the treatment outcome literature would have to conclude with a caveat that the poverty of intensive, controlled research with adequate follow-up provides little in the way of definitive guidance for a clear set of procedures. However, there is a growing consensus about a set of principles for effective intervention with adolescents with sex offending behaviors. These are:

1. Given the complexity of pathways to juvenile sex offending problems, comprehensive assessment of the identified adolescent patient is critical (Rich, 2003, 2009). At a minimum, awareness of the critical developmental areas associated with adolescent sex offending must inform treatment and a risk, needs, and responsivity analysis (Langton & Barbaree, 2006) must be part of the development of any treatment program or protocol. The principles of risk, need, and responsivity provide the conceptual blueprint which ensures that the heterogeneity of adolescent with sex offending problems will inform treatment.

2. Given the heterogeneity of adolescents with sex offending problems and the variability of risk and severity of offending behavior, a one-size-fits-all approach is not likely to work. At least, there needs to be a continuum of care in which low-risk offenders can be treated in a least restrictive and nonintrusive context and, for the fewer, high-risk adolescent, a safe, secure, and, likely, intensive model of treatment must be available. In particular, the areas of empirically relevant risk factors, etiology, and maintenance factors must be accounted for in any treatment plan. For some at risk offenders, this may need to include residential treatment. However, this is an empirical question which should be a focus for research efforts. The cost–benefit analysis of even intensive outpatient treatment (Borduin et al., 2009) compared to residential costs makes the case that only in the interests of community safety and clear treatment advantage should residential treatment be the preferred protocol.

3. The core development task of self-definition for adolescents requires that, whatever and wherever treatment is accomplished, intervention must be supportive of a self-development that is positive and noncontaminating, of a normal developmental trajectory. Moreover, the likelihood of iatrogenic effects mandates that a broad spectrum of outcome domains should be collected as a basic tenet of treatment outcome measurement.

14.6   Basic Competencies of the Clinician

Given that treatment of juvenile sex offenders is complex, has profound legal and social consequences, and is often embedded in multiple social, legal, and correctional contexts, it is unlikely that a new clinician could ever start self-training as the only pathway to competency. This is an area where an apprentice model of training seems imperative. Thus, it is likely that the skills essential to functioning as clinical provider for juveniles with sex offending problems should be acquired in a training context where the specialized assessment and treatment skills can be witnessed, modeled, and performed under close supervision and feedback. It would seem unwise to take on these cases absent a mentor or a training context supportive of the novice clinician.

As articulated by the above analysis, a core basic competency of clinicians in this area is the ability to conduct an appropriate assessment and organize a treatment plan based on a solid risk-level evaluation and a comprehensive treatment needs assessment. Clinicians need to be familiar with the process of risk assessment (Rich, 2009) and adept at using these data to define treatment needs and craft an appropriately articulated and responsive treatment plan. Rich (2003) has an exhaustive framework for a comprehensive psychosocial evaluation and report. Beginning clinicians would be wise to consult his outline. At a minimum, clinicians have to be able to conduct a thorough forensic clinical interview covering the following areas (American Academy of Child and Adolescent Psychiatry, 2000).

1. Assessment of the sexually abusive behavior. It is necessary to have the client describe the behavior which brought them into treatment. Although unlikely to be entirely truthful or transparent, the child's level of disclosure provides significant insight into his accommodation to his offense. It should be noted that denial or defensiveness is normative and the goal of the assessment is not to wring a confession out of the child. Instead, this is an opportunity to evaluate mechanisms for coping with his offense and the consequences which have accrued. At the same time, all relevant forensic and court documents should be obtained. The degree of discrepancy between self report and police reports can be astonishing.

2. Sexual history. What is important is this section of the interview is to ascertain how the child has arrived at this point in their sexual development. The child's exposure to developmentally inappropriate sexuality is particularly important, as there appears to be some link between developmentally inappropriate sexual exposure and risk of sexual offending. (REF) In addition, a full sexual history should be obtained, including both appropriate peer and autoerotic expression as well as inappropriate sexual behaviors and expression. It is important that the examiner be comfortable and forthright in this inquiry. Adolescents rarely answer a question not asked directly.

3. Developmental, family, and social history. It is often the case that children do not know the circumstances of their birth, or developmental milestones, or any of the usual components of a developmental or psychosocial history. Collateral interviews with parents or guardians are extremely valuable and should be obtained if at all possible. The circumstances of the child's attachment history, abuse and neglect history, and family functioning are critical. Children with significant attachment disruption and burdens of abuse and victimization are common in samples of adolescents with sexual behavior problems and knowing the details is valuable in developing articulated treatment plans.

4. Medical and psychiatric history. The base rate of previous psychiatric treatment in adolescents with sex offending problems is very high (REF) and co morbid psychiatric diagnosis is usual. Often, the degree of involvement in various medical and psychiatric settings is an indication of the difficulty of managing these clients; thus, this information becomes significant in the risk/needs analysis informing treatment. A significant part of the risk-needs assessment is identifying the burden of psychological/psychiatric problems and crafting a plan to ameliorate these problems. In particular, the prevalence and extent of depression should be carefully monitored. Suicidal status often is a powerful marker revealing the overall mental health functioning of these adolescents.

5. Academic history and cognitive functioning. Academic and intellectual functioning are core components of the capacity and course of treatment. Often, in fact, usually, these adolescents have histories of outright academic failure or very marginal performance as well as school behavior problems. If there is to be a chance for a good life, academic or vocational success is a critical component. In residential programs, considerable emphasis is placed on being able to be competent in the school environment. Successful outpatient programs such at MST, likewise, place a good deal of emphasis in enhancing the adolescents functioning in their schools. Thus, a thorough and targeted treatment plan will be based on the result of this component of the evaluation.

6. Standardized assessment. In our program (Burkhart et al., 2008), we have relied on several standardized tests and interviews. The extent and quality of information available has been useful in planning and evaluating treatment, and in creating a foundation for our local science. In the population of juvenile in our programs, we have been able to delineate the large

differences between the regular delinquent adolescents and those committed for sex offenses. Based on these data, we create different treatment tracks and have been able to create a better fit between the treatment needs of the boys and treatment resources. Finally, having an extensive pretreatment data base will allow for the development of local actuarial predictions based on follow-up analyses of treatment completion and recidivism.

7. Communicating risk levels. The work of evaluation in this population has far reaching effects as these evaluations provide the foundation for court decisions having lifetime consequences for the adolescent offender and for his community's safety as most jurisdictions have some element of risk informed registration or notification. In Alabama, for example, following completion of treatment, the clinician must provide a statement to the court outlining the adolescent's history and functioning in several behavioral domains, outline the client's response to treatment, and, based on this analysis, provide a recommendation for risk level. Typically, this recommendation is given great weight by the court and becomes the foundation for the court's assignment of a level of risk. The assigned level has profound consequences for how the adolescent will be treated in the justice system. Thus, it is imperative that clinical providers have a basic understanding of the literature on empirically relevant and reliably assessed risk factors and be able to communicate to the court the intricate nature of predicted risk.

Though there is a reasonable consensus that general cognitive behavioral approaches have utility, there is considerable support for the idea that responsive treatment will be defined by explication of the unique and particular needs of the individual adolescent. A boy with an intense burden of victimization and trauma in his history is likely to require considerable work at stabilizing his affective reactivity and inner turmoil before he will be receptive to recognizing his responsibility for his own sexual misconduct. An adolescent with a delinquent history and an early predisposition to an antisocial style may require a strongly structured and boundary-limiting intervention with a strong focus on evaluating violence-producing attributions in order for him to begin to recognize the impact of his behavior on his own life as well as others.

An additional core competency is the ability to work in nontraditional contexts. Clinicians working with adolescents with sex offending problems are going to find themselves having to broker interactions in forensic contexts, correctional settings, foster and child welfare agencies, as well as the usual gamut of academic and social contexts in which adolescents are embedded. Moreover, the work in forensic and correctional settings often require that clinicians provide courts, probation, and child welfare agents with risk analyses about their clients. In fact, this may well be one of the most frequent referral questions.

Thus, in addition to the usual competencies required of those who work with adolescents, a strong grounding in developmental psychology, flexibility in methods, and the ability to work in family and social contexts outside of the consulting room, clinicians have to be familiar with the language and methods of the legal system. Moreover, they have to be able to recognize the value and limits of risk analysis and actuarial procedures of all sorts.

Competencies also vary by setting. Clinicians working in residential setting, particularly, correctional contexts, have to be aware of the tendency for such settings to become custodial rather than truly correctional. There has been considerable evidence in the news about the corruption of correctional settings in which the drift toward coercive control has effectively obviated the practice of any genuine treatment. Inevitably, clinicians in these

settings become the guardians of the principles of noncoercive, nonabusive, psychologically sensitive treatment.

14.7   Transition from Basic Competence to Expert

The most critical skill in the transition from basic competence to expert level of functioning is the ability to perform a well-articulated and accurate risk, needs, and responsivity analysis. To accurately blend the data from actuarial assessment with the data from history and clinical evaluation to create a comprehensive and operational treatment plan is both difficult and essential to the successful result of treatment. In our facility, we invest a great deal of upfront clinical work in the forging of such a plan and rely on it to guide our interventions and keep the adolescent on track (Burkhart et al., 2008). An important corollary skill is to be able to translate this treatment plan into an operational plan for the client. Adolescents have to be engaged, they have to buy into the plan or an adversarial process can evolve. Expert clinicians can speak the language of youth, help them envision a self-worth working for, and pull them into the process of change without this appearing to be a loss of dignity or autonomy. A hallmark of expert clinicians is that they are able to create a relationship of close attachment, but one that allows for the adolescent to have a sense of his own autonomy and choice.

Being able to manage the complex systems and have the different stakeholders all on the same path is an additional level of expertise necessary for work with adolescents with sexual offenses. Clinicians often have to interact with judges, probation officers, school personnel, and district attorneys and influence or persuade them to share a common plan. Such correspondence is difficult as often these stakeholders have different constituencies and very different values relative to the treatment needs of the client. It is not unusual for clinicians to have to function as advocates. The danger in such advocacy is that the risk analysis has to be accurate and the clinician must not distort the level of risk as attached. Given the variability of settings, populations, and legal pathways by which these clients are sorted, the ability to conduct local science to define, evaluate, and manage the specific clinical needs of the adolescents for whom the clinician is responsible is a very important, advanced skill. Particularly given that, in most contexts, treatment is mandated; thus, little to no possibility to do broad based, randomized clinical trials, the necessity of being able to do within group evaluations, know the base rates of co-morbid conditions, have some access to effectiveness in terms of treatment response, both immediate, intermediate, and ultimate, seems to provide the only genuine foundation for self evaluation and program review. The value of having a spreadsheet of all the data for all the clients in a program cannot be overstated. Our ability to hold ourselves accountable depends directly on our ability to humble ourselves before the data.

14.8   Summary

Given that adolescence is the critical period for onset of adult persistent offending; all intervention with adolescents with sexual behavior problems can be considered as early secondary prevention as well as tertiary prevention of adolescent problems. Moreover, the costs of inadequate or insensitive treatment can be steep. The necessity and complexity of being able to match treatment needs to the individual circumstances of each child or adolescent and the

further implication that incorrect matches of treatment to individual needs can have iatrogenic consequences render this work critically important for the individual child and the society into which he will mature. A core research agenda should be to provide clinicians with reliable and valid tools that will allow for the accurate judgments necessary to match the adolescent with the best articulated treatment and develop the methods and principles by which effective interventions can be crafted.

The finding that nonsexual delinquents sexually reoffend at the same rate as treated sex offenders is one with considerable social and legal consequences. There are many more general delinquents moving out of correctional and treatment contexts than sex offending adolescents. If the rates of recidivism are the same, then the overall number of sexual offenders from the delinquent group must be that many times more frequent. Thus, it may well be that general delinquents account for far more victims than released juvenile sex offenders. The obvious implication is that sex offence prevention intervention efforts should be included for general delinquents as a component of their program of treatment.

Perhaps, the most important form of prevention will occur in legislative contexts in which the legal structure for managing adolescents with sex offending behaviors will be created (Zimring, 2004). There is a very likely consequence that failure to distinguish juveniles with sex offending behaviors from adult sex offenders, combined with the increasingly punitive and destructive handling of sex offenders in general, will lead to creating adolescents whose identity will be forged in the crucible of a legal context which condemns them to the stigmatized identity of a lifetime sentence as a sex offender.

Critical issues in the formation of social and legal policy have to be formulated. The downward extension of policies and procedures from adult offenders to juveniles must be thwarted. There is an accumulating conceptual and, recently, empirical literature that has identified the pernicious consequences of these policies (Letourneau, 2006). Developing developmentally appropriate and empirically informed policy is perhaps the most significant work to be accomplished in this area.

15 Peer Problems

Gregory A. Fabiano · Rebecca K. Vujnovic · Meaghan E. Pariseau

Abstract: Peer problems are an issue that cut across diagnostic categories and childhood conditions. Peer problems are a critical target of treatment, as they are a strong predictor of negative long-term outcomes. Currently, there are a number of interventions for peer problems that are supported by research evidence. Notably, these treatments involve working directly with the child in peer settings (e.g., recreational settings, classrooms). Basic competencies for clinicians working to treat peer problems include effective assessment strategies and working with the child in the settings of interest. Advanced strategies include effective supervision of individuals working on peer problems with children and ensuring intervention fidelity, individualizing and tailoring intervention components to address peer problems, and working within systems such as schools or summer treatment programs.

15.1 Overview

The manner in which one interacts and forms relationships with others through early childhood, middle childhood, and adolescence is a cornerstone of most major developmental theories (e.g., Erikson, 1968; Parker, Rubin, Erath, Wojslawowicz, & Buskirk, 2006). The formation of social skills that permit effective negotiation of peer-related interactions and interpersonal relationships is arguably one of the most important developmental tasks. As such, peer relationships make a strong contribution to many aspects of normal and abnormal development (Bukowski & Adams, 2005).

Social acceptance by peers, presence of positive friendships, and using good social skills within the context of friendships predict a host of positive long-term outcomes (e.g., Hartup, 1996; Risi, Gerhardstein, & Kistner, 2003). Conversely, being rejected or neglected by peers, lacking in friendships, and exhibiting behaviors characteristic of poor social skills predict a number of negative long-term outcomes (e.g., Coie, Lochman, Terry, & Hyman, 1992; Ollendick, Weist, Borden, & Greene, 1992; Parker & Asher, 1987). Thus, children not only have to avoid poor peer relationships, but must also develop positive peer relationships to be on a trajectory for positive long-term outcomes.

Peer interactions are reciprocal and recursive in nature. Owing to their complexity, they are vulnerable to breakdowns or impairments across many potential phases of the peer-interaction process, spanning from initiation of social interaction, communication or social skills used during an interaction, to behaviors related to the maintenance or fostering of continued interactions/friendships. Thus, it is not surprising that peer-relationship problems are often impaired in children and adolescents who exhibit impaired functioning owing to externalizing or internalizing behaviors (e.g., Bukowski & Adams, 2005). For example, researchers have long known that children with ADHD (e.g., Pelham & Bender, 1982) or conduct problems (Coie & Dodge, 1998) have problems in peer relationships. Problems may range from simply being ignored by other children (e.g., not being picked to play in recess activities, being the only child not invited to a classmate's birthday party) to being actively rejected by other children

(e.g., being bullied during recess). A child with ADHD or CD may also tease and be teased by peers, get into fights with other children, and exhibit inappropriate social skills (e.g., is a poor sport during games). Likewise, children with internalizing problems may have problems exacerbated by peer victimization or poor peer interactions (e.g., Greco & Morris, 2001; Prinstein, Cheah, & Guyer, 2005).

It is also important to acknowledge that peer relationships are interwoven into most domains of functioning for children and adolescents. Thus, the individual's neighborhood, school, recreational activities, and home will all contribute to the context of the development of adaptive and/or maladaptive peer interactions. Although this point about the context of peer relationships may seem obvious, it is worth noting that many contexts do not have a primary focus on peer relationships as part of formal or informal intervention efforts. For example, Farmer and Farmer (1999) note how schools may not adequately support interventions related to development of appropriate peer relationships through the current standard of care. A practical example of this comes from the work of researchers (Bradshaw, Sawyer, & O'Brennan, 2007; Craig & Pepler, 1997; Craig, Pepler, & Atlas, 2000; Pepler & Craig, 1995) who highlighted a fundamental difficulty in targeting peer interventions in school settings: adults are generally unaware of the negative interactions between peers, such as aggression or bullying. Therefore, while adults are present in these situations, as they are unaware of the majority of negative interactions, it is difficult to institute effective adult-directed intervention efforts to target these behaviors. The situation can only be worse in instances when adults are not present, presenting a real challenge for the treatment of peer problems (e.g., in school cafeterias or on the bus; in unstructured peer interactions in the neighborhood). Thus, it is critical for adults and children to have open lines of communication with respect to information on occurrence of peer problems.

Given the importance of the development of positive peer relationships through childhood and adolescence, it is notable that the Diagnostic and Statistical Manual of Mental Disorders (DSM; American Psychiatric Association [APA], 2000) does not have any category for impaired peer relationships. A few categories include impairment in peer relationships as a hallmark feature of the disorder (e.g., autism, Asperger's disorder). In most cases, however, the DSM integrates a consideration of functioning in the domain of peer relationships into most childhood and adolescent disorders through the diagnostic qualifier stating: "The disturbance in behavior causes clinically significant impairment in social … functioning" (APA, 2000). Thus, regardless of a child's or adolescent's primary diagnosis or reason for referral, a careful focus on peer relationships is necessary during initial and ongoing assessments, as well as in treatment planning and implementation.

As outlined briefly earlier, establishing peer relationships is a critical developmental task, and peer problems are an important target for intervention and treatment. In the rest of the chapter, we will discuss the assessment of peer problems, maintenance factors related to the problem, evidence-based treatment approaches, what is known (and not known) about the mechanisms underlying change in the intervention, and the basic and expert competencies of clinicians charged with treating peer problems.

15.2 Recognition and Assessment

Symptoms exhibited by children who experience peer problems vary greatly due to the complex nature of peer interactions. Much of the information on the topography, variation,

and extent of peer problems comes from sociometric studies. Sociometric measures generally ask children in a group to nominate children who are liked and disliked within a group (Coie & Dodge, 1988; Coie, Dodge, & Kupesmidt, 1990; Masten, Morison, & Pellegrini, 1985; Newcomb, Bukowski, & Pattee, 1993; Pekarik, Prinz, Liebert, Weintraub, & Neale, 1976; Pope, Bierman, & Mumma, 1991). Based on data from sociometric peer nominations, researchers have identified five types of sociometric status that children are classified as per the peer ratings: popular, rejected, neglected, controversial, and average (Newcomb et al., 1993). In developmental research, four behavioral patterns have been linked with peer rejection. These include low rates of prosocial behavior, high rates of aggressive/disruptive behavior, high rates of inattentive/immature behavior, and high rates of socially anxious/avoidant behavior (e.g. Coie et al., 1990; Parker, Rubin, Price, & DeRosier, 1995).

Children of different sociometric status can be described as varying across three broad behavioral domains: sociability, aggression, and withdrawal (Newcomb et al., 1993). Based on the results of a meta-analysis of sociometric status, Newcomb et al. describe distinct behavioral patterns that discriminate the five sociometric status groups from one another. Compared with children of popular and average status, children who fall into the rejected sociometric status have lower cognitive abilities, are less sociable, and more aggressive and withdrawn. Within the broad domain of aggression, rejected children have increased disruptive and negative behaviors, along with higher levels of physical aggression. In addition to elevated levels of inappropriate behaviors, rejected children also exhibit low levels of positive behaviors, such as prosocial actions and friendship skills, and have higher than average levels of social withdrawal. In contrast to rejected children, those who fall into the controversial status exhibit higher levels of sociability than do average children. However, controversial children also show higher than average levels of aggression and disruptive/negative behaviors. Controversial children also have higher cognitive abilities than rejected children, and their positive, prosocial actions are equal to those of children in the popular status. The behavior of neglected children, on the other hand, appears to deviate the least from that of average children. In the domains of aggression and sociability, neglected children show lower levels than do average children, while having higher levels in the domain of social withdrawal. Coie, Dodge, and Coppotelli (1982) describe neglected children as being ignored and receiving little notice from their peers, but they are not actively disliked.

Prosocial behavior has been shown to be a stable predictor of peer acceptance, while aggressive and disruptive behaviors are related to peer rejection. Children who show low levels of prosocial behaviors have difficulty in the areas of positive behavior and communication skills, emotion regulation, and social awareness and sensitivity. Children who exhibit high levels of physical and verbal aggression are at high risk for peer rejection due to their frequent exhibition of disruptive behavior. Difficulties in emotional regulation are often reflected in disruptive and oppositional behaviors that are also linked to peer rejection, such as irritability, insecurity, children who are overly sensitive and quick to blame others, highly reactive to frustration, resentful, easily annoyed, and generally unhappy.

High rates of inattentive/immature behavior are also associated with peer rejection. This includes behaviors, such as high levels of distractibility, difficulty staying on task and concentrating, and socially immature and insensitive behaviors. When children exhibit socially aversive behaviors, such as failing to follow social protocols, joint activities and play become unpleasant and unpredictable (Barkley, 1996; Pope & Bierman, 1999). Children who have low levels of self-control, such as deficits in following rules and understanding principles of fairness

and reciprocity, also tend to experience peer rejection (Landau & Milich, 1988; Saunders & Chambers, 1996). Notably, the negative effects of these behaviors on peer perceptions of a child are almost immediate (e.g., Pelham & Bender, 1982).

An additional behavior that has received recent attention from researchers is relational aggression. Relational aggression involves directing harm at a relationship or friendship. For example, a child may spread gossip or rumors about another, threaten to end the friendship, or shun a child or group of children (Crick, 1996; Ostrov & Crick, 2007). There are measures that can be completed by teachers to investigate the extent of relational aggression (i.e., Children's Social Behavior Scale, Crick, 1996; Preschool Social Behavior Scale, Crick, Casas, & Mosher, 1997), and sociometric measures completed by peers can query the extent to which children exhibit this behavior. In addition to physical aggression, relational aggression is an important construct to assess as well because of its potential impact on aggressors and victims.

The fourth behavior pattern that is associated with peer rejection is with regard to a child who exhibits high rates of socially anxious/avoidant behavior. Children who are fearful, anxious, and appear uncomfortable around other children are at risk of experiencing peer rejection (Rubin & Stewart, 1996). Children who are isolated or ostracized from their peers are restricted in their ability to develop social skills and self-confidence, which can lead to a cycle of negative socialization. Children may also be rejected by their peers because of atypical characteristics, such as a handicap or minority status.

The complexity of peer problems necessitates that assessment be comprehensive and idiographic, and integrate information from multiple informants. Bierman (2004) notes that assessment of peer problems must include consideration of behavioral, affective, and cognitive features of the child, as well as the characteristics of the child's peers. Behavioral characteristics include aggressive, immature, and inattentive behaviors, as well as deficits in prosocial behaviors. There are a number of well-developed and valid measures for documenting the presence of these characteristics (e.g., Child Behavior Checklist and Teacher Report Form, Achenbach & Rescorla, 2004; Behavioral Assessment System for Children, Reynolds & Kamphaus, 1998; Social Skills Rating System, Gresham & Elliott, 1990). Affective characteristics include negative expectations, being easily aroused emotionally, or ambivalence in social situations, which can also be measured with standardized methods (e.g., Asher, Hymel, & Renshaw, 1984; Cassidy & Asher, 1992; Harter, 1982; LaGreca, Dandes, Wick, Shaw, & Stone, 1988). Cognitive characteristics include negatively biased evaluations of social situations, lack of problem-solving skills, or inaccurate perceptions of social situations (Bierman, 2004). Finally, quality of the peer relationship itself might be evaluated using the child's self-report or other measures (Bukowski, Hoza, & Boivin, 1994; Coie & Dodge, 1988; Crick & Bigbee, 1998; Parker & Asher, 1993; Ried et al., 1989; Wheeler & Ladd, 1982).

The purpose of assessment is to inform intervention and treatment efforts; therefore, assessment must be individualized so that each child's unique behavioral, affective, and cognitive characteristics, as well as the context in which problems occur, can be appropriately considered. In each assessment, a functional analysis of the peer problems a child is experiencing should be included. A functional analysis involves isolating and clearly defining the specific peer problems the child is experiencing (e.g., become physically aggressive when peers do not follow his lead during group activities). Next, antecedents or events that occur immediately before the specific behavior(s) are examined. All aspects of the context in which the specific behavior occurs should be considered when identifying antecedents. Consequences

of the specific behavior or what happens immediately following the behavior(s) should be examined to determine what function the behavior is serving for the child. This functional analysis allows for the identification of both the immediate peer problems the child is experiencing, as well as the hypothesizing of long-term correlates such as the child's reputation among peers.

Assessment of peer problems should include information from multiple sources, including peer ratings, teacher ratings, self-ratings or interviews with the child, and direct observation (Bierman, 2004; Coie & Dodge, 1988; Pepler & Craig, 1998). Information from these multiple sources can be integrated to form a more comprehensive picture of the child's peer problems, as gathering information from each source has advantages and limitations, and varies in three important ways: access to information about the child, cognitive biases and limitations, and the nature of the relationship with the child (Newcomb et al., 1993). Newcomb et al. note that adult (parent and teacher) ratings may be limited due to lack of direct contact with the child during salient social situations, as they are more likely to interact with children in structured settings where less peer interaction takes place. Adults also may have limited knowledge about the child's feelings, values, and beliefs. Additionally, adults interact with children as part of a non-equal relationship, which is different from the interaction children have with their peers. Although adults may be poor reporters regarding the nature of children's peer relationships and the specific strengths and weaknesses, there is some evidence that parents and teachers are accurate in their identification of rating whether peer relationships are impaired (Fabiano et al., 2006).

Regarding peers, Newcomb et al. (1993) outline that they have access to information about the child's behavior in terms of the norms of the peer group, and within the structure of interactions among equals. However, utility of peer reports varies with cognitive and developmental levels. Peers may also be biased by past information about the child such as reputation. Children's self-reports are also subject to their cognitive and developmental levels, but are more accurate for identifying the child's beliefs, feelings, and values related to social situations. However, children's accuracy in reporting their self-perceptions can vary greatly (Newcomb et al.; Owens, Goldfine, Evangelista, Hoza, & Kaiser, 2007). Similarly, direct observations of children's behavior are impacted by the pre-existing biases of the observers, the observers' training, the coding scheme used, and the influence that an observer's presence has on the social situation (Newcomb et al.).

15.3 Maintenance Factors

Social competence and cognition, peer response, as well as other external factors may contribute to the maintenance of poor peer relations, if not addressed. Consideration of such socially constructed factors suggests that while discrete behavioral skills may be developed through individual therapy, the key to improving peer relationships relies on interventions beyond the clinician's office.

The foundation of social competency relies on executive functioning within social contexts (Cavell, 1990; Dodge & Murphy, 1984). Several discrete behaviors and social skills have been identified as essential for enabling effective social functioning. Specific behaviors include: encoding skills, considered as the ability to perceive and interpret the situation; decision skills, eliciting and evaluating possible responses; and enactment skills, which include enacting and evaluating the selected response (Dodge & Murphy, 1984; McFall, 1982). Additionally, social

skills include prosocial behavior, adaptive problem-solving skills, and emotional regulation (Bierman & Welsh, 1997).

When considered within a developmental framework, social competence moves beyond a set of discrete social behaviors to include a child's ability to manage her/his own behavior in various social contexts, which elicit a positive response while avoiding a negative response from others participating in the interaction (Bierman, 2004; Bierman & Welsh, 1997; Dodge & Murphy, 1984). The possession of socially appropriate behaviors is necessary, but is not sufficient for one to be considered socially competent (Biernman, 2004). Social competence also requires social-cognitive ability, allowing the individual to utilize such behaviors to accommodate the ongoing social interaction (Beirman, 2004; Bierman & Welsh, 1997). Clearly, this is a quite complex combination of behaviors that have both reciprocal and recursive feedback effects on social interactions.

The foundation of social-information-processing models asserts that children's understanding and interpretation of social situations influences their related behavior, which is, in turn, the basis for other's evaluation. Crick and Dodge (1994) present a complex yet very well-defined model of social-information-processing. The empirically supported cognitive distortions of maladjusted/rejected children within the framework of the social information processing model of children's social adjustment is a useful way to think about the complexity of social interactions, as well as the multiple areas where intervention may be necessary (Crick & Dodge, 1994). In brief, children need to create a mental representation of the social situation, identify their own social goals, access their own memory of social history to generate potential behavioral responses, and select a behavioral response. Maintaining factors in a child with peer problems could occur at any one or more of these steps, and problems could be present at different steps across different social situations. One of the challenges in identifying maintaining factors is to conduct an assessment that comprehensively identifies all antecedents and consequences of peer interaction behaviors (both positive and negative). Furthermore, while deficits in social competence may maintain difficulty in peer relationships, subjective peer expectations may maintain social difficulties, especially for children with acknowledged learning and behavioral problems. Such children with diagnostic labels (e.g., learning or behavioral disordered) were perceived more negatively by their peers, who were less friendly and less involved in the interaction, which in turn, contributes to the maintenance of social difficulties (Milich, McAninch, & Harris, 1992). These problems are compounded by a lack of awareness of how these negative behaviors contribute to negative peer outcomes, compounding the problem over time (e.g., Hoza, Waschbusch, Pelham, Molina, & Milich, 2000). As some maintenance factors may involve cognitions (e.g., a hostile attributional bias), emotions (low feelings of self-worth or feelings of social anxiety), or the behaviors of other children (e.g., teasing/name-calling; Scambler, Harris, & Milich, 1998), clinicians have a tall order to meet in their evaluation and intervention efforts.

After enacting the response decision behavior, children are subjected to evaluation by their peers. Peer rejection has been found to be relatively stable in childhood. Over the course of a 5-year period, rejected children remained rejected, suggesting stability of the status (Coie & Dodge, 1983). Perceptions of rejected children suggest that peers utilize negative or biased stereotypes and expectations, which results in adverse treatment or victimization of the rejected child in comparison with an accepted peer (Bierman, 2004; Perry, Kusel, & Perry, 1988). Consequently, for aggressive children, persistent adverse treatment may elicit and reinforce further aggressive behavior (Bierman & Welsh, 1997).

Finally, maintenance of peer difficulties may result from additional factors, which are considered to be external from the individual's unique social skills and deficits. These include deviant peer-group acceptance, as well as family factors and other community/neighborhood influences. Aggressive or antisocial preadolescents and early adolescents may establish friendships with other deviant peers. This, in turn, supports and reinforces deviant behavior, as it is highly probable that when one member of a deviant peer group engages in problem behavior, other peer group members will also engage in the deviant behavior (Brendgen, Viaro, & Bukowski, 2000; Dishion, Andrews, & Crosby, 1995; Wasserman et al., 2003). Furthermore, exposure to deviant peers is associated with drug use, antisocial behavior, violent offenses, and is a stronger predictor of delinquent behavior than family, school, and community factors (Elliott & Menard, 1996; Thornberry & Krohn, 1997). Neighborhood socioeconomic status may also contribute to peer relationships; however, neighborhood effects may be mediated by parental behavior, especially for young children (Tietjen, 2006). Additional external factors that have been empirically associated with poor peer relationships include an authoritarian parenting style, parental psychopathology, divorce and marital conflict, exposure to neighborhood violence, and no or low quality child-care experience, particularly for children from lower socioeconomic families (Dishion et al., 1995; Tietjen, 2006).

15.3.1 Evidence-Based Treatment Approaches

Given the significant and sustained impairment experienced by children with peer problems, and the impact of this impairment on long-term outcomes, effective treatments are clearly needed. Most task forces or work groups that establish criteria for and evaluate evidence-based practice, aim to evaluate treatments for a particular DSM disorder. Thus, there is a challenge in identifying evidence-based treatment approaches for addressing peer problems, which cut across diagnostic categories. In the present review, evidence-based approaches that primarily focus on the development of appropriate social skills and adaptive peer-related behaviors as well as the reduction of negative behaviors that impact peer interactions will be reviewed.

However, before reviewing evidence-based interventions, interventions that are *not* evidence-based will be briefly discussed. Simply enrolling a child with peer problems in a community activity such as sports or scouting is not an effective intervention – without adequate structure and support, it is unlikely that by simply increasing the frequency of peer interactions there would be an improvement in the existing problems. Further, a commonly used, but not evidence-based, intervention for peer problems is individual counseling or social-skills training conducted by a therapist. In this intervention, individual meetings with a psychologist or other professional and "lunch bunch" meetings facilitated by school psychologists or counselors are included. With notable exceptions (see the discussion of Webster-Stratton's social skills program, below), the preponderance of available evidence does not support this intervention for children with peer problems (e.g., Fox & Boulton, 2003; Pelham & Fabiano, 2008; Rao, Beidel, & Murray, 2008), and clinicians report it as being less effective than other interventions (Miller, DuPaul, & Lutz, 2002). Indeed, in a comprehensive review and meta-analysis of social-skills training programs for children with disruptive behavior disorders conducted by Kavale, Forness, and Walker (1999), a modest effect size was generated (mean = 0.20), with 27% of studies yielding a negative effect size (i.e., treated children fared worse in these studies).

Upon closer review, these results are not surprising. Given the complexity of peer interactions, it is folly to believe that an adult (i.e., not a peer) can meet individually with a child and instruct the child in the best manner for negotiating a variety of evolving and frequently subtle social situations (that are impaired to the point of needing clinical intervention) involving one or more peers. For this reason, peer problems cannot be treated in an office or outside the presence of peers – it is necessary for interventions to be implemented within the settings where peer problems occur. It is clear from the discussion that follows that evidence-based interventions are those that work directly with the targeted child in the problematic settings to teach skills and competencies in important functional domains and implement contingencies or modify setting events to reduce the occurrence of problematic behaviors.

Subsequently, we will briefly provide an overview of evidence-based peer interventions for common childhood disorders. For the most part, peer interventions have focused on children with externalizing disorders, such as ADHD, Oppositional Defiant Disorder, and Conduct Disorder. Interventions for children with internalizing disorders and the prevention of bullying or aggression will also be reviewed. Importantly, this is not intended to be an exhaustive list of evidence-based interventions for peer problems. Rather, the focus is on a brief description of treatments that have a core component that addresses peer problems. Many other evidence-based interventions for childhood disorders address peer problems in addition to other targeted behaviors (see the first issue of the 37th volume of the *Journal of Clinical Child and Adolescent Psychology* for a comprehensive review of evidence-based interventions for child and adolescent disorders).

ADHD. The summer treatment program (STP) for children with ADHD is an evidence-based intervention for peer interactions (Pelham & Fabiano, 2008; Pelham, Fabiano, Gnagy, Greiner, & Hoza, 2005; Pelham, Greiner, & Gnagy, 1997; Pelham & Hoza, 1996). The STP is structured to be comparable with a typical 8-week summer camp; children participate in structured recreational activities, such as basketball, baseball, soccer, and swimming, attend an art class and an academic classroom, eat lunch and participate in recess together, and they transition between activities together. Across activities, 12–15 children with ADHD are grouped together for the entire summer. Thus, in addition to providing ample opportunity to observe peer interactions in ecologically valid settings, the ongoing functioning and interactions can also be evaluated. A unique aspect of the STP is that an intensive contingency management behavior modification program is interwoven into every activity throughout the program day. Children earn points for positive behaviors (e.g., sharing) and lose points for negative behaviors (e.g., teasing a peer), and points may be exchanged for camp privileges or rewards. Additional interventions such as public recognition for appropriate peer-related activities (i.e., a social skills "button" awarded to a child who best exemplified positive social skills the day before), brief social-skills training discussions (i.e., a 15-min discussion of social skills at the beginning of the program day that includes role-plays and modeling), and praise statements directed toward children exhibiting positive social skills are also liberally used in the program.

While the contingency management token economy generally aims to reduce the occurrence of negative peer-related behaviors, one of the goals of the STP is also to teach children skills and competencies in key domains related to peer relationships (Pelham & Hoza, 1996). For example, many children with ADHD are excluded from or struggle during community activities such as sports or other recreational activities (e.g., Pelham & Bender, 1982). To the extent that these activities are an important forum for learning social skills and interacting with

peers, children with ADHD, who already struggle in peer interactions, are placed at a further disadvantage. Therefore, children in the STP receive intense instruction on the rules and applied practice in necessary skills for sports and other group activities. The purpose of these activities is to increase the competencies and skills of the children, so that when they return to their neighborhoods, schools, and playgrounds, they are effective and proficient members of the group or team. Moreover, the progress made and success experienced in the sports domain during the STP possibly contributes to the large parent- and child-reported increases in self-concept at the end of the STP (Pelham & Hoza, 1996).

A recent review of evidence-based treatments for ADHD (Pelham & Fabiano, 2008) evaluated those who had research support for peer interventions. Results of the review indicated that the STP met criteria for a well-established treatment based on a number of group design, cross-over, and single subject studies. What is presently unknown is which components of the STP (e.g., token economy, sports training, staff monitoring of peer-related behaviors) are responsible for the significant effects. Future studies that work to dismantle the intensive intervention to elucidate the active ingredients of the effective peer intervention are needed. In addition, these positive findings in the STP setting for children with ADHD are tempered by a lack of effective treatments outside the intensive programs (see Hoza, 2007 for a review).

Internalizing disorders. There is relatively less research available on explicit peer-problem interventions for children with internalizing disorders related to anxiety or mood. Greco and Morris (2001) reviewed the literature on improving the behavior of children who were shy, and they concluded that there is evidence for cognitive-behavioral interventions aimed at improving social interactions. However, most studies were conducted in clinics or specialized settings, and it is unclear how the results might be generalized to naturalistic peer groups. For example, Beidel, Turner, and Morris (2000) treated children with social anxiety in a 12-session program that included social-skills training, exposure sessions, and generalization activities, such as participating in a recreational activity. When compared with an attention control condition at post-treatment and follow-up, children in the intervention group exhibited improved social skills, and two-thirds no longer met the diagnostic criteria for social anxiety disorder. Importantly, treatment gains owing to the cognitive-behavioral treatment were maintained as long as 5 years post intervention (Beidel, Turner, & Young, 2006). These results are promising, and suggest that increased attention to the treatment of peer problems in children with internalizing disorders is needed.

Conduct problems and aggression. The Coping Power program is a 34-session intervention designed for children with anger- or conduct-related problems, and impaired peer relationships (Lochman, Coie, Underwood, & Terry, 1993; Lochman, Wells, & Lenhart, 2008). The program focuses on skill development related to problem-solving and anger management skills, social skills such as dealing with peer pressure or negotiating peer interactions, and also supports the development of positive school-related skills. The Coping Power program is conducted in group settings with other same-age children. It also includes a parent management training component to facilitate the generalization of child social skills into the home setting. As currently constructed, the Coping Power program can be implemented over the course of a year and a half. A recent review categorized the child social-skills training component of the Coping Power program as probably efficacious (Eyberg, Nelson, & Boggs, 2008).

Another intervention specifically tailored to address peer problems for children with conduct problems is the Incredible Years Dina Dinosaur social-skills training curriculum (Webster-Stratton & Hammond, 1997; Webster-Stratton, Reid, & Hammond, 2001, 2004) for young

children with conduct problems. In this program, children attend weekly groups that target the development of appropriate social skills. Children engage in a number of activities during the session including watching videos of children in a number of different social situations, role-plays, participating in activities and problem solving, and interacting with child-sized puppets used to introduce concepts or promote engagement in activities. Teachers and parents monitor children's behaviors during the week, and are instructed to reinforce children when they exhibit appropriate social skills. The program is highly structured and manualized. A recent review categorized the Incredible Years child training program as probably efficacious (Eyberg et al., 2008).

Another social-skills training curriculum is the Promoting Alternative Thinking Strategies (PATHS) curriculum that is implemented universally by teachers in schools. PATHS is administered within the context of classroom activities, and it aims to reduce the occurrence of aggressive and negative behavior, and also teaches adaptive social skills and behaviors. The PATHS program was part of the multi-component peer treatment in the Fast Track intervention study for young children with conduct problems (Conduct Problems Prevention Research Group, 1999). A recent randomized controlled trial adapting the PATHS program for a preschool setting has also indicated positive results of the intervention (Domitrovich, Cortes, & Greenberg, 2007).

Bullying/aggression prevention. Bullying behavior is clearly related to the emergence, maintenance, and severity of peer problems, as it has consequences for both the bullies and victims. There is now a collection of approaches supported by outcome data to target and reduce the negative effects of bullying in schools (Olweus, 1993; Pepler, Craig, Ziegler, & Charach, 1994; Ross, Horner, & Stiller, 2008). Most approaches are implemented in school settings, and these approaches share some common characteristics. First, there is a universal prevention and intervention component that involves the creation of school-wide expectations and rules, as well as procedures for monitoring and enforcing the rules across all school settings. Programs also involve strong efforts toward increasing awareness of bullying and its consequences throughout the school. In addition, mechanisms for reporting bullying without fear of retaliation are instituted (e.g., an anonymous reporting system). Finally, most programs utilize a tiered system of universal and targeted interventions. In a recent review that included a consideration of bullying prevention interventions, McMahon, Wells, and Kotler (2006) comprehensively reviewed the bullying prevention and intervention literature and concluded such treatments were an effective intervention, in general. This conclusion was qualified in that the interventions appeared to be more effective for younger children than older children in middle schools.

Peer mediation approaches are also widely used in school settings (Gottfredson & Gottfredson, 2002). These universal interventions to address aggression or conflict in school settings involve training peer "mediators" to intervene in problematic social situations between children. Typically, they use a problem-solving approach to resolve the situation. Cunningham et al. have reported on the outcomes of a peer mediation program (Cunningham et al., 1998). In the study, mediation teams were fifth-grade students, trained for 15 hours. The results suggested that peer mediators resolved 90% of the playground conflicts, and direct observation indicated a reduction in physically aggressive behavior by 51–65%, with sustained effects at 1-year follow-up. This study suggests that peer mediation interventions, like the one implemented by Cunningham et al. are promising interventions. One of the innovative aspects of this approach is the reliance on peers as the change agents (i.e., mediators).

There are also targeted treatments for children who are aggressive or bully others. For example, the Reprogramming Environmental Contingencies for Effective Social Skills Training (RECESS) is a well-developed program that aims to improve the social skills of young children who exhibit aggression or are at-risk for antisocial behaviors (Walker, Hops, & Greenwood, 1993). The program is very carefully manualized and structured, and it involves a number of hierarchical components. First, individual social-skills training that includes discussion and role-play with the targeted student and the entire classroom is conducted. Second, a response cost token economy is implemented where the child loses points for inappropriate social behavior (e.g., aggression) and rule violations (Hops & Walker, 1988). Praise and rewards (classwide and home-based) are contingent on appropriate social behaviors exhibited by the child. The program implements the contingency management approach using four phases. The first phase focuses only on behavior in the recess setting and contingency management is implemented by a para-professional. Once the child exhibits improved behavior, similar interventions are implemented in the classroom. After documented progress in the child's behavior, the para-professional's support is faded, and procedures are turned over to the teacher and other school staff to maintain. Developers of the RECESS program have extensively field-tested and evaluated the program (Walker, Ramsey, & Gresham, 2003), making this an effective intervention for children at-risk for peer problems in elementary school.

15.4   Mechanisms of Change

There is currently no consensus across studies regarding the specific mechanisms that promote change in peer problems from intervention. However, there are some commonalities amongst effective interventions that can be discussed, and these are potential contributors to the change seen due to peer interventions. Each of these components will be briefly discussed.

First, as is clearly apparent from an overall review of effective interventions for peer problems, the use of contingency management strategies based on the principles of social learning theory are a component of all effective interventions. That is, establishing clear expectations, rules, and goals for peer-related behaviors, monitoring the exhibition of appropriate and inappropriate behaviors, and following these behaviors with logical consequences for positive and negative behaviors is an approach that appears to be a necessary ingredient of effective interventions. For example, one might argue that the intensive contingency management approach is what makes participation in an STP an evidence-based treatment for ADHD, whereas simply participating in group recreational activities is not (Pelham et al., 2008). Other programs that address peer problems related to anger or conduct problems (e.g., Lochman et al., 2008) and bullying (e.g., Olweus, 1993) also contain contingency management components. It is likely that contingency management helps to support and correct peer-related behaviors that had not been addressed by naturally occurring contingencies for one reason or another. Of course, one drawback of contingency management approaches is that there appears to be only modest evidence of generalization of treatment effects (e.g., Pelham et al., 2005), suggesting that while these interventions improve peer interactions while implemented, they do not appear to result in sustained change in functioning, necessitating long-standing intervention.

A second commonality across the effective treatments outlined earlier is the emphasis on implementing treatment procedures and facilitating social-skills training in naturalistic peer settings, such as during recreational or school-based activities (e.g., Beidel et al., 2000; Pelham

et al., 2005). The exact mechanism for change related to this approach is not well-studied. However, it is reasonable to presume that a child who practices a new behavior in a context similar to that of the situation where treatment effects are aimed to generalize may be more successful in maintaining appropriate peer-related behaviors. It is clear that substantial treatment effects can be generated by having a child practice targeted social skills in a peer setting immediately prior to participating in a peer-group interaction (O'Callaghan, Reitman, Northup, Hupp, & Murphy, 2003). What is unknown is the extent to which other treatment approaches can be generalized, whether treatment effects are maintained, if effects do not maintain with what speed they decrease, and whether additional supports or interventions (i.e., including a parent-related treatment in parallel) promotes generalization (see Pfiffner & McBurnett, 1997 for an example of this approach).

Although, generally an unaddressed parameter in the treatment literature, all the effective interventions reviewed earlier include intervention *within* a peer group. One potential mechanism for change therefore relates to implementation of treatment procedures with same-age peers. Although the precise mechanism of how this peer-group interaction supports the alleviation of peer problems is unknown, it is likely that the peer group provides an ecologically valid setting for intervention, provides a number of models (both positive and negative) for the child to observe, and may reduce feelings of isolation. Further, one important aspect of treatment in the peer group is that it permits peer interactions to occur in a structured and monitored setting. Deficits in social cognitive strategies are one possible reason for peer problems. The structured setting may permit a buffered situation where mistakes or ill-advised peer-related behaviors may be identified, corrected, and retried so that the child can experience different consequences for peer-related behaviors. An additional area that is in need of further study is whether the peer intervention context can serve as a catalyst for the beginning of a friendship that may be maintained after the treatment has ended (e.g., Hoza, Mrug, Pelham, Greiner, & Gnagy, 2003).

A discussion of the mechanisms for change would also be remiss without an examination of potential mechanisms for negative change that may happen within the context of interventions for peer problems. Recent research has highlighted a potential for iatrogenic negative effects of peer interventions in group settings. Dishion et al. (Dishion, McCord, & Poulin, 1999) define this process as *deviancy training* – the shaping of negative behavior when in the company of other children who reinforce the negative behavior. In a study on conduct problem faced by youth, it was demonstrated that teens reinforced rule-breaking behavior and negative comments through their responses (e.g., laughing, smiling), and as Dishion et al. (1999) reported, the participation in group treatment resulted in more negative outcomes for treated youth (e.g., on measures of smoking during follow-up assessments).

These results spurred an immediate reaction in the professional community, and caused concern regarding the potential harm of group interventions for children. However, further research and analysis has suggested that the original conclusions need to be qualified. First, it is clear that in unstructured treatment settings with poor adult supervision or control, children will engage in considerable deviancy training (Onyango et al., 2003). Importantly, rates of deviancy training (and negative behaviors that can be reinforced through peer attention) decrease dramatically with the use of well-defined structure, rules, expectations, and consequences in the peer-treatment setting. Second, in a comprehensive review and meta-analysis, Weiss et al. (2005) examined the child-treatment literature and found that a child intervention with a peer component was actually *less likely* to have a negative effect size (i.e., a negative effect of

treatment). Thus, although deviancy training may occur, it is less likely to occur in situations where treatment facilitators implement contingency management and monitoring strategies, and across multiple studies on research synthesis, there was little indication that peer affiliation during group treatment was a procedure resulting in a negative outcome.

It is clear that like most mechanisms of treatment effects in child-based interventions, the precise mechanisms of treatment for peer problems (i.e., the mediators of treatment effects) are not well-defined. Certainly, additional work in this area is warranted.

15.5   Basic Competencies of the Clinician

A conceptualization of basic competencies for the clinician should begin in the early training stages for professionals. Given the prominence of peer relationships in development, prediction of long-term outcome, and as a marker of adaptive or impaired functioning, peer relationships are relatively under-represented in clinical and professional training programs. This may be partly due to the lack of a DSM category for peer relationships, as discussed earlier, as well as the heterogeneous nature of peer problems. Regardless, there should be an increased emphasis in training programs on evidence-based approaches to assessing and intervening peer problems. For example, it is now well-documented that child report may be a valid approach for assessing the presence of peer problems in some situations (e.g., whether a child is being bullied; feelings of social anxiety), but not for other situations (e.g., a child with ADHD's self report of friendship quality; Owens et al., 2007). An effective training program would review and evaluate assessment approaches specific to peer problems with regard to instruction related to basic principles of assessment. Furthermore, there is a growing literature of evidence-based interventions for children with peer problems. Training programs should educate future clinicians and professionals on how to implement these treatments that are backed by evidence. In addition, there appears to be no viable justification for the provision of practical experience or training in non-evidence-based approaches (e.g., individual counseling with a child). Thus, programs should actively and critically vet potential sites for students, and have procedures in place for the quality control of clinical training experiences, to ensure that training will be consistent with evidence-based approaches.

Basic competencies of a clinician during assessment activities should be grounded within the principles of functional and applied behavior analysis (e.g., Repp & Horner, 1999) as well as social learning theory. Assessments for peer-related competencies and deficits can start with a clinician clearly defining targeted behaviors to increase or decrease (e.g., teasing), obtaining information regarding the antecedents of the targeted behavior (e.g., being provoked or teased by a peer; the child feeling "left out"), as well as the consequences (e.g., obtaining peer attention, albeit for a negative behavior; reinforcement of a maladaptive peer-related behavior; development of a negative reputation with peers). Because of the complexity of peer-related interactions and the concurrent issues of the questionable veracity of child report in some cases, as well as the possibility of parental or teacher ignorance of the antecedents or consequences of some peer-related behaviors (e.g., Hinshaw & Melnick, 1995; Pepler & Craig, 1995), multiple methods and informants are needed to conduct an effective assessment.

Assessment of peer problems may also require assessment strategies that are different from the standard interview and checklists available for most childhood problems. For example, as was discussed in the assessment section earlier, sociometric measures that ask children in a

classroom to nominate their friends as well as children whom they dislike may be needed for a clinician to understand the topography of peer relationships in a group (see Bierman & Welsh for a review, 1997). Such measures may also be re-administered and can be sensitive to changes due to intervention. Drawbacks of this approach include the difficulty in obtaining consent from schools and non-treatment-related families to permit the collection of sociometric information. The difficulty may be worth negotiating, however, given the modest relationship between parent ratings and child self-report and peer ratings of social standing (especially from children with externalizing disorders; Hinshaw & Melnick, 1995).

Observations of child or adolescent behavior in peer-related situations may also be a required part of an assessment if a clinician is to completely understand the nature of antecedents and consequences of peer-related behaviors (Bierman & Welsh, 1997). Observations may be necessary due to the limitations of the child's self-report and adult report noted earlier. Non-obtrusive observations of child behavior may also be helpful for identifying targets of treatment or maintaining factors (e.g., school records of attendance, tardiness, and school nurse visits for a child with social phobia or who is being bullied; discipline referrals for aggression during recess periods).

One additional comment on assessment is that diagnosis or problem identification is but one among many purposes of assessment. Additional purposes include treatment planning, treatment and progress monitoring, and evaluating outcome (Mash & Hunsley, 2005). By using an applied behavioral analytic framework that identifies areas of competencies and strengths, the operational defines the behaviors in these domains and also works to crystallize the specific antecedents and consequences of each behavior should help to promote continuity across the different purposes of assessments related to peer problems. This approach should also help a clinician to focus on impaired areas of peer functioning, which are the socially valid and clinically meaningful targets of intervention (Fabiano & Pelham, 2009). Further, these areas of impaired functioning lend themselves to meaningful measures of progress monitoring. For instance, many children with impaired social behaviors in school receive special education services to facilitate the remediation of these deficits. Services are defined and target behaviors are operationalized in the child's Individualized Education Program (IEP). These targeted behaviors can be easily modified for use in a daily report card or school-home note, so that a child receives frequent feedback on behavior and importantly, the clinician has a consistent way to monitor progress and evaluate treatment effects. This approach is relatively easy to use (see http://ccf.buffalo.edu for instructions) and preliminary evidence suggests that it may be psychometrically sound (Fabiano, Vujnovic, Naylor, Pariseau, & Robins, 2009; Pelham, Fabiano, & Massetti, 2005). Of course, this approach can be used for a child without an IEP with school-based peer problems as well. Progress monitoring is important for school-wide interventions as well. A good example of this is the peer mediation paper by Cunningham et al. (1998) – follow-up observations of the implementation of the program revealed that one school experienced an increase in aggressive behavior. Upon closer review, it was determined that the school had reduced the number of mediators on the recess playground, resulting in a reduction in the effectiveness of the program. Clear procedures for monitoring progress should help to identify and provide the opportunity to remediate these types of situations.

The preceding discussion of a school-based, progress-monitoring measure of social behavior presumes another basic competency. That is, clinicians must be proficient in working with individuals in the child's natural environment. Progress monitoring, identification and

monitoring of targeted behaviors, intervention strategies, and generalization activities must all occur outside the clinic within the context of peer interactions. For this reason, a basic competency involves coordination of care across agents (e.g., parents, teachers, coaches, child care workers) in all settings where peer problems are observed. This presents a practical barrier for professionals accustomed to working in office settings directly with the child only, but it is notable that none of the evidence-based interventions reviewed earlier included solely clinical contact with the child in the clinic. All included some aspect of school intervention, parent training, or generalization activities in the peer group. Clinics working with children with peer problems must therefore engineer staff schedules and responsibilities to permit time for meeting with teachers at the child's school throughout the duration of assessment and treatment, and have staffing patterns that permit children and parents to receive treatment in parallel to reduce family burden related to treatment. This approach also supposes that a clinician is competent in child-focused, parent-focused, and family-focused evidence-based treatment approaches.

As is clear from the sampling of evidence-based interventions described earlier, clinicians must also be competent in their ability to manage a therapeutic group. For instance, clinicians must be adept at setting clear limits and boundaries during group activities. This would include explaining the concept and consequences of confidentiality for issues discussed in the group, the management of disruptive or off-task behaviors, and ensuring that all participants have an opportunity to contribute during discussions. Effective group facilitators during discussion or instruction activities are also effective in asking open-ended questions and in using reflective listening skills. It is also clearly apparent that a basic competency necessary for clinicians working on peer problems in groups is the ability to integrate intervention components into the context of recreational or other peer-related activities. This requires a clinician to maintain the ongoing activity at a level that is interesting and engaging, while also being sure that treatment ingredients specified in manuals, such as modeling, practice, and contingency management are implemented according to the treatment plan.

A final basic competency for all clinicians working to address peer problems relates to their being proficient in contingency management strategies. If it were as easy as simply telling a child that they should not tease, or should really join the group activity at school, or to just ask the school bully to stop bullying, most clinicians would be out of a job. Evidence-based interventions include contingencies for meeting treatment goals or expectations, as well as for missing treatment targets because children with peer problems are not successfully negotiating interactions within the context of naturally occurring contingencies or instructions. For instance, contingency management strategies may include the intensive, comprehensive STP token economy (Pelham, Fabiano, et al., 2005) or the more clinically based contingency management included in the parent management training component of the Coping Power program (Lochman et al., 2008).

15.6 Expert Competencies for the Clinician

As a clinician becomes proficient in basic competencies, skill development also shifts to a consideration of how one increases the depth, breadth, and complexity of clinical skills related to the treatment of peer problems in applied clinical work. Most of the expert competencies relate to enhancing the skills included in the basic competency section to meet additional treatment

needs or goals. Some of these competencies are reviewed, and examples of how these expert competencies might be used clinically are described.

One expert competency relates to developing supervision skills. The evidence-based treatments for child and adolescent peer-problems are well-manualized and contain multiple components. Notably, most of these components can be effectively implemented by para-professional providers without advanced degrees (i.e., college undergraduates, individuals with bachelor's degrees). In fact, it has been long known that there are few differences in treatment outcome owing to the degree of the professionals implementing the intervention (Kent & O'Leary, 1977). In contrast, what is important is the degree of integrity and fidelity incorporated into the treatment implementation (see expanded discussion later). Thus, as professionals master basic skills in treatment implementation for peer problems, and concurrently advance in the field, it is likely that part of their role will be the supervision of others conducting the interventions for peer problems (i.e., student trainees, interns, other professionals). Although there is a growing realization regarding the need for effective supervision (e.g., Neill, 2006), there is also currently substantial variability in the availability, quality, and frequency of supervision available to clinicians working with children who have problems in peer relationships. An expert competency therefore relates to being an effective supervisor. This involves not only using effective supervision skills, but also strategies. For example, research indicates that supervisors typically spent the least amount of time in activities that are the most effective for supervision (e.g., reviewing audio or videotapes; Ward, 1999). Most peer-problem interventions require multiple staff members (i.e., monitor of the child component, facilitator for the parent portion of treatment, etc.). Given the highly manualized and structured nature of the evidence-based peer-problem interventions reviewed, effective supervision that uses procedures known to be effective is needed.

In addition, expert application of evidence-based treatment is a skill that develops with experience and good supervision. Many excellent manualized programs that are evidence-based for peer problems were reviewed earlier. As a clinician masters the basic skills required to implement a manualized treatment, the focus shifts to expert competencies. This includes the ability to work fluidly within the prescribed treatment, while at the same time, applying the treatment procedures with clinical skill, integrity, and fidelity. As Kendall, Chu, Gifford, Hayes, and Nauta (1998) conceptualized, the manual provides a guide for the parameters of treatment, but it is up to the individual to tailor and individualize the treatment to be clinically meaningful for the client. Expert clinicians can use the strategies outlined in a manualized intervention protocol in an individualized manner, to be maximally effective for a referred client. Many treatment manuals provide explicit information on how to individualize treatment in this way, but it is up to the clinician to do this effectively.

An example of individualizing treatment within the context of a highly structured treatment program comes from the STP (Pelham, Fabiano, et al., 2005; Pelham, Greiner, & Gnagy, 1998). The standard program components include a token economy, individualized daily report card, time-out procedures, and additional contingency management strategies (e.g., contingent praise for appropriate peer-related behaviors). However, there are additional treatment components that can be added as needed. These include group contingency procedures wherein the consequences for an entire group are dependent on the behavior of a child or subset of children in the group, or the group as a whole (Litow & Pumroy, 1975). Group contingencies have been successfully employed in the STP to manage the peer attention directed toward negative behaviors. For instance, some children engage in "class clown"

behaviors during the classroom activities in the STP. These behaviors are disruptive, yet yield an incredible amount of reinforcing peer attention for a child. In these cases, the target child's behavior needs to be treated, but it is also necessary to treat the response of the group as a whole to the child's behavior. In these cases, the class can be informed that a group reward (extra free time; picking a piece of candy from a grab-bag) is made contingent on the target child meeting behavioral goals during the class period. In most cases, peer attention for the child's "clowning" behavior decreases immediately, effectively changing the positive consequence for the negative behavior. When the child meets the goal, it is also very effective to see he/she beam with delight as the class cheers and claps for the successful attainment of the reward. Group contingencies can also be applied to entire groups of children to reduce the occurrence of negative peer behaviors such as tattling, or even disruptive or aggressive behavior in schools (Fabiano et al., 2008; Hops & Walker, 1988).

A more specific expert competency for a clinician targeting peer problems is to work to engage fathers in treatment efforts. Fathers are considerably under-represented in intervention studies (Fabiano, 2007; Phares, 1996). However, fathers contribute to many aspects of their child's development, including the development of emotion regulation, social cognition, and focused attention, and probably because of these factors, appropriate peer relationships (Parke et al., 2002). Further, fathers are most likely to be interacting with or supervising a child during activities where peer interactions are likely to occur (e.g., play, outdoors time; Russell & Russell, 1987). Thus, when targeting the treatment of peer problems, fathers may be a critical agent to include in intervention efforts.

Clinicians can also work to focus evidence-based peer interventions on specific contexts or situations where peer problems are present. For instance, behavioral parent training and the intensive peer-focused STP are evidence-based ADHD treatments (Pelham & Fabiano, 2008). The Coaching Our Acting-Out Children: Heightening Essential Skills (COACHES) program combines these two interventions, and it is an approach intended to promote effective parenting by fathers *and* improved peer relationships for children with disruptive behavior disorders. The COACHES program is an 8-week behavioral parent-training program held for 2 hours each week that includes an evidence-based behavioral parent-training program for fathers (Cunningham, Bremner, & Secord, 1998) and STP soccer skill-building activities and game activities (Pelham, Fabiano, et al., 2005). The COACHES program was created based on the premise that, including a recreational, sports activity within the context of BPT for fathers would increase the palatability of the intervention for fathers as well as provide a forum for improving peer-related behaviors and athletic skills for children, and these two factors together were hypothesized to result in a synergistic treatment effect.

During the first hour, fathers review how to implement effective parenting strategies in a group setting (e.g., using praise, using time out). Concurrently, children practice soccer skill drills with para-professional counselors, to increase competencies in the sports domain (Hupp & Reitman, 1999; Pelham, Fabiano, et al., 2005; Pelham, Greiner, & Gnagy, 1998; Pelham & Hoza, 1996; Pelham et al., 1990). Then, during the second hour, the parent and child groups join together for a soccer game. The soccer game provides a context for the fathers to interact with their children and practice the parenting strategies taught in the classroom (e.g., praise, using effective commands), for the children to practice good social and soccer skills, and for clinicians to provide immediate feedback to the fathers (e.g., Pelham et al., 1998; Reitman, O'Callaghan, & Mitchell, 2005). After each quarter of the game, fathers meet with the COACHES group facilitator, and the group has a brief, 5-min meeting on the playing field.

During the meeting, the facilitator asks the parents to report on observations of the use of the weekly parenting strategy employed successfully during the game (either their own use or use by others), asks them to answer attributional questions similar to those described in the COPE program (Cunningham et al., 1998), and offers a chance for fathers to ask each other for advice on how to handle situations that arose during the game.

The COACHES program compares favorably with the standard parent-training program approaches, but offers some specific benefits. First, children were significantly more likely to drop out of treatment if they were in a typical social-skills group and did not experience father–child interactions in the context of the soccer game (Fabiano et al., 2009). As child and parent satisfaction with treatment are important predictors of persistence with treatment (Kazdin, Holland, & Crowley, 1997), this is an important outcome. Fathers are also highly satisfied with the program, and anecdotally report on treatment evaluation ratings that the COACHES program was the first successful community activity they participated in with their child. This suggests that participation in a highly structured and supported recreational activity with other children and the father may be a good beginning approach to working on improving children's peer problems. Similar approaches of combining evidence-based approaches for a problematic behavior have also yielded promising results (e.g., parent training, teacher training, and a peer-intervention; Webster-Stratton et al., 2001).

Expert clinicians will not only be adept at working with an individual family or groups of children, but will also be able to consult effectively to enact change in systems. Peer relationships, and potential problems, typically occur within the context of a system such as a school, neighborhood, or a recreational activity. In some cases, to effectively change problems in peer relationships, the entire system will have to change. Cunningham et al. (1998) emphasize on the importance of a school-wide embracement of the peer-mediation program that includes endorsement by all individuals in the school from administration to teachers to students, school assemblies to emphasize and kick-off the program, and clear support for the mediators from teachers and other school personnel. The Positive Behavioral Intervention and Support approach (e.g., Sugai & Horner, 2008) as well as anti-bullying programs (e.g., Olweus, 1993; Ross et al., 2008) also require consulting with schools to ensure that a whole-school approach is implemented. Thus, clinicians must be able to successfully attain the support of school personnel across levels of a district (i.e., superintendent, principals, teachers, parents, students), often requiring the time, persistence, and ingenuity to negotiate bureaucratic red tape, a knowledge of the history of past programs targeting social development that failed to maintain, and the need to fit an intervention into existing district priorities. Truly partnering with consumers of interventions is therefore necessary, and an ability to listen and integrate consumer-provided feedback or needs into the framework of an evidence-based intervention is an essential component of effective consulting (see Leff, Costigan, & Power, 2004 for a practical example of this approach for targeting peer-related behaviors on a school playground). Clearly, this is not a simple task, and it is one that will require expert experience as well as adherence to the principles of evidence-based treatment, which can be diverted or can experience drift if not continually monitored (e.g., Gottfredson & Gottfredson, 1998).

A final expert competency worthy of discussion relates to the need to maintain treatment as long as is needed. It is notable that most of the evidence-based treatments discussed are not brief interventions. This makes sense when one considers the complexity of peer interactions – children with peer problems have had possibly years of practice with poor interaction skills,

and it is reasonable to presume they may need just as long to master new skills that are adaptive. This may require clinicians to utilize strategies to maintain motivation and engagement over time. For instance, motivational interviewing strategies (Miller & Rollnick, 2002) may be useful for adolescents with peer problems related to affiliating with negative peers or engaging in behaviors where they do not see the benefits of changing (e.g., using alcohol; Monti et al., 1999). Clinicians should also be cognizant of critical periods throughout development where peer interventions may be particularly important. The Incredible Years Dina Dinosaur program is a good example of an intervention that facilitates the transition to interacting with others in a structured school setting, and the Coping Power program targets the transition to middle school. In addition to maintaining treatment as long as is necessary, experienced clinicians will also build-in expectations for families that peer interventions may need to increase in intensity during critical periods of development.

15.7   Transition from Basic Competence to Expert Competence

Because of the multiple strategies that can be used for treating peer relationships, it is best to think of the development of clinical skills along a continuum of expertise. A conceptualization of skills in this way leads to a discussion of how a clinician may transition from fundamental skills or strategies to more advanced approaches to working with children with peer problems. Strategies that facilitate a therapist's increasing competence will be discussed in the following paragraph.

One straightforward way to obtain increased levels of skill in the area of treating peer problems is through participation in trainings and continuing education opportunities that include instruction on how to implement evidence-based strategies. Professional associations, such as the American Psychological Association, Division 53 Society of Clinical Child and Adolescent Psychology (http://www.clinicalchildpsychology.org), offer conferences aimed toward clinicians which provide expert instruction on evidence-based treatments, including those mentioned in this paper. Similar offerings are conducted by the National Association for School Psychologists (http://nasponline.org) as well as the developers of the interventions reviewed in this paper. These trainings are excellent starting points for learning about effective strategies and making contacts with program developers. It is important to point out that attendance at a single conference or training, however, is unlikely to substantially modify a clinician's practice. Therefore, to truly move from basic to expert competence, it is likely that a clinician will need to view these trainings as an ongoing professional development enterprise. Further, trainings may need to be supplemented by on-site training or supervision on a regular basis to ensure successful implementation of procedures, and integrity and fidelity to intervention components.

Related to training is the issue of treatment adherence, integrity, and fidelity. According to Waltz, Addis, Koerner, and Jacobson (1993), the terms *adherence* and *competence* distinguish between degree of implementation by the treatment agent and the care in which the agent implemented the intervention. As such, *adherence* is referred to as "the extent to which a therapist used interventions and approaches prescribed by the treatment manual" (Waltz et al., 1993, p. 620). *Competence* is referred to as the "level of skill shown by the therapist in delivering the treatment" (Waltz et al., p. 620). Considering the distinction between adherence and competence is especially important when an intervention is implemented by a secondary treatment

agent, such as a para-professional or teacher. For clarity in the current discussion, *adherence* is considered as the degree to which the parent/teacher implements the intervention as intended, while *competence* is considered as the care and skill shown by the parent/teacher in delivering the treatment. Hereafter, the term *treatment integrity* refers to the combination of the essential components, adherence and competence.

Gresham (1989) identified several factors related to treatment integrity. They include: (1) the complexity of the treatment, (2) time required to implement the intervention, (3) resources required for treatment implementation, (4) number of treatment agents required, (5) perceived and actual effectiveness of the intervention, and (6) motivation of the treatment agents. The degree of treatment integrity has been directly related to the complexity of treatment, such that greater complexity results in lower treatment integrity (Yeaton & Sechrest, 1981). For instance, treatments considered more complex usually required more time to implement and resulted in lower integrity, with lack of time being the most cited reason for failure to implement an intervention (Gresham, 1989). Lower levels of treatment integrity were found amongst treatments that required additional materials or resources, beyond what was found in a typical classroom or clinic. Treatments requiring more than one treatment agent were likely to have greater complexity, and were often implemented with less integrity. Treatments perceived to be more effective were implemented with greater integrity than those lacking perceived effectiveness.

Notably, these contributors to lowered treatment integrity (e.g., complexity, intensity, etc.) noted by Gresham (1989) are typical of evidence-based peer interventions. Therefore, clinicians need to have procedures for ensuring treatment integrity and fidelity built-in to intervention efforts as a standard part of the intervention. This may make interventions more costly because they become more staff- and time-intensive, yet, if that is what is necessary to promote effective intervention, the additional cost is warranted. As clinicians transition from basic competencies, where they are likely being evaluated for the integrity of the interventions they implement, to expert competencies, it is probable that they will begin to be in the position to evaluate the integrity of others' interventions aimed at reducing problems in peer relationships.

Perhaps, the clearest distinction between novice and expert clinicians relates to the *fidelity* of the intervention. Fidelity relates to the genuineness, interpersonal style, and ability to form a therapeutic alliance with a client and family. This is much harder to do if a clinician is preoccupied with implementing the "nuts and bolts" of an intervention correctly. Only after the basic strategies of an intervention are mastered can a clinician focus carefully on the fidelity of the intervention. Importantly, it does not appear that the opposite direction of focus makes clinical sense – a clinician who is warm, genuine, and has a strong therapeutic alliance, but does not implement treatment procedures that work, would not be helping the child and family, even if the therapy experience was pleasant for both parties. Therefore, after careful training and experience with an intervention, the clinician should maintain focus on the integrity of the treatment while also expanding focus to their interactional style and engagement strategies.

An additional consideration in the transition from novice to expert relates to the ability to construct idiographic treatment plans that are relevant to the child and family. For instance, an expert clinician would use initial assessment information to gather data on the antecedents, consequences, and setting events of peer problems, use this information to define treatment targets, and tailor the initial intervention to these targets. Expert clinicians would also institute relevant progress-monitoring measures (i.e., daily report card, peer sociometrics) that can be administered throughout the duration of treatment to inform data-based decision-making.

Finally, an expert clinician would coordinate care across agents of change in the home, school, and community settings to ensure a comprehensive approach. With experience, good supervision, adherence to protocols, and integrating consumer feedback into future interventions, clinicians should be successful at refining their clinical approach for treating peer-related behaviors.

15.8   Summary

In this chapter, we have outlined the impact of peer problems across a host of functional domains, described the symptoms and impairments related to peer problems, and provided a brief overview of the assessment methods supported by research. In addition, potential maintenance factors related to peer problems were discussed. Fortunately, given the considerable impairment experienced by children with peer problems in the short and long term, there are evidence-based interventions available for clinicians to implement. Notably, these are often intensive and complicated treatments that need to be implemented with good integrity and fidelity to be effective. Clinicians must work to develop clinical skills that are effective for remediating peer problems.

Establishing positive peer relationships may be one of the most critical developmental milestones for children and adolescents (Parker et al., 2006). Importantly, problems in peer relationships are not circumscribed to a handful of child DSM diagnostic categories, but rather span categories, and may even constitute a referral for treatment as a stand-alone problem. Therefore, clinical skills related to the assessment and treatment of peer problems are needed for all clinicians working with children and families. As outlined in this chapter, the stakes are high for children experiencing problems in peer relationships, and these children cannot afford to participate in interventions that do not work. An approach that integrates evidence-based interventions, consistently over time, in all settings where impairment is present, is what is needed to make a real difference for affected youth and those around them.

16 Somatoform Disorders and Chronic Pain

Amanda A. Drews · Brenda Bursch

Abstract: Children and adolescents commonly experience physical symptoms that are not readily explained by identifiable medical illness or tissue pathology. Such symptoms can be transient and benign, or they can be persistent, severe, and disabling. Whether or not the symptoms are explained by a medical problem, some children have great difficulty coping with them. Among children that appear more distressed or disabled by physical symptoms than expected, a diagnosis of Somatoform Disorder can be made. There are presently seven identified Somatoform Disorders that can be applied to children, despite the lack of empirical data regarding the appropriateness of such diagnoses in this age group. A large and growing literature on pediatric chronic pain has informed the conceptualization, assessment, and treatment of childhood somatoform disorders. Most clear regarding the current understanding of chronic somatic symptoms is their multifaceted etiological nature and the necessity of interventions to address biological, psychological, and social precipitating and maintaining factors. Important areas of assessment include the nature of the physical symptoms themselves, including their location, duration, quality, variability, and intensity; the social, emotional, physical, cognitive, and academic functioning of the symptomatic child; and, family factors such as parenting style, response to child symptoms, and psychopathology. Frequently employed treatment strategies include medications, individual and/or family cognitive behavioral interventions, and body-based therapies. Ideally, these assessment and treatment methodologies are collaboratively implemented within a biopsychosocial framework by medical and psychological professionals who are familiar with the related research evidence base.

16.1 Overview

Children and adolescents often experience physical symptoms that are not readily explained by identifiable medical illness or tissue pathology (Eminson, 2007). Such symptoms can be transient and benign, or they can be persistent, severe, and disabling. Irrespective of whether or not the symptoms are explained by a medical problem, some children have great difficulty coping with them.

Individuals described by the DSM-IV as having a somatoform disorder are more distressed or disabled than would be expected by one or more physical symptoms or by the misperception of a serious medical problem or deformity. Symptoms are not explained by a known medical disorder and are not intentionally produced. As with many other psychiatric diagnoses, criteria for somatoform disorders were developed for adults, and the bulk of the research has been conducted with this age group. Thus, diagnoses are applied to children without child-specific criteria. There are seven somatoform disorders in DSM-IV: Somatization Disorder, onversion Disorder, Pain Disorder, Hypochondriasis, Body Dysmorphic Disorder, Undifferentiated Somatoform Disorder, and Somatoform Disorder Not Otherwise Specified (NOS). These were

not revised in the DSM-IV-TR. Reclassification of diagnoses reflecting somatic symptom presentations based on developmental stage was attempted in the DSM-PC (Diagnostic and Statistical Manual for Primary Care; Wolraich, Felice, & Drotar, 1996). Working groups are currently in progress for publication of DSM-V, with the expectation that revisions to the somatoform disorder criteria will be made. For the purposes of this chapter, we will use DSM-IV criteria. Additionally, the larger literature on pediatric chronic pain, which has greatly informed conceptualization, evaluation, and treatment of somatoform disorders, is also included in this chapter.

Criteria for *Somatization Disorder* includes several years of physical complaints with at least four pain symptoms, two gastrointestinal symptoms, one sexual symptom, one pseudoneurological symptom, and associated treatment-seeking or disability. Although research in pediatric community samples demonstrates that children and adolescents commonly experience multiple somatic symptoms (Aro, Paronen, & Aro, 1987; Zuckerman, Stevenson, & Bailey, 1987), the formal diagnosis of Somatization Disorder in youth is rare owing to the requirements for manifestation of one sexual symptom and several years of symptom-related disability (Bisht, Sankhyan, Kaushal, Sharma, & Grover, 2008; Lieb, Pfister, Mastaler, & Wittchen, 2000).

Along with excessive distress or functional impairment, criteria for a *Conversion Disorder* includes one or more unexplained neurological symptoms or deficits affecting voluntary motor or sensory function suggesting a neurological condition. Additionally, psychological factors, conflicts, or stressors must be temporally associated with the symptom onset or exacerbation. The subtypes include Motor Symptom or Deficit, Sensory Symptom or Deficit, Seizures or Convulsions, and Mixed Presentation. Lieb et al. (2000), who studied adolescents and young adults, found a lifetime conversion disorder prevalence of 0.4% and a 12-month prevalence of 0.2%. Some pediatric research has been conducted on this topic, identifying symptoms such as non-epileptic seizures, paresis, paresthesia, ataxia, and gait disturbances (Bisht et al., 2008; Grattan-Smith, Fairley, & Procopis, 1988; Leslie, 1988; Plioplys et al., 2007; Spierings, Poels, Sijben, Gabreëls, & Renier, 1990; Thomson & Sills, 1988).

Although psychological factors influence all types of pain, there is a growing literature on pediatric *chronic pain* that has significantly influenced the conceptualization of child somatization overall. This literature also serves as an empirical base that informs the assessment and treatment of both pediatric chronic pain and somatoform disorders. Chronic pain is any type of persistent pain, with or without the presence of associated tissue pathology or inflammation. Some children can function well with chronic pain and others become highly distressed or disabled by it. Examples of chronic pain include burns, cancer, fibromyalgia, headache, juvenile rheumatoid arthritis, myofascial and temporomandibular joint pain, neuropathic pain, phantom pain, complex regional pain syndrome, sickle-cell pain, and visceral pain (American Pain Society, 2001).

Headache and abdominal pain are the most frequently reported types of childhood chronic pain. Population-based studies suggest that recurrent abdominal pain (RAP) is experienced by 10–15% of school-age children (Apley, 1975; Apley & Naish 1958) and about 20% of middle school and high school students (Hyams, Burke, Davis, Rzepski, & Andrulonis, 1996). Among those who report abdominal pain, irritable bowel syndrome (IBS) symptoms are experienced by 8% of the middle school students and 17% of high school students (Hyams et al., 1996). Headaches become more prevalent over the course of childhood, increasing from 8.3% in children 7–10 years old and to 17–20% in those 10–18 years old (Groholt, Stigum, Nordhagen,

& Köhler, 2003). Chronic pain symptoms increase significantly in those with chronic medical conditions. For example, 40–86% of children with arthritis report chronic pain (Lovell & Walco, 1989; Petty et al., 2004; Schanberg, Keefe, Lefebvre, Kredich, & Gil, 1998; Sherry, Wallace, Kelley, Kidder, & Sapp, 1999).

Among a smaller group of children, somatoform *Pain Disorder* is diagnosed when the predominant symptom is unexplained pain that causes distress or impairment and for which "psychological factors are judged to have played a significant role in the onset, severity, exacerbation, or maintenance of the pain." The subtypes include Psychological Factors and both Psychological Factors and a General Medical Condition. The disorder is designated as "acute" if it is present for less than 6 months and "chronic" if persists longer. Lieb et al. (2000) found a lifetime prevalence of 1.7% and a 12-month prevalence of 1.3% for childhood pain disorder.

Hypochondriasis does not require the presence of an unexplained symptom. Rather, it includes 6 months of significant distress or impairment owing to the misinterpretation of bodily symptoms that leads to a preoccupation with unwarranted fears of having a serious disease. Medical evaluations and reassurance do not reduce anxiety. However, excluded are those who meet the criteria for Delusional Disorder, Body Dysmorphic Disorder, or another explanatory anxiety disorder. A qualifier, "with poor insight," is used if the individual does not recognize that his or her health anxiety is excessive or unreasonable. Very little is known about the occurrence of hypochondriasis in children and adolescents. "Hypochondriasis by proxy" may be more likely in pediatric settings, especially among younger children, as parents are almost exclusively involved in appraising their children's physical symptoms and accessing medical care.

Anxiety sensitivity, the tendency to view physical sensations as dangerous, is a related construct that has been recently studied in children. Anxiety sensitivity has been found in adults to be associated with anxiety disorders (Taylor, 1999) and chronic pain (Asmundson, Norton, & Veloso, 1999). Tsao, Meldrum, Kim, and Zeltzer (2007) found that anxiety sensitivity, anxiety symptoms, and anticipatory anxiety, together explained for 62% of the variance in pain intensity reported by children.

Body Dysmorphic Disorder (BDD) is similar to hypochondriasis, in that it does not require the presence of an unexplained symptom. It is defined as the excessive concern and preoccupation with a real or imagined defect in the body appearance, not better explained by an eating disorder, psychotic disorder, or other psychiatric diagnosis. One study identified the mean age of onset for BDD as 16 years, with a range of 4–43 years (Phillips & Diaz, 1997). The community prevalence of BDD in an adolescent community sample was 2.3%, with skin concerns being the most common (Mayville, Katz, Gipson, & Cabral, 1999).

Undifferentiated Somatoform Disorder diagnosis requires 6 months of distress or unexpected functional impairment, along with one or more unexplained physical complaints that do not better fit in the criteria for another somatoform (or other DSM) disorder. Furthermore, *Somatoform Disorder Not Otherwise Specified (NOS)* includes other somatoform disorders that do not meet the criteria for one of the specific disorders.

16.2 Recognition of Symptoms and Their Assessment

Owing to their physical nature, somatic symptoms and concerns in children are typically initially assessed by a pediatric medical provider. If these evaluations do not account for the

entirety or intensity of a child's symptoms and/or the findings do not adequately assuage child and/or parental concerns, then the role of a pediatric psychologist in comprehensively evaluating the symptom picture becomes valuable.

For the assessment and treatment recommendations to make sense, it is often necessary to provide education before, during, and/or after the assessment related to the biopsychosocial model. An introduction to this model will initiate the families' understanding of physical symptoms as the product of a complex interaction of biological, psychological, and social factors. Campo and Fritz (2001) offered the following general guidelines for assessing childhood somatic symptoms: (1) acknowledge the patient's and family members' suffering, (2) explore previous experiences with health care practitioners, (3) investigate fears related to the symptoms, (4) communicate a willingness to suggest further medical assessment if indicated, and avoid excessive tests and procedures if unnecessary, (5) avoid diagnosis by exclusion, and (6) explore the symptom timing, characteristics, and context.

Many patients and families will appreciate discussion about the distressing physical symptoms prior to being questioned about a psychosocial nature. In doing so, it is important to obtain the perspective of the child, parents, and other pertinent family members, who are present for the evaluation, including siblings. A thoughtful discussion of the symptoms and previous medical evaluations may highlight the need for further medical evaluation and reassure the patient and family that their symptom concerns are well understood.

It is important to assess alexithymia before asking questions related to emotional functioning (De Gucht & Heiser, 2003). Most children are capable of assessing their ability to readily identify and express their emotions. Those without this ability, on the other hand, may describe that when something distressing occurs, their emotions get confused with one another, they simply feel overwhelmed, or they do not have an emotional reaction at all. Such children may have an easier time identifying the physical symptoms of depression, anxiety, or other feeling states than the affective or cognitive aspects of them.

In addition to gaining an understanding of the specific nature of the somatic symptoms, an evaluation of the psychosocial factors assumed to be triggering, exacerbating, reinforcing, and/or maintaining the symptoms should also be conducted. Other possible contributing co-morbid problems to be assessed include: anxiety, depression, sleep disturbance, known or unsuspected learning disorders (even in high achieving children), poor coping skills, a vulnerable temperament, cognitive, developmental or communication disorders, social problems, physical or emotional trauma, family illness, and/or prominent family distress (Bursch, Ingman, Vitti, Hyman, & Zeltzer, 2004; Bursch & Zeltzer, 2002; Campo, Comer, Jansen-McWilliams, Gardner, & Kelleher, 2002; Campo, Jansen-McWilliams, Comer, & Kelleher, 1999; Egger, Angold, & Costello,1998; Eminson, 2007; Fritz, Fritsch, & Hagino, 1997; Garber, Zeman, & Walker, 1990; Hodges, Kline, Barbero, & Flanery, 1985; Hodges, Kline, Barbero, & Woodruff, 1985; Hyman et al., 2002; Lester, Stein, & Bursch, 2003; Livingston, 1993; Livingston, Witt, & Smith, 1995; Salpekar et al., 2008; Schanberg et al., 1998; Stuart & Noyes, 1999; Zuckerman et al., 1987). ◗ Table 16.1 presents a list of clinical assessment topics.

Among those children who are not attending school, psychoeducational testing may be needed to identify problems that are difficult to assess through interview alone. Such testing should be considered if the child is academically behind, has peer problems including poor social problem-solving skills, or has high overall achievement with a pronounced difficulty in a particular area. Children in this latter group may be working extremely hard to maintain high (or perfect) grades, in spite of an unsuspected learning disorder.

In cases of non-epileptic seizures (NES), stereotypic motor presentations often differ considerably from true motor seizures, but can be difficult to differentiate when relying exclusively on the history or routine electroencephalography (EEG) data. Video EEG can be used in the hospital to evaluate confirmed episodes (Cohen, Howard, & Bongar, 1992; Duchowny, Resnick, Deray, & Alvarez, 1988), and "postictal" elevations in serum prolactin levels can be measured 10–20 min after a suspected event (Chen, So, & Fisher, 2005; Fisher, Chan, Bare, & Lesser, 1991). Pediatric psychologists are sometimes called upon to aid in the video EEG evaluation, because

◘ **Table 16.1**

Clinical assessment topics

Current Symptoms • Location, quality, intensity, duration, variability, predictability, and types of symptoms under differing circumstances • Exacerbating and alleviating factors • Other associated sensations/symptoms • Past evaluations, treatment attempts, home remedies, alternative/complementary therapies • Ability to self-management symptoms • Response to symptoms • Impact of symptoms on daily life, including school, social activities, eating, sleep (onset and maintenance), and, in BDD, checking or grooming behavior **Beliefs about the symptoms** • Etiology • What will and will not help • Dangerousness • Prognosis **Physical functioning** • Basic functioning: walking and eating • Change in participation in P.E., sports, exercise, social outings, school, chores, homework, ADLs, driving **Social functioning** • Changes in social functioning • Satisfaction with social life • Contact with and types of friends • Types of activities with friends **Cognitive/developmental functioning** • Tendency to approach or avoid a problem or challenge • Few friends or "friends with everyone" • Impaired social behaviors • Unusual interests, worries, habits or hobbies	• Early developmental delays • Sensory hyper- or hypo-sensitivities **Emotional functioning** • Alexithymia • Cognitive vs. somatic symptoms of anxiety • Worry, nervousness, fears, general anxiety, perfectionism, test anxiety, panic, excessive concerns about safety, separation, germs, competence, health, symptoms, routines/rituals, and/or symmetry; tendency to catastrophize • Trauma (including prematurity and medical procedures), grief, changes • Depression, suicidality **Family factors** • Parental coping, anxiety, depression • Parental illness, pain, or disability • Parental understanding of pain • Marital distress, problems in co-parenting, substance abuse, domestic violence • Discipline styles of parents • Problems with siblings or others at home **Medical history** • Time spent in NICU, procedures, injuries, trauma, other illnesses, sensory overload, opioid use, other medication use **Co-morbid symptoms** • Sensory sensitivity • Sleep disturbance, fatigue • Nausea, decreased appetite, fear of eating, conditioned aversions, vomiting • Panic symptoms (with/without panic): heart pounding, sweating, shaking, SOB, choking, lump in throat, chest pain, nausea, dizziness, numbness/tingling, chills/hot flashes

(continued)

● Table 16.1 **(Continued)**

Symptom consequences	Perceived stressors
• Argue with parents or teachers about school, stay home from school, or switch to home schooling • Parent stays home from work, quits working, or does not return to work • Parents get along better or argue more • Child exempt from chores or homework • Parent more sympathetic to child or more upset with child	• School • Peers • Parents • Other relatives • Siblings • Living arrangements • Health • Extra-curricular activities
Academic functioning	**Major life events**
• Perfectionism and/or near perfect grades • Heavy workload and/or advanced classes • Learning disorders or subjects that are more challenging or aversive to the child • Problems with handwriting, homework, tests • Changes in school or classroom • Bullies, relational aggression, isolation • Problems with teachers • Problems with athletic ability	• Starting new school • Move to new house • Parent remarried • Birth of sibling • Learning to drive • Menstruation • Important birthday • Death and/or illness of family member • Death of a pet

motor NES can sometimes be triggered with verbal encouragement or hypnosis techniques (Martínez-Taboas, 2002; Zalsman, Dror, & Gadoth, 2002). Visualization of a typical event is paired with suggestion that such an event will occur. Parents are asked to confirm whether the induced event appears to be representative of the child's typical events. Contraindications of this technique include patient or a family opposition, psychotic symptoms, or a history of sexual or physical abuse (Olness & Kohen, 1996).

Those with BDD often spend a substantial amount of their time engaging in behaviors related to the imaged defect. Assessment of suspected BDD should include queries regarding frequent or unusual means of checking on the defect, grooming behavior, efforts to disguise the defect, avoidance behaviors, social comparisons, and wishes for cosmetic surgeries.

Identification of specific symptoms, their typical precipitants and reinforcers, psychosocial stressors, and co-morbidities allow for feedback that makes sense to the child and parents, particularly, when subsequent treatment recommendations are closely linked to assessment findings. For example, a homebound child with tension headaches, perfectionistic traits, and a bully at school may be anxious about maintaining his straight As and avoiding his aggressor. The effort required for him to maintain his grades might be excessive owing to an unrecognized math disorder. His parents, who feared he might have a brain tumor, may have inadvertently exacerbated his anxiety and muscle tension. This type of comprehensive evaluation provides multiple targets for intervention to improve the functioning of the child and potentially decrease headaches.

16.3   Maintenance Factors of the Disorder or Problem

Consistent with the idea that somatoform and chronic pain symptoms result from a complex interaction of biological, psychological, and social factors, is the notion that symptoms are

maintained by these same factors. At the risk of creating artificial boundaries between these factors, the following will review the biological, psychological, and social factors implicated in the perpetuation of chronic somatic symptoms in children. A biological tendency toward heightened responses to stimuli or chronically elevated levels of stress hormones, for example, have become central to the understanding of what puts children biologically at the risk for ongoing and debilitating somatic symptoms. Psychological factors, such as attention, attributions and beliefs, and coping style will also be reviewed. And finally, as children and adolescents with chronic somatic complaints are situated within a social context – within families, classrooms, and peer groups – it is important to understand the role the social environment might play in the persistence of disability among these youngsters.

16.3.1 Biological Factors

Increasingly, biological mechanisms other than structural pathology are being explored as potentially important factors in the maintenance of chronic somatic symptoms. Sensitization, the tendency to have a heightened response to stimuli because of prior experience of them (Deary, Chalder, & Sharpe, 2007), is one such mechanism. Children who have endured early exposures to pain or other physical insults may experience a reduced threshold for subsequent future noxious physical stimulation, and thus, exhibit heightened physiological and behavioral responses. Somatic hypervigilance and/or the effects of anxiety, depression, or stress, may tax the already-sensitized pathways, lowering the threshold for stimulation even further (Rygh et al., 2005).

The down regulation of the hypothalamic-pituitary-adrenal (HPA) axis in the context of chronic stress and illness is yet another biological factor implicated in the maintenance of somatic symptoms (Deary et al., 2007). The HPA axis controls the body's hormonal response to acute and chronic stress. Under chronically stressful circumstances, the cortisol production has been found to slow, leading to pain, fatigue, and stress sensitivity. These, in turn, are thought to precipitate the "illness response" characterized by lethargy and behavioral avoidance (Fries, Hesse, Hellhammer, & Hellhammer, 2005). Supporting this conceptualization of the role of the HPA axis in the maintenance of somatic symptoms are findings that low levels of cortisol are found in patients with chronic somatic symptoms (Griep, Boersman, Lentjes, Prins van der Korst, & de Kloet, 1998; Roberts, Wessely, Chalder, Papadopoulus, & Cleare, 2004). The automatic biological tendency to "over respond" to physical stressors owing to sensitization combined with the down regulation of the HPA axis represents the seemingly viable mechanisms in the maintenance of somatic symptoms and their associated impairment.

16.3.2 Psychological Factors

Attention. The overwhelming majority of the ongoing physical sensations experienced by the body are processed outside the conscious awareness. However, for those with chronic somatic complaints, the physical sensations are recognized and attended to with more facility than by individuals without these complaints. Considerable work has been carried out in this area (e.g., Brown, 2004; Rief & Barsky, 2005; Ursin, 2005) and researchers have generally concluded that orienting toward a sensation or symptom heightens the perception of it, while not attending to it decreases its salience. Such attentional processes work closely with the

aforementioned process of sensitization. Among those with somatoform disorders and chronic pain, somatic symptoms are generally perceived as aversive, to-be-feared stimuli. Selective attention is therefore directed to the symptoms and the negative thoughts and feelings associated with them. Thus, a cognitive bias for symptoms develops and further sensitizes "the neural loops supporting the cognitive rumination…[P]ain and illness lead to more pain and illness" (Ursin, 2005, p. 1063).

Attributions and beliefs. Attribution is also closely related to the psychological processes of sensitization and attention. Individuals who perceive themselves as more vulnerable, or a symptom as more threatening, are more likely to pay attention to the symptom (Deary et al., 2007). Beliefs about the severity of one's condition, its dangerousness, and the likelihood of amelioration have also been linked to the maintenance of chronic somatic symptoms. Konijnenberg et al. (2005) examined the health beliefs of 149 children who presented medically unexplained pain. Children's beliefs that their health is poor and likely to get worse were independently predictive of having significant impairment in multiple domains of functioning, including activity, school, social, and sleep. In a similar study, an exaggerated and fearful appraisal of pain and its consequences significantly predicted pain severity, somatic complaints, and pain-related disability in school-age children with and without pain complaints (Vervoort, Goubert, Eccleston, Bijttebier, & Crombez, 2006).

Coping style. The manner in which a child or adolescent copes with the physical and emotional aspects of having a somatoform disorder or chronic pain has been linked to the chronicity and impact of the symptoms. Walker, Smith, Garber, and Claar (2005) examined children's reports of coping with RAP symptoms. They reported that passive coping (i.e., a tendency toward neither changing nor adapting to the immediate situation) was strongly associated with increased levels of somatic and depressive symptoms. Accommodative coping responses (i.e., attempts to adapt to the immediate situation) were related to decreased levels of pain, and active coping responses (i.e., attempts to change the immediate situation) were related to increased physical and decreased depressive symptoms. These findings were extended in the study by Walker, Smith, Garber, and Claar (2007) where children with abdominal pain, when compared with the normal children, were determined to be less confident of their ability to change or adapt to stress and were less likely to use accommodative coping strategies. The tendency to avoid using accommodative coping strategies was significantly related to somatic symptoms and functional disability. Similarly, Rocha and Prkachin (2007) demonstrated, in a community sample of children, that the tendency to exhibit less adaptable behavior was related to children's reports of somatization and maternal reports of health care utilization and psychosocial health status.

16.3.3 Social Factors

Parents' own physical and mental health complaints are associated with greater levels of pain and other physical symptoms reported in their children (e.g., Blount, Morris, Cheng, Campbell, & Brown, 2004; Craig, Boardman, Mills, Daly-Jones, & Drake, 1993; Craig, Cox, & Klein, 2002; Hotopf, 2002; Walker, Garber, & Greene, 1994; Walker & Greene, 1989). Hotopf (2003) hypothesized that childhood experience of parental illness could be a risk factor for the development of medically unexplained symptoms owing to vicariously learned illness behavior. Examining this hypothesis, Marshall, Jones, Ramchandani, Stein, and Bass (2007) compared the health

beliefs in children of parents with a diagnosed somatoform disorders and a control group comprising children of parents with an identified physical illness. The children in the former group scored higher on bodily preoccupations and disease phobia when compared with those in the control condition. Perhaps, the most interesting observation was that the pattern of the differences between the two child groups reflected the self-reported differences in health beliefs of the parents in each group.

There is also growing evidence that parents of children with chronic somatic complaints respond to symptoms with increased attention and special privileges (Muris & Meesters, 2004; Walker, Garber, & Greene, 1993; Walker & Zeman, 1992), and that these parental behaviors are linked to the ongoing child somatization (Muris & Meesters, 2004; Walker et al., 2006). Walker, Claar, and Garber (2002) evaluated the role of social consequences (i.e., positive attention, negative attention, activity restriction, and privileges) on the maintenance of children's abdominal pain symptoms. Both positive attention and activity restriction predicted symptom maintenance, but the effect was moderated by children's perceived self-worth and academic competence. That is, if the children positively rated their self-worth and academic competence, the impact of parental attention and activity restriction on RAP-symptom maintenance was lessened. In 2006, Walker et al. evaluated the impact of parent attention and distraction behaviors on symptom complaints by children with and without chronic functional abdominal pain undergoing a pain-producing lab task. The symptom complaints by all the children nearly doubled in the "attention" condition and were reduced by half in the "distraction" condition. Girls with functional abdominal pain were especially vulnerable to parental attention behaviors. Interestingly, children reported that they felt better when their parents used distraction and worse when they used attention behaviors to help them cope. Parent behavior has been found to account for up to 55% of variance in child distress behavior (Frank, Blount, Smith, Manimala, & Martin, 1995). These findings point to the critical importance of educating parents about the effective responses to children's symptoms, as well as directly targeting the affected child's coping repertoire as part of a comprehensive intervention.

16.4 Evidence-Based Treatment Approaches and Their Mechanisms of Change

Ideally, interventions for childhood somatoform disorders and chronic pain are derived from a biopsychosocial model and are collaboratively implemented by medical and psychological professionals. Regardless of the diagnosis, taking a family's fears and beliefs seriously, offering an explanation of how both biological and psychosocial factors are involved in the expression of pain and other somatic symptoms, and adopting a rehabilitative approach to treatment are crucial (Eminson, 2007).

Despite the fact that chronic somatic symptoms are commonly brought to the attention of child and adolescent healthcare providers, there is a dearth of clinical treatment trials for somatoform disorders. The emerging empirical literature on the treatment of childhood chronic pain is comparably vast and thought to be applicable to many of the somatoform disorders. What follows is a brief review of the psychological/behavioral, physical/body-based, and medication treatments and their associated mechanisms of action that have been evaluated for use in children with various and persistent somatic symptoms.

16.5 Psychological/Behavioral Treatments and Their Mechanisms of Change

Psychological and behavioral interventions have a direct effect on a child's symptoms and promote children's sense of self-efficacy by improving their ability to manage symptoms on their own. For these interventions to be most effective, parents and children may need an initial and ongoing explanation of the manner in which psychological techniques alter the physiological function and thereby provide symptom relief. Psychological/behavioral treatments have traditionally been cognitive-behavioral in nature and typically include modalities such as family and parenting interventions as well as individual therapy. Symptom self-management training can include specific strategies, such as relaxation, distraction, hypnotherapy and guided imagery, and biofeedback. These treatment strategies can work synergistically with medications and sometimes be sufficient to address symptoms, allowing children to avoid medications and their possible side effects completely. Expertise with the techniques requires training and practice.

There is an overall lack of high-quality evidence for psychological and behavioral treatments for adults with somatoform disorders (Ruddy & House, 2005) and none for youth. However, there are two exceptions. Efficacy has been established via meta-analysis for adults with body dysmorphic disorder (Williams, Hadjistavropoulo, & Sharpe, 2006) and hypochondriasis (Thomson & Page, 2007). Additional research on the long-term outcomes of psychological and behavioral treatments for both of these conditions is needed.

Stronger empirical support exists for the use of such treatments with childhood chronic pain, including functional abdominal pain, irritable bowel syndrome, headaches, and burn pain (Damen et al., 2006; Duarte et al., 2006, Finney, Lemanek, Cataldo, Katz, & Fuqua, 1989; Hicks, von Baeyer, & McGrath, 2006; Hoffman et al., 2008; Humphreys & Gevirtz, 2000; Robins, Smith, Glutting, & Bishop, 2005; Sanders, Shepherd, Cleghorn, & Woolford, 1994; Trautmann, Lackschewitz, & Kröner-Herwig, 2006; Vlieger, Menko-Frankenhuis, Wolfkamp, Tromp, & Benninga, 2007; Weydert et al., 2006). Preliminary research is promising for children with cancer pain, sickle cell anemia pain, complex regional pain syndrome, and arthritis pain (Lee et al., 2002; Walco, Sterling, Conte, & Engel, 1999; Wilder, 2006). For this reason, this literature serves as a model for the treatment of children with less-studied somatoform disorders.

While psychological and behavioral interventions have the strongest empirical support among the existing treatment options, the interpretation of this literature is complicated by the fact that intervention modalities and specific strategies are frequently implemented in combination with one another (e.g., psychoeducation with individual therapy and parental support). Most existing research has not been designed to identify the most "active ingredient(s)" of an intervention package. Future studies would benefit from dismantling combination treatment packages to isolate and identify the most efficacious treatment components. Additionally, studies directly comparing the psychological and behavioral treatments with medications are needed.

What follows are brief descriptions of the often overlapping psychological and behavioral interventions. Although some of the included psychological and behavioral interventions are often used by other disciplines and could also be considered "physical/body-based," all of those described in this section are potentially within the scope of a trained clinical psychologist.

Family and parenting interventions. Family-based treatment approaches are used to facilitate the acceptance of a rehabilitation approach to treatment, teach parents strategies to help them better tolerate their own and their children's distress, alter family-patterns thought to maintain and/or exacerbate symptoms, and to develop behavioral plans that support children's self-management of symptoms and independent functioning. Modification of environmental contingencies can attenuate reinforcement for behavioral expressions of somatic symptoms (e.g., avoidance of activity, increase symptom monitoring, guarded movements) – behaviors that can lead to increased distress and disability. For example, frequently monitoring a child's symptoms or regularly asking a child about the symptoms reinforces his or her attention and focus on the symptoms. In these cases, it is helpful to teach parents how to briefly acknowledge their child's symptoms (if the child raises the topic) and then encourage the child's use of distraction or other active coping strategies. It is also beneficial to work with medical professionals to ensure that parents understand how to differentiate symptoms of their child that require rest, or further medical work up from those associated with an expected flare that could be exacerbated by rest or further medical work up. Involving parents in the treatment of pediatric chronic pain has been shown to be helpful in maintaining treatment gains (Chambers, 2003).

For example, Sanders et al. (1994) compared a cognitive-behavioral family intervention (CBFI) to standard pediatric care (SPC) in children with RAP. Content of the family sessions included an explanation of RAP along with a rationale for pain-management procedures, contingency management training for parents, and self-management training for children. Children in the CBFI group had higher rates of pain elimination at post-treatment and 6-month follow-up, with fewer child- and parent-reported relapses at 6- and 12-month follow-up and less pain-related impairment in functioning at the 12-month follow-up.

Effects of family interventions can be immediate. For example, Duarte et al. (2006) evaluated a similar CBFI for children with RAP and reported that by the second session, children receiving the family intervention reported significantly fewer pain crises than those in the control condition.

Individual therapy. General goals of individual psychotherapy involve the reduction of somatic and co-morbid psychological symptoms and their associated impairment. Cognitive-behavioral therapy (CBT) achieves these goals by modifying inaccurate and/or unhelpful cognitions and beliefs, self-monitoring symptom triggers, improving adaptive coping ability, encouraging graduated exposure to previously avoided activities, and learning symptom self-management skills. Among other benefits, self-management strategies such as relaxation, distraction, hypnotherapy, guided imagery, and biofeedback can induce a relaxation response. Induction of the relaxation response triggers reductions in heart rate, respiratory rate, blood pressure, and muscle tension, improved gastrointestinal functioning, normalization of stress hormones, and improved mood (Kutz, Borysenko, & Benson, 1985; Lea et al., 2003; McMillin, Richards, Mein, & Nelson, 1999; NIH, 1996; Prior, Colgan, & Whorwell, 1990; Whorwell, Houghton, Taylor, & Maxton, 1992).

For example, Hicks et al. (2006) compared a CBT intervention, adapted for the internet, to a waitlist control for children with recurrent pediatric headache and RAP. Although there was a parental support component to the intervention, the main elements of the internet treatment were focused on the child. The content included education on recurrent pediatric pain, relaxation techniques, physical pain management, the importance of social and school functioning, and cognitive strategies. During follow-up, significantly more participants in the treatment

group were rated as being improved, defined by a 50% reduction in reported pain, than the control condition.

Relaxation techniques. Relaxation techniques (e.g., progressive muscle relaxation and controlled breathing) have been shown to decrease somatic symptoms and alter pain perception by inducing a relaxation response. The following are the examples of commonly used relaxation methods:

– *Tension-relaxation method*: The child is guided to contract the muscles in specific muscle groups for 5–10 s and then relax them. Normally, this will start at one end of the body and progress to the other end (e.g., from head to feet). This technique can be combined with suggestions of relaxation, heaviness, warmth, and images of relaxing situations.
– *Suggestion method*: The child is given repeated suggestions of calmness, relaxation, heaviness, and warmth combined with pleasant imagery, but without instructions to tense the muscles.
– *Differential relaxation method*: The child is guided to relax one part of the body while maintaining tension in the other part. This technique is used to allow the child to continue functioning, while also self-managing a symptom. For example, in the treatment of headaches, the child is guided to relax the jaw and shoulders, but to simultaneously keep the tension in the arms and trunk.

Paradoxical reactions and increased anxiety can occur in individuals who experience increased distress while attending to bodily sensations as would be required in the above mentioned relaxation techniques. For this subset, distraction or imagery without body scanning is typically more effective.

Distraction techniques. Distraction is used to shift the attention away from somatic symptoms and has been shown to increase pain tolerance and decrease pain perception. Distraction techniques vary widely, but can include formal interventions like meditation, hypnotherapy/guided imagery, and the use of virtual reality devices. They can also include everyday distracters like games, television, or school. Distracters, such as school, social events, or athletic challenges, can also improve the functioning and decrease distress by helping the child gain mastery over situations they find difficult.

Hypnotherapy and guided imagery. Hypnotherapy and guided imagery are symptom-management strategies that combine an intentional focus on a visual image with deep relaxation to produce a reduction in distress and an improved sense of self-control. Weydert et al. (2006) randomized children with RAP to either a guided imagery group for training in progressive muscle relaxation combined with guided imagery, or to a control condition for training in breathing techniques alone. The results indicated that children in the guided imagery group had a significantly greater decrease in the days with pain and missed activities during the initial month and at 2 months post-intervention, when compared to those in the control condition.

A specific type of hypnotherapy, gut-directed hypnotherapy (HT), has been developed and evaluated for use with digestive disorders. Hypnotherapy of this type involves the conjuring up of a visual image of the digestive system, its structure, and various functions. The efficacy of HT was evaluated in a sample of children with RAP (Vlieger et al., 2007). In the HT condition, the participants received six sessions over a 3-month period. They were introduced to general relaxation and visualization, control of abdominal pain and gut functions, and provided

information on the mind–body connection. The control-group participants received standard medical care and six sessions of supportive therapy. Although the HT and control groups both evidenced significant decreases in both pain intensity and frequency, the HT intervention was significantly more likely to produce a pain "cure."

Biofeedback. Biofeedback is a facilitated relaxation technique that makes use of computer-generated auditory or visual representations of a youngster's physiological state – muscle tension, peripheral skin temperature, and/or respiration rate. The auditory or visual signals provide children with a real-time, concrete indicator of the physiological changes they are able to produce using various relaxation and breathing techniques. Children as young as 6 years of age have successfully used biofeedback. Although biofeedback has most often been evaluated as part of a multi-component treatment package, it has been shown to produce symptom improvement, beyond that of adding fiber to the diet, in a group of children with RAP (Humphreys & Gevirtz, 2000).

16.6 Physical/Body-Based Treatments and Their Mechanisms of Change

Physical/body-based treatments for childhood somatoform disorders and chronic pain may be more familiar to patients and families, given their more logical link to physical symptom complaints. However, children and families may find them difficult to consistently implement owing to their fear of causing injury or exacerbating existing symptoms. These therapies have most commonly been used for chronic pain in children, but could theoretically be beneficial for those with other somatoform disorders who feel equally unable to control their bodies and have become disabled by their symptoms. Like the psychological/behavioral interventions, some body-based approaches (e.g., exercise and yoga) have the additional benefit of promoting self-efficacy through their focus on teaching the child skills that they can use on their own to self-manage symptoms.

When compared to the psychological/behavioral treatments, physical/body-based treatments are far less represented in the empirical literature. Nonetheless, very preliminary work suggests that targeting the body directly, through physical manipulation, stimulation, movement, or massage, may be a worthwhile intervention strategy, and as such, psychologists should be familiar with these approaches so as to be able to make appropriate referrals when needed. What follows is a summary of the existing treatment data on physical therapy, transcutaneous electrical nerve stimulation (TENS), acupuncture, yoga, and massage therapy. The available information calls for randomized controlled research in pediatric samples with chronic somatic symptoms. Expertise with the following techniques requires training and practice with the specific disorder being addressed.

Physical therapy. Physical therapy (PT) is primarily designed to improve the gross and fine motor skills, balance, coordination, and posture, and to increase strength, flexibility, and endurance through physical manipulation, exercise, heat, cold, electrical stimulation, and massage. Promising results from a case series point to possible efficacy of PT for complex regional pain syndrome (Sherry et al., 1999), and a more recent randomized controlled trial demonstrated positive effects of PT for children and adolescents with chronic musculoskeletal pain (Jones, Stratton, Reilly, & Unnithan, 2007). However, the preliminary research is less clear for youth with arthritis (Takken et al., 2008).

Transcutaneous electrical nerve stimulation (TENS). TENS provides electrical stimulation through the skin via electrodes placed around the painful region along the peripheral nerve routes or at the spinal segments. The device generates electrical currents to stimulate large afferent-A nerve fibers to inhibit pain transmission to the spinal cord that typically occurs via the smaller diameter nerve fibers. The child usually feels tingling and vibrating sensations instead of pain. The TENS units may also trigger the release of endogenous opioids. Children and parents are trained to use the TENS so that it can be worn during normal activities at home and school. The TENS has been demonstrated via meta-analysis to be an effective treatment for adult chronic musculoskeletal pain (Johnson & Martinson, 2007), but little research has been made with children. A few controled trials have supported the use of TENS for children experiencing procedural pain (Lander & Fowler-Kerry, 1993) and pediatric dental pain (Baghdadi, 1999; Modaresi, Lindsay, Gould, & Smith, 1996).

Acupuncture. Acupuncture involves the stimulation of various anatomical points on the body using very thin needles to stimulate the hypothesized release of endogenous opioids. Although there have been no controlled trials conducted with children with somatoform or chronic pain disorders, Zeltzer et al. (2002) found that acupuncture is a feasible and acceptable form of treatment for pediatric chronic pain.

Yoga. Yoga combines physical postures, controlled breathing, and meditation or relaxation to promote a sense of energy, relaxation, strength, and flexibility. To date, one controlled trial (Kuttner et al., 2006) has provisionally supported the use of yoga in adolescents with IBS. Participants reported overall improvements in their gastrointestinal symptoms, but no appreciable decrease in their levels of pain.

Massage therapy. Massage therapy involves the manipulation of the muscles and other soft tissues of the body. A recent meta-analysis revealed that one session of massage can reduce state anxiety, blood pressure, and heart rate; multiple sessions have been shown to produce reductions in pain ratings (Moyer, Rounds, & Hannum, 2004). In their controlled study, Field et al. (1997) reported significant pain reduction in children with arthritis who were massaged by their parents for 15 min a day for 30 days.

16.7 Medication Treatments and Their Mechanisms of Change

Patients and families may anticipate the prescription of a medication for the management of chronic somatic symptoms, while others may prefer to avoid medications altogether. Regardless of the expectation, it is important for families: (1) to be reminded that biological, psychological, and social factors interact to produce somatic symptoms, and (2) to have correct information related to the expected benefits and risks associated with medication options. In the case of childhood somatoform and chronic pain disorders, medications may be prescribed for the direct treatment of somatic symptoms and/or for psychological co-morbidities that frequently accompany them. Unfortunately, very little research has been conducted on the use of medications for somatoform disorders and chronic pain in children. In most cases, pediatric medication recommendations have been derived from the adult literature.

In their review of pharmacological treatments for childhood RAP and IBS, the Cochrane Collaboration (Huertas-Ceballos, Logan, Bennett, & Macarthur, 2008) reported on findings from the only three available placebo-controlled trials. They assessed the efficacy of pizotifen, a serotonin agonist (Symon & Russell, 1995), peppermint oil (Kline, Kline, DiPalma, & Barbero,

2001), and famotidine (See, Birnbaum, Schechter, Goldenberg, & Benkov, 2001). The proposed mechanisms of action of these medications have been hypothesized to include: (1) vasoconstriction, inflammation reduction, and serotonin-reuptake inhibition in the case of pizotifen, (2) relaxation of the lower esophageal sphincter, reduction of colon spasm, and relief of symptoms of dyspepsia in the case of peppermint oil (Dalvi, Nadkarni, Pardesi, & Gupta, 1991; Leicester & Hunt, 1982), and (3) inhibition of gastric secretion in the case of famotidine. The collaboration concluded that there is a lack of clear evidence for the effectiveness of these medications and that they should only be considered if simple management is unsuccessful.

❯ Table 16.2 presents a summary of other medications commonly used for chronic pain and somatoform disorders. Given the frequent co-morbidities of anxiety and depression, medications that target these symptoms are overlapping, and thus, are also frequently considered. The exact mechanisms of action are often unknown, but those that are known or hypothesized are included in the table.

It is important for the families to have correct information related to the expected benefits and risks associated with commonly used medications. Psychologists must understand medication treatment approaches to make appropriate referrals and monitor side effects.

16.8   Basic and Expert Competencies of the Clinician

During the last 25 years, basic research on the neurobiology of somatic symptoms, including chronic pain, and clinical trials of psychosocial therapies for somatoform disorders and chronic pain have demonstrated that psychological variables are of fundamental importance in mediating the appraisal and expression of somatic symptoms (IASP, 1997). Consistent with these developments, psychological and behavioral assessment has expanded beyond the evaluation of personality structure and psychiatric co-morbidities. Likewise, psychological service delivery has extended into the context of multi-disciplinary treatment. Mental-health clinicians have been established as critical team members in the multidisciplinary management of somatoform and chronic pain disorders, and thus, the creation of basic and expert clinical competency standards for psychologists serving in these roles is both timely and necessary.

16.8.1 Basic Competencies

Conceptualization and feedback. At the most basic level of competency, clinicians confronting childhood somatoform disorders and chronic pain should utilize a biopsychosocial conceptualization of the problem. Minimally, this will require clinicians to be alert of their own tendencies toward dualistic thinking about the nature of the somatic symptoms and to resist the pressure from others to revert to dualistic thinking. When working with families, this will require avoiding the categorization of symptoms as either a purely mind *or* body problem. Equally important for clinicians in this regard is to be on the lookout – within themselves, medical providers, and families – for conclusions drawn about children's symptoms that imply that they are intentionally producing or exaggerating their symptoms.

Identification. To achieve a basic level of competence, all clinical psychologists should include queries about physical symptoms, medical conditions, and health care-services utilization in their evaluations, regardless of the presenting problem.

◻ **Table 16.2**

Medications commonly used for chronic pain and/or somatoform disorders

Medication/type	Indications/example references	Mechanism of action	Benefits	Side effects/cautions
Acetaminophen Non-opioid analgesic	Mild to moderate pain	Inhibits the cyclooxygenase enzyme pathway in the CNS	Does not cause dependence or depression No GI or anti-platelet effects Not associated with Reye's syndromerespiratory	No anti-inflammatory effect Toxicity from a large dose or cumulative dosing over days is possible Overdoses have resulted in acute liver failure
Nonsteroidal Anti-inflammatory Drugs (NSAIDs) Non-opioid analgesic	Mild to moderate pain Rheumatoid arthritis, dental pain, bone pain, muscle pain, menstrual cramps, headaches, trauma with swelling	Inhibition of the cyclooxygenase and lipoxygenase enzyme pathways, decreasing production of prostaglandins (thromboxanes and leukotriens)	Does not cause dependence or respiratory depression Has anti-inflammatory effects	Rare side effects include GI bleeding, kidney dysfunction, or impaired hemostasis Aspirin has an anticoagulant effect. It is rarely used in children due to concerns about Reye's Syndrome Aspirin contra-indicated in children with a viral illness, including chickenpox or flu
Opioids	Moderate and severe pain, such as acute sickle cell crisis pain and cancer pain	Mimics action of endogenous opioids to inhibit the release of pain neurotransmitters, spinal analgesia	Can be administered via numerous routes Rarely helpful for inflammatory or mechanical/ compressive pain; not useful for chronic headaches	Potential for increased pain sensitivity over time Side effects include decreased GI motility, itching, urinary retention, sedation, respiratory slowing and respiratory arrest Physical dependence occurs within 7 days. After that, a wean may be required to discontinue them

Tricyclic Antidepressants (TCAs) Adjuvant Amitriptyline is the most frequently studied. Others include clomipramine, desipramine, imipramine, and nortriptyline	Peripheral neuropathies, phantom limb pain, fibromyalgia, pain related to the invasion of nerves by tumors, other neuropathic pain, somatoform disorders, pediatric migraine Clomipramine more effective than desipramine for body dysmorphic disorder (Hollander et al., 1999; Volz et al., 2000)	Mechanisms suggested include potentiation of descending inhibitory pathways, increased serotonin availability, endogenous opioid peptide release, and a direct action on opioid receptors Appears to have a direct analgesic effect	Can work synergistically with opioids The effect of TCAs on pain reduction and improved sleep is rapid (3–7 days) at a relatively low dose Can be useful for anxiety and depression Can be useful for co-morbid insomnia and diarrhea	Anticholinergic side effects including dry mouth, constipation, blurred vision, urinary retention, confusion, and delirium Autonomic side effects include orthostatic hypotension, profuse sweating, palpitations, tachycardia, and high blood pressure EKG monitoring needed at baseline and after achieving a therapeutic, dose Imipramine and nortriptyline are reasonable options if amitriptyline causes excessive side effects
Selective Norepinephrine Reuptake Inhibitors (SNRIs) Adjuvant Venlafaxine	Undifferentiated somatoform disorder, multisomatoform disorder,[a] headache, neuropathic pain, fibromyalgia, diabetic peripheral neuropathy, and reflex sympathetic dystrophy (Han et al., 2008; Kroenke et al., 2006)	Inhibits norepinephrine, serotonin, and dopamine reuptake	Fewer side effects than TCAs Can be useful for anxiety and depression	Monitor for suicidal thoughts, clinical worsening, and/or unusual behavior changes, especially during initial treatment phase and after dose changes

(continued)

● **Table 16.2 (Continued)**

Medication/type	Indications/example references	Mechanism of action	Benefits	Side effects/cautions
Selective Serotonin Reuptake Inhibitors (SSRIs) Adjuvant Including citalopram, paroxetine, escitalopram, fluvoxamine, St. John's wart	Somatoform and multisomatoform disorders,[a] pediatric recurrent abdominal pain (Campo et al., 2004; Greeven et al., 2007; Muller, Mannel, Murck, & Rahlfs, 2004; Muller et al., 2008; Noyes et al., 1998; Volz et al., 2002; Williams et al., 2006)	Selectively inhibits serotonin reuptake Appears to have a direct analgesic effect (interaction with the opioid system; Singh, Jain, & Kulkami, 2001)	Fewer side effects than TCAs Can be useful for anxiety and depression	Monitor for suicidal thoughts, clinical worsening, and/or unusual behavior changes, especially during initial treatment phase and after dose changes
Anticonvulsants Adjuvant Including gabapentin, pregabalin, oxcarbazepine, carbamazepine, topiramate	Migraine, diabetic neuropathy, trigeminal neuralgia, postherpetic neuralgia, complex regional pain syndrome, postpolio-myelitis neuropathy, HIV neuropathy, phantom limb pain, multi-somatoform disorder (Garcia-Campayo et al., 2002)	Reduces post-tetanic potentiation; exact mechanism of action for pain unknown	Gabapentin and pregabalin have fewer side effects and less drug interactions than other anticonvulsants, and do not require serum level monitoring Can also be helpful for mood stabilizations	Potential to cause behavioral changes Requires serum-level monitoring (except gabapentin and pregabalin)

Membrane stabilizers Non-opioid analgesic	Lidocaine for mucositis pain, cancer pain and neuropathies Verapamil for migraines and cluster headaches Mexiletine for diabetic neuropathy	Lidocaine and mexiletine are thought to act through a sodium channel-binding mechanism	Used to enhance the efficacy of opioids, antidepressants, anticonvulsants	Mexiletine's common side effects: nausea, vomiting, sedation, confusion, diplopia, and ataxia Lidocaine infusion is stopped if patient has drowsiness, dysarthria, tinnitus, seizures, dysphoria, or dysrhythmias
Alpha-2 adrenergic agonist Adjuvant	Clonidine for diabetic neuropathy and postherapeutic neuralgia Intrathecal clonidine to reduce muscle spasms in patients with spinal cord injuries	Clonidine may work both peripherally and centrally by increasing conduction of potassium	Clonidine is a second line drug, but has advantages such as its transdermal route of administration Its sedative effect may also be advantageous	Side effects include hypotension and sedation Abrupt cessation may cause rebound hypertension and nervousness
Psychostimulants Adjuvant	Methylphenidate and dextroamphetamine for spasmodic torticollis, spastic colon, and headaches	Anti-nociceptive properties that may be mediated by via norepinephrine, serotonin, or dopamine, or by or endogenous opioid mechanisms	Can allow for decrease in opiate dose without reduction in analgesic effect Used to decrease drowsiness caused by sedating medications	Side effects can include activation of the sympathetic nervous system, insomnia, headaches, reduced appetite Potential for abuse

(continued)

● **Table 16.2** (Continued)

Medication/type	Indications/example references	Mechanism of action	Benefits	Side effects/cautions
Antipsychotic Agents Adjuvant	Cancer, arthritis, migraine, neuropathy, and phantom limb pain	The mechanism of action unknown; antagonizes dopamine D2 receptors, serotonin 5-HT2 receptors; may have a local anesthetic action in spinal nerves	Can improve mood and reduce anxiety Also used as second line option for nausea/vomiting	Requires initial CBC with history of low WBC or drug-induced leukopenia/neutropenia, and glucose monitoring with diabetes risk factors Monitor for suicidal thoughts, clinical worsening, and/or unusual behavior changes, especially during initial treatment phase and after dose changes
Anxiolytic Agents Adjuvant	-Benzodiazepines can be useful by reducing co-morbid anxiety, muscle spasm and insomnia -Short-term use can be effective in sickle cell crises	Binds to benzodiazepine receptors; enhances GABA effects	Hydroxyzine can augment opioids in sickle cell crises	Benzodiazepines can cause respiratory depression and physical dependence Benzodiazepines can cause fear, disorientation, and/or paradoxical reactions Anxiolytics alone do not provide analgesia; they can make a child less able to report pain and distress

ªMultisomatoform Disorder (MSD): three or more currently bothersome, medically unexplained physical symptoms, together with a history of somatization for at least 2 years (Kroenke et al., 1997), listed as a subtype of USD in the Primary Care edition of DSM-IV (DSM-IV-PC) (APA, 1995).

Assessment. When evaluating a child with distress or disability related to a physical symptom or defect, a clinician with basic competency skills should know and assess for common somatic-symptom presentations, psychological and social stressors, psychiatric co-morbidities, functional deficits, and presumed symptom precipitants and reinforcers reviewed earlier in the chapter. The identification of psychiatric co-morbidities assumes a basic competence with psychodiagnostic assessment.

Treatment. Another basic competency for clinicians presented with cases of chronic somatic symptoms involves an appreciation for empirical data pointing to CBT's modest, yet consistent success in improving somatic symptoms and disability. Clinicians possessing a basic level of competency ought to have the knowledge of various CBT techniques, such as relaxation, diaphragmatic breathing, guided imagery, activity scheduling, self-monitoring, and contingency management. Their application to somatoform disorders and childhood chronic pain is similar to their application in other childhood psychiatric disorders.

Care coordination, consultation, and referral. Clinicians who possess basic competency must effectively coordinate care and/or refer care to an expert. A child with distressing or disabling somatic symptoms often sees (sometimes multiple) medical care providers and struggles to manage their school responsibilities. Consequently, the psychologist must have the ability and willingness to co-manage interventions with physicians, nurses, teachers, and school principals, as needed.

A basic competency for any clinical psychologist is to know how to access appropriate consultation. This is extremely important for a child with physical symptoms, as consultation may need to be solicited from both physicians and mental health experts.

Finally, the psychologist must appropriately identify the circumstances under which the care of a child should be referred to another professional. Management of patients with somatoform disorders or chronic pain and their families can be highly complicated and time-intensive. Referrals can be made for all or part of the management as appropriate. For example, while a clinician may be competent to conduct appropriate parent training, another may be more suited to teach the child how to use self-hypnosis or biofeedback for symptom management. Likewise, there are times when it is helpful to have one clinician working with the child and another working with the parents, especially if the child is unhappy with behavioral plans being recommended. A referral to another medical or mental-health professional might also be indicated when there is a new symptom or concern that requires investigation by a specialist.

16.8.2 Expert Competencies

Researchers in the area of learning and competence development have characterized *experts* in a field on the basis of their superior knowledge and proficient performance within the relevant domain of experience (Eveleth, 1999; Lajoie, 2003). However, Jones (2008) cautioned that even if psychologists obtain "extensive knowledge on what to do and how to do it, they are not experts. This is because in order to be an expert one must be able to actually do it rather than just know how to do it" (p. 39). Thus, in addition to all the skills of a clinician with a basic level of competence, one at the expert level will possess a consistent and proficient ability to apply such knowledge in a flexible manner to real-world cases. Additionally, it is the responsibility of the expert to stay abreast of research findings related to etiology, assessment, treatment, and controversies in the field.

Conceptualization and feedback. Beyond having a passing familiarity of a biopsychosocial conceptualization of somatic symptoms, an expert clinician in this area must be facile with communication of a biopsychosocial and non-dualistic model of somatic symptoms to patients, families, and other professionals, medical and non-medical alike. As patients and families will not adhere to a treatment plan that does not make sense, it is essential for the expert clinician to effectively explain the problem. For many patients and families, a well-articulated explanation of the problem is the most useful intervention of all. Achieving a balanced, accurate, and consumable description of such disorders is a skill that requires practice and expert knowledge.

Identification and assessment. While a basic level of competence requires a clinician to be familiar with the diagnostic criteria for somatoform disorders of childhood, an expert level of competence would require an individual to be facile with *specific* common somatic symptom presentations (e.g., non-epileptic seizures [NES], pain, fatigue, vocal cord dysfunction) and chronic pain conditions (e.g., complex regional pain syndrome, RAP, chronic headache), as well as with the indicated assessment and treatment strategies for each. An expert clinician in childhood chronic pain disorders should also be familiar with the standardized assessment tools routinely used to evaluate pain symptoms (For a recent review, see Stinson, Yamada, Dickson, Lamba, & Stevens, 2008).

Treatment. An expert clinician should possess specific and detailed knowledge about the appropriate treatment strategy for specific somatoform and chronic pain diagnoses. A clinician expert in the area of NES, for example, should be able to develop, communicate, and implement a treatment plan that supports a child's ability to function at school by providing teachers, school nurses, and classmates with a concrete plan for responding to non-epileptic events that may occur during a school day. Similarly, an expert clinician in the area of childhood RAP should be familiar with the implementation of guided imagery, in general, as well as with that of specific "gut-directed" imagery or hypnotherapy exercises (Vlieger et al., 2007). This will require an understanding of the anatomy and functioning of the gut and the ability to create developmentally appropriate analogies (e.g., a car) for these structures and functions that can be used in "gut-directed" exercises.

Care coordination, consultation, and referral. In addition to the basic competency of communicating with collateral care providers, expert clinicians in childhood somatoform and chronic pain disorders should have the ability to *function within* a multidisciplinary team, often leading such a team. Doing so will require psychologists to be familiar with the general medical milieu, technical jargon, and the medical treatment plan. In addition, expert clinicians should be intimately familiar with the impact of a child's symptoms on school functioning, school officials' expectations for a student's fulfilling of academic requirements, school policy regarding his/her absences from the school, and the process for initiating and/or monitoring a child's need for special education services.

16.9 Transition from Basic to Expert Competence

A frequently replicated finding in the work of scientists interested in the transition from novice to expert is that there is more than one trajectory to competence. Jones (2008) proposed that the pathway to expertise among psychologists involves a "journey of highly motivated, goal-directed behavior that is prompted by a desire to persevere through hard work in the context of significantly relevant experiences" (p. 39). Thus, a primary task for those whose duty is to support the psychologists' transition from the basic to the expert level of competence in a

particular area is the intentional provision of training opportunities that introduce demanding and complex clinical cases. These training opportunities may be found in the form of academic instruction as well as practical clinical experiences.

The International Association for the Study of Pain (IASP) has undertaken the call to develop training guidelines for psychologists seeking to develop a specialty in the area of pain. In their *Curriculum on Pain for Students in Psychology* (IASP, 1997), the IASP ad hoc subcommittee for psychology graduate curricula proposed a series of training objectives considered important for the expert training of psychologists adopting a specialty in pain disorders. They assert that the "curriculum can be considered to form the academic base from which professional competencies can be developed." These objectives can be accessed on their website (see: www.iasp-pain.org). A similar curriculum could be created for childhood somatoform disorders. Moreover, academic objectives could be addressed not only in the context of graduate study, but also in professional and post-graduate coursework, conferences, and seminars.

Beyond academic instruction, those transitioning to an expert level of competence in the area of childhood somatoform disorders and chronic pain will require targeted and sustained clinical experience. Given the symptom presentation of these disorders, the ideal training sites include primary and tertiary medical settings. Exposure to these clinical settings could be introduced as part of the undergraduate and graduate psychology training, as well as in pre-doctoral internship and post-doctoral fellowship training programs. Securing additional clinical experience by establishing professional relationships with existing experts and participating in multi-site supervision groups and clinical research trials are also recommended to move from basic to expert competence.

16.10 Summary

There has been a growing and converging interest across a variety of medical specialties, including gastroenterology, rheumatology, psychiatry, and neurology, in understanding the development of chronic somatic symptoms and their treatment. Most pivotal to this understanding is the intentional reexamination of long-held dualistic distinctions, like those of organic versus psychological causes for symptoms, and a reorientation toward common neurobiological and behavioral mechanisms that operate across childhood somatoform disorders and chronic pain, such as disrupted physiological sensation and modulation, affect regulation, and illness coping (Naliboff, 2007). Thus, clinical psychologists with expert competency in this emerging field are needed to work with children suffering from physical symptom complaints and associated disability and their families.

17 Pharmacological Adjuncts

*Nirbhay N. Singh · Ashvind N. Singh · Giulio E. Lancioni ·
Angela D. Adkins*

Abstract: Clinical psychologists provide services to children and adolescents who are often on psychoactive medication for psychiatric or neurological disorders, or for challenging behaviors that have not been amenable to psychosocial treatments alone. Regardless of whether clinical psychologists aim to prescribe pharmacological adjuncts or to refer children and adolescents to child psychiatrists for adjunctive pharmacological treatment, it behooves them to have basic competencies in psychopharmacology. The basic competencies that clinical psychologists should know well and utilize in their practice include recognition and assessment of symptoms, developmental course of childhood disorders, protective and risk factors, maintenance factors, principles and practice of evidence-based treatment approaches, cost-effectiveness of various treatments, drug algorithms, and mechanisms of change underlying psychopharmacological interventions. The APA Board of Educational Affairs has identified three levels of training in psychopharmacology for clinical psychologists: Level 1 is a single semester doctoral-level training program focusing on basic psychopharmacology that enables a clinician to provide assessment and treatment services to their patients. Level 2 is a post-doctoral training program focusing on collaboration between clinical psychologists and physicians to provide an integrated psychosocial and psychopharmacological treatment. Level 3 is another post-doctoral training program focusing on psychopharmacology training at the expert level that is prerequisite for prescribing privileges. The knowledge base of psychopharmacology is increasingly scientific, but its practical application with children and adolescents in alleviating psychological distress is an art. Thus, clinical psychologists need to have basic competencies in both the science and art of pharmacological adjuncts.

17.1   Overview

Five years ago, the National Institute of Mental Health (2003) estimated that between 2% and 3% of children in the United States were treated with some type of psychotropic medication. The rates increased dramatically for specific subgroups of children. For example, 52–71% of the children and adolescents[1] with Attention-Deficit Hyperactivity Disorder (ADHD) and about 76% of children with serious emotional disturbance were prescribed psychotropic medications (Connor, Ozbayrak, Harrison, & Melloni, 1998; Ryan, Reid, Gallagher, & Ellis, 2008; Safer & Zito, 2000). Though the evidence-base for the efficacy of psychotropic medications in improving emotional, behavioral, and cognitive functioning of children with psychiatric disorders is increasing (e.g., MTA Cooperative Group, 1999), it is not yet fully established (Singh & Ellis, 1998). However, this has not reduced the use of these medications in the treatment of

---

[1] Unless otherwise specified, in this chapter, the terms child and children are used to denote both children and adolescents.

children either in the community or in residential facilities (Landrum, Singh, Nemil, Ellis, & Best, 1995; Ryan et al., 2008; Singh, Landrum, Donatelli, Hampton, & Ellis, 1994). Furthermore, prevalence of psychotropic medication use in children in the United States far exceeds that of any other country (Zito et al., 2008).

Clinical psychologists who provide services to children and adolescents inevitably deal with patients who are on psychoactive medication for psychiatric or neurological disorders, or for challenging behaviors that have not been amenable to psychosocial treatments alone. Irrespective of whether the aim is to prescribe pharmacological adjuncts or to refer children in their care to a child or adolescent psychiatrist for adjunctive pharmacological treatment, it behooves the clinical psychologists to have basic competencies in psychopharmacology. To rephrase William Osler, "psychopharmacology is a science, the practice of which is an art." The knowledge base of psychopharmacology is increasingly scientific, but its practical application with children in alleviating psychological distress is an art. Thus, clinical psychologists need to have basic competencies in both the science and art of pharmacological adjuncts.

In this chapter, we have described the areas that child clinical psychologists should know well and utilize in their practice, including recognition and assessment of symptoms, maintenance factors, principles and practice of evidence-based treatment approaches, and mechanisms underlying psychopharmacological interventions. Then, we have presented two levels of competencies that the child clinical psychologists should possess to enhance their understanding of psychopharmacological interventions for children. We have also presented a third level of competencies for those clinicians who wish to obtain prescription privileges.

17.2 Recognition of Symptoms and Their Assessment

To use pharmacological adjuncts, the clinical psychologist will need to carefully evaluate multiple psychological, physiological, and social parameters that affect the child's functioning. Optimal treatment requires a clear psychiatric diagnosis and baseline measurement of the target symptoms across multiple settings.

17.2.1 Diagnosis

In general, the clinician's goal is to understand the presenting problems or symptoms at the highest level of diagnostic sophistication that can be achieved based on a comprehensive interdisciplinary assessment. There are at least four accepted levels of diagnostic sophistication: (a) *symptomatic*, which includes isolated symptoms (e.g., auditory hallucinations) that provide an indication of a possible diagnosis (e.g., psychotic disorder not otherwise specified); (b) *syndromic*, which includes the constellation of signs and symptoms that have been present for a given time period, and standardized inclusionary and exclusionary criteria can be used to derive a diagnosis (e.g., depression); (c) *pathophysiologic*, which includes structural or biochemical changes that indicate the diagnosis (e.g., an individual presenting with anxiety, depression or manic excitement, weakness, excessive sweating, tremors, and in some cases, disturbances of thought and cognition, may have elevated thyroid function tests that suggest a diagnosis of hyperthyroidism); and (d) *etiologic*, in which the diagnosis is based on known causative factors (Singh, Sabaawi, & Singh, 2004).

With children, most psychiatric diagnoses are at the symptomatic and syndromic levels of sophistication, because we currently do not have a complete understanding of the pathophysiology or etiology of many childhood disorders. Therefore, it is not uncommon to find wide variability in treatment outcomes in children diagnosed with the same syndrome, because they have similar presentations, but substantially different underlying mechanisms. This means that often clinicians treat children's behavioral symptoms or psychiatric disorders without fully appreciating the biological and genetic underpinnings or how these factors transact with their physical, psychosocial, and cultural environments.

17.2.2 Symptoms

Once a firm or provisional diagnosis is made, the clinician determines the specific (or target) symptoms that will be the focus of pharmacological treatment. In some cases, the target symptoms will be a defining characteristic of the disorder, such as delusions or hallucinations for someone with a diagnosis of schizophrenia. In other cases, the target symptoms may arise in the context of the disorder, but they do not necessarily define the disorder. An example would be self- or other-directed aggression in the context of intellectual disabilities or autism. In addition, although the focus may be on a specific psychiatric disorder (e.g., major depression), the symptoms of the disorder targeted for pharmacological treatment may vary depending on the child's symptom profile. Thus, the target symptoms chosen for psychopharmacological treatment are either included in the criteria for the disorder, as defined by the DSM-IV-TR (American Psychiatric Association, 2000) or some other taxonomic classification system (e.g., ICD-10; World Health Organization, 1992), or are related to or exacerbated by the disorder.

The clinician may want to determine the severity (i.e., frequency, intensity, and duration) of all the symptoms, as well as the collateral behaviors that could be the targets of pharmacological treatments. In the absence of formal ratings, the clinicians can usually rate each of the sub-components of severity as mild, moderate, or severe for each possible target symptom. Further refinement may be necessary prior to determining which target symptoms merit the treatment. Thus, it would be clinically prudent to determine the nature of the symptoms, such as context-dependency, possible functions, and maintaining contingencies. For example, if an adolescent with conduct disorder exhibits aggressive behavior only at school, then it indicates site-specific psychosocial intervention rather than pharmacological intervention. Similarly, if the school-based aggressive behavior is further determined to be prevalent only with one specific teacher, then it may indicate a very specific behavioral intervention that focuses on the teacher, the adolescent, or both.

17.2.3 Assessment

A comprehensive baseline assessment is necessary before a child can be considered for pharmacotherapy. Assessment provides the basis for determining the child's psychopathological condition, indications for treatment, and the nature of the proposed treatment. Baseline assessment is necessary for measuring the outcomes of psychosocial and adjunctive pharmacological therapy. It is multidimensional and interdisciplinary, incorporating assessments of the child's symptoms and functioning across multiple domains, as well as an evaluation of his or her

family history and physical and cultural environment. In general, a baseline assessment includes (a) the source of and reason for referral, including the target symptoms that may be the focus of treatment; (b) history of the presenting symptoms; (c) psychiatric history and current mental status; (d) developmental and medical history; (e) family and education/school history; and (f) an evaluation of cultural context of the family (e.g., determining if the family has any specific religious, spiritual, or cultural beliefs that may interact with the child's treatment in general, and psychopharmacological treatment, in particular).

Symptom clusters. Many, if not most, clinicians in the United States use the DSM-IV-TR taxonomic classification system for diagnostic labeling. While helpful in guiding theory, research and practice, each revision of the DSM system has been criticized for its failure to adequately classify the symptoms of real-world children who present with symptom clusters that cut across multiple disorders (Jensen, Knapp, & Mrazek, 2006; Kupfer, First, & Regier, 2002; Watson & Clark, 2006). In addition, determining whether a child meets the symptom criteria for having a disorder is often difficult because the task is based on subjective and impressionistic judgments rather than on well-defined behavioral observations or empirical ratings. Further, heterogeneity within diagnostic categories weakens the utility of the system for deriving treatments at the level of the individual child or adolescent. Thus, it is imperative that the clinician moves beyond the disorder and the specific syndromal criteria for the disorder and assesses the individual symptoms, as well as the symptoms secondary to other disorders.

Symptom assessment. Assessment of specific symptoms can be achieved via different modalities. Clinicians typically use direct, open-ended questions (e.g., What do you feel like when you are sad?) to gain information from the child. Symptom-oriented descriptive interviews have the benefit of building therapeutic alliance, because it gives the child the feeling that the clinician is keenly interested in his or her psychological distress. Of course, the language used must be aligned with the developmental and cognitive functioning level of the child. For example, young children may better understand terms such as "sad" and "not happy," but not "depressed." Other measures may also be used, including structured or semi-structured interviews, checklists, or rating scales, including visual analog scales with young children. Further information can be obtained from mental-health records, school records, and interviews with family members. The essential issues concern the reliability and validity of the data pertaining to the symptoms experienced by the child. Of course, this will vary depending on the nature of the disorder, because it is somewhat more difficult to establish symptom validity with internalizing than externalizing disorders. Once the symptoms are identified, the clinician has a responsibility to determine the severity of the symptoms across multiple settings.

17.3   Maintenance Factors of the Disorder or Problem

Clinicians need a good knowledge of the developmental course of childhood disorders, because it provides information about how the symptoms of specific psychiatric disorders vary across the life span, and how children's individual differences may affect their psychopathological pathways (Singh & Singh, 2001). In addition, it enables clinicians to differentiate normal and psychopathological development in children at various ages and stages, and an appreciation of the patterns of continuity and discontinuity between variations within the normal range and specific childhood disorders. That is, it is not uncommon for children to display normative

as well as abnormal behavioral patterns over time, depending on their biopsychosocial and cultural interactions. For all childhood disorders, it is essential that clinicians have an appreciation of the multiple factors that may be involved in the genesis and maintenance of each disorder or presenting problems. This would entail having the knowledge of risk and protective factors, the child's transactions with layers of ecological contexts, effects of both nature and nurture, and the interplay of the brain, mind, body, and spirit.

There are a large number of factors that either protect and enhance or risk and compromise children's normal developmental processes. Although these protective and risk factors fall along a continuum of possibilities, they have a transactional relationship among themselves as well as with children's developmental processes. That is, it is the balance of the effects of the protective and risk factors that are most obvious in terms of the normal variations in children's behavior or psychopathology. Children who grow up in conditions that are at risk for producing psychological distress and do not experience sustained protective processes are those who end up displaying behavior problems or symptoms of psychiatric disorders.

17.3.1 Protective Factors

At least three sets of protective factors impinge on children's developmental processes, including child, parental, and contextual protective factors. The child protective factors can be general or associated with each developmental stage. For example, general protective factors would include genetic inheritance, personality characteristics, good physical and mental health, above-average intelligence, and a good-natured temperament. Others are important at the given developmental stages; that is, they are mediated by the child's developmental level. For example, lack of feeding and sleeping problems are important protective factors in infancy, and getting along with peers, good communication skills, good academic performance, social skills, and emotional stability are strong protective factors in middle childhood. Critical parental protective factors include secure attachment, parental support of their child during stressful situations, firm rules regarding the expected child behaviors, parental monitoring of the child, consistency rather than chaos at home, supportive extended family, extended family caregiving, stable parental relationship, family religious faith, and well-educated parents (Masten, Best, & Garmezy, 1990; Werner & Smith, 1992). Contextual protective factors may include a positive stable relationship with adults other than parents (e.g., grandparents, teacher, mentor, adult family friend); high socioeconomic status of family (i.e., middle-class or higher); access to physical health, mental health, and social services; parental employment; acceptable housing; family involvement in religious practices; enrollment and positive experiences at good schools; family having adequate financial resources; and living in a safe neighborhood.

17.3.2 Risk Factors

As with protective factors, at least three general groups of conditions create developmental risk for children, including vulnerabilities in the child, inadequate parenting, and socioeconomic and systemic factors. Many biological conditions place children's development at risk, including genetic syndromes (e.g., fragile X, Prader-Willi syndrome, Lesch Nyhan syndrome, Down syndrome), familial risk factors for psychiatric disorders (e.g., ADHD, mood disorders,

schizophrenia), exposure to teratogens in utero (e.g., toxic substances such as alcohol and other drugs, or infectious diseases in the mother), prematurity and low birth weight, anoxia, birth complications, and chronic diseases. Other child vulnerabilities include difficult and behaviorally inhibited temperament or characteristic emotional responses. For example, young children demonstrating higher levels of behavioral inhibition tend to develop anxiety disorders by the time they reach middle childhood (Hirshfield et al., 1992).

There are a number of potential parental risk factors that have long-term consequences for children. Parental risk factors relate not only to parent–child interactions (e.g., maltreatment, lack of warmth, and responsiveness), but also to parental vulnerabilities (e.g., single parenthood in the absence of extended family support, paternal unemployment, family disruption or divorce, low maternal educational status, large family size [four or more children], parental psychopathology, and substance abuse). Parents who are at high risk have reduced ability to mediate or buffer children's stresses during critical developmental periods, thus leaving them more vulnerable to intrinsic and environmental risk factors, and psychopathology. This vulnerability is heightened by age, as younger children are inherently less able to cope with negative life events, such as witnessing domestic violence. For example, preschool children are not only traumatized by witnessing domestic violence, but in the absence of parental buffering of these stresses, they develop emergency coping strategies, such as aggression and emotional numbing that may prove to be maladaptive as the child grows older. When parents are unable to teach their young children adaptive coping strategies, and the family has few protective factors that may overcome the negative effects of the risk factors, it makes the children more vulnerable to later psychopathology.

Community and socioeconomic risk factors also contribute to the well being of children. These risk factors are external to the family, but may have serious outcomes for parents and children. Age of the children is important in terms of effects and consequences of exposure to community risk factors, as younger children need more parental mediation than older children. These risk factors include: poverty; inadequate or lack of access to medical and mental health care, health insurance, and social services; parental unemployment, homelessness, or frequent change of residence and schools; inadequate child care; exposure to racism, discrimination, and community violence; poor schools; exposure to environmental toxins; and dangerous neighborhoods.

Finally, there are transactional developmental variables that increase children's risk for later psychopathology. Young children, especially those under 6 years of age who have not acquired adequate appraisal strategies because of their immature cognitive processing abilities, are more vulnerable to acute or enduring internal or external stressors because of their developmental status. They may not have developed adequate coping mechanisms, and are therefore unable to marshal enough internal or external resources to overcome adversity. Children who appear to have a favorable protective versus risk factors balance may be at risk for psychopathology if life circumstances increase their vulnerability and reduce their coping ability. For example, children in poverty may be resilient enough to withstand the daily hassles of life but may not be able to cope well following the death of a loved one. They are likely to show signs and symptoms of apathy and depression. In other cases, children may learn passive ways of coping with events that occur repeatedly, because they may feel that there is no way out for them. These children exhibit learned helplessness in the face of adversity. For example, children exposed to repeated physical and emotional abuse from an early age often show no emotional responsivity to the events, and later may show signs of dissociation. For these

children, no active coping mechanisms may work, and the stressors are too great to be offset by whatever protective factors available to them.

17.3.3 Maintenance Factors

Maintenance factors are not often explicated in the research and treatment-outcome literature, especially in terms of protective and risk factors for later psychopathology. ADHD provides a good example for a discussion of maintenance factors in this context. Beginning with infant temperament as a predisposing factor for ADHD, the typical age of onset when a clear diagnosis can be made is about 3 years (Smith, Barkley, & Shapiro, 2007). Regardless of the effectiveness of psychosocial and/or psychopharmacological treatments, a majority of children with ADHD do not outgrow its symptoms during adulthood (Nigg, 2006). Toddlers who are temperamental, have high levels of activity, and are thought by their parents to be non-compliant, are at high risk for ADHD by the time they are preschoolers. Although not all toddlers with these characteristics develop the symptoms of ADHD, many who do, seem to share these traits. In general, these toddlers engage in excessive crying in infancy, and have colic, feeding problems, and sleep disturbances. They are difficult to bond with, and their excessive crying, colic, and feeding problems may form the basis of insecure mother–child attachment, and may slowly lead to negative mother–child transactions. The mother–child transactions may become increasingly negative as the infant grows into a toddler, and warm positive interactions may decrease, less positive affection may be shared between the mother and child, and the child may show increasing non-compliance to parental requests. These transactions result in a stressful mother–child relationship, and the child may be engaged in other behaviors that parents perceive to be problematic.

This kind of interactional process takes place until parents (or clinicians) recognize and alter the environmental context so that "normal" development of the child can occur (Sameroff & Fiese, 2000). The interactions between mother and child are bidirectional, and changes in both must occur for the child to proceed along the normal developmental pathways. For example, infants with difficult temperaments have a tendency to develop childhood psychiatric problems, including ADHD (Davies, 2004). Psychosocial intervention at this stage is often aimed at increasing the goodness of the fit between the child's temperament and the mother's parenting style, because a poor fit is likely to increase the maladaptive functioning in the child. Furthermore, a poor fit increases the mother's feelings of anxiety and inadequacy in handling the child, because she sees the child as being demanding and difficult. When intervention produces a better fit, the mother reacts in a more accepting and warm manner, and is reinforced by the infant's responsiveness and more acceptable temperament. Overall, the mother–child transactions take a more positive developmental pathway, and future behavior problems are averted.

Alternatively, if effective psychosocial intervention is not provided, then the child will increasingly exhibit serious problems with attention, overactivity, impulsivity, and non-compliance – behaviors that may eventually meet the syndromal criteria for ADHD. Symptoms of ADHD transact with normal developmental processes and change the developmental pathways for children diagnosed with the disorder. According to parental reports, about a third of the children with hyperactivity had a number of behavior problems even during the first year of life. These behavior problems are thought to be developmental correlates of ADHD, and

include excessive crying, sleep problems, delays in vocalization, feeding problems, and physical anomalies. It is not that these behaviors are evident only in infants who grow up having ADHD, but rather that these behaviors are often more difficult to deal with in infants who grow up having ADHD. For example, "hyperactive" infants do not respond well to the usual parental calming methods of rocking, cuddling, and comforting, and continue to cry for no apparent reasons.

17.4   Evidence-Based Treatment Approaches

The term *evidence-based practice* refers to the informed use of empirically supported treatment approaches in routine patient care. In the context of medicine, this practice has been described as "the conscientious, explicit, and judicious use of current best evidence in making decisions about the care of individual patients. The practice of evidence-based medicine means integrating individual clinical expertise with the best available external clinical evidence from systematic research. By individual clinical experience we mean the proficiency and judgment that individual clinicians acquire through clinical experience and clinical practice" (Sackett, Rosenberg, Gray, Haynes, & Richardson, 1996, p. 71). Evidence-based practices enable the clinician to access and utilize empirically proven treatment approaches that match the clinical needs of individual children.

To use evidence-based treatment approaches, clinicians can rely on reviews of the treatment outcome literature, follow consensus panel guidelines, or systematically evaluate the scientific evidence. However, it is highly unlikely that clinicians can stay abreast of the changing architecture of possible treatment approaches when one compares the time required for reading pertinent research with the time that they actually have for the task. For example, over a decade ago, it was estimated that physicians would need to read 19 journal articles a day, 365 days per year to keep abreast of the current literature in general medicine (Davidoff, Haynes, Sackett, & Smith, 1995). Of course, this requirement would be even higher today. Thus, it is not surprising that clinicians rely more on their own experience with a limited number of patients, academic detailing from pharmaceutical representatives, or workshops by experts, than on systematic reviews of the current literature (Greenhalgh, 2001). Further, when personal beliefs and scientific evidence are at odds, clinicians invariably accept their personal beliefs over science (Garb, 1998).

We have discussed general and specific evidence-based practice methodologies that busy clinicians can use to enhance their choice of effective treatments (Singh & Oswald, 2004a–c). Evidence-based practice provides an efficient system for searching the published and unpublished research literature, a structure for organizing and interpreting the data, and critically evaluating treatment outcome literature to derive an effective treatment for individual patients. In addition, it provides the clinician with a framework for evaluating alternative therapies for a given disorder and for applying the results to a specific child with that disorder.

17.4.1 Evidence-Based Practice Methodology

There are several ways by which a clinician can engage in the evidence-based practice process. In general, all of them include the following five steps: (a) define the disorder, (b) search the treatment literature for the evidence, (c) critically evaluate the literature, (d) choose and apply

the therapy, and (e) monitor patient outcome(s). Defining the disorder or a specific problem can be done through individual or team assessments. This first step is essential because it assists the clinician in formulating the question that will be the focus of the second step. The second step is the literature search. The nature of the question formulated in the first step will determine the outcome of the literature search. For example, if the question is too narrow, the clinician may find very little in the treatment literature, and if the question is too broad, too many references may be found. In either case, the clinician may be discouraged from continuing with the evidence-based practice pathway to find the therapy that has the most valid evidence. A well-formulated question will produce the best results. Further, the clinician must be aware of other factors, such as publication bias and the clinician's own bias that may compromise the search.

The third step involves the critical appraisal of the selected literature, a pivotal task in the evidence-based pathway. This requires the clinician to not only critically review the individual studies, but also assess the corpus of the literature relevant to the target question. Individual articles are assessed in terms of standard, step-wise criteria including patient-entry criteria, appropriate assessments, experimental design with valid controls, replicable treatment protocol(s), fidelity of treatment implementation, follow-up, reliability of data collection, appropriate statistical analysis of the results, interpretation of the data, and so forth. If the original question is to be answered via systematic reviews of the topic, then the clinician must exercise the same rigor that would be expected in reviewing the original articles. In the absence of an evidence-based practice approach, the clinician will invariably introduce bias by using just one or two original articles or systematic reviews to select a solution that is not based on a careful, critical evaluation of the research evidence. Given an emphasis on clinical rather than research training of many child clinical psychologists, the critical review and evaluation of the treatment outcome studies are the most demanding steps in this process.

Once the clinician makes a choice of an empirically validated treatment, the fourth step involves implementation at an acceptable fidelity level, and the fifth step involves monitoring the outcome(s) to determine if the desired or expected results are obtained. Of course, other variables should also be monitored to evaluate the changes correlated with the implementation of the therapy, and these can be both intended and unintended effects and either positive or negative in terms of contributing to the patient's overall enhancement of quality of life. Further, if the clinician uses a scientist–practitioner model of clinical practice, then the evaluation of evidence-based practice with individual children can be carried out using single-case experimental designs (Barlow, Nock, & Hersen, 2009). If the monitoring suggests that the child's adherence to the evidence-based clinician recommendations is less than desirable, then the child-specific reminders can be instituted to enhance therapeutic outcomes. A good example of this can be found in the treatment of diabetes mellitus, where a computerized decision-support system based on evidence-based practice provides patient-specific recommendations for the patient and the physician (Hunt, Haynes, Hayward, Pim, & Horsman, 1998). Although this kind of service delivery is yet to be developed in the treatment of children with psychiatric illness, it is a direct outcome of evidence-based practice.

The final step requires the clinician to consider other critical issues related to the selected treatment approach before implementation, including the following (Donald & Muthu, 2001, p. 36):

1. Is the treatment or technique available/affordable?
2. How large is the likely effect?

3. How uncertain are the study results?
4. What are the likely adverse effects of treatment? Are they reversible?
5. Are the patients included in the studies similar to the patient(s) I am dealing with? If not, are the differences great enough to render the evidence useless?
6. Was the study setting similar to my own setting?
7. Will my patient receive the same co-interventions that were used in the study? If not, will it matter?
8. How good was adherence (compliance) in the study? Is adherence likely to be similar in my own practice?
9. Are the outcomes examined in the studies important to me/my patients?
10. What are my patients' preferences regarding the treatment's likely harms and likely benefits?
11. If I apply the evidence inappropriately to my patient, how harmful is it likely to be? Will it be too late to change my mind if I have inappropriately applied the evidence?

17.4.2 Cost Effectiveness of the Selected Treatment

A key issue in evidence-based practice is what the clinician means by effectiveness; that is, how do clinicians decide if a treatment for a specific disorder or condition works? If we take the pharmacological treatment of an adolescent with obsessive-compulsive behaviors as an example, then effectiveness can be defined in a number of specific ways: (a) Is a chosen drug's action pharmacologically effective in inhibiting the physiological mechanisms that are expressed as obsessive-compulsive behaviors? (b) Is the drug clinically effective in controlling the obsessive-compulsive behaviors? (c) Is the drug effective from the adolescent's point of view? (i.e., does it enhance the quality of life of the adolescent being treated), and (d) Is the drug effective in terms of value for money?

A given drug's mechanism of action is often inferred from its clinical impact, because we know so little about its actual mechanism of action. Thus, researchers and drug companies are interested in pharmacological effectiveness, because of their focus on the properties of the drug itself. However, clinicians are interested in clinical effectiveness, because it shows them whether a given drug reduces or controls a given disorder or condition. Patients are interested not only in whether their disease or disorder is reduced or controlled, but are also keen in knowing whether the treatment has enhanced his or her quality of life. That is, does the drug have unintended negative effects ("side-effects") that compromises their functional skills? For example, if the obsessive-compulsive behavior is completely controlled by the drug at a given dose, but its side effects include cognitive dulling and lethargy, the adolescent may conclude that the treatment was not very effective for him or her.

For those interested in health policy or utilization management, effectiveness is defined in terms of cost-benefit relationships. A drug that provides total control but is twice as expensive as another that provides reasonably good control, then the first drug does not represent value for the money, at least for the health care systems (Fraser, 1996; Wickizer & Lesser, 1998). Clearly, factors other than just clinical outcomes determine what is meant by effectiveness and what treatment will be chosen in clinical practice. The clinician's final choice of an empirically validated treatment may be inextricably bound to the overall system of care that provides the framework for financing and delivering such services to children. These are extremely important considerations in the current era of managed health care.

17.4.3 Information on Evidence-Based Treatment Approaches

Clinicians who wish to use a broad range of evidence-based treatment approaches for treating childhood disorders can access multiple sources of information. First, there are reviews of the literature on evidence-based treatment approaches. One of the best sources for pharmacological adjuncts for childhood disorders is the *Child and Adolescent Psychiatric Clinics of North America*, a hybrid of a research journal and a research book (Martin, 2006). Recent issues of this series have included relevant issues on evidence-based practice (Burns & Hoagwood, 2004, 2005), psychopharmacology (Martin & Bostic, 2006), and specific disorders, such as ADHD (Rohde & Faraone, 2008). Furthermore, the *Journal of the American Academy of Child and Adolescent Psychiatry* publishes 10-year reviews of psychopharmacological treatments of childhood disorders, as well as clinical guidelines (Gleason et al., 2007) and special communications (DeVeaugh-Geiss et al., 2006). In addition to psychopharmacology adjuncts, reviews of evidence-based psychotherapies (Goodheart, Kazdin, & Sternberg, 2006; Kazdin & Weisz, 2003) and other treatments (Barrett & Ollendick, 2004) are also available.

Second, specifically with regard to psychopharmacology adjuncts, the American Psychiatric Association (APA) periodically develops Practice Guidelines, which are analogous to evidence-based practices for particular psychiatric disorders, through consensus panels of experts and approved by a vote of the APA Assembly and Board of Trustees (Frances, Docherty, & Kahn, 1996). Furthermore, the APA publishes and periodically updates a compendium of Practice Guidelines on major psychiatric disorders (American Psychiatric Association, 2006). The American Academy of Child and Adolescent Psychiatry publishes Practice Parameters in the *Journal of the American Academy of Child and Adolescent Psychiatry*. These Practice Parameters are designed to assist clinicians in providing high-quality assessment and treatment that is consistent with the best available scientific evidence and clinical consensus. While they describe generally accepted practices, Practice Parameters should not be considered rigorously evidenced-based. In general, Practice Guidelines and Practice Parameters are useful in providing clinicians with a treatment framework in areas where there is limited empirical data to determine evidence-based practices. However, clinicians are reminded that practice guidelines developed by consensus panels or groups of reviewers may be biased in some ways and may also diverge from the research literature (Barlow, 1994; Beutler, Clarkin, & Bongar, 2000).

Third, clinicians have access to treatment algorithms – a formal set of rules and step-by-step approach that can be used to solve a clinical problem. There are several algorithms for the use of psychopharmacology in treating individuals who have psychiatric disorders. The best known of these is the Texas Medication Algorithm Project (TMAP), which provides medication algorithms for treating persons with serious mental illness, including the treatment of schizophrenia, bipolar disorder, and major depression. Expert panels developed these algorithms based on literature reviews, consensus conferences, consumer input, and reviews by academic and non-academic clinicians (Crismon et al., 1999). However, clinicians will be well advised to take a cautious approach, because there has been controversy regarding bias towards certain drugs advocated in published treatment algorithms. This has resulted as a direct outcome of pharmaceutical companies funding the consensus panels that have developed the psychopharmacology treatment algorithms. Further, certain drugs may not be advocated because of cost considerations even though they may have proven to be effective in randomized control trials.

In summary, there are a number of methods available in the research literature that enables clinicians to search for specific treatments that have been empirically validated for

the treatment of specific disorders or conditions. However, the field of child and adolescent psychiatry is relatively juvenile when compared with that of adults, and there is only an emerging research literature on empirically validated treatments. In the absence of data from well-controlled clinical trials, clinicians might utilize other sources of information, such as practice guidelines and expert consensus guidelines, to inform their clinical work. Clinicians should be aware that many practitioners have significant concerns regarding the use of evidence-based approaches in routine clinical care. They point to the fact that evidence-based research is not based on real-world patients, and thus, the treatment approaches may well produce different results in routine clinical practice. There is also the finding that evidence-based approaches do not consider clinicians' tacit knowledge or "knowledge in practice" (Polanyi, 1967). The clinician should perhaps be better advised to engage in *evidence-informed practice* that begins with the particulars of the individual patient, and develops a course of treatment that is informed by empirical evidence. Thus, good evidence forms a part of the discussions with the individual patient about his or her specific treatment.

17.5   Mechanisms of Change Underlying the Intervention

Even with the vast amount of research being undertaken in psychopharmacology and molecular biology, our understanding of the mechanism of change brought about through the use of psychopharmacological agents for treating psychiatric disorders is, at best, incomplete. For example, we know that all clinically effective typical and new generation (atypical) antipsychotics block the central dopamine receptors. The focus of the typical antipsychotics is on the D2 receptors, while the focus of the new generation (atypical) antipsychotics is on the D1, D4, and serotonin (5HT) receptors. Beyond these general findings, implications for a mechanism of action are unclear in terms of a specific antipsychotic drug prescribed for a specific psychiatric symptom for a specific child. Fortunately, clinical psychologists do not necessarily need to have a complete understanding of the mechanism of action of drugs to consider pharmacological adjuncts as part of their treatment regimen for a particular child.

Psychopharmacology is a subspecialty of pharmacology that deals with the chemistry, disposition, actions, and clinical pharmacology of psychotropic drugs. The two most important branches of psychopharmacology that should be of interest to clinicians are pharmacokinetics and pharmacodynamics. Pharmacogenetics, which can be considered as a component of pharmacodynamics, is increasingly viewed as being very important in our understanding of the effects of psychotropic drugs (Singh & Ellis, 1998). When psychotropic drugs are prescribed primarily for psychiatric disorders, they are intended to affect the mental processes of the individual (i.e., to sedate, stimulate, or otherwise change mood, thinking, or behavior).

17.5.1 Pharmacokinetics

Pharmacokinetics describes the time course of drug concentrations and the effects of drugs and their metabolites on the body. Thus, it describes what the body does to a drug.

Pharmacokinetic factors. The most important pharmacokinetic factors that affect time course and the effects of drugs on individuals include the following: (a) *absorption*, which is the process that determines how a drug travels from the site of administration to the site of measurement

(e.g., plasma, whole blood); (b) *first-pass effect*, which is the hepatic extraction of orally administered drugs before they reach the systemic circulation; (c) *distribution*, which indicates how much of a drug is distributed to the various organs or sites of action throughout the body; (d) *steady-state concentration*, which indicates the concentration of the drug when the amount administered is equal to the amount eliminated per unit time; (e) *half-life*, which is the time required for the concentration of the drug in plasma or whole blood to fall by one half; (f) *elimination rate constant*, which is the proportion of the drug in the body that is eliminated per unit time; (g) *clearance*, which provides a measure of elimination of the drug from the body and is calculated by multiplying the amount of drug in the body by the elimination rate constant; (h) *first-order kinetics*, which occurs when the amount of the drug eliminated per unit time is directly proportional to its plasma concentration; and (i) *zero-order kinetics*, which occurs only when a fixed amount of the drug is eliminated per unit time regardless of the plasma concentration. Data on these factors can be used to draw a unique kinetic profile of a given drug.

Steady-state condition. As the name implies, an individual taking prescribed medication on a regular dosage schedule will reach a steady-state condition. In principle, 50% of the eventual steady-state plasma drug concentration is reached in one half-life of the drug, 87.5% in three half-lives, and more than 97% in five half-lives. For example, if a drug has a half-life of 24 h, its steady-state level in an individual can be estimated on days 5 or 6. When a steady-state is reached, the individual's mean plasma drug concentration will remain constant as long as his or her dosing schedule and drug clearance does not change. Physicians often use the mean steady-state drug concentration to predict the likelihood of therapeutic efficacy or adverse effects, such as toxicity (Friedman & Greenblatt, 1986).

Several factors may alter an individual's steady-state condition. For example, unless the prescribed drug is given by continuous intravenous infusion, it is likely that the individual will experience interdose fluctuation in his or her mean plasma drug concentration, because he or she will be on discrete multiple doses. Under these conditions, his or her plasma drug concentration will rise above and fall below the mean steady-state value during each dosage interval. The extent of fluctuation that occurs depends on many factors, including the half-life value and absorption profile of the drug. For example, greater interdose fluctuations occur with drugs that have short half-life value (e.g., stimulants) than those with long half-life values (e.g., antipsychotics). Clinically, this signifies that the daily dosage of drugs with short half-life values may need to be given more frequently in subdivided doses. An alternative is to use sustained release formulation of the same drugs, because their slow absorption profile will reduce the interdose fluctuation in plasma drug concentration.

Many psychotropic drugs have pharmacologically active metabolites that reduce the interdose fluctuation at steady-state, because the active metabolites usually fluctuate less than their parent drug (Caccia & Garattini, 1990). One of the practical implications of such drugs is that the relationship between plasma drug concentration and clinical outcome becomes more complicated, because the levels of both the parent drug and those of its active metabolites must be considered simultaneously. Given that some active metabolites may have a longer half-life than the parent drug, the drug effects may persist well beyond the clearance of the parent drug at discontinuation because of the sustained levels of the long half-life metabolites. For example, pharmacokinetic studies show that the effects of norfluoxetine persist when fluoxetine, the parent drug, has cleared from the body (Plato, Murphy, & deVane, 1991).

Clinicians must also be aware of time-dependent kinetics, which refers to changes in the rates of pharmacokinetic processes over time, because these may alter the steady-state

drug concentrations. For example, research on plasma kinetics of carbamazepine shows that the drug may induce its own metabolism. That is, the half-life of carbamazepine is longer in an individual just starting the therapy than in those who have used it chronically, suggesting that steady-state drug concentrations decrease over time (Eichelbaum, Ekbom, Bertilsson, Ringberger, & Rane, 1975). This finding has important implications in terms of dosing and clinical outcome across individuals. Other concurrent events that may alter the steady-state drug concentrations include disease states, such as cardiac, renal, and liver disorders, which can markedly alter the kinetics of the psychotropic drugs through changes in the metabolism, excretion, distribution, and protein-binding of the drugs. Clinically, this means that the dose adjustments may be necessary when these disease states occur (Bennett, 1988; Williams & Benet, 1980). For example, clinicians often use creatinine clearance as a measure of renal function to estimate a dose adjustment for many drugs in renal failure (Bennett, 1988).

17.5.2 Pharmacodynamics

Pharmacodynamics deals with the relationship between drug dosage or concentration in the body and its drug effects, both desirable and undesirable. Thus, it deals with the mechanism(s) of drug action and generally describes what a drug does to the body.

Pharmacodynamic factors. The most important pharmacodynamic considerations include the following: (a) *receptor mechanism*, which describes how the drug binds at the cellular level and initiates its pharmacodynamic effects; (b) *dose-response curve*, which provides a plot of the drug concentration against the effects of the drug, and it allows the comparison of the efficacy and potency of the drugs; (c) *therapeutic index*, which provides a relative measure of the toxicity and safety of a drug and is calculated by dividing the median toxic dose by the median effective dose; (d) *lag time*, which is the time taken for the full therapeutic effects of a given drug to appear, and the reasons for a delay in the effects may be pharmacokinetic, pharmacodynamic, or both; and (e) *tolerance*, which refers to the responsiveness of an individual to a particular drug as it is administered over time.

Pharmacogenetics. Pharmacogenetics deals with idiosyncratic or unusual drug responses that have a hereditary basis (Weber, 2008). Responses to psychotropic and other drugs are modulated by their genetic predisposition. This is because "genes encoding enzymes or proteins that play a role in the drug response differ in some respect from one individual to the next" (Nebert & Weber, 1990, p. 469). When all other variables are held constant, an individual's pharmacogenetic response reflects a genetic difference in the metabolic rate when compared with that of a control participant. For example, Zhou, Koshakji, Silberstein, Wilkinson, and Wood (1989) compared the physiologic effects and the pharmacological disposition of the drug propranolol in a group of Caucasian Americans and a group of Chinese Asians. They reported that the Chinese participants were more responsive to the drug, displaying a larger reduction in the heart rate and blood pressure because they metabolized the drug more efficiently than the participants in the Caucasian group.

According to Nebert and Weber (1990), idiosyncratic drug responses that may be owing to the genetic variation in any of the subcellular steps involved in pharmacokinetics include the following mechanisms: (a) transport (absorption, plasma protein-binding); (b) transducer mechanism (receptors, enzyme induction, or inhibition); (c) biotransformation; and (d) excretory mechanisms (renal and biliary transport). Typically, clinical observations, family or twin

studies, protein polymorphisms, animal modeling, and deoxyribonucleic acid (DNA) poly-morphism characterizations are methods used to discover new atypical drug responses that may have a pharmacogenetic basis. The clinical importance of pharmacogenetics is that clinicians should be aware of the possibility of differences in drug response and dose requirements among children from various ethnic and racial groups.

17.5.3 Other Factors Affecting the Outcome of Pharmacological Treatments

The effects of psychotropic drugs are seldom determined solely by their pharmacological properties. Indeed, psychotropic medication is prescribed and used within a transactional *system* among children with psychiatric disorders, his or her family, physician, and other clinicians, as well as others (e.g., teachers, peers) who are significant in the life of the individual (Singh & Aman, 1990). Of course, we must remember that children often do not request assistance from physicians directly; but, their parents and other caregivers do. The child's views of the treatment process, his or her therapeutic alliance with the physician, and his or her attributions of the effects of medication are also important and may be responsible for at least some of the effects of pharmacotherapy (Towbin, 1995). Furthermore, other factors, such as compliance, placebo effects, and sociocultural factors are important in treatment outcome. However, almost all the studies on psychopharmacology of children have focused on biological, behavioral, and learning variables with the exclusion of many others.

Singh and Aman (1990) noted that our knowledge of the intended effects of psychotropic medication in children is often based on an assessment of the changes in the target behavior, symptoms, and syndrome as a result of a controlled trial of a given drug. They criticized this approach on the grounds that it does not include the study of interactions and interrelationships among environment, behavior, and drugs. A majority of the child and adolescent psychopharmacology researches, in general, focus on the consequences of specific drugs or drug combinations on the target behavior or diagnosis, without regard to the setting events or contextual factors that may influence the effects of these drugs. A transactional analysis would require that effects of pharmacological therapy be examined in terms of setting events; that is, the relevant contextual variables that transact to determine the treatment outcome. Some of these variables include behavioral teratogenesis, behavioral toxicity, compliance, comorbidity, placebo effects, reciprocal interactions, social variables (e.g., smoking and use of non recreational drugs), various sociodemographic variables (e.g., age, gender, and ethnicity), among others (Singh, Ellis, & Axtell, 1998). Psychopharmacology for children is a complex and rapidly moving field of research and clinical practice, and interested clinicians should read expert texts (Janicak, Davis, Preskorn, Ayd, Pavuluri, & Marder, 2006) and clinical handbooks (Preston, O'Neal, & Talaga, 2008; Werry & Aman, 1999) to keep abreast of the field.

17.6   Basic Competencies of the Clinician

A majority of the child clinical psychologists within APA's Division of Clinical Psychology are consulted by or consult with physicians on medical issues in the treatment of children with psychiatric disorders (Barkley et al., 1990). In addition, child psychologists assist physicians in

evaluating or monitoring the effects and side effects of medication on child and adolescent patients. Many primary care physicians include psychologists when discussing the psychopharmacological treatments with their patients (Bell, Digman, & McKenna, 1995). Owing to their broad knowledge of assessment and psychosocial treatments, the increasing use of pharmacological adjuncts in children in their practice, and their increasing collaboration with physicians in making medication decisions, the child clinical psychologists have sought to advance their knowledge of psychopharmacology through systematic training (Barnett & Neel, 2000). Given that most clinical psychologists see individuals who are on medication, particularly psychotropic medication for psychiatric disorders, it behooves them to have a working knowledge of clinical psychopharmacology (American Psychological Association [APA] Board of Educational Affairs, 1995). Indeed, it has been suggested that lack of such knowledge would be tantamount to malpractice (Foxhall, 1999).

An APA Task Force identified three levels of training in psychopharmacology (American Psychological Association [APA] Board of Educational Affairs, 1995, 1997) for clinical psychologists. Level 1, a single-semester doctoral-level training program, focuses on basic psychopharmacology that enables a clinician to provide assessment and treatment services to their patients. Level 2, a post-doctoral training program, focuses on collaboration between clinical psychologists and licensed prescribers "to manage medications prescribed for mental disorders and integrating these medications into psychosocial treatment" (Smyer et al., 1993, p. 398). Level 3, another post-doctoral training program, focuses on psychopharmacology training at the expert level that is prerequisite for prescribing privileges. The Level 1 course includes the following nine modules that can be adapted to predoctoral internships, doctoral programs, post-doctoral residencies, and CE workshop series:

1. Biological Bases of Psychopharmacological Treatment – 1 module
2–3. Principles of Psychopharmacological Treatment – 2 modules
4. General Introduction to Clinical Psychopharmacology – 1 module
5. Introduction to Psychopharmacological Treatment of Psychoactive Substance-Abuse Disorders – 1 module
6. Introduction to Psychopharmacological Treatment of Psychotic Disorders – 1 module
7. Introduction to Psychopharmacological Treatment of Mood Disorders – 1 module
8. Introduction to Psychopharmacological Treatment of Anxiety Disorders – 1 module
9. Introduction to Psychopharmacological Treatment of Developmental Disorders – 1 module

The modules include the purpose, learning objectives, major content areas of the syllabus, and sample test questions. The composite modules 2 and 3 are presented as an example in the subsequent section.

17.7   Principles of Psychopharmacological Treatment

17.7.1 Purpose

The purpose of these modules is to provide a fundamental understanding of how drugs are delivered to and removed from their site(s) of action; impart basic knowledge on the pharmacological features of different classes of drugs and the way in which these drugs produce their biological effects; give examples of clinically relevant drug interactions that illustrate the

pharmacodynamic and pharmacokinetic principles of drug effects; and describe the methods by which drugs are classified, regulated, and controlled by governmental agencies. These modules will provide the learners with basic mechanisms and principles of drug action that will enable more focused study on psychopharmacologic treatments.

17.7.2 Learning Objectives

These modules are designed to help the learner to:

1. Know the major chemical features of drugs that influence their effects on biological systems. Identify the major influences of drug absorption, distribution, and elimination, including a fundamental understanding of: (a) body compartments throughout which drugs distribute; (b) relationships between different routes of administration and bioavailability; (c) role of kidney, liver, and other organs in the elimination of drug and drug metabolites; and (d) the meaning and relevance of clearance rate, half-life, and first-pass effect.
2. Know the different types of receptors through which the drugs exert effects and the various mechanisms by which the drugs produce the effects through the receptors. Understand the principles that govern the actions of drugs at receptors and know the definitions and biological relevance of affinity, efficacy, and spare receptors. Recognize the pharmacological and physiological parameters that determine the selectivity, specificity, and potency of a drug.
3. Be able to describe and give examples of the various mechanisms by which drugs from the same and different pharmacological classes can interact. Know the therapeutic implications (positive and negative) of the drug combinations and drug interactions.
4. Understand the dynamic interactions that occur between drugs and behavior, and appreciate the importance of environment in determining drug action.
5. Appreciate the sources of individual differences in drug action that occur in association with gender, ethnicity, age, and specific physical conditions.
6. Know the various ways by which drugs are classified, including categories assigned by therapeutic uses. Identify how drugs are scheduled and the characteristics that lead to the classification in Schedules I through V.

17.7.3 Major Content Areas of the Syllabus

I. PHARMACOKINETICS

A. Absorption
    1. Passage through cell membranes
        (a) Passive diffusion
        (b) Carrier-mediated transport
            1. Facilitated diffusion
            2. Active transport
        (c) Pinocytosis
    2. Factors affecting absorption
        (a) Drug solubility
        (b) Route of administration

    (c) Concentration at the site of absorption

    (d) Blood flow at the site of absorption

    (e) Weak acids and bases, pH, and ionization

    (f) Age, gender, and ethnic considerations

  3. Sites of drug absorption

    – Oral, gastrointestinal, parenteral, others

B. Distribution

  1. Blood flow

  2. Plasma protein-binding

  3. Barriers (blood–brain, placenta)

  4. Redistribution (e.g., thiopental)

  5. Age, gender, and ethnic considerations

C. Elimination

  1. Biotransformation (metabolism)

    (a) Deactivation, activation (e.g., prodrug)

    (b) Sites of transformation

      1. Liver

      2. Lung

      3. Gastrointestinal

      4. Kidney

      5. Blood

    (c) Filtration and bulk flow

    (d) First-pass effect

    (e) Factors affecting metabolism

      1. Age

      2. Gender

      3. Ethnic

      4. Others (e.g., diet)

    (f) Enzyme inhibition

    (g) Enzyme induction

  2. Excretion: Renal, biliary, pulmonary, sweat, saliva, tears, milk, hair, skin

  3. Plasma half-life and biological half-life

  4. Physiologic modulation of drug elimination (e.g., pH)

D. Clinical pharmacokinetics

  1. Bioavailability

  2. Volume of distribution (Vd)

  3. Single and multiple compartment models

  4. Single and multiple administrations and constant infusion

  5. Steady state

  6. Zero- and first-order kinetics

II. PHARMACODYNAMICS

A. Receptor-mediated drug action

  1. Families of receptors

    (a) Cell surface (transmembrane)

1. Ligand-gated (channel)
2. Second-messenger linked (e.g., cAMP)
   (b) Intracellular (e.g., steroid)
2. Receptor regulation
3. Receptor desensitization
4. Receptor theory
   (a) Importance of free drug concentration at the receptor
   (b) Affinity (Kd)
   (c) Efficacy
      1. Full, partial, and inverse agonists
      2. Spare receptors
      3. Structure–activity relationships
   (d) Antagonism
      1. Simple competitive
      2. Noncompetitive
      3. Irreversible
      4. Pharmacologic versus physiologic
   (e) Specificity and selectivity of the drug action
      1. Relative affinities
      2. Availability of specific receptor types and subtypes
   (f) Dose–response relationships
      1. Threshold dose
      2. Potency
      3. Quantal and graded effects
      4. ED50
      5. LD50
      6. Therapeutic index
B. Receptor-independent drug action
   1. Alter normal metabolism (antiparkinson, antihypertensives)
   2. Alter chemical actions (anticoagulants)
   3. Alter physical structure (general anesthetics)
   4. Alter enzymatic activity (antibiotics)

III. DRUG INTERACTIONS (PHARMACOKINETIC AND PHARMACODYNAMIC)

A. Types of interactions
   1. Addition
   2. Synergism
   3. Potentiation
   4. Antagonism
   5. Novel action
B. Consequences of interactions
   1. Adverse effects
      (a) Tolerance
      (b) Dependence
      (c) Allergic reaction
   2. Altered (increased or decreased) therapeutic action

IV. BEHAVIORAL MECHANISMS OF DRUG ACTION

A. Environmental considerations
  1. Pharmacological history
  2. Behavioral history
B. Pharmacological and behavioral history and drug action
C. Tolerance and cross tolerance
  1. Pharmacokinetic
  2. Pharmacodynamic
  3. Behavioral (associative versus nonassociative)
D. Physical dependence and withdrawal
  1. Acute
  2. Chronic
E. Animal models of central nervous system dysfunction
  1. General experimental designs
    (a) Depression
    (b) Anxiety
    (c) Aggression
    (d) Schizophrenia
    (e) Movement disorders
    (f) Cognitive disorders
    (g) Drug abuse
  2. Validation of procedures
    (a) Face validity
    (b) Pharmacological validity
  3. Predictive value
  4. Problems and confounds

V. NOMENCLATURE, REGULATION, SCHEDULES

A. Ways in which drugs are classified:
  1. Origin
  2. Action
  3. Mechanism of action
  4. Site of drug action
  5. Therapeutic use
  6. Chemical structure
  7. Proprietary/trade names
  8. Street names
B. Common classification system for psychoactive drugs:
  One commonly accepted classification system of psychoactive drugs organizes them into seven classes by therapeutic use:
  1. Sedative-hypnotic compounds (CNS depressants)
  2. Stimulants and anticonvulsants
  3. Analgesic agents
  4. Antianxiety agents
  5. Mood-stabilizing agents

6. Antidepressant agents
7. Antipsychotic agents
C. Drug regulation and scheduling
   1. Controlled Substance Act, 1991
   2. Comprehensive Drug Abuse Prevention and Control Act of 1970
   3. Scheduling of drugs
     (a) Role of Health and Human Services
     (b) Role of Food and Drug Administration
   4. Enforcement of drug laws
     (a) Role of Department of Justice
     (b) Role of Drug Enforcement Administration
       – Controlled Substances Inventory
   5. Factors considered in scheduling of drugs
     (a) Abuse potential
     (b) Scientific evidence on pharmacological effects
     (c) Scientific evidence on pharmacologic properties
     (d) Current and historical patterns of abuse
     (e) Scope, duration, and significance of abuse
     (f) Risk to public health
     (g) Evidence on psychological and/or physiological dependence
     (h) Relationship to an already-controlled substance
D. List of Schedules, defining characteristics, and examples of the drugs
   1. Schedule I
   2. Schedule II
   3. Schedule III
   4. Schedule IV
   5. Schedule V
E. Teratogenic potential categories, defining characteristics, and examples of drugs
   1. Category A
   2. Category B
   3. Category C
   4. Category D
   5. Category X

17.7.4 Sample Test Questions

1. What route of administration typically delivers a drug fastest to the brain?
   (a) Intravenous
   (b) Oral
   (c) Transmuscular
   (d) Inhalation

2. What kind of action takes place at the post-synaptic membrane if a re-uptake inhibiting drug is applied?
   (a) Potentiation of the action of the synaptic neurotransmitter
   (b) Antagonistic properties

    (c) Upregulation

    (d) Termination of the action of the synaptic neurotransmitter

3. The half-life of a drug is_____.

    (a) A fixed property

    (b) Usually a function of urinary output

    (c) Affected by individual and group differences

    (d) Dependent on the disorder being treated

4. LD50 is a measure of a drug's_____.

    (a) Lowest dose that is effective for 50% of patients

    (b) Blood plasma level

    (c) Elimination rate for 50% of the drug

    (d) Lethality

5. Serotonergic function is most related to which of the following?

    (a) Abuse of benzodiazepines

    (b) Depression

    (c) Mania

    (d) Schizophrenia

6. Affinity and efficacy are properties of which types of drugs that act as receptors?

    (a) Agonists

    (b) Antagonists

    (c) Both agonists and antagonists

    (d) Neither agonists nor antagonists

7. Hepatic first-pass effect will not affect a drug that is administered by the_____ route.

    (a) Intramuscular

    (b) Sublingual

    (c) Transdermal

    (d) All of the above

8. The apparent Vd of a drug increases with_____.

    (a) Increased molecular weight

    (b) Increased first-pass effects

    (c) Increased lipophilicity

    (d) Increased polarity

9. Increases in the number of functional receptors will_____.

    (a) Increase the half-life of a reversible antagonist

    (b) Decrease the potency of a low-efficacy agonist

    (c) Have little or no effect on a high-efficacy agonist

    (d) Increase the potency of agonists and antagonists

10. A decrease in the gastrointestinal motility will have what effect on a drug that is absorbed slowly and incompletely from the small intestine?

    (a) Increase elimination

    (b) Decrease absorption

(c) Increase absorption

(d) No effect

11. Darvon is classified under which Schedule?
    (a) Schedule I
    (b) Schedule II
    (c) Schedule III
    (d) Schedule IV
    (e) Schedule V

12. The Comprehensive Drug Abuse Prevention and Control Act specifically excludes:
    (a) Distilled spirits and look-alike drugs
    (b) Cigarettes and antidiarrheal drugs
    (c) Wine and malt beverages
    (d) Immediate precursors of controlled substances
    (e) Herbal medications and look-alike drugs

17.8   Expert Competencies of the Clinician

Advanced training is available at Level 2 once the clinician has demonstrated prerequisite competencies at Level 1. Such training is at post-doctoral level, with one of the four areas of training being child and adolescent psychopharmacology. The curriculum and competencies for this course are presented in the following section.

17.8.1 Child and Adolescent Psychopharmacology

I. Professional and Legal Issues

Purpose and Learning Objectives

The participants will acquire advanced knowledge and understanding of:

A. The nature of the collaborative relationship between psychologist and pediatrician/psychiatrist/family practitioner. A focus on the benefits obtained and difficulties involved in collaborative practice for the purpose of facilitating an integrative relationship in the care of children and adolescents.

B. The legal and ethical issues to consider as part of a collaborative practice with the introduction of or changes in the pharmacological interventions with children and adolescents.

Content Areas

A. Interdisciplinary collaboration between psychologist and pediatrician/child psychiatrist/family practitioner
    1. Benefits
    2. Training, philosophical, assessment, and treatment differences between psychologists and physicians
    3. Responsibility issues
    4. Child/parent/family variables and their effects on the collaborative process

     5. Development of or difficulty in an integrated collaborative relationship

     6. Teacher and appropriate school personnel

B. Legal and ethical issues

    1. Scope of practice limitations

       (a) Consultation and referral

       (b) Providing mental health services to those referred by others

       (c) Boundaries of competence and need to maintain current knowledge

       (d) Avoiding harm

       (e) Vicarious liability

    2. Confidentiality

    3. Informed consent

       (a) Providing information

       (b) Volunteering for consent

       (c) Individuals' competencies to provide consent

       (d) Special ethical considerations where consent may not be obtained

       (e) Specific consent issues with pediatrics populations

          i. Parental or caretaker authority

          ii. Authority of children

          iii. Developmental issues in assessing competency

          iv. Assent

       (f) Procedures for obtaining consent

       (g) Documenting consent

       (h) Issues of consent and custody

          i. Refusing treatment

          ii. Child

          iii. Parent or caretaker

          iv. Privilege

          v. Malpractice as a function of psychologists having better knowledge of psychopharmacology

    4. Governmental restrictions related to prescribing practices

      – COBRA 1987 restrictions (Medicare/Medicaid patients)

    5. Practice guidelines for treatment of mental disorders

      – APA guidelines

II. Assessment

Purpose and Learning Objectives

The participants will acquire advanced knowledge and understanding of:

Assessment and monitoring of physical effects, behavioral, emotional, and cognitive effects of various pharmacotherapies for children, adolescents, and individuals with specific developmental/medical disabilities

Content Areas

A. Physical

    1. Baseline physical assessment

    2. Medical review of organ systems

    3. Physical and neurological examination

4. Speech and language assessment
5. Monitoring untoward side effects
    (a) Side-effects rating scales
    (b) Physical and neurological examinations
6. Laboratory measures
    (a) Biochemical assessment of blood and urine
    (b) Electrophysiological measurement (e.g., EKG)
B. Psychological
    1. Rating scales
        (a) Self-ratings
        (b) Parent
        (c) Teacher
        (d) Families
    2. Direct observations of behavior
    3. Laboratory measures
        (a) Mental abilities
        (b) Measures of executive functioning
        (c) Vigilance measures
        (d) Measures of learning and tests of achievement
        (e) Effects of medication on mental abilities
        (f) Use of psychological tests and measures to determine appropriateness of medication
            i. Mental abilities
            ii. Neurocognitive functioning
            iii. Social/emotional competencies
            iv. Adaptive competencies
            v. Use of psychological tests to assess compliance
    4. Psychological and substance-abuse-disorder evaluation
C. Pharmacological
    1. Efficacy and untoward effects
    2. Evaluating response to medication
D. Environmental
    1. Misattributing behavior change to medication
        (a) Teacher
        (b) Parents
        (c) Child
        (d) Peers
    2. Placebo effects
    3. Informed consent
    4. Interaction of environment with psychopharmacotherapy

III. Pharmacological Issues and Pediatric Variations

Purpose and Learning Objectives

The participants will acquire advanced knowledge and understanding of:

Basic tenets of pharmacology, including pharmacokinetics and mechanisms of drug actions (pharmacodynamics), as they specifically relate to: (1) normally developing pediatric populations;

(2) pediatric populations with mental disorders; (3) pediatric populations with developmental and/or physical disabilities requiring medication; and (4) pediatric populations with developmental disabilities with comorbid mental disorders.

Content Areas

A. Common psychological disorders and drugs used to treat them
    1. Attention deficit disorders: stimulants
    2. Oppositional defiant and conduct disorder: clonidine
    3. Mood disorders: tricyclic antidepressants, heterocyclic antidepressants, specific serotonin reuptake inhibitors
    4. Anxiety-related disorders: anxiolytics
    5. Psychotic disorders: neuroleptics
    6. Regulation disorders: tricyclic antidepressants, antihistamines
B. In each of these conditions and for each of these drugs, the following factors need to be considered
    1. Routes of drug administration
    2. Distribution
    3. Elimination
        (a) Biotransformation
            i. Hepatic
            ii. Intestinal
            iii. Gastric
            iv. Renal
        (b) Variability in biotransformation in pediatric populations
        (c) Excretion
            i. Urine
            ii. Feces
            iii. Lungs
            iv. Sweat
    4. Pharmacokinetics
        (a) Volume of distribution
        (b) Metabolism
            i. Gender differences
            ii. Ethnobiologic considerations
            iii. Physically disabled considerations
        (c) Elimination and clearance
    5. Pharmacodynamics
        (a) Receptor density
        (b) Function
        (c) Gender differences
        (d) Ethnobiologic differences
        (e) Physically disabled differences
    6. Drug concentrations
    7. Time course of action
    8. Dose-dependent drug effects
        (a) Gender differences
        (b) Ethnobiologic differences
        (c) Physically disabled differences

9. Mechanisms of drug action
10. Tolerance and dependence
11. Pediatric pharmacokinetics

IV. Unique Issues for Youth with Developmental and Medical Conditions

Purpose and Learning Objectives

The participants will acquire advanced knowledge and understanding of:

The interaction between psychopharmacological treatment and developmental/medical conditions that might affect the side effects and treatment outcome.

Content Areas
A. Physical sequelae
B. Pharmacological factors
C. Unique untoward side effects
D. Response factors

V. Treatment Issues

Purpose and Learning Objectives

The participants will acquire advanced knowledge and understanding of:

A. Social and environmental factors that influence medication administration, efficacy, and untoward effects. Emphasis will be placed on the role of institutions including schools, general hospitals, and residential, rehabilitation, and psychiatric facilities, as they influence pharmacotherapy with children and adolescents with and without medical disabilities.
B. Various phases in psychopharmacotherapy including the decision of whether or not to initiate pharmacotherapy, assessing long-term benefits as well as untoward effects, and considering whether discontinuation of pharmacotherapy is warranted.
C. Psychopharmacotherapy, in particular, as it interacts with various nonsomatic psychotherapies. This will include an essential understanding of the efficacy of various psychopharmacologies either in combination with psychotherapy or alone.
D. Assessment and management of nonadherence with prescribed psychopharmacotherapy.

Content Areas
A. Overall planning of treatment strategies
    1. Clinical judgment
    2. Use of behavioral evidence
    3. Use of clinical pathways
    4. Use of algorithms/decision trees
B. Initiation of treatment of psychopharmacotherapy
    1. Physical assessment, baseline physical assessment, and laboratory tests
        (a) Pre-drug physical
        (b) Laboratory assessment
        (c) Substance-abuse assessment
    2. Patient and family education
    3. Obtaining consent for treatment
    4. Gender and ethnic considerations

C. Stabilization of psychopharmacotherapy
    1. Monitoring efficacy of psychopharmacotherapy
        (a) Cross-situational evidence of efficacy
            i.   Parents
            ii.   Teachers/school personnel
            iii. Child
        (b) Rating scales
        (c) Direct observations of behavior
        (d) Laboratory measures of cognition
    2. Assessment of untoward side effects
        (a) Formal behavioral assessments
            i.   Rating scales
            ii.   Direct observations
            iii. Physiological assessments
            iv.   Blood and urine measurements
        (b) Parent assessments
            i.   Parent education and anticipatory guidance
            ii.   Rating scales
        (c) Teacher assessments
            i.   Rating scales
    3. Dose–response relationships
D. Maintenance of pharmacotherapy
    1. Tolerance
        (a) Behavioral and psychological tolerance
        (b) Physical tolerance
    2. Dependence
        (a) Assessment of addiction potential
    3. Ongoing monitoring and assessment of efficacy
    4. Ongoing monitoring and assessment of untoward side effects
    5. Short-term versus long-term gains
    6. Normalization of behavior, cognition, and learning
    7. Domain specificity and individual differences
E. Discontinuation/follow-up
    1. Patient education
    2. Systematic evaluation of behavior across informants
        (a) Rating scales
        (b) Direct observations of behavior
    3. Titration of dose
    4. Ongoing psychoeducation and psychotherapy
F. Multimodal therapies
    1. Attributional effects of medication used alone
    2. Benefits of both biologically mediated therapies and psychological therapies (Biopsy-chosocial model)
    3. Systematic evaluation of comparative efficacy of psychopharmacotherapy and traditional psychotherapy, and the combination of therapies

G. Compliance
    1. Enhancing compliance
    2. Counseling and education
    3. Relationship between client or patient and prescribing physician
    4. Assessment of compliance
       (a) Length of psychopharmacotherapy
       (b) Number of doses
    5. Direct measures of compliance
       (a) Laboratory measures
       (b) Blood levels
    6. Indirect measures of compliance
       (a) Interviews
       (b) Pill counts
    7. Factors associated with treatment adherence
       (a) Patient-related variables
          i. Cultural
          ii. Biological
          iii. Gender
          iv. Religious issues (i.e. Jehovah's Witness)
          v. Untoward side effects
       (b) Clinician-related variables
       (c) Family-related variables
       (d) Peer-related variables
H. Psychoeducation
    1. Patient and parent education
    2. Teacher and school education

VI. Research

Purpose and Learning Objectives

The participants will acquire advanced knowledge and understanding of:

A. The importance of new developments in the field of pediatric psychopharmacology through systematic reading and critical analysis of recent research with regard to safety, efficacy, and cost-benefits analysis
B. Systematic controlled clinical research including clinical trials and single subject designs
C. Available sources for new research in the area of pediatric psychopharmacology including accessing of databases, informational services, and other resources
D. Theoretical models of central nervous system mechanisms

Content Areas
A. Research preparation
    1. Literature retrieval strategies
    2. Pharmacological retrieval strategies and databases
    3. Research strategies for single case and group studies

B. Preclinical/clinical research
1. Theoretical models of mechanism of disorder
2. Models of drug development
3. Measurement and design strategies
4. Safety/abuse liability
C. Conducting clinical research
1. Acute trials
2. Long-term follow-up trials
3. Developmental issues
4. Multimodal trials
5. Consumer satisfaction
6. Cost-effectiveness
7. Meta-analytic strategies

17.9 Transition from Basic Competence to Expert

Once Level 1 and 2 training (or some variant of these two training programs) is completed, clinical psychologists can begin the training process for obtaining prescription privileges. In addition to training in psychopharmacology, the psychologist must meet the following requirements: (a) a doctoral degree in psychology (i.e., Ph.D., Psy.D., Ed.D.); (b) current state license as a psychologist; and (c) practice as a "health services provider" psychologist, as defined by state law wherever applicable, or as defined by APA. APA's recommended postdoctoral training in psychopharmacology for prescription privileges (American Psychological Association, 1997) has the following requirements:

Demonstrated knowledge of human biology, anatomy and physiology, biochemistry, neuroanatomy, and psychopharmacology is a necessary prerequisite for embarking on this postdoctoral training. Demonstrated knowledge involves evidence of (1) successful completion of a planned sequence of courses at a regionally accredited institution of higher learning, or (2) evidence of successful completion of a planned sequence of continuing education courses offered by an accredited institution of higher learning or an approved provider of continuing education, and passage of an examination covering the content of such a program. Individuals who are licensed health professionals with comparable prescription privileges in another profession and who are also licensed psychologists may be considered as an exemption from these training requirements by state boards of psychology.

A minimum of 300 contact hours of didactic instruction is recommended in the following core content areas:

I. Neurosciences
(a) Neuroanatomy
(b) Neurophysiology
(c) Neurochemistry

II. Clinical and Research Pharmacology and Psychopharmacology
(a) Pharmacology
(b) Clinical Pharmacology

(c) Psychopharmacology
(d) Developmental Psychopharmacology
(e) Chemical Dependency and Chronic Pain Management

III. Pathophysiology

This includes normal anatomy and physiological processes, as well as common pathological states, with an emphasis on how alterations in cardiovascular, renal, hepatic, gastrointestinal, neural, and endocrine functions affect the bioavailability and biodisposition of drugs. This area should also address the variability in drug bioavailability and disposition owing to ethnic and cultural differences. The course should include normal human anatomy and physiology as well as common pathological conditions that impact on the safety and efficacy of psychotherapeutic medications. Furthermore, variability in response owing to age, gender, disability, and ethnic differences should also be addressed. In addition, medical conditions affecting drug biodisposition and the likelihood of side effects, including contraindications for medication use, should be covered in this course.

IV. Introduction to Physical and Laboratory Assessment and Laboratory Exams

It provides familiarity with medical charts, physical exams, laboratory, and radiological examinations.

V.   Pharmacotherapeutics
    (a) Professional, ethical, and legal issues
    (b) Psychotherapy/pharmacotherapy interactions
    (c) Computer-based aids to practice
    (d) Pharmacoepidemiology

VI. Clinical Practicum

The clinical practicum is designed to be an intensive, closely supervised experience involving exposure to a range of patients and diagnoses. Ideally, it will take place in both inpatient and outpatient settings, and allow the practitioner to gain exposure to acute, short-term, and maintenance medication strategies. Age, gender, disability, and ethnicity should be important factors in determining an appropriate patient mix. The trainee should treat a sufficient range and number of patients to gain experience across these dimensions. To achieve competency in treating a sufficiently diverse patient population, a minimum of 100 patients, for whom the trainee assumes direct clinical responsibility or participates in case conferences, should be a goal of training. The patient mix should be relevant to the psychologist's current and future practice. Additional didactics, such as the sequence in pharmacotherapeutics outlined earlier can be included as seminars or colloquia during clinical training, along with additional training in physical and laboratory assessment. Supervision should be provided by qualified practitioners with demonstrated skills and experience in clinical psychopharmacology.

The requirements for the clinical practicum include: (a) minimum of 100 patients seen for medication; (b) inpatient and outpatient placements; (c) inclusion of appropriate didactic instruction; and (d) minimum of 2 h weekly of individual supervision.

17.10 Summary

Clinical psychologists are well-trained in assessment, diagnosis, and a diverse range of psychosocial interventions. Clinicians in other disciplines, particularly psychiatry, pediatrics, and family medicine continue to find psychologists with these skills to be valuable collaborators in patient care. As with adults, psychologists working with children and adolescents increasingly find themselves treating patients whose treatment regimen includes medication for psychiatric or medical disorders and diseases. Thus, it behooves them to have a working knowledge on psychopharmacology, not only because it enables them to make informed judgments about the psychosocial interventions that they may prescribe, but also collaborate with their medical colleagues as well as provide guidance to children, adolescents, and their families on psychopharmacological adjuncts. Further, given that there is a continuing interest by some clinical psychologists to obtain prescription privileges, the need to obtain further training in psychopharmacology is paramount (Ax, Forbes, & Thompson, 1997; Ax & Resnick, 2001; Fagan, Ax, Liss, Resnick, & Moody, 2007).

We have outlined the rationale for clinical psychologists to have basic, advanced, and expert knowledge on the general field of psychopharmacology. The suggested APA Level 1 and 2 curricula provide the essential elements of basic and advanced training in psychopharmacology. The courses are designed to be adaptable so that the Level 1 program can be integrated into the doctoral programs in clinical psychology, and the Level 2 program into post-doctoral programs. In addition, both can also be provided as Continuing Education programs for practicing clinical psychologists. The APA Level 3 program is designed for those psychologists who are interested in obtaining prescription privileges. There is a number of training programs that appear to incorporate these requirements (Levant & Shapiro, 2002). In addition, clinical psychologists and training directors should review the training materials from other disciplines that have a history of teaching psychopharmacology and preparing physicians to prescribe psychopharmacological treatments. For example, the ASCP psychopharmacology curriculum for psychiatric residency programs is an excellent model that clinical psychologists can use in their training programs (Glick et al., 2008). Certainly, the current core competencies of doctoral psychologists will not be enough to adequately prepare them to prescribe medications to children and adolescents. Hence, they may need further foundational and advanced core competencies in psychopharmacology. Psychologists can begin the course work at the doctoral level, and achieve the required competencies at the postdoctoral, postlicensure level.

18 Family Issues

Alyson Williams · Jessica Bolton

Abstract: The aim of the present chapter is to discuss basic and expert competencies for effectively treating children and adolescents with family-related difficulties. Critical to developing competencies in any area involves an appreciation for gaps in knowledge; therefore, limitations to the current state of generalist training with regard to family issues are briefly outlined. The authors promote a systems theory approach for assessment and treatment that hinges on thoughtful consideration of the context in which an individual and family is embedded. Specifically, a number of conceptual and practical elements of assessment are highlighted, such as theoretical underpinnings, important domains of inquiry, and complementary forms of measurement. With regard to treatment, it is suggested that by adopting a systems-oriented conceptualization of the presenting problem, the therapist will engender a better understanding of maintenance factors and be better equipped to facilitate necessary change. While the authors promote evidence-based practice, training clinicians and supervisors alike are admonished to balance their empirical stance with a relational warmth and thoughtful creativity that can easily become neglected. To summarize, several suggestions germane to facilitating a fluid transition from novice to expert practitioner are discussed.

Overview

Psychologists and other mental health service providers in the roles of instructors and supervisors have the difficult task of teaching students to be at once respectful toward individual differences, mindful of general themes that might ring true for clients in particular groups, and also competent in seeing the "big picture" or context in which individual problems are embedded. Generally, the "big picture" includes the family and "family issues" – especially in child and adolescent psychology. Although this may seem intuitive rather than surprising, there are many barriers preventing effective training in the assessment and treatment of family-related problems. Limitations of current generalist training and methods for service reimbursement add to the difficulty of training psychologists to practice in a way that is appreciative of the impact of family issues on individual functioning, and also sustainable and efficient.

To overcome these limitations and motivate students and their instructors to pursue new directions in training, this chapter provides a road map for teaching and learning about the multiple components that lead to competency and expertise in treating family issues that involve children and adolescents. It is intended that the reader will gain a better understanding of the following: (a) competent assessment and recognition of family issues, (b) maintenance factors of problematic family issues, (c) basic mechanisms for facilitating change in family issues, (d) the current state of family-oriented empirically-based interventions, and (e) steps required to develop competence and expertise in the assessment and treatment of family issues. We begin by providing some background regarding the barriers faced by instructors and supervisors in the pursuit of effectively training students of psychology to assess and treat family issues that impact child and adolescent clients.

18.1 Contextual Information: History, Current Definition, Assumptions, and Limitations

18.1.1 History

Our conceptualization of "family issues" as a target for assessment and treatment in psychology has some foundation in systems theory. In family therapy, organizational behavior, and clinical theories courses, students are usually exposed to theories on system dynamics (e.g., Bronfenbrenner, 1977, 1979). In these courses, training might be centered on historical theories guiding the family therapy, organizational and general systems interventions, and specific, clinically oriented systems theory applications. A thorough review of systems theory is beyond the scope of this chapter. For further reading, the reader is referred to texts written by Becvar and Becvar (1998) and Broderick (1993). For the purpose of this chapter, it is useful for the reader to know that systems theory informs our definition of "family issues" as well as our suggestions on how to become competent in treating them. In a simpler way, the basic systems principle we draw on here is that any symptom or problem in an individual impacts the system in which that person is embedded. Specific to child and adolescent psychology, this implies that whether the child or other family member is struggling psychologically, everyone in the family is impacted in some way.

A separate, but perhaps less touted, contributor to family issues is encompassed in what we refer to here as *context*. Though not located in any one book or even one sector of the literature in psychology or other fields, an emphasis on the understanding of the context surrounding a child or adolescent client is crucial in assessing and treating family issues. That is, beyond paying homage to systems dynamics, it is suggested here that instructors, supervisors, and students use the plethora of historical and current literature on contextual factors impacting individuals. For example, behaviorism relies on the idea that the environment shapes behavior (Skinner, 1971, 1974). *Behavior setting theory* pays specific attention to how specific characteristics of the environment actually make certain behaviors impossible or almost certain (Schoggen, 1989). A number of other references allude to the interaction of systems in an individual's life that impact overall well-being and psychological functioning (e.g., Feldman & Pinsoff, 1982; Fingerman & Bermann, 2000; Magnusson, 1995). So, beyond systems dynamics, we draw here from the history of understanding provided in psychology and several other fields that the broad contexts in which the person is embedded and the people, resources, and situations they provide or lack also have an influence.

18.1.2 Current Definition

An initial barrier in treating "family issues" is a lack of consensus in defining them. For example, is depression a family issue? Several researchers would say "yes" (e.g., Katz, 1999; Messer & Gross, 1995). Is childhood anxiety a family issue? Siqueland and Kendall (1996) would argue it is so. Problems relating to juvenile delinquency are certainly "family issues" according to developers of many currently well-established models for treating adolescents who are incarcerated, detained, or on probation (e.g., Alexander & Sexton, 2002; Henggeler, Schoenwald, Borduin, Rowland, & Cunningham, 1998; Liddle, 2004). While the vaguely defined construct of family issues seems to unify researchers and practitioners across distinct problem areas, it still remains difficult to understand without some parameters. In this chapter, family issues are

defined as *problems or challenges in the familial, interpersonal/relational context of an individual that impact his or her functioning.*

There are a few things to be noted about this definition. First, the definition was designed to be inclusive of those relational difficulties that may not be occurring currently but continue to impact the individual. For example, a family issue of parental conflict during a client's childhood may impact his or her ability to attain satisfaction in intimate relationships as an adult (e.g., Bowlby, 1969, 1973, 1980). This type of difficulty might often be labeled as a family-of-origin issue (Nichols, 2003) and would fit into our definition of family issues.

An additional critical quality of the above definition is that the issues in question are not defined by the domain of treatment (e.g., individual, family, couple, or group therapy), but rather by their impact on an individual's functioning. This allows for the discussion of how to assess and treat family issues across individual, couple, group, and family therapies regardless of who is seen in treatment. It also necessitates explanation of who is defined as "the client," which is provided later in this chapter. For now, it is useful to note that family issues are not restricted to those addressed in family therapy. As such, this chapter offers tools and perspectives applicable to the treatment of family issues across different types of therapy.

Finally, the characterization of family issues as utilized throughout this chapter does not specify a separate definition for "family." Thus, there are no biological tests required to establish whether something is in fact a family issue. In addition, there is no inherent bias or value placed on family structure from which the family issues are derived. Using this definition of family issues implies that the therapist adopts an open and culturally sensitive view on what constitutes a family. It would be inappropriate to constrain the definition of family to the therapist's own perspective and contextual background. Instead, avoiding assumptions of biological relation, heterosexual parents, and married partners, for example, is required for the relationship of issue to be labeled as a "family" relationship. Within this definition, an unmarried couple of any sexuality may be considered a family. In addition, a single, foster mother and a best friend or neighbor of the client may also be considered the client's family. This way of characterizing families also allows for definitions of "family" unique to diverse cultures to be included. Perhaps, the most concrete examples of what one would consider a family issue would be parent–child conflict, or stressors between partners who consider themselves family. However, given our broad parameters for defining "family issues" such as general distress, interpersonal conflict, individual psychopathology, and any other range of problems may be assessed and treated as family issues.

Therapists might ask clients whom they consider family to determine which members of any given system may be important to include in treatment considerations. In addition, finding out with whom the clients live, and who is important to them in positive and negative ways can assist in identifying potentially important players in any family-sensitive intervention. Being an important player does not mean the identified person must be a part of therapy. Instead, it means the therapist must consider this person and his or her impact on the client and any intervention to be suggested throughout the course of therapy. The therapist must combine the client's definition of "family" with an astute observation of the important players to be as inclusive and thoughtful as possible when inviting family members to therapy, and when carrying out systemically oriented interventions for individual clients.

Apart from knowing the definition of "family issues" relevant for this chapter and effective training in psychology, it is also imperative that the reader become aware of some underlying assumptions regarding psychological problems embraced by the literature and the current authors.

18.1.3 Current Assumptions and Limitations

It is critical to make psychologists in training aware of the ways in which they might efficiently build competence in areas that are individually focused with regard to diagnosis. It is also critical, however, to foster in students the notion that whatever the specific diagnosis of a child or adolescent, treatment requires an appreciation for and critical thinking about the family context surrounding that individual. In line with this assertion, this chapter is written with the following underlying assumption: family issues are concurrent with any and every mental health strength and challenge that children and adolescents present in treatment. To be competent as a mental health provider, it is impossible to ignore them. As such, we argue that traditional, generalist training in psychology is limited with regard to its emphasis on using the Diagnostic and Statistical Manual ([DSM-IV-TR], 2000) and other diagnostic manuals (e.g., International Statistical Classification of Diseases and Related Health Problems, [ICD-9], 2008; Psychodynamic Diagnostic Manual [PDM], 2006) to assess and treat children and adolescents (and arguably many other types of clients). The limitations noted here are that presenting problems are assessed, treated, and billed as separate, individualized disorders. This, in turn, requires individually focused training for trainees to develop competency and appropriate practices for medical billing. As a consequence, psychologists in training acquire more skills in areas of individual diagnosis and individually focused treatment. Not surprisingly, the importance of family-related issues is underemphasized or dismissed in training, and the psychologists in training enter their professional careers with a fundamental challenge: while they see the connection between family contexts and individual diagnoses, they do not know how to work within family systems to maximize success in treatment.

To adequately address this challenge, the current authors assume that our trainees in psychology are required to become more than just technicians who can assess for diagnostic criteria and apply a worksheet from a manual by handing it to their clients. As may be a common experience, we have come across students and veteran psychologists who can implement specific techniques, but offer very little in warmth and the ability to think on their feet. Effective practice in the mental health field requires quick, critical thinking and creativity *in addition* to tools and diagnostic ability. The premise on which the remainder of this chapter is based is that intervention and diagnostic "tools" do not generally encourage critical thinking and creativity. Instead, they provide some important structure for the very complicated pursuit of helping children and adolescents in distress. It is argued here that this structure is necessary but not sufficient. We suggest that becoming competent in the assessment and treatment of family issues (and arguably any mental health issue presented by children and adolescents) requires knowledge of the "tools" as well as a solid foundation of critical thinking skills and creativity. The following section provides an overview of specific methods to facilitate the assessment and recognition of family issues as a primary challenge in treating youth.

18.2 Recognition and Assessment of Family Issues

As in any area, assessment and recognition of issues in the family realm is important. However, family issues involve multiple people and therefore multiple perspectives on "the problem." As such, problem recognition and assessment is arguably more complicated when it comes to family issues. Many clients enter treatment with a very clear definition of "the problem."

No detective work is required to hear and respond to a client's idea of the presenting problem. The challenge, however, is in how a clinician defines the problem prior to entering the therapy room. Prior to describing methods for assessing family issues, it is necessary to define "the problem" within the context of the family.

18.2.1 Defining the Problem

First, a psychologist treating family issues must acknowledge and examine how he or she views the nature of any clinical problem. In this chapter, the nature of any clinical problem is assumed to be relational. While this may sound logical with regard to the treatment of family issues, seeing the problem as between people rather than within an individual requires quite a shift in perspective for most clinicians.

One reason therapists may tend to see problems *intra*personally rather than *inter*personally is that the diagnostic and medical billing system for services is organized on an individual basis. Even in the diagnostic manual for mental disorders (DSM-IV-TR, 2000), there are no formal relational or familial diagnoses. This is true despite fairly widespread recognition that family strengths and challenges have a great deal to do with determining the causes, prevention factors, and continuance of problems, and effectiveness of treatment for child and adolescent mental health problems (Davis, 2004). While "V-codes" that describe family and relationship difficulties exist in the DSM-IV-TR (2000), none are reimbursed by insurance companies, and the manual itself is not geared toward relational assessment. It is important, however, for the reader to entertain the idea that problems are relational in nature rather than simply intrapersonal. This does not dismiss the notion that individuals experience legitimate, unique, non-relational difficulties captured within any given disorder listed in the DSM-IV-TR (2000). It is only to say this is not *all* an individual experiences. For appropriate assessment and recognition of family issues, the clinician must first entertain the idea that issues are, at least in part, relational in nature.

The second component of problem definition that warrants discussion with regard to family issues is the multiplicity of problems. As mentioned earlier, family issues imply the involvement and responsibility of more than one person; therefore, the number of perspectives on the problem multiplies. As such, it becomes essential for the family-focused clinician to observe presenting problems as indicative of a pattern that should be recognized and intervened upon as such, rather than a pile of problems requiring a variety of distinct solutions (Alexander & Sexton, 2002; Henggeler, Borduin, & Mann, 1993; Kazdin, 1997; Minuchin, 1974). This becomes especially important when considering family issues as a central focus of therapy. Although one could (and many clinicians do) simply pose the "what's the problem" question and go about treatment based on the client's answer, it is suggested here that this is an oversimplification of the nature of the problem at best. At worst, it becomes the platform for misguided and ineffective treatment.

To sum up, clinicians hoping to be effective should assume that the content of problems presented by clients is indicative of a problematic pattern of behavior, thoughts, or other things, and that this pattern is a more reliable and efficient target for change than the surface content (Minuchin & Fishman, 1981). If a therapist cannot recognize such patterns, she or he may end up in an endless pursuit of solving one, distinct problem at a time and will unwittingly discourage self-sufficiency in the client system.

18.2.2 Assessing and Recognizing the Problem

While reading the subsequent paragraphs on the assessment and intervention for family issues, it will be useful for the reader to keep in mind the two aspects of the "problem" described earlier: (a) problems are relational, and (b) assessing the recurring pattern underlying the content presented about the "problem" is important. The next sections describe conceptual and practical components of effective recognition and assessment of family issues in clinical work.

Assessment of family issues requires consideration of factors on multiple levels including individual, dyadic, and systemic factors. Therefore, the clinician must be aware of risk factors at each of these levels and craft an intervention that will address them cohesively, comprehensively, and concurrently. This section provides some examples of how this is done to maximize the chances for recognizing family issues, understanding the nature of the family issues, and setting up effective treatment to address them. It is organized to distinguish between conceptual and practical elements of assessment, which should begin to answer the questions of "what does assessment require?" and "how do I do it?" respectively.

Conceptual. Taking into account the required attention to multiple levels within any family system, it is first necessary for a clinician assessing family issues to be aware that any information (s)he gathers could be of value at any single level or all levels at once. Specifically, Bronfenbrenner's (1977, 1979) model of systems provides a useful framework to prepare a clinician to attend to them. At the very least, what Bronfenbrenner referred to as the individual, microsystem, macrosystem, and exosystem should be considered when assessing family issues. In addition, clinicians should attend to each relevant subsystem. That is, at each of these systemic levels, there will be biological factors, psychological or emotional factors, and relational factors affecting any client's well-being (Engel, 1977). With these systems in mind, the task of assessing family issues is to identify risk and protective factors influencing client functioning embedded in each of these complex levels.

A second conceptual tenet of adequate assessment of family issues involves an acknowledgement of multiple perspectives. To be poised to recognize and treat issues of a family nature, clinicians must keep in mind that more perspectives can lead to a more thorough and therefore effective assessment and understanding of clinical problems, which ultimately leads to a more efficient, effective treatment of child and adolescent clients. A few tips on how to assess risks and buffers (i.e., protective factors) within these multilevel systems and intra-individual domains are provided here. In addition, pathways to gather multiple perspectives are carved for therapists who practice individual, family, group, or other types of therapy with children and adolescents.

Practical. A first step in the effective assessment of family issues is to become acquainted with general and specific risk factors for children and adolescents. There are several sources conveying a variety of risk and protective factors for this population (Kazdin, Rogers, & Colbus, 1986; Linehan, Nielsen, & Chiles, 1983). A brief perusal of this literature suggests that there are several commonly agreed-upon factors that can put a child or adolescent at risk for negative outcomes and impairment in functioning. In addition, several factors promote positive development and high functioning or resilience in young people. Risk factors include poverty, experience of abuse, parental conflict or divorce, single parenting, teen parenting, parental substance abuse or other psychopathology, large family size, and lack of parental support system (Coley & Chase-Lansdale, 1998; Davis, 2004). Protective factors that may prevent negative consequences despite risks include having a strong relationship with an adult, parental warmth, modeled

coping skills, developmentally appropriate expectations by caregivers, clear rules, and structure with regard to daily tasks and longer-term traditions (Masten, Best, & Garmezy, 1990; Werner, 2000). Such factors are important, as they make up the context of any individual child or adolescent and can influence the outcome of therapy. They might be assessed using multiple methods, such as direct questioning of the child and relevant adults, implementation of surveys that pull for information about these factors, behavioral observation of individuals and relational interactions, and active listening throughout the therapy process for these factors and their influence on the child or adolescent. It is suggested that clinicians prepare for early sessions with these factors in mind, which will increase the chance of these factors being assessed adequately.

In practical terms, there are several ways in which a therapist can assess for priority family issues or risks present. First, as recommended earlier, the clinician should come to the first session prepared to gather information about individual, relational and contextual risks and buffers. Informal assessment of family issues requires ongoing monitoring of risk at each of these levels. This type of assessment is done in the beginning and throughout the course of therapy to appropriately inform practice. Viewing every interaction with a child or adolescent client as part of the process of assessment will help steer the clinician toward being maximally apprised of client risk in an enduring way. Asking direct questions about family context, historical and current risks regarding substance use, violence exposure and experience, medical history and developmental history, social relationships, educational status, and family dynamics is useful. In addition, adolescents as well as their parents and guardians may disclose different components of their history and current status in these domains when they are allowed to write them instead of simply reporting them verbally to the therapist. It is suggested that the clinician provide written surveys or brief questionnaires at intake in addition to the verbal questioning necessary in a first session. This may add to the breadth and depth of initial assessment information. Some suggested areas of questioning for useful inquiry initially and throughout the therapy with children and adolescents are presented in ❯ Table 18.1. These are presented to assist therapists in creating multiple methods (i.e., verbal questioning, informal written surveys at intake and throughout therapy, etc.) for gathering this type of information.

In addition to informal methods of assessment for family issues, formal assessment measures can be used to add information in any of the categories highlighted in ❯ Table 18.1. Ideally, the use of formal measures occurs across multiple sessions to monitor progress and outcomes. Here, we provide a brief discussion of current, psychometrically sound measures that are widely used when working therapeutically with children and their families.

One recommended measure is the Hudson's Index of Family Relations (IFR; 1982). The IFR was designed to measure the severity of the problem with regard to family functioning. Hudson's IFR also provides a format for a comprehensive assessment of family perspectives. An additional useful component to data collection is to assess for interaction styles that are obstructing desired family functioning. The Family Environment Scale (FES; Moos & Moos, 1994) is a 90-item scale using a dichotomous true–false format to assess aspects of family functioning in multiple areas including family cohesion, expressiveness, and culture. To supplement the FES measure, there is a Children's Version of the Family Environment Scale (CVFES; Pino, Simons, & Slawinowski, 1984) that was developed for children of ages 5 to 12. The CVFES is a 30-item measure that requires the child to select one of the three cartoon pictures that best represents his or her family. Another useful scale is the Parent–Adolescent Communication Inventory (PACI, Form A; Bienvenu, 1969). The PACI is a 40-item test designed to measure an

◘ **Table 18.1**

Recommended domains of inquiry for initial interview

Area of inquiry	Specific probes
Family context	• Family structure • Living situation • Siblings and birth order • History of abuse, neglect, or exposure to domestic violence • Parental relationship and structure (traditional, two moms, two dads) • Parental functioning (e.g., substance use, mental health history) • Current relationships with family and family dynamics • Identified client's number of children • Other children not living with family • Other family members important to child or adolescent • Family losses (e.g., death or estrangement)
Educational context	• General school affinity • Grade history • History of suspensions, expulsions, referrals • Peer relations • High school, college, or other completions and current attendance
Social relationships/activities	• Number of perceived friends and acquaintances • Intimate relations history and current status, including sexual orientation • Physical violence in peer or intimate relationships • Perpetration or victimization of bullying • Isolation from peers • Amount of contact with peers • Activities for leisure • Religion/spirituality • Occupational history and relationships with co-workers • Impairment due to symptoms
Medical history and developmental context	• Significant history or current medical problems • Current medication • Satisfaction with medications • Achieved developmental milestones • Developmental delays
Mental health history	• Previous treatment for current or other symptoms • Length and experience of previous treatment (e.g., helpful or otherwise) • Family mental health history and treatment • Prior hospitalizations • Suicide attempts • Other current mental health services

◙ Table 18.1 (Continued)

Area of inquiry	Specific probes
Substance use history	• Use of alcohol, drugs, cigarettes, caffeine (i.e., self or family member) • Prior treatment for substance use (i.e., self or family member) • Functional impairment
Legal history	• Legal history • Pending trials or other legal matters • Dates and nature of cases pending
Behavioral observations and mental status	• Oriented X 4 (i.e., person, place, time, and purpose) • Cooperation and presentation • General affect and appropriateness for situation • Thought processes • Speech characteristics • Hallucinations or evidence of delusions
Risk concerns	• Current suicidal or homicidal thoughts or behaviors • Dates and times of suicide attempts, psychiatric hospitalizations • Current plan or intent • Current supports to prevent self or other harm • Accessibility • Current victim of abuse • Family history of suicide or homicidal behavior

adolescent's perceived communication style with his or her parents. There is also a parallel parent form (i.e., PACI, Form P) that assesses the parents' perspective regarding communication interactions.

In addition to assessing individual symptoms and perspectives and general family functioning, it may also be useful to assess the quality of the parental relationship. It is a common view among therapists concerned with treating family issues that troubled parent interactions creating a trickle-down effect by which the rest of the family is negatively influenced (e.g., Friedlander & Tuason, 2000; Minuchin, Nichols, & Lee, 2007; Patterson & Chamberlain, 1988; Stern & Reid, 1999). One well-known assessment measure regarding the primary relationship in the family is the Marital Satisfaction Inventory-Revised (Snyder, 1979). This self-report measure identifies key stressors among several dimensions of the relationship, including affective communication, problem-solving, aggression, sexual dissatisfaction, role orientation, family history of distress, dissatisfaction with children, and conflict over child rearing. Another option is the Dyadic Adjustment Scale (DAS; Spanier, 1976), a measure that can be used for both traditional marital relationships and for cohabitating partners in less traditional, heterosexual family structures. The DAS is a 32-item instrument used to assess relationship satisfaction and quality of communication between partners.

Beyond formal assessments directed particularly toward family relationships, individual measures of distress may also be used for formal assessment of family issues. The Outcome Questionnaire (Lambert et al., 1996) and Youth Outcome Questionnaire-Self Report (YOQ-SR; Burlingame, Wells, Lambert, & Cox, 2004) versions are helpful as well as brief

and low cost. The areas probed in these assessments are symptom distress, school or work functioning, and interpersonal relationships, all of which provide useful information on potential family issues from the individual perspective. In addition, critical items regarding substance use and suicidal ideation provide an additional probe for these important individual risk factors.

Several of these measures require a training clinic or an agency to purchase the license, manual, and the measure itself. While this may be potentially cumbersome and expensive, it is advisable for clinicians and training clinics to research these options and others to assess what would best meet the needs of clients served. Individually, some measures are fairly low cost and easy to learn for administration and scoring. Alternately, components of these measures may appear on formal assessments located in the public domain. These can be found by searching the Internet learning about measures used by other training clinics serving similar clientele. This may result in skill-building for the clinician in training and the creation of a checklist of issues to address when seeing child and adolescent clients and assessing for family issues. Finally, trainees should be encouraged to make good use of assessments already adopted at their training site. Often we educate students of psychology in the area of "critiquing" assessments versus thinking critically about their potential applicability. We suggest here that such critiquing may lead trainees to dismiss potentially useful (if imperfect) aspects of formal assessments that already exist within the system in which they are training. They should instead use such assessments with supervision, caution, and critical thought rather than dismissing them altogether.

Critical thinking and creativity. As in other areas, measures described above for use in assessing and addressing family issues may be limited in their cultural appropriateness. They should be used with caution with clients in alternative family structures, such as same-sex parent families, as many measures include insensitive, heterocentric language, and lack appropriate norms.

With regard to the treatment of family issues, some creativity combined with good clinical judgment as applied to the use of these imperfect measures may expand their utility. It is important for trainees to know that the goal of assessment is to gather information to be used to inform treatment. They should note that this goal does not include finding the perfect, comprehensive, culturally sensitive formal measure for identifying family issues – such a thing does not exist. This is why multiple methods for assessment are taught across different areas in psychology. For example, if the language in an instrument is heterocentric or makes assumptions about families that are not appropriate for certain clients, the clinician may determine for whom the assessment may be useful despite these flaws, and administer it to those clients. This is perhaps a means of utilizing available resources by the clinician, but acknowledging their shortcomings in use and interpretation for clients. One way to increase awareness of these types of shortcomings is to incorporate the manuals into clinical training, such that clinicians are able to make a careful evaluation of the tool prior to its administration. In addition, a clinician may re-word items in their own assessment process and construct informal surveys during intake and other sessions. This will allow gathering similar information in a more sensitive way that matches the client.

From a training perspective, it is critical that students of therapy for children and adolescents learn to think critically about the use of these measures – not to rigidly use or dismiss any single measure. Further, while data collection is useful for identifying symptom change, it is important to keep in mind that a decrease in symptoms alone does not necessarily constitute

successful treatment. Positive outcomes in family therapy may also include subjective report of healthier functioning (e.g., improved conflict-resolution skills, development of appropriate boundaries) and well-being of the family as a whole (Gaylin, 1999). The therapist will gain most information by using multiple methods for tracking change, such as clinical observation and idiographic or written self-reports in addition to formal assessments. In any case, the clinician should avoid allowing any one method of data collection speak solely for the client's status regarding risk and salience of family issues.

Ideas listed in the preceding text should provide direction regarding where to start to ensure that the clinician is assessing for risk and family issues thoroughly and efficiently. Assessment of family issues must also include understanding what patterns (i.e., behavioral, cognitive, and emotional patterns) maintain a child or adolescent's psychological difficulties. These maintenance factors as a portion of the assessment process and an essential domain of understanding for therapists are discussed in the next section.

18.3 Maintenance Factors

Systems theorists have a long history of describing the factors that maintain family problems (Becvar & Becvar, 1998; Broderick, 1993; Feldman & Pinsof, 1982; Fingerman & Bermann, 2000). The reader is referred to these multiple authors for detailed descriptions of the fundamental uniting force across theories: family issues are maintained by the family itself. Some systems theorists, such as Virginia Satir, posited that this is due to inherent, maladaptive patterns employed by individuals within the family system (as cited in Lawrence, 1999). Others subscribe to the idea that homeostasis is the ultimate goal of any system and, as such, problems are maintained because they serve to preserve homeostasis, despite their negative consequences (Guerin & Guerin, 2002). The list of interpretations and differing perspectives within the systems theoretical community about problem maintenance is long. For current purposes, we describe a basic framework for therapists to rely on for guiding their understanding of family issues their clients present.

Most students may already be aware of the notion of "secondary gain" used to describe why any clinical problem is maintained. Secondary gain, a term first coined by Sigmund Freud, has been described as a reason for clients to have difficulty in changing their thoughts, feelings, behaviors, or circumstances (Craighead & Nemeroff, 2001). The notion holds that the preservation of the problem serves some benefit to the client. We find this idea compelling and useful in application except for its potential for negative interpretation. That is, the implication that clients benefit from their own problems, we believe, sets the therapist up somehow to see the client in a negative light, as manipulative or resistant to change. At best, it requires the therapist to remain hopeful despite this negative view. At worst, this view may propel a therapist to intervene by "educating" the client about what is being gained by problems. This, we suggest as potentially harmful in that it may become dismissive of a client's struggle and may therefore lead a therapist to attempt to convince the client that his or her problems are of some benefit. When a therapist begins attempting to convince client families of any matter, this is often a sign that the relationship is poor. It can also foster an argumentative interaction and imbalanced alliance amongst family members. Clients with family issues may respond more positively to an *experience* that provides evidence that their problems are being maintained by their own patterns versus being told by the therapist that it is so.

Regarding the treatment of family issues, we suggest a different label for understanding a similar concept: function. As systems theory holds, problems serve a function within any family system (Becvar & Becvar, 1998; Broderick, 1993). Some current models of family treatment suggest that clinicians avoid judging the positivity or negativity of the function, but design interventions to maintain it (e.g., Alexander et al., 1998). That is, respecting system dynamics that will always be maintained by the behavior of embedded individuals, the therapist might more effectively assess the function of certain behaviors and simply replace the poor behavior with a more adaptive behavior, versus being concerned with disrupting or eliminating the function (Alexander & Sexton, 2002, Alexander et al.).

As an example, consider a teen client with disruptive and oppositional behavior problems. The client presents in therapy at the mandate of her mother, who reports the client interrupts, is otherwise disrespectful to her as a parent, and at times becomes physically aggressive if she is not granted things she demands. A systems-oriented clinician would do well to inquire about the relationship between this client and her mother, and seek understanding of the pattern of interactions leading to client outbursts. In this process, the clinician may apprise that the client's behavior is protective in nature. Although destructive physically and emotionally at times, it may be determined that such acting out protects the client's mother from feeling isolated, in that third party supports are engaged. In this way, the "function" of the client's behavior may be to summon third party (i.e., counselor, police, school personnel) assistance. If each time the teen is disruptive, the mother receives outside support; an intervention to stop the disruptive and oppositional behavior may also unintentionally cause the mother to lose support. If systems theory principles of homeostasis and interdependence hold, another type of behavior will erupt to preserve this important function if the function is lost due to intervention. The discussion of how to facilitate change in a manner appreciative of such complicated problem functions is presented here.

18.4   Mechanisms of Change

Describing the mechanisms of change with regard to any problem resolution of the clinical type is important. Essentially, knowing the mechanisms of change for family issues is akin to answering the critical question of *how do we facilitate therapeutic change*? With particular regard to family issues, there are at least two very relevant domains to acknowledge in order to answer this fundamental question: *elements facilitating change* and *sequence of implementation*. Exploring the *elements facilitating change* provides trainees with *what* needs to occur to facilitate change, and the *sequence of implementation* assists with determining *when* is the best time to implement which tools to foster change. As described here, these domains must be understood and combined to maximize the chance of facilitating client change for youth experiencing family difficulties.

18.4.1 Elements Facilitating Change

Some conceptualize mechanisms of change as the intervention "tools" that make therapy effective. These are what we refer to here as the elements facilitating change. Essentially, they comprise the "what to do" piece of the formula for maximizing therapeutic change. In the

simplest of terms, these are the actual interventions used by any professional helper (e.g., reframing, building a relationship, teaching new skills, fostering insight, etc.). We know to a large extent about useful elements that, if implemented, may foster change in a client. Texts on psychological theory include a variety of these elements that are attached to particular theories (e.g., Prochaska & Norcross, 2002). More recently, the common factors of therapeutic change have taken the spotlight as a respectable place for clinicians to target their energy. Common factors are said to be those elements common across all different types of intervention and all classes of intervention theory that provide the groundwork for change (Ahn & Wampold, 2001; Sprenkle & Blow, 2004). Examples of common factors established as vehicles for change include client characteristics (e.g., motivation, readiness for change), therapist skill level, therapeutic alliance, expectancy (i.e., placebo factors) and nonspecific treatment variables, such as behavioral regulation, cognitive mastery, and affective regulation (Duncan, Miller, & Sparks, 2003; Hubble, Duncan, & Miller, 1999). These factors or "elements", as we refer, are useful because they provide a trans-theoretical framework to inform psychologists on "what" to do in therapy to facilitate change. Application of these factors to the actual therapy room is perhaps more clear than applying theoretical constructs into practice. That is, if a student clinician knows that the therapeutic relationship is important to build and foster for a change to occur, that clinician has something to focus on during therapy to guide practice. The "what" to do in therapy becomes more clear. This is the major contribution of common factors' literature. However, what remains after understanding common factors is the answer to "when" in the therapy process to focus on these various elements. This is discussed here.

18.4.2 Sequence of Implementation

When it comes to family issues (and arguably important to consider in the treatment of any issue), a competent clinician should probably consider the location in the therapeutic process with a given client. A useful question for child and adolescent clinicians to ask themselves is: Am I in the beginning phases, middle of therapy, or in the end of treatment with this client? Depending on the answer, appropriate interventions can be selected. For example, teaching new skills may be an effective vehicle for change when used after a client has already been engaged in the process, but may be highly ineffective if implemented in the first few minutes of a first session. Likewise, many authors suggest that there is a sequence of contingent mechanisms of change a therapist must be aware of and work toward providing it (Fraser & Solovey, 2007; Hill, 2004; Sexton, Ridley, & Kleiner, 2004). That is, some change mechanisms are important to attend to early in therapy and some are more important later. Also, some interventions or "tools" are useful across different phases of treatment, and some are critical at various points throughout the process. Therapeutic alliance is an example of a primary change mechanism (Bordin, 1979; Horvath & Greenberg, 1989). It seems that without doing this first (i.e., paying attention to and working toward a strong alliance as an early-therapy change mechanism), any subsequent intervention may not be effective. In addition, once alliance is established, it should be monitored throughout the therapy process. Knowing this fact about the therapeutic alliance gives the therapist a specific, early therapy goal to target and something important and specific to monitor throughout treatment.

Fostering insight (Hill, 2004) and teaching new skills (Fraser & Solovey, 2007) are examples of middle-of-therapy tasks that serve as mechanisms for change when implemented adeptly

and at the appropriate time. End-of-therapy change mechanisms may include teaching relapse prevention strategies and establishing strong networks of support to promote maintenance of change (Alexander et al., 1998; Fraser & Solovey, 2007).

Using the same case described above, it may become clear that attempting to teach the disruptive teen client or her mother new ways of relating to each other or solving their problems may not be effective in the early sessions of therapy. In fact, hinting that the teen must change and is to blame would likely decrease the chance that she would be willing to practice new skills at the therapist's suggestion. Undoubtedly, some understanding of the teen–mother relationship and each person's perspective on the problem would be a useful precursor to any advice or instruction regarding how to change their ways. In addition, the client in this case would not be able to prevent relapse of symptoms without first learning how to manage them within the relationship with her mother. The timing of these specific interventions to facilitate change is critical.

18.5 Evidence-Based Treatment Approaches

Within the field of clinical psychology, disagreement exists regarding what has been termed *best practice* (Sprenkle & Blow, 2004). There continues to be a lack of integration between research findings and clinical practice (Sexton, Alexander, & Mease, 2004), and it has been argued that this disconnectivity is due to the contrived nature of such clinical research trials. Although it is commonly known that family therapy is widely applicable and facilitates positive outcomes, clinicians continue to struggle with how to integrate research into their practice for working with families without compromising the art of the craft.

One area where this disconnectivity continues to thrive can be seen by examining attitudes of training clinicians toward evidence-based practice in psychology (EBPP). Luebbe, Radcliffe, Callands, Green, and Thorn (2007) conducted an online survey in which 1,195 training clinicians in graduate clinical psychology programs participated. The results indicated training clinicians are generally in favor of EBPP. However, those students who studied in programs that subscribed to a science practitioner or clinical science model were more likely than students from other training models (e.g., scholar practitioner model) to favor and utilize EBPP. It was also found that misunderstandings about what exactly constituted EBPP were common among the sample.

In conjunction with the results of the aforementioned study, we believe the reluctance to embrace treatments with supportive empirical evidence into therapeutic practice has something to do with the misunderstanding of semantics. In this chapter, we wish to promote evidence-based treatments. In stark contrast, we do not suggest therapists in training or others haphazardly apply what are known as empirically supported treatments (ESTs) without critical thought regarding the therapeutic relationship or client characteristics, as this can be particularly problematic. Luebbe et al. (2007) help clarify the difference between EBPP and ESTs when they state, "An empirically supported treatment is a product derived from randomized clinical trials…Evidence-based practice in psychology is a process that incorporates the retrieval and examination of the scientific evidence" (p. 645). Luebbe and colleagues go on to clarify that *evidence-based treatments* include not only treatments continually supported by means of randomized clinical trials but also to a collection of case studies, for example.

In 2006, the American Psychological Association Presidential Task Force on Evidence-Based Practice defined EBPP within the field of psychology as "the integration of the best available research with clinical expertise in the context of patient characteristics, culture, and preferences" (APA, p. 273). In other words, the Task Force urges trainees and licensed psychologists to first utilize treatment modalities supported by research to provide positive outcomes. In line with this thought, we provide a short review of evidence-based interventions that incorporate or utilize family interventions. ❯ Table 18.2 provides the reader with information regarding current interventions across individual, couples, family, and group therapy domains. Therapies chosen for this table were selected because they represent a variety of approaches that have considerable empirical support for their effectiveness, and all emphasize within their approach the relative importance of family issues. This list is by no means exhaustive, but rather serves as a quick reference for clinicians providing individual, couples, family, and group treatment as well as parent management training.

18.6   Basic Competencies of the Clinician

An important factor to highlight is the overwhelming demand for competent family-oriented therapists, including family therapists in the training sector. Training clinicians may be surprised to know that over 30% (n = 205) of the pre-doctoral and post-doctoral training centers listed on the Association of Psychology Postdoctoral and Internship Centers include a major rotation in family therapy (APPIC, retrieved October 2008). This finding highlights the necessity for acquiring basic competencies, at least, for a large portion of training clinicians. For this reason, we now turn to a discussion of building basic competencies in this domain including both conceptual and practical elements of basic competency development.

18.6.1 Conceptual Framework

The following have been established as eight core competencies in professional psychology: "Application of scientific knowledge to practice, psychological assessment, psychological intervention, consultation and interprofessional collaboration, supervision, professional development, ethics and legal issues, individual and cultural diversity" (Kaslow, 2004 and Kaslow et al., 2004 as cited in Kaslow, Celano, & Stanton, 2005, p. 338). Kaslow and colleagues (2005) provided a framework for principles to guide trainees in the development of these competencies within family psychology in particular. With regard to *applying knowledge to practice*, these authors recommended family-oriented trainees to learn about evidence-based psychological work that is grounded in systems theory. In the competency domains of *psychological assessment* and *psychological intervention*, Kaslow et al. (2005) again suggested a systems-oriented framework for developing clinical competency. They advised that students of family psychology should learn how to use measures that directly target systemic variables for individual, couple and family clients, including several of those mentioned earlier. For intervention that is systems-based, Kaslow and colleagues recommended training in comprehensive models of relationally oriented therapy.

In their summary, Kaslow et al. (2005) also addressed the *consultation and collaboration* competency by suggesting that students be trained in working across systems to facilitate

■ **Table 18.2**

Descriptive summary of evidence-based family therapy treatments

Treatment	Domain	Description	Reference
Behavioral Family Systems Therapy (BFST)	Individual/family	• Incorporates behavioral shaping, cognitive restructuring, problem-solving communication strategies as well as strategic/structural family therapy techniques to target weight problems, maladaptive eating patterns, and negative family interactions • Therapist works on a multidisciplinary team with a dietician and pediatrician to treat adolescents with anorexia nervosa, and parents are made an integral part of the multidisciplinary team to optimize family involvement and treatment gains	Robin et al. (1999)
Ego Oriented Individual Therapy (EOIT)	Individual	• Framework for working with adolescents with eating disorders • Focus is on strengthening ego functioning and insight in relation to eating issues • Empirically supported for producing positive outcomes with regard to depression, internalizing behavior problems, ego strength, maturity, fears, and perfectionism	Lock and Grange (2004)
Emotionally-Focused Couples Therapy (EFCT)	Couples	• Based on attachment theory and addresses problematic interaction patterns in the relationship by focusing on unresolved emotions from early parent–child interactions that may have resulted in insecure attachment styles	Johnson and Greenberg (1985, 1988)
Behavioral Marital Therapy (BMT)	Marital/couples	• Brief, time-limited, empirically supported framework for producing effective change in as few as three sessions • Interventions based on this framework focus on the couple's cognitive processes in treatment	Baucom, Shoham, Mueser, Daiuto, and Stickle (1998)

Cognitive Marital Therapy (CMT)	Marital/couples	• Empirically supported and manualized for the treatment of alcoholism and Posttraumatic Stress Disorder	Monson, Schnurr, Stevens, and Guthrie (2004), Wakefield, Williams, Yost, and Patterson (1996)
Brief Couples Therapy	Couples	• Supported as an effective framework for addressing substance abuse in the context of couple's treatment	Chaim, Armstrong, Shenfeld, Kelly, and Li (2003), Davidson and Horvath (1997)
Multisystemic Therapy (MST)	Family	• Empirically supported and manualized treatment for delinquent youth who are identified as abusing drugs and alcohol, behaving in a sexually offensive manner, or exhibiting other forms of antisocial behavior	Henggeler, Schoenwald, Borduin, Rowland, and Cunningham (1998)
Multidimensional Family Therapy (MDFT)	Family	• Hallmark of this framework is the implementation of an educational component for family members • Empirically supported for adolescent drug abuse and there is a manual specific to cannabis dependence	Liddle (2002, 2004)
Brief Strategic Systems Engagement (aka Family Effectiveness Training; FET)	Family	• Empirically supported for clinical work with immigrant Hispanic families with children (aged 6–12) exhibiting behavioral problems, anxiety, phobias, or experiencing parent–child communication problems	Szapocznik and Hervis (2001)
Functional Family Therapy (FFT)	Family	• Effective for reducing recidivism rates among high-risk adolescent and adult populations with a variety of problematic externalizing behaviors, including drug abuse	Alexander and Sexton (2002)
Structural Family Therapy	Family	• Framework for working with children diagnosed with eating disorders	Minuchin, Rosman, and Baker (1978)
Couple Communication Program	Group	• Marriage and family treatment provided in a group format • Focus is on building better communication skills	Butler and Wampler (1999)

◾ **Table 18.2 (Continued)**

Treatment	Domain	Description	Reference
Parent–Child Interaction Therapy (PCIT)	Parental	• Treatment is for children (aged 2–7) years who exhibit disruptive behaviors • Parents are taught skills that facilitate secure attachments, while children are encouraged to increase prosocial behavior and decrease negative behavior • Model is based on two stages: (a) child-directed interaction phase that resembles play therapy, and (b) parent-directed interaction phase that helps parents develop realistic expectations, limit setting skills, and consistency and fairness in disciplinary actions	Eyberg, Boggs, and Algina (1995), Eyberg, Nelson, Duke, and Boggs (2005)
Parent Training	Parental	• Family-based parent training program for managing child and adolescent behavioral problems, such as Attention- • Deficit/Hyperactivity, Oppositional Defiant, and Conduct Disorders • Manualized for clinicians working with teens and school-aged children are available	Barkley (1997), Barkley, Edwards, and Robin (1999)
The Incredible Years	Parental/child	• Evidence-based parent training program designed to prevent and treat early onset Oppositional Defiant and Conduct Disorders • A corresponding program, known as Dinosaur School, for kids (aged 4–8) facilitates direct intervention with the children by teaching social skills and problem solving skills and increases parent attendance	Webster-Stratton (2006)
Parent Management Training	Parental	• Behavioral treatment program that incorporates a corresponding psychoeducational component for parents of children with autism spectrum disorders • Focus is on teaching parents social learning and operant conditioning	Lovaas (1987)

solutions that are "in the best interests of the family" (p. 341). With regard to *supervision*, these authors urged family psychologists to provide integrative and relationally based guidance to supervisees and suggested that more research on family-oriented supervision is needed to establish supervisory competencies in family psychology. For establishing family psychology competency in *professional development*, Kaslow and colleagues advocated for trainees to broaden their self-awareness regarding personal familial and relational experiences. These authors also described how trainee personal awareness must be facilitated in an ethical manner with clear parameters set on the role of instructors and supervisors to encourage such growth and also maintain trainee privacy as well as the integrity and boundaries of the instructor–student or supervisor–supervisee relationship.

Ethical competencies proposed by Kaslow et al. (2005) for family psychology included the ability to navigate and address unique ethical situations in family work such as confidentiality constraints and handling multiple relationships within the family. These authors also emphasized the need for those training and working in family psychology to accurately represent their competency in this domain. Not surprisingly, Kaslow et al. (2005) also noted the importance of an integrative approach to training about *individual and cultural diversity* within family psychology. They described that family psychology competencies with regard to diversity are best developed in training and supervisory environments where trainees are encouraged to share their own perspectives regarding oppression, disability, spirituality, sexual orientation, and other diversity factors as a foundation for becoming open, systemically-oriented professionals.

Using this thorough framework for family psychology competency development, here we describe its application to the practice of family-oriented psychology. Though not identical to "family issues," we acknowledge that this summary of "family psychology" guidelines provides a reasonable foundation for our discussion of the treatment of family issues. The following paragraphs provide basic competency suggestions with an emphasis on the psychological intervention, professional development, ethics, and diversity domains of professional psychology competencies. Family-oriented suggestions in the assessment domain were made in previous sections.

18.6.2 Practical Suggestions Regarding Basic Competencies

As mentioned previously, the clinician has to learn intervention tools as well as critical thinking skills to achieve basic competencies in working with family issues. With regard to our earlier discussion on the importance of sequencing interventions, our description of tools to acquire for basic competency is reflective of those basic skills required throughout the therapy process. In addition, we discuss *when* in the therapeutic process these skills seem to be the most important in treating family issues.

Psychological intervention. First, any therapist hoping to be effective with youth and families must attain basic competencies in the areas described previously to complete any generalist-training program and be adept at practicing in professional psychology. The content of this section highlights particular skills as markers for particular competency in treating family issues. This is done with the assumption that generalist competencies are also acquired along the training pathway.

Firm grounding in a model to guide clinical work is essential for clinicians seeking competence in the treatment of family issues. We use the word "model" here to denote the importance of a family-oriented clinician adopting not just a systems-oriented theory about conceptualization, but a systems-sensitive and clinically instructive guide through the therapy process. The emphasis on therapists acquiring a model to guide clinical practice is seen in generalist texts (Fraser & Solovey, 2006; Hill, 2004), theoretical papers (Sexton, Ridley, & Kleiner, 2004), and specific treatment models (Alexander et al., 1998; Kanfer & Grimm, 1980). Such a model should include information on how the therapist moves clients through phases of therapy. General components of such models across their articulations include early process goals of engagement and development of alliance, middle-therapy goals of facilitating change through insight, behavioral activation, or cognitive restructuring, and later-therapy tasks of facilitating maintenance of change and relapse prevention (Alexander et al.; Fraser & Solovey, 2006). These models have in common an emphasis on sequencing intervention and matching it to unique client needs and symptoms. This allows for adequate structure and flexibility to guide the process and also shape therapy to best fit client systems. Instructors and supervisors of beginning clinicians treating family issues can assess for competency in this area by encouraging therapists to pay attention to where they are in the process of therapy itself to inform intervention with regard to both the sequence of therapy and the individual needs of the client.

Apart from grounding in a model like those mentioned above, facility with contextually oriented techniques is also a requirement for basic competency in the treatment of family issues. Reframing is a skill to be used throughout the process of therapy, but is perhaps the most important during engagement processes in the early phase of treatment. In work with youth and families, it is important to learn how to actually collaboratively redefine the presenting problem, each family member's perspective, individual feelings, thoughts and behaviors. This is the definition of reframing used here and suggested for basic competencies in the area of family issues. In addition, we support the Functional Family Therapy (FFT, Alexander & Sexton, 2002) suggestion that reframing itself is a process, and it should be practiced as such in therapy with family systems. Effective reframing often relies on the therapist seeing a more complicated, less negative definition of the problem than the client presents. In turn, it requires the therapist to hypothesize with clients about alternate ways of understanding their situation. Reframing as a process involves continuous co-construction of a new, collaborative understanding of problems on which further intervention is based. In addition, effective reframing relies on the therapist addressing his or her own barriers to seeing alternate definitions of client problems. If a therapist is unable to understand the client and his or her problems in a less blaming or shaming way than they are presented, the therapist will struggle to try to do so collaboratively with the client. With the assistance of their supervisors, beginning clinicians should learn to redefine the nature of the client's feelings, thoughts, and overall perspectives for themselves. This can provide the impetus for critical thought on the part of the new clinician and encourage therapist compassion for clients with complex, frustrating problems. A useful question for therapists to ask themselves might be: how do I understand this client's situation in a way that allows for hope that change can occur? In supervision, the answer may be derived from the therapist recalling what they have observed as important to the client and the strengths the client demonstrates.

A second area of focus for clinicians interested in gaining basic competency to treat family issues is *relationship-building skills*. While it sounds obvious, our experience suggests that

relationship skills must be acquired via training and practice rather than assuming to exist in our future psychologists. Youth and family clinicians must purposefully focus on how to build relationships with clients to be effective in facilitating therapeutic change. One of the most common mistakes beginning clinicians make is to hastily proceed into specific change interventions before developing a proper therapeutic alliance or setting an appropriate therapeutic structure to foster relationship building (Nichols & Schwartz, 2005). This often occurs because the beginning therapist feels disorganized and has anxieties about his or her competency level. Further, with all of the best intentions in mind, the beginning clinician often rushes through the most fundamental pieces of the therapeutic process with a strong sense of responsibility for the child and family's well being.

Apart from these reasons of new therapists "skipping" the relationship development process of therapy, we assert that many therapists do not have adequate relationship building skills; so they move quickly to the teaching or implementing of psychological strategies with the client, which, to be honest, is much easier. Building a relationship with individual or multiple people defined as "the client" requires management of bias, compassion, warmth, and complex listening skills. For beginning therapists, it is difficult to do all these relationship-building things at once, and to do them while also completing therapy milestones of assessment, planning treatment, and facilitating the maintenance of change.

While relationship-building skills are essential in the beginning of therapy, we argue that they continue to be of utmost importance throughout the course of therapy as well. In early sessions, a therapist must establish a working relationship with the individual client or each member of the client system. This may be done by engaging new clients in conversation regarding their interests, attending to their use of language and adjusting therapist language to match that of the client, and ascertaining motivations and values of the client to convey understanding. As therapy progresses and methods to produce change in the client are introduced, it is also crucial for the therapist to attend to the relationship with each member of the client system and maintain a strong relationship or respond to decreases in alliance in a manner that facilitates continuing progress.

A unique component of relationship building with regard to family members is the need to *balance* alliance when working with more than one person. It is essential for therapists working with couples, families or within any client relationships to realize that building alliance within a system of clients is different from doing so with an individual client. Relationship building must occur with each client in the room, and is often difficult to achieve in a balanced way, because therapists may align more with one client than another or absorb one family member's definition of the problem more easily. The FFT model of family therapy has, at it's foundation, an emphasis not only on relationship building skills for the therapist, but the ability to weave through the client system and work toward strong alliances with every member (Alexander & Sexton, 2002). This occurs over time and must be a constant focus of any therapist hoping to facilitate change in a client system. The reader is referred to this FFT reference for a useful description of balanced alliance.

The reader is also referred to our previous discussion of assessment of family issues at this point, as basic competencies in intervention for family issues include the recognition of relational dynamics and interactive styles of clients (Kaslow et al., 2005). With regard to interpersonal dynamics, one relevant marker for competency is whether the clinician observes and then attends to hierarchical structures in the client family system. In addition, clinicians treating family issues should become adept at intervening in a way that matches the client

tendencies to be connected to or distant from others in their relationships. Minuchin's (1974) structural family therapy is noted for emphasis on the importance of considering hierarchy and interpersonal closeness or distance in families. Other evidence-based models also take hierarchy and relational distance into account for planning family intervention (e.g., FFT, Alexander & Sexton, 2002).

Professional development, ethics, and diversity. In relation to the assertion made by Kaslow et al. (2005) that therapists must monitor their own professional development by becoming more aware of their own contexts, the self-as-instrument notion is the need to pay close attention to personal reactions when working with each family and its individual members. Commonly, clinicians of all competency levels feel a pull to identify with a single family member, and this is especially true when working with children and adolescents in inpatient settings (Schneider, 1985). Kaslow and colleagues (2005) suggest that beginning therapists conduct and share their own family genogram in supervision so as to identify their own family strengths and stressors, as well as highlight potential triggers when working with families. For a more comprehensive discussion about genograms, the reader is referred to McGoldrick and Gerson (1985).

Ethical practice in work with youth presenting family issues involves basic competency on the part of the clinician in recognizing the unique ethical challenges posed within systems-focused work. Confidentiality is an ethical principle that may become confusing to beginning family-oriented clinicians (Kaslow et al., 2005). Being aware of therapist duty to protect confidentiality for all those defined as "the client" is important in family therapy. Knowing when this becomes a challenge (i.e., when conducting individual therapy with children that necessitates involvement of parents) and seeking supervision on how to protect child privacy and also explain parents about the important treatment issues they should be aware of is critical. Again, supervisors can encourage therapists to note when confidentiality issues are less clear because of the multiple relationships and individuals within family systems. Supervisors can also purposefully target confidentiality and other ethical issues for focus in supervision and facilitate the development of clinical competency in this area.

Diversity considerations related specifically to the treatment of family issues include hierarchical and relational dynamics. The competent clinician should be adept at assessing these and intervening in a way that is respectful of the observed power differential within family systems and the subtle or obvious disparate amounts of connection or distance between family members. In addition, the general competency description of individual diversity (Kaslow, 2004) is relevant in the treatment of family issues. Reframing may assist the clinician in developing competency in truly understanding the client and his or her problems in a way that appreciates intrapersonal diversity as well as systems dynamics, in which the individual is embedded.

Although the previous paragraphs provide only a short list of the basic competency areas particularly relevant for treatment of family issues, they are grounded in generalist competencies and suggest a pathway to develop clinician strengths that will facilitate greater effectiveness in family-oriented clinical practice.

18.7 Expert Competencies of the Clinician

The American Board of Professional Psychology (ABPP, www.abpp.org) provides designations in specialty domains including family psychology. Qualifications and training required to

achieve such a designation are described as a beginning to our discussion on expert competencies in treating family issues. Two components of the ABPP designation requirements provide some parameters for defining expertise: extensive time dedicated to the area of desired designation, and evaluation by those already designated in the specialty area. Clinicians who have not dedicated extensive time via training and accrual of family-oriented internship and post-doctoral training are not considered for such a designation. In addition, failure at examination by other ABPP family psychology designees is a symbolic and concrete instance of how the label of expert is granted or withheld. Thus, these accepted standards hold quality of experience, time of dedication, and performance under review of other experts as indicators of expertise.

In addition to this framework for determining expertise, we suggest here that expert competencies of clinicians treating family issues are not altogether different in content than basic competencies. Instead, the marker of an expert in this area is higher level of facility with those basic skills. For example, the expert clinician would need to be adept at reframing, attending to relational dynamics, and in other areas mentioned earlier. However, expertise would be marked by the clinician's ability to practice these skills with a degree of efficiency and automaticity that a clinician at a basic level could not. In addition, someone reaching expert level competency in the treatment of family issues may intervene in a contextually cognizant way without the use and guidance of a supervisor to do so. Whereas the clinician with basic competency might be able to build relationships with family clients after using supervision to discuss how to do this, the expert would likely demonstrate automatic and immediate facility in responding to the multiple interpersonal dynamics operating in family systems practice. These are markers for expertise in the psychological intervention domain of core competency.

With regard to professional development, experts may not depend on supervision to guide their moment-to-moment practice in sessions, but may be so aware of their own contextual background that they seek consultation for specific, systems-oriented questions from a colleague who has expertise in family issues intervention. Experts would be more likely to seek supervision that is focused on systems processes and the complexities of intervening in a contextually appropriate way. Novice therapists treating clients with family issues may understand the systemic implications if told, but may not have the practice and self-awareness to raise this type of systems-specific question in supervision and consultation.

18.8   Transition from Basic Competence to Expert Competence

Our suggestions for moving from basic to expert competencies in the treatment of family issues are explicitly stated as follows: get intensive, focused training and supervised experience. With regard to family issues and their treatment, this means expertise is developed within settings serving this group that are capable of providing intensive training and supervision in putting principles of systems into practice. In all instances, the student must actively seek out this level of experience and dedicate a substantial amount of time (e.g., practicum experience, additional training, and supervision meeting attendance). Also, this is very different from simply gaining experience with families or with a supervisor who has family issues experience and an orientation that is systems-conscious. We maintain that just getting experience does not foster expert competencies without the intense focus and supervision in a particular area or with a particular model of treatment. Live supervision may be particularly useful for facilitating competence (Kaslow et al., 2005).

Unfortunately, many students are eager to learn and easily "thrown in" to see complex individuals, couples, and families. While this constitutes experience, it can actually damage competence and cause harm to clients if the student is not monitored properly in the areas described above, which are the basic skill domains for the family issues-focused clinician. In addition, it can increase clinician self-doubt or clinician over confidence, neither of which constitute the makings of an expert. We hope it has become obvious at this point that moving from basic to expert competencies does not just "happen." It occurs only as a result of purposeful choice and determination on the part of the trainee interested in becoming an expert in the area of family issues. The choice begins with placing oneself in an environment that can provide such intensive training, supervision, and experience.

It may happen that the doctoral training clinic is such a setting. As in the case of the first author (AW), movement from basic competencies was facilitated by active participation with a faculty mentor who also provided training to community agencies about how to conduct a specialized treatment for youth. Through this relationship, AW was able to train and practice with families in a setting where sessions were recorded, treatment integrity was monitored through supervision, and multiple trainings were available. With time and improved competence, as measured by the supervisor and through clinical outcomes such as returning clients and high client-reported treatment adherence, AW was then promoted to supervisor, and eventually trainer throughout the course of her doctoral program and into postdoctoral years. From this experience, we note the relative utility of training and supervising others as a facilitator of greater competence in systems-oriented clinical work. It should be noted that markers of basic competence should be evaluated as met prior to thrusting a novice family-oriented clinician into a training or supervisory role.

In most instances, the level and amount of training and supervision required to become an expert in the treatment of family issues is accessed outside of the graduate training facility or apart from work with program faculty. This type of opportunity can be accessed as part of a practicum, internship, and postdoctoral experience in a public or private agency that has acquired certification in a particular systems-based intervention strategy (i.e., several of those listed above). This implies the interested person in training must look for agencies or other settings that practice the systems-oriented intervention and have the staff to supply the training in their area of choice. An application for a position usually follows. For the application process to go smoothly, the applicant must have acquired some previous experience and demonstrated interest in the area. In addition, interviewing and working in such a setting may require sacrifices such as moving to the area providing the training. Being flexible is essential to obtain experience. Becoming an expert in this area requires creativity and foresight, as well as the personal and professional choice to dedicate time and resources to acquire expertise.

Having planned to gain access to an expertise-developing environment, it is wise for the clinician interested in becoming highly competent to take advantage of every training opportunity available in work specific to families and youth. It is suggested that the intensive experience in training, practice, and eventually supervision should be centered on one particular intervention model versus several less structured or intensely trained and supervised "models" of how to work with youth. Diversifying early in training can lead to confusion versus expertise. The utility of the one-model focus is that, if the model is well grounded, it can instill in the clinician a set of principles to guide practice-even practice with different populations.

Becoming an expert systems-oriented clinician is also facilitated by the clinician graduating to become not just a therapist, but a supervisor and trainer in the area of treatment for family issues. As an educator, and one who gained expertise by moving from therapist to supervisor to trainer in a family therapy model, AW can attest to the essential refining of intervention skills and critical thinking with regard to family issues that occur when teaching others and critiquing their work. Again, supervising others and training novice family-oriented clinicians is not an activity for the aspiring expert to just "do," but can facilitate movement from basic to expert competencies when done in an environment that provides mentoring and supervision after a clinician has mastered basic skills and demonstrated therapeutic effectiveness in this area.

Along with the sequence of events suggested for becoming an expert clinician in this area, we recommend the clinician seeking expertise in treating family issues attend professional conferences and gain membership to some of the organizations that support and inform clinicians in this area. We recommend the aspiring expert to consider joining and attending affiliated organizational conferences, meetings and trainings: Society for Family Psychology (Division 43, American Psychological Association, www.apa.org), and the American Association of Marriage and Family Therapy (AAMFT, www.aamft.org). There are several others that vary in attention to clinical skills, research, training, and theory with regard to psychology and family issues. These two organizations and their members have solid histories of appreciation for the complexity of family issues and a priority on welcoming like-minded professionals to expand their effectiveness in psychological treatment in this area. As such, they provide a strong base for affiliation from which the aspiring expert may expand his or her professional network and clinical breadth.

18.9 Summary

To facilitate the use of tools and principles of critical thinking discussed regarding training in and treatment of family issues, our summary is presented as a review of main points to take from each of the sections of this chapter. Together, these provide the pathway for students to develop expertise in this area of treatment for children and adolescents and a road map for instructors to guide trainees.

First, we encourage trainees and their instructors to acknowledge both the values and the limitations inherent in their generalist training programs. Specifically, they may find that entertaining the following assertions is helpful for approaching family issues as a treatment focus: (a) problems are relational in nature; (b) severity and importance of family issues are defined by their impact on functioning; (c) individual problems have an impact on multiple levels of an individual's context and within his or her family system; (d) "family" must be defined to be inclusive of the client's perspective and circumstances; (e) in pursuing expertise, be reminded always that skills or "tools" must be supplemented by critical thinking that is systems-oriented and considerate of diversity.

Next, we underscore the importance of education in systems theory and contextual risk factors, training in a particular model of clinical change, and supervision that encourages relationally focused assessment and intervention for trainees to develop competencies that increase their effectiveness in working with family issues. Throughout a trainee's development in becoming more adept at treating family issues, we urge supervisors to focus specifically on

ethical issues unique to working with families. There are established professional organizations and standards to be relied and that inform training pathways in this regard (Kaslow et al., 2005).

The pathway to expert competency in the treatment of family issues is composed of creating and taking advantage of opportunities for focused training and supervision in work within contexts that are systems-oriented. This requires forethought and dedication on the part of the trainee as well as extra work outside generalist program training requirements. Basic competencies may be measured using the parameters of general clinical competencies in clinical psychology with attention to additional, unique factors pertaining to the complicated skills and techniques required for effective work within family systems. Expert competencies may be developed through the acquisition of supervisory and training roles, and through extensive, intensive, focused training in systems-oriented intervention and conceptualization. Current guidelines for ABPP in family psychology provide a useful framework for expert competency domains and highlight that expertise includes a high level of automaticity and efficiency uncharacteristic of therapists with entry-level competence in the treatment of family issues. While further iterations of the pathway to clinical competency and effectiveness regarding the treatment of family issues are needed, current literature and elements of the summary provided here comprise a strong foundation for trainees and educators.

19 Academic Problems

James K. Luiselli · Derek D. Reed · Brian K. Martens

Abstract: Many school children have academic problems. We describe contemporary methods for assessing learning difficulties and properly identifying remediation strategies. Evidence-based treatment approaches include procedures for motivating student performance and eliminating conditions that are associated with academic failure. The chapter reviews basic clinician competencies such as conducting consultation with educational personnel, performing curriculum-based measurement, and implementing functional behavioral assessment. Our discussion about expert competencies centers on an understanding of the social influences on consultation, developing expertise in brief experimental analysis, and acquiring advanced skills through post-graduate education, professional activities (speaking, writing), and peer supervision.

19.1 Overview

Each year millions of children enter the American educational system hoping to acquire the academic skills needed to become productive members of the society. Although the majority of these children demonstrate sufficient mastery of the curriculum to succeed at each grade level, many students do not. The National Center for Education Statistics (NCES, 2004) reported that approximately 37% of the nation's fourth grade students and 26% of eighth graders were below the basic level in reading. These percentages were higher for African American and Hispanic children (60% and 56%, respectively) and for children who qualified for free/reduced-price lunch (55%; Martens et al., 2007). Percentages were also high with respect to mathematics, with 23% of fourth graders and 32% of eighth graders being below the basic level. According to the National Assessment of Educational Progress scoring rubrics, the category "below basic" means that children lack even "partial mastery of prerequisite knowledge and skills that are fundamental for proficient work at each grade" (NCES, 2004).

Most children who exhibit academic problems in school are neither formally identified with a disability nor receive special education services. Rather, these children (referred to as low achievers) benefit from regular class instruction just enough to avoid special class placement. Over time, however, low achievers fall farther and farther behind their peers as gaps in their skills accumulate and demands of the curriculum increase. In the absence of an effective intervention, at some point, low achievers fall far enough behind their peers to qualify for special education services as students with disabilities. This situation has been termed "the problem of cumulative dysfluency" (Binder, 1996, p. 183), and explains in part why placement in special education has been criticized as a "wait to fail" model that delays services and reduces their effectiveness (Vaughn & Fuchs, 2003).

While a small percentage of students receiving special education services are classified as severely disabled (between 1% and 2% of the school-age population; Reschly, 1988), approximately 10% of students nationwide are classified as having a "mild" or high incidence disability. Included among these high incidence disabilities are the categories of learning disabled, speech/

language impaired, mildly mentally retarded, and emotionally disturbed. More than 85% of all students with disabilities receive a high-incidence classification, with learning disabled as the most prevalent designation (Reschly, 2004). In fact, the number of children diagnosed with a learning disability as a result of severe academic problems has increased more than 35% since 1977 (compared with a 24% population increase), and these children now comprise approximately 52% of all students with disabilities (U.S. Department of Education, 2000; Vaughn & Fuchs, 2003).

Chronic academic problems have important social consequences for children both in school and later in life. Early school failure has been linked to peer and teacher rejection, conduct disorders, and high school drop-out, as well as adult underemployment and criminal behavior (Martens & Witt, 2004; Patterson, Reid, & Dishion, 1992; Snow, Burns, & Griffin, 1998; Walker, 2004). Given the prevalence of children's academic problems and the implications of such problems for life-long success, the need for effective instructional practices in our schools has never been greater.

This chapter addresses competencies of clinical psychologists who design interventions to address children's academic problems. We focus on principles of behavior analysis and behavioral skill instruction (e.g., stimulus control) that can be applied to a variety of academic skills and have received considerable support in both basic and applied research (e.g., Daly, Martens, Barnett, Witt, & Olson, 2007). Toward this goal, we begin this chapter with a discussion of categorical versus dimensional models of service delivery in schools, and describes assessment strategies used to diagnose academic underachievement within each model. Consistent with the dimensional model, we then describe principles that underlie behavioral approaches to academic skill instruction and outline an approach for identifying potential causes of academic problems as instructional antecedents and consequences. We then describe evidence-based strategies for treating academic problems based on this approach, followed by a discussion of basic and expert competencies required for clinicians to apply these strategies in schools and other child-related settings. We conclude the chapter with recommendations that clinicians may find helpful in the transition from basic to expert competency.

19.2 Recognition of Symptoms and Their Assessment

What constitutes academic underachievement? This is a complex question, and two competing models for answering this question currently exist side by side in schools. Each of these service delivery models has its own set of assumptions, and these have led to very different approaches to assessing and treating children's academic problems.

The first model, termed a *categorical* model, continues to dominate school-based service delivery and is based on the assumption of qualitative differences between children classified as handicapped and their typical peers (e.g., Hynd, 1988; Kavale, 1990; Reschly, 2004). These differences are assumed to reside within the child, to be relatively stable over time, and to be a result of poor academic performance (Martens & Ardoin, in press). When diagnosing children's academic problems, advocates of this model focus on the assessment of psychological attributes, traits, or constructs believed to underlie classroom performance. This typically is accomplished by administering one or more standardized, norm-referenced tests which allow children to be compared with their same age or grade peers on measures of general achievement and related abilities (e.g., intelligence, verbal memory, and receptive vocabulary) (Reschly, 2004).

Guidelines for using test scores to determine whether children are eligible for a disability classification are contained in federal legislation known as the *Individuals with Disabilities Education Improvement Act* (IDEIA) first passed in 1975 as the *Education for All handicapped Children Act* (P.L. 94–142). Each state has its own set of additional regulations for making eligibility determinations, but these must be consistent with federal legislation. Two disability categories that are particularly relevant to children exhibiting severe academic problems are "learning disabled" and "mildly mentally retarded." According to federal guidelines, children may be classified as learning disabled based on the evidence of a disorder in one or more of the basic psychological processes involved in any of the major academic skill areas (e.g., reading, writing, spelling, or math). Currently, this determination can be made using either of the following two approaches. The first approach involves obtaining a significant discrepancy between scores on individually administered tests of intelligence and achievement (i.e., a one-to-one and a half-standard deviation difference). The second approach, which was included in the 2004 amendments to *Individuals with Disabilities Education Improvement* Act (IDEIA, P.L. 108–444), allows children to be classified as learning disabled when they fail to make sufficient progress to meet grade-level standards after receiving a research-based intervention. Satisfactory progress is evaluated based on a dual-discrepancy criterion, in which a child's academic performance is compared with that of peers in terms of both level and slope of improvement (Burns & Senesac, 2005).

IDEIA regulations stipulate that children may be classified as mentally retarded based on the evidence of significantly below-average intellectual functioning concurrent with deficits in adaptive behavior. Significantly below-average functioning in each of these areas is typically operationalized by scores less than one standard deviation below the mean (borderline), less than two standard deviations below the mean (mildly mentally regarded), and less than three standard deviations below the mean (moderately or severely mentally retarded).

Providing services to children under the categorical model has historically involved a series of steps known as the *refer-test-place sequence* (Erchul & Martens, 2002). Within this sequence, children are first identified as needing services by their regular education teacher based on observations of chronic or severe academic failure. The child is then *referred* for evaluation by a multidisciplinary team of support personnel, who evaluate the child in each area of suspected disability using batteries of standardized tests supplemented by classroom observations, interviews, and reviews of educational records as needed (*test*). Once the evaluation is complete, the team determines the child's eligibility for services under one or more disability classifications, recommends appropriate placement options, and identifies target areas for remediation. Following review and approval of these recommendations by representatives of the school district and the child's parents, the child is *placed* with a special education teacher for some or all of the school days, and this person provides the extra instruction needed to address the initial referral concern. Each person involved in the refer–test–place sequence is responsible for a different aspect of the child's case, and this allows the assessment and treatment of academic problems to occur independently of the regular classroom context in which those problems were initially observed (Martens & Ardoin, in press).

Despite its widespread use, the categorical model of service delivery has been criticized on a number of grounds including the high cost and delay in receiving the special education services that result from pre-placement evaluations (twice the cost of regular education; Reschly, 1988), the questionable value of norm-referenced ability tests used in pre-placement evaluations to inform treatment design (Gresham, 2006; Gresham & Gansle, 1992), lack of

differential treatment based on differential classification (Ysseldyke, Christenson, Thurlow, & Bakewell, 1989), and the limited effectiveness of special class placement (Kavale, 1990). Problems with this model have led to increased adoption of a dimensional model of service delivery, and it is this latter model which forms the basis of the strategies recommended in this chapter.

The *dimensional* model assumes that children's skills, abilities, and behavior fall on a continuum that approximates a normal distribution. By definition, most children (68%) will fall in the average range on any measured performance variable, with academic achievement dropping incrementally to a point about 2–3 standard deviations below the mean (Reschly, 1988). In this model, differences among children at adjacent points in the distribution (e.g., learning disabled versus low achiever) represent "differences of degree not kind" (Reschly, p. 462). This position has been supported by research showing that low achieving students differ from those classified with a high incidence disability (i.e., as learning disabled) based on their degree of underachievement but not the presence of physical symptoms, biological anomalies, or even intelligence-achievement discrepancies (Fuchs, Mock, Morgan, & Young, 2003; Merrell & Shinn, 1990; Reschly, 1988).

Rather than searching for underlying ability differences that correlate with academic performance, the dimensional model focuses on the assessment of academic performance itself. Assessment strategies used in this model tend to be more "direct," in that they assess the actual academic behavior of concern at the time and place of its natural occurrence (Cone, 1977). Two direct measures commonly used to diagnose academic performance problems in the dimensional approach include systematic observation of classroom behavior as well as curriculum-based measurement (CBM) probes in reading, writing, and math (Ardoin et al., 2004; Shinn, 1989; Volpe, DiPerna, Hintze, & Shapiro, 2005).

Although a variety of observation codes exist for assessing children's classroom behavior (Shapiro, 2004a), they have several features in common. First, each code defines several categories of students' on-task (e.g., active engaged time, school work, and responding to teacher) and off-task (e.g., motor movements, out of seat, and peer interaction) behavior. Some codes also define instructionally relevant categories of teacher behavior such as teacher-directed instruction or teacher approach to the child. Second, presence or absence of children's behavior within these categories is recorded within brief intervals of time (e.g., 15 s) using partial-interval or momentary time sampling methods. Third, many observation codes require the observer to record the behavior of randomly chosen, nontarget peers in addition to the target child for comparison purposes. Generally speaking, children who show levels of on-task behavior that are low (e.g., less than 80% of intervals) and below that of their typical peers are likely to be at risk of academic performance problems.

CBM (Shinn, 1989) is a direct approach to assessing children's academic performance that requires children to make production rather than selection responses within the context of actual curricular tasks or curriculum-like tasks (e.g., reading passages from a basal curriculum, grade-level math computation sheets). Production responses involve rate measures of free-operant behavior and as such combine the performance dimensions of accuracy and fluency (e.g., words read correctly per minute, digits written correctly per minute). Brief, curriculum-based measurement probes (e.g., 1 min of reading aloud, 2 min of math computation) have been shown to be reliable and valid measures of global achievement, are sensitive to short-term instructional intervention, and can be used for long-term academic progress monitoring (Hintze, Daly, & Shapiro, 1998; Shinn, 1989). Because they can be administered repeatedly,

scores on curriculum-based measurement probes can be used to make both normative (e.g., screening) and idiographic (e.g., progress monitoring) comparisons. The former are often used to diagnose academic performance problems, and many schools routinely collect schoolwide curriculum-based norms, against which the reading fluency of target children can be compared (Ardoin et al., 2004). Instructional placement standards also exist for CBM based on larger, national samples. For example, students are considered to be at a frustrational level in third to sixth grade material if they read fewer than 70 words correctly per minute with six or more errors (Shapiro, 2004b).

A second important assumption of the dimensional model is that similar variables are assumed to affect children's achievement and behavior at all points in the distribution. Unlike the categorical model, these variables are external to the child, include teachers' planning, instructional, managerial, and evaluation practices, and have been shown to be causally related to student achievement (Christenson & Ysseldyke, 1989; Martens & Witt, 2004). Thus, whether one is talking about deficient self-help skills in an adult with developmental disabilities or poor oral reading fluency in a typically developing third grader, the same conditions are assumed to have contributed to the problem (e.g., inadequate instruction), and the same principles can be used to solve the problem (e.g., practice with modeling, prompting, corrective feedback, and reinforcement) (Daly et al., 2007). Thus, in the dimensional model, assessment focuses on the interaction of children's skills and teachers' instruction. Although this requires the majority of assessment activities to be conducted in children's natural classroom environments (e.g., systematic observation), information collected during the assessment process is directly related to intervention design.

19.3   Maintenance Factors of the Disorder or Problem

Fundamental to the effective remediation of academic problems is a focus on what we can see children *do* rather than on what we assume they *know* (Daly, Lentz, & Boyer, 1996; Martens & Witt, 2004). Focusing on what children do allows the measurement of the performance of any skill over time and under different conditions in terms of accuracy (e.g., percent correct and errors) and fluency (e.g., correct rate per unit time). Rate measures of responding (i.e., fluency) are particularly useful because of their sensitivity to individual (e.g., fatigue, illness, and ability) and environment (e.g., setting, instructor, and reinforcement) variables and therefore are widely used in applied behavior analytic research (Johnston & Pennypacker, 1980). It is only by closely monitoring the dimensions of performance that we can relate changes in academic responding to the antecedents and consequences of their occurrence (Daly et al., 2007). Moreover, lawful principles exist for describing observed relationships between academic responding and the conditions surrounding its occurrence (i.e., principles of operant conditioning), and these principles can be exploited to both diagnose and treat academic performance problems.

Key to the understanding of how academic responding improves with training and instruction are the principles of *stimulus control* and *stimulus generalization*. Stimulus control involves bringing an academic response (e.g., saying the word "cat") under the control of target instructional stimuli (e.g., seeing the printed letters c-a-t) (Daly et al., 2007). Stimulus control develops gradually over time through the use of instructional procedures that (a) call the learners' attention to cues which signal when a correct response will be reinforced (i.e., discriminative

stimuli) and (b) differentially reinforce correct responding in the presence of these stimuli (Lannie & Martens, 2008; Wolery, Bailey, & Sugai, 1988). Stimulus generalization involves an increase in the range of instructional stimuli that control academic responding, and develops when responding is reinforced in the presence of varied or more naturalistic discriminative stimuli or in the presence of discriminative stimuli in more complex contexts. Principles of stimulus control and stimulus generalization underlie all forms of skill training. Moreover, these principles represent an instructional sequence in which accurate and fluent responding is first established, brought under control of key instructional stimuli, strengthened through practice in the presence of these stimuli, and then systematically programmed to occur when these stimuli are varied or occur in different contexts.

Daly, Witt, Martens, and Dool (1997) proposed a useful model for diagnosing academic performance problems based on the two principles described earlier. Specifically, this model allows one to examine deficits in academic responding as a function of insufficient instruction needed to establish, strengthen, or program for the generalization of stimulus control. These various "gaps" in a child's instructional history are summarized by five reasons children may respond incorrectly to curricular demands: (a) they don't want to do it (i.e., reinforcement for correct responding is insufficient or lacking), (b) they have not spent enough time doing it (i.e., prior instruction did not contain enough practice to strengthen stimulus control), (c) they have not had enough help to do it (i.e., prior instruction did not establish stimulus control through modeling, prompting, and corrective feedback), (d) they have not had to do it that way before (i.e., there were no prior systematic attempts to program for stimulus generalization), and (e) it's too hard (i.e., student responding consists mainly of errors as a function of overly difficult material).

19.4 Evidence-Based Treatment Approaches

Daly et al. (1996) defined academic intervention "as the process of eliciting academic responses in a more deliberate and explicit manner beyond those types of responses currently elicited by the natural classroom environment" (p. 382). As discussed previously, academic problems can occur as skill or performance deficits. In turn, these deficits are influenced by antecedent and consequence events during instruction and test situations. The challenge to school-based clinicians is to isolate sources of control over these deficits, formulating functionally relevant intervention procedures, and evaluating outcome through objective measurement of academic responding.

Haring, Lovitt, Eaton, and Hansen (1978) proposed the Instructional Hierarchy (IH) as a model for "identifying instructional procedures that could reliably improve performance at different levels for a variety of skills" (Martens & Eckert, 2007, p. 83). In effect, the IH informs intervention by tailoring behavior-change procedures along a continuum of student learning objectives. The first stage of the IH is *acquisition*, by which a student first learns an academic skill and demonstrates it accurately in the context of a curricular task. The second stage, *fluency*, requires that a student exhibit accurate responding with speed and proficiency. Next, the IH targets *generalization* of academic behavior to settings and contexts where it is expected. The final stage of the IH, *adaptation*, represents a student showing that she/he can modify what was learned when confronted with unfamiliar environmental demands.

Selecting academic intervention procedures according to the IH requires proper measurement at each of the four stages. Haring et al. (1978) advised direct daily measurement of

academic task performance as an essential component of intervention evaluation. The combination of continuous data-based measurement aligned with IH stages can be viewed as a *functional assessment and analysis* of academic responding (Daly et al., 1996).

In what follows, we describe several evidence-based academic intervention procedures. Referencing the IH, we focus on acquisition, fluency, and generalization targets. Each target is also described relative to antecedent and consequence procedures. Antecedent intervention refers to instructional methods that *precede* academic responding (Luiselli, 2006). Various cueing, prompting, and previewing strategies qualify as antecedent intervention. Consequence methods, most commonly positive reinforcement and error correction, are applied contingent on academic responding. As illustrated in the research literature, most academic intervention programs combine antecedent and consequence procedures as a "treatment package."

Interspersal training. Academic task difficulty itself is an antecedent variable that can be manipulated to change behavior. For example, Gilbertson, Duhon, Witt, and Dufrense (2008) measured on-task behavior and digits correct per minute (DCPM) of fourth grade students who had poor mathematics performance. During independent seatwork in their classrooms, the students were presented with high-difficulty tasks, moderate-difficulty tasks, and low-difficulty tasks. Using CBM, the degree of task difficulty was set individually with each student. All of the students had the highest percentage of on-task behavior and the highest DCPM in response to low-difficulty tasks.

Students also may display more challenging behaviors when they are confronted with difficult as opposed to easy assignments (Weeks & Gaylord-Ross, 1981). Behaviors that interfere with learning include verbalizing out-of-turn, throwing materials, disrupting peers, and getting out-of-seat. These and similar behaviors interfere with instruction, acquisition of skills, and academic productivity. By modifying task difficulty, it may be possible to reduce problem behaviors without more intensive intervention (Friman & Poling, 1995).

To manipulate task difficulty as an academic intervention, the challenging features of instruction must be identified. Some students struggle with learning and performance, because the subject matter is too advanced, task requirements are not explained clearly, or work effort is excessive. Once the source of task difficulty is confirmed, student learning can be improved by interspersing easy tasks with more difficult tasks. Essentially, this procedure entails establishing a ratio of "knowns" and "unkowns" (Gickling & Armstrong, 1978), starting with a combination that produces the strongest positive effect, and then gradually adding more "unknowns" without diminishing success. This may be illustrated as follows. A student may be able to accurately complete a 12-problem mathematics worksheet when all of the problems are "easy." Interspersal training could be accomplished by changing the worksheet to include ten "easy problems" and two "moderately difficult" problems, then eight "easy" problems and four "moderately difficult" problems, and so on until the student is consistently successful at the highest possible level of difficulty.

Modeling, previewing, and prompting. Showing students how to perform an academic behavior and then giving them help as required represents modeling and prompting procedures, respectively. Say, for example, that a teacher asks a student to read words printed on "flash" cards. Modeling would consist of the teacher displaying cards to the student and reading the words correctly before requesting a response. Prompting might consist of the teacher pointing to the first letter of each word or assisting the student with "sounding out" the words. These procedures have the objective of increasing the probability of accurate responding in the presence of a discriminative stimulus.

"Cover-Copy-Compare" (CCC) is a mathematics academic intervention that incorporates modeling with other instructional procedures (Skinner, Bamberg, Smith, & Powell, 1993). CCC has a student look at a mathematics problem showing the answer (the modeling component), and then cover the problem with the answer, record the answer, uncover the problem with the answer, and compare the answer. Typically implemented as a self-managed intervention, CCC addresses both acquisition and fluency objectives for a variety of mathematics calculation skills.

Previewing enables students to perform an academic activity that will be presented to them subsequently in an assignment or test situation. In a study with four 8–11-year-old students who had learning disabilities, Daly and Martens (1994) evaluated the effects of three preview methods on oral reading of sight words and narrative passages. The *student passage preview (SPP)* had students read passages without assistance, the *listening passage preview (LPP)* allowed students to listen to passages on audiotape while following along with their fingers, and with the *taped words preview (TWP)*, students read along with the audiotape. Although reading accuracy and fluency improved with each procedure, *LPP* was associated with the most robust performance improvement. Consistent with the IH conceptualization, "the strength of the LPP intervention lies in the combination of modeling plus drill under criterion stimulus conditions for the target academic behavior of oral reading" (Daly & Martens, 1994, p. 467).

Practice, performance feedback, and positive reinforcement. When an academic behavior has been acquired with acceptable accuracy, it is possible to build fluency by giving students opportunities to practice their skills. In many cases, simply scheduling brief and frequent "drills" during the school day is sufficient to strengthen fluent responding (Skinner, Belfiore, Mace, Williams-Wilson, & Johns, 1996; Skinner, Fletcher, & Henington, 1996).

Scheduled practice sessions typically are combined with other procedures, usually performance feedback and positive reinforcement. With performance feedback, a teacher informs students about their academic activity. Feedback can be implemented verbally (e.g., "Bill, you had ten correct and one incorrect on the worksheet."), in writing, or visually through graphic display (Shapiro, 2004b). Feedback also can be adapted to the type of academic task such as the number of completed assignments (Kastelen, Nickel, & McLaughlin, 1984), total answers produced (Van Houten & McKillop, 1977), or digits correct and incorrect per minute (Codding, Eckert, Fanning, Shiyko, & Solomon, 2007). Performance feedback is optimally effective when it is behavior-specific (i.e., it describes what a student has done) and is delivered immediately following completion of an academic activity.

Positive reinforcement, which by definition must be contingent on behavior, is highly effective in increasing academic engagement, accuracy, and fluency. Despite admonitions of the lay public (Kohn, 1993), "rewarding" academic performance does not undermine motivation and success in school (Akin-Little, Eckert, Lovett, & Little, 2004; Eisenberger & Cameron, 1996; McGinnis, Friman, & Carlyon, 1999). The key to using positive reinforcement most effectively is to "match" it to each student's preferences, present it consistently following desired performance, deliver it frequently, and over time, teach a learner to delay gratification by gradually increasing the time between receipt of reinforcers (Berkowitz & Martens, 2001; Neef & Lutz, 2001; Northup, George, Jones, Broussard, & Vollmer, 1996). Allowing students to earn tangible objects, tokens that can be exchanged for preferred activities, and home-based rewards are some of the reinforcers that can be included in an academic intervention. It should be noted that positive reinforcement could be programmed for individual students or through a group contingency that is applied classwide.

Error correction. When students make errors during instruction, teachers usually prompt the correct response. This behavior-contingent consequence can be implemented in different ways depending on the academic assignment and method of error correction. For example, Barbetta, Heron, and Heward (1993) demonstrated that students learned, maintained, and generalized sight-word reading when they repeated the correct word that was modeled by the teacher following an error when compared with simply attending to the correct word without repeating it. In another study, Barbetta et al. (1993) found that sight-word reading was more accurate when students were required to repeat the whole word following an error, instead of repeating the initial sounds of whole words.

It appears that error correction can be an effective academic intervention when it is both relevant (e.g., correctly spelling or reading words from tests) and irrelevant (e.g., correctly spelling or reading non-test words) to an instructional activity (Axelrod, Kramer, Appleton, Rockett, & Hamlet, 1984; Cuvo, Ashley, Marso, Zhang, & Fry, 1995). Furthermore, using response repetition as an error correction procedure during sight-word instruction, Worsdell et al. (2005) reported that when compared with single repetition of correct words, multiple repetition of correct words resulted in more cumulative words mastered, more words read correctly, and better post-instruction maintenance. Worsdell et al. also showed that the multiple repetition procedure was better when it was contingent on every incorrect response instead of an average of every third incorrect response. Additionally, research by Bennett and Cavanaugh (1998) found that *self-correction* by student following errors can facilitate learning when it is immediate but not delayed.

19.5 Mechanisms of Change Underlying the Intervention

Each of the academic interventions we reviewed influences behavior in similar and different ways. Positive reinforcement principally addresses motivation by programming incentives for learning. Poor motivation is evident for many students who resist difficult academic assignments or appear disinterested in specific content areas such as mathematics, reading, and language arts. Improving motivation through positive reinforcement occurs by making pleasurable consequences contingent on performance objectives that are negotiated between student and teacher. As students successfully contact positive reinforcement with regularity, their skills are strengthened.

Effectiveness of positive reinforcement depends on the assessment of individual student preferences. That is, what is considered pleasurable by a teacher may not, in fact, be pleasurable for a student. Therefore, students should be asked about their preferences before designing an academic intervention that incorporates positive reinforcement. Because preferences can shift over time, it is also critical to inquire about them routinely and not rely on a one-time assessment. Magnitude, or the quantity, intensity, and duration of reinforcement, is another parameter that must be considered, because it can influence response rate (Hoch, McComas, Johnson, Faranda, & Guenther, 2002). Finally, too much access to reinforcers (satiation) or too little access to reinforcers (deprivation) can affect motivation such that desirable behaviors decrease and increase, respectively (Friman & Hawkins, 2006).

Positive reinforcement may function as the mechanism for change with other academic interventions. With performance feedback, students receive information about their work, a consequence that can motivate them to surpass previous accomplishments. Referencing

interspersed task presentation, the procedure seems to operate through conditioned reinforcement because a student's success with "easy" tasks reinforces eventual completion of all required tasks ("easy" and "hard") (Skinner, 2002).

All of the various prompting procedures function by increasing the probability that a student responds correctly during instruction. Modeling, previewing, and verbal and visual cueing implemented as antecedent intervention set the occasion for responses that can be reinforced subsequently. By systematically removing (fading) prompts while maintaining criterion performance, students eventually learn and demonstrate skills without assistance. Error correction, a behavior-contingent procedure, also prompts correct responding, the mechanism of change being the following: (1) more opportunities to respond accurately in relevant stimulus conditions and (2) punishment of incorrect responses causing a student to avoid error correction (Worsdell et al., 2005).

19.6   Basic Competencies of the Clinician

We discussed earlier in the chapter that the default approach to assessing a student referred for academic skills problems was to test the student using standardized norm-referenced cognitive and achievement instruments to determine whether or not the student met the required discrepancy scores for consideration of special education services (see Fagan & Wise, 2000). In recent years, however, school psychologists have begun to adopt the problem-solving model of behavioral consultation due to the legislative influence of the IDEIA (P.L. 108–444), which mandates a response to intervention (RTI) model of service delivery (Gresham, 1991, 2006). Under the RTI model, a student is provided with an empirically supported treatment and is then formatively evaluated over time. If the student fails to respond to the first intervention, the school psychologist then institutes a more intensive treatment. Following a second failure to respond, the school psychologist then implements an individualized intensive treatment for the referred academic skills problem. Failure to respond at this level then indicates that testing the student for special education placement may be warranted.

The core clinical competency most germane to the RTI model and fundamental to best practices of the treatment of academic skills problems – thereby in direct compliance with IDEIA – is the problem-solving model of behavioral consultation. Generally speaking, behavioral consultation is a highly structured approach to problem-solving both academic and behavioral concerns (see Erchul & Martens, 2002; Martens & DiGennaro, 2008). Derived from the problem-solving approach of D'Zurilla and Goldfried (1971), behavioral consultation consists of four tasks (see Bergan, 1977; Bergan & Tombari, 1975): (1) problem identification, (2) problem analysis, (3) plan implementation, and (4) problem evaluation. During steps 1, 2, and 4, the consultant meets with a consultee to discuss a target student using an interview format. Step 3 consists of all treatment procedures used to target the academic problem.

During step 1 (the problem identification interview) of the problem-solving process, the clinician (i.e., the consultant) should meet with the consultee (i.e., the student's parent, teacher, caregiver, etc.) to identify the academic skill(s) being targeted and arrive at an operational definition of the student's performance (see Erchul & Martens, 2002). In addition, during this stage the clinician should obtain estimates from the consultee regarding both the severity of the problem (e.g., how far behind grade level is the target student's academic problem?) and the environmental conditions which appear to occasion the occurrence of the

problem the most (e.g., how does the student respond when contingencies are placed on his/her academic performance?). As the clinician gains an understanding of the nature of the academic problem, he/she should then work with the consultee to devise a plan to collect baseline data.

The problem analysis task (step 2) of the problem-solving task should involve a dialogue between the clinician and consultee about the results of their baseline assessments and a discussion of possible treatment plans based upon their collaborative findings (Erchul & Martens, 2002). With baseline data collected and analyzed, the clinician should work with the consultee to arrive at a reasonable goal for change. Moreover, to rule out possible performance deficits, the clinician should evaluate environmental factors such as the antecedents or consequences to the academic problems being observed through functional assessment methodology (e.g., Martens & Ardoin, 2002; Durand & Crimmins, 1988) developed in accordance with behavior analytic principles (Skinner, 1953). The clinician should work with the consultee to design and implement an academic intervention based on the findings from the problem analysis task as part of the plan implementation (i.e., step 3 of the problem-solving process). The findings of the plan are then reviewed during the problem evaluation interview of the problem-solving process (i.e., step 4) to determine whether or not the goals of the problem analysis interview were met, and whether the plan should continue. If the results of the problem evaluation interview suggest that the plan did not improve the academic problem, the clinician and consultee should return to the problem analysis stage and discuss the possible pitfalls in their previous approach as well as ways to address these issues in the subsequent implementation of a new and improved plan.

Imminent to the problem-solving process of behavioral consultation is the basic competency of the clinician in evaluating whether or not the referred academic problem results from either a skill deficit (i.e., the student lacks the ability to adequately complete the academic demand) or a performance deficit (i.e., the student has the ability to complete the academic demand, but is not motivated to do so). The clinician must be able to identify and accurately implement empirically supported assessments of the referred academic problem, as verbal reports often generated in consultative interviews are typically insufficient to gather data (e.g., Martens & DiGennaro, 2008). Two such empirically supported assessment techniques for academic skills problems – of which clinicians should have a basic competency to conduct – are (1) curriculum-based measurement and (2) functional behavioral assessment.

Curriculum-based measurement. To reiterate earlier discussion, curriculum-based assessment refers to a general model of academic assessment where the clinician assesses the academic environment to examine the degree of instructional match (Eaton & Lovitt, 1972) between the present curriculum and the referred students' current levels of academic ability relative to his/her peers within that curriculum (Deno, 1987; Shapiro, 2004b). Under the umbrella of curriculum-based assessment is the specific assessment technology of curriculum-based *measurement*. As for academic problems, curriculum-based measurement enables the clinician to accurately produce data-based decisions regarding instructional interventions and special education placement (see Shinn, 1989). Specifically, through the use of local norms (Deno, 1985, 1986), the clinician identifies the referred student's instructional level with regard to the instructional hierarchy (Haring et al., 1978), and compares these data to the student's peer group to determine the relative significance of the academic problem. Through analyses of the errors made during the assessment (Howell & Nolet, 1999; Howell, Zucker, & Morehead, 1982), the clinician can begin to isolate the exact problem area of the academic concern

(e.g., errors involving whole words versus letter sequences in reading, or subtraction with regrouping versus subtraction without regrouping in mathematics). Using such data, the clinician can then determine whether the student lacks accuracy or fluency with regard to the academic problem, which would influence the type of academic intervention to be implemented subsequently (Daly & Martens, 1994). Determining that a student lacks basic academic skills (i.e., accuracy) may suggest a skill deficit. In cases where accuracy is high, but fluency in the academic problem remains average or even low may suggest the need for more practice or for some simple motivational systems to be implemented. When a student demonstrates near-grade level performance during the academic assessments but exhibits poor academic skills throughout the school day, the clinician should take further steps to understand the variables surrounding the student's *performance* deficits through the use of functional behavioral assessment technologies.

Functional behavioral assessment. To competently design interventions targeting academic skills problems resulting from performance deficits, clinicians should have a basic understanding of various functional behavioral assessment methodologies. Functional behavioral assessment posits that many behaviors, regardless of topography or form, serve a purpose for the behaving individual (Skinner, 1957). More specifically, researchers (e.g., Iwata, Dorsey, Slifer, Richman, & Bauman, 1982/1994) postulate that people behave (a) to gain access to something (e.g., attention, tangible items such as food/drink or goods/activities, or sensory input), (b) to escape/avoid something (e.g., demands, attention, or setting events), or (c) because of a pre-existing medical condition.

While federal legislation (IDEIA) mandating use of functional assessment in educational settings does not define this assessment technique, researchers and behavior analysts have proposed several procedural models (e.g., Crone & Horner, 2003; Matson & Minshawi, 2007), which clinicians should be competent to use during the academic problem assessment process. Such strategies include, but are not limited to, questionnaires/scales, direct observation procedures, and experimental analyses of behavioral functions. Questionnaires/scales such as the Motivation Assessment Scale (MAS; Durand & Crimmins, 1988), the Functional Analysis Screening Tool (FAST; Iwata, 1995), and the Questions About Behavior Function (QABF; Matson & Vollmer, 1995) may be used to quickly identify hypothesized functions through the verbal report of respondents such as teachers/caregivers. Typically, the respondent is instructed to rate consequences delivered contingent on problem behavior, with each one mapping onto a specified behavior function. With such information gleaned from this indirect approach to functional assessment, the clinician should then analyze these hypotheses in more detail using direct observation procedures.

With respect to direct observation approaches to functional assessment, the clinician should be competent in the collection of antecedent-behavior-consequence chains (ABC analysis) using narrative descriptions, scatterplots, and conditional probabilities. Narrative descriptions typically document events immediately prior (i.e., antecedents) and subsequent (i.e., consequences) to occurrences of the problem behavior (Bijou, Peterson, & Ault, 1968). Scatterplot analyses (Touchette, MacDonald, & Langer, 1985) offer more information to the clinician about behavior function by identifying temporal patterns associated with problem behavior (e.g., does the behavior occur more often during independent seatwork or group instruction in the afternoon?). Perhaps the most accurate means of summarizing direct observations is by calculating conditional probabilities of differing consequence types (i.e., attention, escape, and tangible) given the occurrence of problem behavior (Bakeman &

Gottman, 1986; Martens, DiGennaro, Reed, Szczech, & Rosenthal, 2008; McKerchar & Thompson, 2004; Vollmer, Borrero, Wright, Van Camp, & Lalli, 2001). Given the appropriate behavior, by comparing such a conditional probability to the conditional probability of the same consequence types, the clinician can determine the strength of the contingency (Martens et al., 2008). Using such conditional probabilities, the clinician can gain greater confidence in hypothesizing the function of the target behavior (i.e., stronger contingencies suggest a greater likelihood that the consequence is indeed the maintaining function of the problem behavior).

19.7 Expert Competencies of the Clinician

When clinicians first approach consultees about a referred student's academic skill(s) problems, there has likely been a history of repeated treatment failures for this student. Thus, teachers entering the consultative relationship with the clinician often begin this process with a great deal of frustration and helplessness (Erchul & Martens, 2002). In addition, due to this frustration, these teachers may believe that the academic skills problems are caused by within-student characteristics (Ysseldyke & Marston, 1990). Collectively, such consultee attributes may evoke a situation where the consultee is skeptical of the clinician's ability to successfully assist in addressing the referred student's academic problems.

In an effort to circumvent these issues, Erchul and Martens (2002) advocate the use of an integrated model of consultation, wherein the consultant uses social influence strategies and skill-building supports for the consultee in concert with the problem-solving process (described above) to create a cooperative and productive consultative approach. Research into the causes of academic problems addressed via consultation suggests that 38% of cases are the direct result of the consultees' lack of knowledge (Gutkin, 1981). Thus, clinicians should "empower" consultees to effectively change their instructional techniques. Moreover, due to consultees' lack of awareness of their own limitations and contributions to the academic problems of their students, social influence strategies are necessary to promote changes without loss of cooperation or resentment of the clinician's assistance.

Social influence strategies in consultation stem directly from French and Raven's (1959) identification of social power bases. Particularly, social power represents a means of influence in the modification of one's behaviors or thoughts through the deliberate use of conversational or dialectical techniques. To date, 14 social power bases have been identified (Raven, 1992, 1993), with four of these bases (informational, expert, legitimate dependence, and referent) being empirically supported as effective in school consultation (Erchul, Raven, & Whichard, 2001). Thus, clinicians should be competent in the use of these four social influence strategies to effectively consult with teachers or other change agents relevant to academic skills problems.

The first social power basis for use as an influence strategy in consultative relationships is the informational approach. Within this approach, clinicians present a logical and sound rationale for his/her recommendations to increase the likelihood that the consultee will accept these proposals and comply with the clinician's requests (Raven, 1992, 1993). In practice, clinicians may benefit from presenting the consultee with research articles or other empirical sources documenting the efficacy of the recommended procedures. Likewise, the clinician may also present data from the referred case as evidence supporting the recommendations to the

consultee. Such data may be derived from any relevant curriculum-based or functional behavioral assessments conducted on the target student's academic-related problem behaviors.

The second social influence technique for use in school consultation is the expert social power base. Competent use of the expert power base requires the clinician to present himself/herself to the consultee as an expert in the particular treatment or approach being advocated (Raven, 1992, 1993). For instance, at the onset of the consultative relationship, the clinician should introduce himself/herself to the consultee by using any credentials or certifications that suggest to the consultee that he/she is well qualified to assist with the given case (e.g., "Hello Mr. X, my name is Mrs. Y and I am a nationally certified school psychologist with a Ph.D. in school psychology"). As the consultative relationship progresses through the problem-solving process, the clinician should call upon other expert credentials or experiences to bolster his/her status. For example, as issues arise or treatment approaches are discussed, the clinician should use statements such as "I took a course on that topic during my doctoral training" or "I am familiar with that technique because I attended a workshop conducted by Dr. Z." Clinicians may also point out previous cases that they assisted that were similar to the one being discussed. Through successful use of this power base, the consultee may be more likely to trust the clinician's judgments and perspectives on the case.

Legitimacy of dependence power base is the third social influence approach a clinician should be competent to use in consultation on academic skills problems. In practice, this process translates to the clinician being competent in presenting himself/herself as an essential part of the solution to the academic problem (Raven, 1992, 1993). Clinicians may be successful in this power base by fostering the perspective that he/she has the skills/knowledge to do something that the consultee cannot. For example, the clinician may ask the consultee to collect certain data that only the clinician has the ability to analyze or interpret. As the consultee grows dependent on the clinician, he/she will be more likely to view the clinician as a source of help and assistance, rather than an unwelcome visitor or criticizer.

The final social power base of relevance to consultation on academic skills problems is that of the positive referent (Raven, 1992, 1993). Competent use of the positive referent power base builds a level of rapport between the clinician and the consultee that directly influences the consultee to accept and welcome the clinician's assistance in the case. For instance, the clinician may illustrate that he/she has worked in a setting similar to that of the consultee, that they share similar clinical interests, or that they share similar backgrounds/interests related to education or psychology. The clinician may also benefit from pointing out any appropriate personal similarities that may come up throughout the case, such as seeing something on the consultee's desk (e.g., vacation pictures or magazines) that may spark conversation about unrelated topics, which nonetheless develop meaningful rapport between individuals. As the clinician paints himself/herself as increasingly similar to the consultee, the consultee may become more trusting and accepting of the clinician, and thereby be more likely to view the relationship as favorable. Successful use of this influence strategy may increase the consultee's drive to appeal to the clinician and follow the clinician's recommendations to maintain the relationship.

Functional analysis. While the questionnaires/scales and direct observations of functional assessments described previously are well-documented approaches to describing possible antecedent–behavior–consequence chains in the examination of behavioral functions, only experimental analyses can identify causal relationships between function and behavior (e.g., Iwata et al., 1982/1994; Skinner, 1953). Functional analysis, as an experimental approach to

functional assessment, is typically conducted in an analog format, wherein the clinician purposefully delivers either attention, escape from demands, or access to tangible goods or activities contingent upon the occurrence of the problem behavior in an effort to examine whether the behavior will increase in the context of any of these conditions (see Hanley, Iwata, & McCord, 2003). When the clinician observes an increase in problem behavior during one or more of these conditions, the clinician can then design a function-based intervention. For example, a clinician may observe that a student's calling-out behavior during independent seatwork is maintained by escape from the academic demands. A successful function-based treatment in this situation may be to institute an incentive system whereby 5 min of on-task behavior during independent seatwork earns the student a 5 min break.

Brief experimental analysis. As discussed in the introductory section, the primary goal of the clinician with an academic problem referral is to identify influences on student behavior before formulating intervention. Given this keystone objective in academic interventions, the clinician should be competent in adapting functional analysis to examine both instructional and classroom management techniques. As Daly et al. (1997) propose, the clinician should seek to understand whether the academic problem is a function of: (a) a performance deficit, (b) lack of experience, (c) lack of support, (d) improper instructional tools, or (e) a skill deficit. Using single-case design methodologies in a format similar to the functional analysis approach outlined earlier, the clinician can experimentally pinpoint the root of the academic problem with these various functions in mind.

Specifically, proper translation of functional analysis to academic related behaviors requires an understanding of brief experimental analysis methodology. Clinicians should note that functional analysis is but one technique comprising brief experimental analysis. Generally speaking, brief experimental analysis relies upon short data collection sessions conducted in an alternating treatment format (i.e., randomized sequence of experimental conditions; Martens, Eckert, Bradley, & Ardoin, 1999). Such experimental designs should incorporate reversal to baseline conditions, or repeated demonstrations over time of the intervention conditions in an effort to demonstrate experimental control. In brief experimental analyses of academic interventions, the clinician seeks to find differentiated outcomes associated with environmental conditions controlling behavior – in the same vein as functional analysis of challenging behavior. However, contrary to functional analysis, brief experimental analysis of academic interventions targets conditions that increase accurate responding rather than increase challenging behavior.

When selecting possible instructional techniques for a brief experimental analysis of academic interventions, the clinician should include empirically supported methods which correspond to the various dimensions of academic skills problems described by Daly et al. (1997) and outlined earlier. During such analyses, both antecedent- and consequence-based strategies may be programmed. For instance, in a study on the benefits of brief experimental analysis in selecting interventions targeting reading fluency, Daly, Martens, Hamler, Dool, and Eckert (1999) combined antecedent and reinforcement procedures through sequential applications to identify the most effective "treatment packages" for four students. Antecedent procedures consisted of listening passage preview and repeated readings, while consequence procedures consisted of error correction and reinforcement contingencies for surpassing previous reading scores. For all students, the empirically derived "treatment packages" increased reading fluency relative to baseline measures. A recent meta-analysis on the efficacy of brief experimental analysis such as the one described earlier for reading fluency found a mean effect

size of 2.87 (*SD* = 2.68; Burns & Wagner, 2008) for treatments identified as the most effective from brief experimental analyses over other fluency building techniques across 41 children in 13 studies. Thus, brief experimental analysis of interventions for reading fluency has evidence confirming its status as an empirically supported procedure in the selection of academic interventions.

Programming for generalization and maintenance of treatment gains. The work of the clinician is not complete without thoughtful consideration of how to ensure that the plan decided upon by the consultative process will continue to be carried out in the absence of the consultative relationship. While careful decision-making and skillful use of problem solving and social influence strategies may increase the likelihood that the consultee will accept and implement intervention procedures, the clinician must program the plan to be successful in his/her absence. That the desired behavior change will transfer across people, settings, and responses should be a goal for all intervention plans (Stokes & Baer, 1977). Fortunately, there are several procedures that can promote generalization and maintenance of treatment gains.

Identified by Stokes and Baer (1977), one common but unsuccessful approach to programming the lasting success of an intervention plan is to train a particular skill and "hope" that the skill maintains itself naturally. More successful approaches strategically incorporate generalization-facilitating strategies during intervention. For example, as a student begins to master a particular response set (e.g., addition facts), the teacher should address new response sets or other similar but unmastered sets (e.g., subtraction facts). Using ongoing data collection and formative decision-making, the teacher can monitor the student's progress and introduce the new stimuli upon completion of some predetermined criterion (e.g., introduce new stimuli upon 80% accuracy across three consecutive days).

Another component of a successful generalization/maintenance plan is to use naturally occurring reinforcers for success (Stokes & Baer, 1977). For example, tangible rewards may be highly successful during the initial phases of intervention but may be impractical long-term. However, if the teacher pairs delivery of tangibles with social praise, the tangibles could be faded out over time as long as social praise continues. Moreover, social praise will likely occur naturally from the student's peers, parents, or other teachers, making the effects generalize across settings or persons.

Finally, the clinician should work with the consultee to identify several sets of academic materials similar to the target skills. Like the example of sequential modification, using exemplar sets increases the chances that the student's academic skills will persist in the absence of the formalized training materials. Stokes and Baer (1977) also advocated the usage of stimuli that the student will encounter throughout the day to increase the chances that the skills learned during treatment will easily translate to academic tasks outside of the formalized intervention. Throughout this process, approximations to the correct response should be reinforced to shape appropriate responding and to increase the reinforcing value of the task.

19.8 Transition from Basic Competence to Expert

The transition from basic to expert competence depends on experiences, mentoring, and dedicated efforts that lead to exemplary practice. Graduate school, internship, and postdoctoral training are critical milestones toward career development but by themselves are insufficient in achieving expert competency.

Establishing recognized expertise in the area of academic problems should be planned strategically with several objectives in mind. For example, clinicians should be licensed psychologists in the state(s) in which they practice. An applicant for state licensure must have requisite academic qualifications, complete an internship program, and receive postdoctoral supervision to become "license eligible." Upon passing each state's licensure examination, the clinician can practice as a psychologist.

Beyond psychology licensure, there are other professional credentials that confer expert competency. Like board certification in medicine, the *American Board of Professional Psychology (ABPP)* grants diplomat status in several areas of specialization. Consistent with the orientation and procedures presented in this chapter, the diplomat in Behavioral Psychology from ABPP would be a first-choice option. An ABPP applicant must be a licensed psychologist with a minimum of 5 years post-licensure experience. The application process requires submission of a "work product" detailing clinical skills that if reviewed favorably, culminates in an oral examination by a panel of ABPP-credentialed experts.

Board certification in behavior analysis (BCBA) is another credential for clinicians specializing in academic problems. Like other credentialing agencies, the *Behavior Analyst Certification Board (BACB)* has academic and practice qualifications that must be met before examination eligibility. Applicants to the *BACB* must also document mandatory hours of approved supervision. A licensed psychologist who is board-certified in behavior analysis is recognized as a professional with specialized training and expertise consistent with the competencies outlined in this chapter.

Continuing education (CE) is another consideration in the transition from basic to expert competence. Licensed psychologists must accumulate a specified number of continuing education credits annually to maintain licensure. Similarly, other credentialing agencies such as *ABPP* and *BACB* require completion of continuing education activities yearly and during multiple-year cycles. There are many venues to fulfill continuing education requirements such as conferences, training workshops, topical seminars, and home-study courses. Clinicians with expert competency are diligent in meeting their continuing education obligations by embracing new learning opportunities. For those specializing in academic problems, some relevant continuing education providers include the American Psychological Association (APA), the Association for Behavioral and Cognitive Therapies (ABCT), the Association for Behavior Analysis International (ABAI), and the National Association of School Psychologists (NASP).

Reading the peer-reviewed literature is essential to be on the "cutting edge" of evidence-based and empirically supported practices. Research dissemination through publication informs professional conduct and practice standards. In fact, we propose that expert competency of a clinical psychologist can be judged by his/her knowledge of the contemporary literature. Experts must be able to cite seminal studies, acknowledge salient topics within the professional community, recognize future directions among disciplines, and translate research to practice. The number of books and journals available to clinicians can be overwhelming, so it is worthwhile to focus attention on those most relevant to day-to-day practices.

Another activity in the expert competency trajectory is speaking to other professionals and writing for publication. Local, regional, and national conferences give a clinician many presentation formats, for example, symposia, workshops, roundtable discussions, or poster sessions. By speaking to a large audience of colleagues, one's expository skills are honed, knowledge is put to the test, and reputations are forged. Writing for publication has the same benefits and

importantly, is one of the best ways to gain "free advice" from peers who are recognized experts. As a clinician builds a curriculum vitae (CV) with multiple publications, there is increased awareness of his/her expert competency over professionals who don't publish.

When a clinical psychologist prepares for and achieves licensure and related credentials, participates in continuing education activities, reads the peer-reviewed literature, presents to colleagues, and writes for publication, he/she receives supervision from and interacts meaningfully with a large professional community. Regular support, direction, and advice from experienced peers should be ongoing throughout a psychologist's career. We propose that achieving the highest level of competence depends on routine collaboration with individuals who are knowledgeable, offer constructive criticism, and serve as admirable role models. Many psychologists pursue enduring collaborative relationships through formal "peer supervision" groups, networking, and involvement with state and national professional associations.

19.9 Summary

A large number of school children have academic problems. Poor academic achievement and performance have negative consequences for students in school and as adults later in life. Both categorical and dimensional models are used to quantify academic underachievement. Consistent with a dimensional model, assessing academic performance through direct observation and curriculum-based measurement has the advantage of focusing on teacher-to-student instructional interactions. Effective assessment then leads to informed decisions about the objectives, type, and intensity of academic intervention. Acquisition, fluency, generalization, and adaptation are four stages along a continuum of student learning objectives. There are numerous evidence-based intervention procedures targeting these objectives, including interspersal training, modeling, previewing, prompting, positive reinforcement, and error correction. Clinical psychologists specializing in academic problems should have basic competencies in consultative problem-solving, curriculum-based measurement, and functional behavioral assessment. Some expert competencies for the clinician are understanding social influence strategies in the process of consultation, functional analysis, brief experimental analysis, and methods for programming generalization and maintenance of intervention produced behavior change. The transition from basic to expert competence entails proper credentialing, continuing education, familiarization with peer-reviewed literature, dissemination activities through public speaking and publication, and ongoing supervision and collaboration with senior colleagues.

20 Role of the Environment in Prevention and Remediation

Sandra Twardosz · Vey M. Nordquist

Abstract: The environment, broadly defined, has long concerned clinicians who work with children and families because it impacts prevention and intervention with problems and disorders. In this chapter, we specifically define "environment" as the organization of the individual's immediate setting in terms of space, time, materials, activities, and people, variables that have received scant attention in the child clinical literature. Operant behavioral and ecological developmental perspectives are presented to describe the processes by which these variables can affect behavior and development, and their relationship to the more distal surroundings of community and culture. Next, we present illustrative research from behavior modification and related literatures which demonstrates that architectural features, spatial divisions, and furnishings; objects, materials, and activities; routines and schedules; and the presence, characteristics, and location of people, affect engagement and modify a wide range of behavior in community settings and homes. Professional psychologists should appreciate the role of the immediate environment in shaping behavior, alone and in conjunction with contingency management and other therapies. They should recognize when a setting must be modified because it is promoting problem behavior or hindering the therapeutic process, and be able to implement changes in the organization of space, time, materials, activities, and people. Changes in the setting may also be effective components of individualized treatment programs, and may be essential for the generalization of treatment effects. Although modifications to the environment cannot usually substitute for contingency management or other therapeutic strategies, they are essential adjuncts and supports to the clinical process, and can contribute to the prevention of dysfunctional and problem behavior.

20.1   Overview

Behavioral, cognitive-behavioral, operant, and other learning-based therapies are used to address a wide range of childhood problems and disorders including anxiety, depression, conduct disorder, social skill deficits, school refusal, enuresis, sleep disorders, tics, learning disabilities, and developmental disabilities. In most cases, family members are an essential aspect of the treatment program, or the main focus of treatment as in child abuse and neglect. Teachers and staff who interact with the child in community settings may also participate and, in some cases, are the primary means by which treatment is delivered.

The therapeutic process typically involves a planned sequence of interactions and a progression of treatment steps directed toward modifying behavior, feelings, and cognitions to ameliorate the presenting problem and to achieve more optimal functioning in everyday life (e.g., Kazdin & Weisz, 2003). Treatment follows the assessment and case conceptualization, and is corrected based on the measurement of progress (e.g., Freeman & Miller, 2002). It can involve didactic instruction, homework, video presentations, and simulations, as well as verbal

communication with the therapist and is frequently based in a clinic or office. Therapists also work directly with clients in homes, classrooms, and childcare programs, and in settings deliberately designed to be therapeutic, such as preschool early intervention classrooms and residential treatment centers. Contingency management, gradual exposure to feared stimuli, and the systematic teaching of adaptive behavior are common types of intervention. There has been an increasing focus on developmental and cultural issues, as they pertain to the intervention process (e.g., Barry & Pickard, 2008; Holmbeck, Greenley, & Franks, 2003; Knight & Ridgeway, 2008), and on the need for adjunctive therapy to address the parental depression, extreme stress, and marital conflict that can accompany childhood disorders (e.g., Chronis, Chacko, Fabiano, Wymbs, & Pelham, 2004; Griest et al., 1982).

There is also frequent discussion on the influence of the environment on the development of disorders, the possibility of prevention, difficulties in accessing treatment services, and the likelihood of adherence to treatment (e.g., Ammerman & Hersen, 1997). In these discussions, the word "environment" has multiple meanings and uses. For example, the environment can include anything that interacts with heredity in the etiology of disorders. A wide range of community and societal variables including economic conditions, violence and crime, educational opportunities, the willingness of insurance companies to pay for mental health services, and the availability of drugs also constitute the environment. "Environment" can refer to the countless variables that interact with one another in a home or similar setting including cultural practices, domestic violence, parental psychopathology, household chaos, social networks, family relationships, single parenting, and a host of other factors. The home environment of a child can be described as altered by the participation in therapy and the implementation of a treatment plan. Finally, the "natural environment" is contrasted with the laboratory or clinic as a location for research or service delivery (e.g., Stichter, Clarke, & Dunlap, 2004; Wilson, Mott, & Batman, 2004). Given these and numerous other uses of the term, it is mandatory for us to define what we mean by the environment.

We use the term "environment" to refer to the organization of an individual's immediate setting in terms of space, time, materials, activities, and people. Specific variables include architectural features, spatial divisions, and furnishings; objects, materials, and activities; routines and schedules, and the presence, characteristics, and location of people in the setting. The way in which these variables function forms part of the context for people's behavior and interactions, including those involved in therapy. In many cases, they can be modified to encourage or discourage particular types of behavior or to support therapeutic programs.

With some exceptions, the organization of the immediate setting in which treatment occurs or to which the effects of treatment must generalize has received scant attention in the child clinical literature. There is usually little reference to how the organization of a home, classroom, or residential treatment center might support or hinder therapy. It is even rarer for changes in the organization of a setting, such as its routines, materials, or activities, to be a major part of the intervention, or for settings to be designed deliberately to foster appropriate engagement and prevent problem behavior. This is unfortunate because these variables are continually operating in settings where prevention and treatment occur regardless of whether they are made explicit. Almost any therapy will be adversely affected, for example, by the lack of time management skills and family routines that lead to missed clinic appointments and the inability to carry out the treatment tasks. More specifically, a contingency management intervention designed to decrease aggression among children will probably be supported by a setting in which toys and games that prompt violence have been replaced by those that foster cooperation.

A recent descriptive analysis of the content of selected parent training programs illustrates the lack of attention paid to such variables. Prinz and Jones (2003) described the characteristics of ten family-based treatment approaches for preschool and elementary school children's conduct problems that involved a Parent Management Training Approach delivered either individually or to a group of families. These programs were described in terms of their operational facets (e.g., feedback and coaching, home observation, and modeling), and their content pertaining to increasing positive behavior, managing misbehavior, and building family relations. Of the more than 50 types of content that were found in these ten programs, only two pertained to family organization or context rather than to ways of interacting with, teaching, or disciplining, a child. One of these was "maintaining a predictable routine," which was part of the content of Reciprocal Skills Training (Barrett, Turner, Rombouts, & Duffy, 2000). The other was "providing engaging activities and environment for child," which was part of the Triple P-Positive Parenting Program (Sanders, Markie-Dadds, & Turner, 2001). The inclusion of such information in addition to that on teaching and discipline may be a critical feature for parents in the program who do not have predictable family routines or who do not realize the contribution that activities and play materials can make to the encouragement of appropriate behavior. Including this type of knowledge could contribute to the maintenance of treatment gains and the prevention of future problems.

Research on the power of the environment to influence behavior points to four major reasons for clinicians and others involved with treatment and prevention to be cognizant of the impact that the organization of the immediate setting can have on the therapeutic process. First, aspects of the setting may make it difficult or even impossible for treatment procedures to be implemented consistently, or they may be particularly supportive of such procedures. The absence of predictable routines, for example, means that therapy cannot be integrated into them. On the other hand, the presence of a spouse or a relative may make it easier for one parent to focus on therapeutic tasks because someone is available to supervise other children. Second, some aspects of the setting may support the inappropriate or dysfunctional behavior, feelings, or cognitions that are the focus of therapy. A program to address school refusal, for example, may be hampered by a curriculum that is inappropriate for the student and school policies that do not adequately address the issue of bullying. Third, organizational features of the setting can support or hinder maintenance and generalization. An office-based program to teach social skills to an elementary school student requires everyday settings where it is useful to display those skills and where they can be practiced; there may be few opportunities to do so if recess has been eliminated, socialization at lunch prohibited, and where a lack of sidewalks and playgrounds makes it difficult for children to play together after school. Fourth, the need for therapy directed at individual children may, in some cases, be avoided if settings are organized to support engagement and discourage disruption and aggression. A childcare program that subjects children to long periods of waiting makes it likely that some of the children might use the time for aggression, which may become so serious that they are referred for individual therapy. Modifying the schedule may help to eliminate some of the situations in which aggression is most likely to occur.

Although the organization of space, time, materials, activities, and people in the immediate setting does not receive sufficient emphasis, these variables are sometimes mentioned in descriptions of therapeutic procedures or circumstances that give rise to child problems. For example, Harrington (2005) notes that having little to do makes most psychiatric conditions worse. Thus, an hour-by-hour schedule of daily activities is part of the treatment for youth

depression. Comprehensive behavior management programs for attention deficit disorder include an emphasis on organization at home, such as having an area for homework and keeping materials in order (Rapport, Kofler, Alderson, & Raiker, 2008). Green (2005) considered the organizational features of child and adolescent inpatient psychiatry units that seemed to be appropriate for the use of cognitive behavior therapy. He described the therapeutic opportunities provided by these settings including intensive supervision when necessary, structuring of the day around school, meal, leisure, and therapeutic activities and the social therapy that can occur in the context of the routines of daily living.

In the remainder of this chapter, we will highlight the role of the environment, defined as the organization of the immediate setting, for prevention and intervention with childhood problems and disorders. First, we will discuss operant behavioral and ecological developmental perspectives on the way in which variables pertaining to the organization of space, time, materials, activities and people are conceptualized and the processes by which they can affect behavior and development. Second, we will discuss illustrative research from behavior modification and related literatures which demonstrate that these organizational variables can affect behavior. Third, we will suggest ways in which clinicians can integrate this knowledge into therapeutic work with children and families.

20.2   An Operant Behavioral Perspective on the Environment

Although operant approaches to behavior modification have emphasized consequences, especially those mediated by people, as a powerful means of controlling behavior and remediating childhood problems, it has long been recognized that complex antecedents to behavior are also highly influential. These antecedent conditions are referred to as setting events (e.g., Bijou & Baer, 1961, 1978; Kantor, 1959; Twardosz, 1985; Wahler & Fox, 1981) and are of two general types. One type consists of the individual's immediate surrounding circumstances, such as the presence of particular objects or people that influence stimulus–response relationships, i.e., facilitate or inhibit the occurrence of behavior that is already in an individual's repertoire. For example, some types of games "set the occasion" for cooperative play; other types make aggression more likely (e.g., Bay-Hinitz, Peterson, & Quilitch, 1994). The immediate surroundings of a shopping mall encourage wandering and exploration, but the presence of several televisions in a home could make sedentary behavior more likely.

A second type of setting event occurs separately in space and time from the behavior it influences and includes the individual's response to the event. The biological state of an individual, produced by food or sleep deprivation, illness, or drugs (e.g., Carr, Reeve, & Magito-McLaughlin, 1996) can function as a setting event because it changes the way in which the individual responds to a current situation. Teaching parents to be alert, that is, fully focused on the present moment, can be viewed as influencing the neuropsychological state with which an individual copes with child behavior, perhaps leading to the use of more effective interaction strategies (e.g., Singh et al., 2007). Another example of this type of setting event is the influence that events at home on a "bad morning" can have on the likelihood that a child might refuse to follow the teacher's instructions or get into arguments with peers at school.

Wahler and his colleagues (Wahler, 1980; Wahler & Graves, 1983) viewed the operation of social networks as setting events. On days when mothers of oppositional children had pleasant interactions with friends, they interacted with their children less negatively than on days when

such pleasant interactions did not occur. Similarly, coercive interactions that low-income mothers in parent training had with relatives and helping agencies increased their likelihood of becoming involved in coercive interactions with their children on those days and would disable the correct implementation of contingency management procedures. Another example is a schedule in which active play precedes an event that requires focused attention, thereby making it more likely that young children will be inattentive (Krantz & Risley, 1977). Clearly, variables pertaining to the organization of space, time, materials, activities, and people, which are the focus of this chapter, can function as setting events; however, other variables, such as illness or upsetting interactions can function this way as well.

As functional behavioral assessment and intervention with the challenging behavior of individuals with severe developmental disabilities started dominating mainstream applied behavior analysis, the term "establishing operations" was introduced to refer to the way in which some antecedent events function to alter the reinforcing or punishing effectiveness of other events and the frequency of the behavior relevant to those consequences (e.g., Laraway, Snycerski, Michael, & Poling, 2003; McGill, 1999). This term appears to overlap with "setting events" to some extent. Research on establishing operations has typically been conducted in highly controlled situations and focuses on well-established problem behavior. The types of organizational variables that are the focus of this chapter are only occasionally manipulated in such studies within the natural environment of the participants. Those studies are included in our literature review.

A perusal of the behavioral literature indicates that currently there is widespread disagreement about the terminology, with the terms antecedents, setting events, and establishing operations sometimes being used interchangeably and sometimes distinguished from one another (e.g., Kazdin, 2005; Luiselli & Cameron, 1998; Repp & Horner, 1999). We will use the term "setting events", because it has been associated with behavioral research conducted in a wide range of natural settings, with a great diversity of problems and participants, both typically developing and developmentally disabled, and with research on the effects of complex organizational variables on behavior.

20.3 A Developmental Perspective on the Environment

Bronfenbrenner's (1979) ecological model of human development incorporates not only variables operating in the immediate settings of an individual, but also the influences of the larger community, society, and culture on what occurs in those immediate settings (e.g., Anderson & Mohr, 2003; Bradley & Whiteside-Mansell, 1997). Knight and Ridgeway (2008) described the world of the child and family who are in therapy using this model. The child's psychopathology exists within the family microsystem, where it affects and is affected by events and relationships within that system. The microsystem exists within larger circles of influence comprising interactions among microsystems, such as communication or conflict between home and school, and organizations outside the family, such as workplaces with schedules and sources of stress that impinge upon family time and activities. The values of the society and culture that may be similar to, or different than, the ones held by family members form the outer circle of influence. The authors encourage clinicians to use this model as a rubric when conceptualizing the presenting problem and intervention; they view their clinical work as a process of creating a new microsystem for the child in which change can occur.

However, a later and more elaborated version of Bronfenbrenner's model (Bronfenbrenner & Ceci, 1994; Bronfenbrenner & Morris, 1998; Ceci & Hembrooke, 1995) is more relevant for our understanding of the influence of the organizational variables in the immediate setting. It focuses more precisely on what occurs within microsystems, which are defined as patterns of activity, social roles, and interpersonal relationships in settings made up of physical, social, and symbolic features that invite or inhibit engagement. Homes, childcare centers, classrooms, residential treatment centers, and other community settings are classified as microsystems. These, in turn, are nested within more distal systems. "Proximal processes", frequent, stable, reciprocal, and progressively more complex patterns of interaction between an individual and the persons, objects, and symbols that surround them occur within microsystems, and are the means by which development occurs, changing genotypes into phenotypes. Adult–child interaction, playing with objects and peers, acquiring new skills, and caring for others are examples of proximal processes. The number and level of proximal processes in an individual's microsystems help to determine, in conjunction with the characteristics of the developing person, individual competence or dysfunction.

Proximal processes occur within and draw upon the physical, social, and symbolic resources provided by the immediate environment of the microsystem, including whether or not the physical environment invites exploration and is responsive to behavior and whether or not there is temporal regularity or unpredictability of activities. The microsystem must also import resources, such as knowledge, from the more distal surroundings of the neighborhood and larger society. The presence, absence, and use of resources either supports or hinders proximal processes and is part of what is meant by saying that an individual's environment is enriched, well organized, and advantaged or impoverished, chaotic, and disadvantaged. A study by Evans, Maxwell, and Hart (1999) illustrates the interplay between a proximal process and the resources of a setting. They found that parents in more crowded homes speak in less complex and diverse ways to their children and are generally less responsive to them than parents in less crowded homes; this effect was unrelated to socioeconomic status or number of children in the family. They proposed that people cope with the unwanted social interaction that accompanies crowding by withdrawing from one another. Too many people in a confined space may be a hindrance for some of the proximal processes involved in language acquisition.

The distinction that Bronfenbrenner and his colleagues draw between proximal processes and the resources of the surroundings is very helpful. Environment is not simply defined as everything that exists or is experienced within a setting, but has a more precise meaning. Organizational features are ways in which the physical and social resources of a setting are arranged to support or hinder individuals' interactions with people, objects, and symbols (Roskos & Twardosz, 2004). The prevention of childhood problems can be viewed as resulting partially from settings in which these resources support the proximal processes that lead to competence. The consistent implementation of an intervention may be viewed as a proximal process which is surrounded by the way in which space, time, materials, activities, and people are organized and operate in the immediate setting. Some of these resources support the intervention and others do not. Knight and Ridgeway (2008) point out that people in a child's life can be a resource, because more are available to help with the therapeutic process. However, people can be a hindrance as well if they disagree about the usefulness of therapy.

Both operant behavior modification and developmental ecological perspectives contribute to our understanding of the effects of organizational variables on the individual. As setting events, they are linked to the operation of consequences, to other setting events, and to other

antecedent events, such as prompts, that also act to make behavior more or less likely to occur. It connects them to a change-oriented point of view, that is, these variables can and should be changed to benefit children and their families. On the other hand, the bioecological framework connects the genetic makeup of the individual with the surroundings that contribute to gene expression. It focuses attention on the importance of fostering the development of the individual as well as responding to the occurrence of specific problems and disorders. The distinction between proximal processes and the resources that support or hinder them helps bring organizational variables into sharper focus. Both of these perspectives emphasize the critical importance of an individual's engagement with the surroundings; engagement brings the individual into contact with consequences and is one of the means by which development occurs.

20.4 Basic Competencies

All professional psychologists should be knowledgeable about how the environment shapes behavior and how manipulations of the physical and social aspects of the immediate setting can be used to achieve desired changes in a client's behavior, social and family relationships, success in school and other settings, and mental health. They should have skills commensurate with this knowledge and be able to implement such environmental changes. In working with children and families, the basic competencies include: appreciating the relationship between productive engagement and the prevention of problem behavior, and using the environment to increase engagement; recognizing how architectural features, spatial division, and furnishings can influence the shaping of behavior; using materials and planned activities to achieve goals; modifying the organization of time through new routines and scheduling to achieve change; using the presence, characteristics, and location of people to naturally modify behavior; and recognizing that the setting is a system with all the implications for planned and unplanned changes that are involved. This section describes theory, research, and examples of effective practice for each of these competency areas.

20.4.1 Organization of Settings for Prevention and Remediation

Engagement. The productive engagement of people with their surroundings is fundamental to development, learning, and the prevention of problems that may ultimately require intervention (Bronfenbrenner & Ceci, 1994; McWilliam, Trivette, & Dunst, 1985; Risley, 1977, 1996). Individual characteristics, nature of the relationships people have with one another, culture, neighborhood safety, developmental level, and a host of other variables contribute to the amount and type of engagement that occur. The organization of space, time, materials, activities, routines, and people in the immediate setting interact with all of those factors to contribute to engagement, because they operate continuously as setting events, making the occurrence of some types of behavior more likely than others.

Homes, classrooms, and residential facilities where productive engagement is high are likely to be those where angry, disruptive, and aggressive behaviors are infrequent. In those settings, there are no long periods of waiting with nothing to do; children are supervised; there are some planned activities and routines with clear goals; space and materials are organized to support them; there is a predictable schedule; and adults' relationships with one another are

positive and supportive. Adults in these settings are working hard but they are not overwhelmed because characteristics of the setting, such as the right equipment, support them. These are settings that are most likely to support intervention for a specific child problem, disability, or skill deficit because parents, teachers, and staff have the time and energy to implement therapeutic procedures consistently and the organization of the setting does not work against the goals of treatment. Moreover, since people are productively engaged most of the time, there is less need to use procedures to decrease behavior, and when such procedures are necessary, they can be gentle rather than severe (Risley & Twardosz, 1976; Twardosz, 1984).

Lack of productive engagement takes many forms. At home, children may spend hours watching anything that is on television, engage in fights with siblings, and annoy parents with minor complaints and major tantrums. At school, children may have little to do for significant periods of the day, as they transition from room to room and wait for teachers to complete administrative duties or cope with children with challenging behavior. Asking about engagement implies that the operation of setting may be the problem rather than, or in addition to, the individual who has been referred for treatment and that some of the organizational features of the setting may need to be altered. In general, if many children are not productively engaged or are involved in dysfunctional behavior, the setting is viewed as problematic. Not only might the development and learning of everyone in the setting be at risk, but also it would be extremely difficult to make progress with the clinical problem of an individual in that situation.

There are many specific ways in which settings can be organized to promote engagement and discourage dysfunctional behavior. Family or program composition, cultural and socioeconomic circumstances, resources and dangers in the environment outside of the immediate setting, and so forth, will help determine how this occurs. People are also remarkably good at adjusting their behavior to the characteristics of even the most inconvenient settings to meet the challenges of supervising, caring for, and educating children, often at great cost to themselves. However, although there is not just one "right" way to do things, research conducted in natural settings, using primarily single-case experimental designs and direct observation of behavior, does indicate that specific arrangements of organizational variables can promote engagement, discourage dysfunctional behavior, and facilitate adults' activities and interactions with children. This research can provide clues about why a setting might be functioning well or badly and how the everyday operation of that setting could be altered for the benefit of all the members.

However, no matter how well-organized homes and community-based settings are in terms of promoting productive engagement and preventing problem behavior, individualized therapeutic programs will still be required. These programs rely primarily on the behavior of other people who must, for example, change the way they give instructions, grant or deprive children of privileges, ignore certain types of behavior, assist children in coping with anxiety-provoking situations, and teach specific skills. Modification of aspects of the immediate setting, such as materials and activities, schedules, the structure of routines, and the types of people in the setting can form part of these interventions, perhaps substituting for some of the personal effort.

The illustrative research described here contains examples of both of these uses of organizational variables, that is, to increase engagement and prevent dysfunctional behavior and to address the problems of individual children. The research was conducted in group care settings, classrooms, and homes, and involved typically developing children including children with disabilities, as well as their parents, caregivers, and teachers. Reversal and multiple baseline experimental designs and the direct observation of behavior were the primary methods

used in these studies. Definitions of engagement varied across studies, sometimes including a broad range of behavior appropriate to an activity or time of day, and sometimes focusing more specifically on behaviors such as cooperation with peers, language use, or compliance. (Common measures of engagement can be found in Nordquist & Twardosz, 1992.)

Architectural features, spatial division, and furnishings. The architectural features of existing settings cannot be easily modified; people typically adapt to them but can also become more aware of how they may impact their activities. A limited number of architectural features have been examined in the behavioral literatures for their effect on ease of supervision and engagement. For example, how open (not divided by many permanent walls) or closed a space is can make supervision easy or more difficult. Twardosz, Cataldo, and Risley (1974) conducted experimental studies using movable partitions in infant and toddler day care classrooms. They found that open space did not interfere with children's sleep or participation in preacademic activities, but it did make it easier for staff to see children or to bring them into view in just a few steps. It also made it easier for the supervisor to see the staff. However, these classrooms were divided into areas by low barriers and furnishings. Not only can this practice increase engagement, but it can also provide a degree of privacy and seclusion in group care settings.

Spatial definition, the degree to which parts of a setting are differentiated from one another and contain the resources necessary for the intended activity was found by Moore (1986) to be associated with more exploration, immersion in activities without interruption, cooperation among children in preschool classrooms, and teacher encouragement rather than attempts to control. The division of space into areas furnished to set the occasion for particular types of play is the most common and effective way to design group care settings for young children. It is also currently used as a means of encouraging independent or group work in elementary school classrooms. Weinstein (1977) addressed problems in the way second and third grade students were using a classroom that was divided into subject areas. Design changes were made to areas that were infrequently used or that were used for unintended purposes, such as roughhousing in the reading and writing area. They included the addition of shelving, chairs and tables so that materials could be used more easily, and the addition of a cardboard house that provided some private space. No changes or additions were made to materials or equipment. Results indicated that children were dispersed more evenly across areas after the changes, they engaged in a greater range of appropriate behavior, and girls used the science and games area more frequently. However, the author noted that design changes did not necessarily counter children's strong preferences or dislikes for certain activities.

Consideration of the ways in which architectural features can support engagement, supervision, and privacy extend to community-based treatment settings and to homes. For example, semi-private rooms arranged along a corridor in residence and day treatment programs provide more privacy for clients. Unfortunately, they also make it easier for assaults, self-injury, tantrums, and other dysfunctional behavior to occur without staff knowledge, whereas openward conditions facilitate more immediate delivery of consequences or other forms of therapy (Clark, Ichinose, & Naiman, 1990).

In homes, parents must continually adjust their supervision and children's access to privacy as their children develop; the effort required to do this varies depending on how homes are constructed. Given the number of permanent walls in many homes, supervision of activities such as the use of computer, television, and video games may be facilitated by locating them in the more public, open spaces of a home. Spatial division in homes, with areas set aside deliberately for activities that require extra support, such as doing homework, may encourage

engagement in these activities. An oft-repeated recommendation for encouraging children to read for pleasure at home is to provide a sheltered space with books nearby that is quiet and comfortable (e.g., Morrow & Temlock-Field, 2004).

Materials and planned activities. The judicious use of materials and activities is probably one of the most effective ways of insuring that a setting promotes engagement and discourages disruption, aggression, and other dysfunctional behavior. Studies indicate that simply providing specific types of materials can set the occasion for social rather than isolated play in an after-school recreation program (Quilitch & Risley, 1973) and in an integrated summer program for prekindergarten children (Martin, Brady, & Williams, 1991); for attention and play rather than self-stimulation and handling of medical equipment on a pediatric intensive care unit (Cataldo, Bessman, Parker, Pearson, & Rogers, 1979), and for the incorporation of literacy themes into children's play (Neuman & Roskos, 1992).

Books can also be useful for keeping students productively engaged when teachers are working with other students or engaged in administrative tasks. This was the practice in a middle school religion class; nevertheless, the disruptive behavior of a 12-year-old boy who had been diagnosed with AD/HD and oppositional defiant disorder (ODD) persisted until a book without pictures was replaced with religious comics or books with pictures. Disruptive behavior decreased – an effect that was enhanced by moving him away from preferred peers. It should be noted that this classroom was part of a residential facility, in which a token economy and other behavioral programming operated (Hoff, Ervin, & Friman, 2005).

McGee and Daly (1999) evaluated arrangements of play materials within a therapeutic preschool program serving both children with autism and typical children. The explicit philosophy of this program was to encourage engagement and discourage dysfunctional behavior through setting organization; individual treatment occurred in this context. The most effective condition for promoting engagement and decreasing negative behavior during freeplay was twice weekly toy rotations and inclusion of hobby boxes that contained materials preferred by individual children. Teacher behavior remained consistent throughout all the conditions of the study, lending more credibility to the conclusion that it was the materials and not differences in teacher attention that were responsible for the behavior changes.

Determining which materials are preferred through direct observation or designing toys specifically for individuals with developmental disabilities who may have difficulty becoming productively engaged has a long history (e.g., Favell & Cannon, 1977; Murphy, Carr, & Callias, 1986; Reid, DeCarlo, Schepis, Hawkins, & Stricklin, 2003). The purpose of this approach is to promote engagement and discourage dysfunctional behavior by enhancing the everyday environment with preferred materials. The following studies extend this idea to games and to the combined use of organizational variables and contingency management.

Murphy, Hutchinson, and Bailey (1983) addressed the problem of aggression on an elementary school playground where more than 300 children congregated in the morning by experimentally evaluating the provision of organized games (races and jump rope). The number of aggressive incidents dropped drastically as soon as the games were introduced. Although a time-out procedure was implemented along with the games, it was seldom used despite the fact that several hundred instances of aggression occurred daily during baseline. Similar results with preschool children's aggression and cooperation were obtained by providing competitive versus cooperative games (Bay-Hinitz et al., 1994).

Teaching parents to use planned activities in conjunction with contingency management was investigated in a group of studies with parents whose preschool-aged children were difficult

to manage. Sanders and Dadds (1982) focused on the problems parents had using contingency management procedures outside of the home, when shopping or waiting in doctors' offices, or when they were occupied at home, such as talking on the telephone, and there was little for children to do. They trained parents first to anticipate that problems might arise in certain situations and then to arrange the situation to minimize their occurrence by briefly discussing rules in advance, and providing activities for children in those settings (games that could be played in the car, finding items on a shopping list). The addition of Planned Activities Training (PAT) to a package of contingency management procedures (CMT) resulted in improvements above and beyond what was found with CMT alone.

PAT has been evaluated in combination with CMT (Sanders & Christensen, 1985; Sanders & Plant, 1989) and alone (Huynen, Lutzker, Bigelow, Touchette, & Campbell, 1996). In the latter study, mothers of children with developmental disabilities who had sought help for their children's disruptive and noncompliant behaviors were taught a variety of planning, interaction, and teaching strategies for problems that occurred at specific times of the day and in the community. Praise and mild consequences for inappropriate behavior were included in this version of PAT, but the majority of the training involved preventing the problems through arranging setting events. The skill of designing planned activities for situations that are likely to set the occasion for children's undesirable behavior is also included in Project SafeCare, an in-home ecobehavioral approach for treating and preventing child neglect and abuse (e.g., Gershator-Molko, Lutzker, & Wesch, 2002).

The provision of materials and planned activities not only helps to prevent problems but also assists children's learning, because both the materials and peers provide feedback that may lead to increased skill development. Specific arrangements of materials also form an essential part of the context of highly developed teaching strategies to assist children with language difficulties (e.g., Hancock & Kaiser, 2006). However, simply providing materials is often not sufficient to increase engagement; some children with disabilities will require individualized instruction and reinforcement to promote even the simplest types of materials' use. Any child, however, will need adult guidance, teaching, and encouragement with materials that they cannot use productively alone. The presence of such materials in homes can provide opportunities for parent–child interaction.

Organization of time through routines and scheduling. The way in which routines are structured, predictability of scheduling, precedence of certain activities over others, and the way people share responsibility for managing routines in home and community settings can function as complex setting events for engagement and inappropriate behavior. Two studies illustrate the way in which replacing cafeteria-style with family-style dining can set the occasion for particular types of engagement. Doke, Feaster, and Predmore (1977) evaluated family-style dining with youths at a psychiatric treatment facility who obtained their trays, ate, and then left the dining room to smoke and socialize in a poorly supervised area. When family-style dining, which included table-setting and cleanup tasks, serving one's food from bowls, music, and rules for appropriate behavior, was implemented, the youths remained in the dining room and participated longer compared with conditions of cafeteria-style dining and youths who did not eat in family-style. This effect was replicated in a residential facility for developmentally disabled boys, where family-style dining simply involved helping oneself to portions from serving bowls rather than obtaining food on a tray (VanBiervliet, Spangler, & Marshall, 1981). Staff did not sit at the tables with the boys or serve the food but simply supervised residents in the entire dining room. Not only did the boys remain at the table longer, but they also talked more to one

another and their comments went beyond asking for food. If the boys had been involved in structured programs to encourage more elaborate language, this situation would have provided the opportunity for generalization of those skills.

There are few existing studies in which scheduling was viewed as an independent variable, systematically changed, and the effects on engagement observed. Much like architectural features, the schedule that operates in group care settings or homes may be viewed as something unchangeable to which people must adjust their behavior. The following examples indicate that this need not be the case. Several studies conducted in compensatory preschool classrooms demonstrated that a schedule comprising concurrent activities, where children could leave an activity when they were finished and become involved in another activity, was superior in promoting engagement compared with sequential schedules where all children were required to finish an activity before any of them could move to the next one (Doke & Risley, 1972; LeLaurin & Risley, 1972). It is easy to imagine what could occur during the lengthy periods of waiting that often accompany sequential scheduling. In these kinds of situations, children have little to do except whine, bicker, and perhaps become aggressive. When periods of waiting are repeated day after day, children who are more likely to respond with negative behavior will have ample opportunity to engage in it. Under these circumstances, any type of adult attention that follows negative behavior may function as a reinforcer. Concurrent schedules require that teachers divide the responsibilities by supervising the different areas in which activities occur, rather than accompanying specific groups of children as they move from area to area. This is the division of responsibilities that often occurs in families when one adult assists a child with homework and another cleans the kitchen, answers the phone, and supervises another child in doing a chore.

Another aspect of the organization of time is the predictability of schedules. This dimension was investigated by Frederiksen and Fredericksen (1977) in a classroom for developmentally delayed adolescents. Activities in the classroom occurred in a fixed sequence and then in random order; the teacher was instructed to apply the same consequences for appropriate and inappropriate behavior throughout the study. Random schedules resulted in more disruptions and less task completion. Effects were more serious for students who had performed most poorly during the predictable schedule. However, there was some indication that students were responding more favorably to the unpredictability by the end of the study.

Krantz and Risley (1977) compared the alteration of a setting event to contingency management for their effects on kindergarten children's attention during story periods. When an active period of dancing, musical chairs, or outdoor play preceded book reading children took a longer time to transition to the activity, displayed a lower amount of attention, and engaged in a much greater number of disruptions. These problems were remediated using contingent praise and privileges, but they were prevented by preceding storytime with a brief heads down period. In this situation, a mild problem was addressed just as effectively by modifying a setting event as by using consequences.

Sometimes changes in a personal schedule or routine can be effective in the remediation of individuals' severe challenging behavior that does not appear to be related to opportunities for engagement in the immediate setting. Functional assessment was used to investigate the problem behavior of two students with severe disabilities who were attending a special education class at a high school (Kennedy & Itkonen, 1993). It was determined that when one of the students overslept a series of events occurred, including needing help to get dressed, that

culminated in aggression toward herself and other students during the school day. For another student, problem behaviors seemed to be provoked by the particular route taken by the aide who drove her to school. Insuring that the former student woke up on time so that her morning routine went smoothly and that the aide took the highway rather than the city route all but eliminated the problem behaviors in both students.

Routines and schedules obviously provide some of the basic structure for family life and can serve as the context for the implementation of treatment procedures. This point will be illustrated in the clinical cases presented at the end of this chapter.

Presence, characteristics, and location of people. Simply locating children who need to acquire or elaborate their skills with children who already display those skills can be an effective intervention. Buell, Stoddard, Harris, and Baer (1968) demonstrated this effect experimentally when they deliberately used teacher attention to increase the time that a socially isolated preschool girl spent on outdoor play equipment. Simply being where other children were playing led to social interaction with them and improvement in several social skills with no further teacher direction. Another use of peer presence and characteristics was Furman, Rahe, and Hartup's (1979) study involving 24 children from 19 childcare classrooms who were mildly socially withdrawn. They were randomly assigned to play sessions outside of the classroom with younger peers or same age peers. Although both treatments were effective compared with a control group in increasing classroom peer interaction, play with younger peers produced greater improvement for a larger number of children, perhaps because they had more opportunity to exercise leadership with younger children. The results of these studies draw attention to variables that are operating in natural settings continually and that can sometimes be used effectively to address mild childhood problems.

Mixed income groupings of children in preschool classrooms are currently being evaluated as a strategy for increasing the gains in language development for low-income children. It has been argued that middle-income peers may provide more modeling of diverse vocabulary and perhaps prompt adults to engage in more child-directed talk in contrast with preschools composed entirely of low-income children (Schechter & Bye, 2007). Preliminary evidence confirmed that there were gains in receptive language without additional language instruction. Unfortunately, direct observation in the classrooms did not occur, so we do not know the process by which these gains might have been produced. It is important to remember that locating children together will only be the first step in an intervention program for children with serious social and language deficits. The existence of numerous approaches for the deliberate development of social competence, including language acquisition and use, is testament to the fact that setting the occasion for these behaviors may be a small part of the intervention effort (e.g., Brown, Odom, & McConnell, 2008).

Another dimension of settings pertaining to the presence of people is how many occupy a defined space. It was mentioned previously that Evans et al. (1999) found that parents in crowded homes speak in less complex and diverse ways with their children. As noted by McAfee (1987), there is conflicting evidence about the effects of crowding on negative behaviors such as aggression in group care settings for children, partly because teachers may adapt more structured and directive styles, children may isolate themselves, and the activity that is occurring may affect the outcome. McAfee used an alternating treatments design and observed developmentally delayed adolescents in two public school classes using a portable partition to reduce work space per child. The results indicated that, although aggression was

quite variable across children, the vast majority of them exhibited more aggression during the crowded conditions.

Krantz and Risley (1977) experimentally addressed crowded and uncrowded conditions during kindergarten storytime and teacher demonstration periods. They systematically varied the density of children by seating them apart or together on a blanket, and found that much higher rates of on-task behavior occurred in the uncrowded condition. Contingent praise and classroom privileges, however, were effective in increasing such behavior during the crowded conditions. Studies like these point to the obvious fact that it is sometimes more reasonable and efficient to set the occasion for engagement rather than to provide consequences that are necessary in large part because of the inefficient arrangement of the setting.

20.4.2 The Setting as a System

Most of the research described in the preceding text focused on changes produced in engagement or problem behavior when one organizational feature of a setting was changed. However, each of these elements depends on the others and also on the behavior of people in the setting (e.g., Nordquist & Twardosz, 1990; Thompson, Robinson, Dietrich, Farris, & Sinclair, 1996). Specific architectural features, such as openness for supervision, make it possible for a greater number of concurrent activities to occur because another adult does not need to be present for the space on the other side of a wall to be used. This, in turn, can prevent the problems that may occur from crowding. Similarly, an abundance of toys and books that attract the attention of children in a household may not exert much effect on learning if children's schedules do not leave sufficient time for play and parents' schedules do not include time for them to help their children use the materials.

Nordquist, Twardosz, and McEvoy (1991) investigated the effects of combined changes in spatial division, availability of materials and activities, the daily schedule, and division of teacher responsibilities. They reorganized two classrooms for children with autism that operated in a mental health facility. Each classroom served three school-aged boys with a teacher and aide. Lack of child engagement and teacher frustration characterized these classrooms before the study. The rooms were divided into instruction and freeplay areas of equal size with some toys, many of which were broken, located on shelves. All children and both teachers moved from the instruction area to freeplay together, approximately every 20 min in a sequential schedule. During instruction, one teacher moved from one child to another administering discrete trial training while the aide tried to prevent the other two children from self-stimulating and becoming disruptive. Instructional materials often were out of reach of the teacher, which caused even more waiting. During freeplay, the children typically lay on beanbag chairs, manipulated materials, often in a stereotyped fashion, or wandered around the classrooms; there were no organized activities or games. It was concluded that the organization of the setting was the primary problem because it was promoting dysfunctional behavior and preventing the efficient implementation of individual therapy. Reorganization was implemented in a multiple baseline design and was comprehensive. Most of the classroom space was devoted to freeplay with a smaller area for discrete trial instruction. Freeplay was divided into areas for art, music, small manipulatives, water play, and large motor toys; approximately one-third of these were rotated each week, partially based on children's

preferences, which were recorded daily by the teachers. Children rotated individually through short periods of discrete trial training and longer periods of freeplay, which usually meant that the opportunity to engage in preferred activities followed successful task completion. Teachers assumed responsibility for areas and were not given any instructions about how to interact with children in freeplay other than asking them at the beginning of the intervention to encourage the children to use the materials.

This comprehensive reorganization resulted in substantial increases in children's engagement with materials and compliance in both the instruction and freeplay areas. These increases could not be explained by changes in concurrent teacher attention, prompts, or the use of time-out. An unexpected and more surprising result was the immediate and sustained increases in smiling and affectionate statements teachers directed toward the children, even though there was little increase in the total amount of adult attention children received. The complex combination of setting events that characterized these classrooms at the end of the study clearly served as a quite different context for the individually tailored clinical programs designed for these children.

Space considerations do not permit a comprehensive review of the research on organizational variables or the numerous applications of the results in fields devoted to improving the circumstances of individuals with developmental disabilities and challenging behavior. Additional sources on the use of setting events include a discussion by Kern and Clemens (2007) on classwide and individual applications of antecedent strategies to enhance motivation and prevent problems in schools. Many of these strategies involve changes in the presentation of academic tasks (e.g., Munk & Karsh, 1999), a topic that has not been discussed in this chapter.

20.5 Expert Competencies

The expert clinician is able to apply all of the basic competencies in everyday practice; such a clinician's practice may be defined by the creative use of environmental modification to achieve goals with or without the concurrent use of contingency management or other therapeutic strategies. These psychologists are recognized in their communities as the people to be contacted for consultation or assistance in solving complex problems. These experts understand the implications of the basic competencies for clinical practice and, in each assignment or client case, creatively answer three questions while designing and implementing changes. We begin this section with a review of the implications for clinical practice of the basic competencies and present the questions about the immediate environment employed by experts to shape their practice.

20.5.1 Implications for Clinical Practice

Research on the environment, defined as the organization of space, time, materials, activities, routines, and people, shows that these variables can affect behavior in a wide range of settings where prevention and remediation occur. This research points to the importance of considering the organization of settings as part of the clinical process similar to the importance of considering developmental and cultural issues and the impact of the more distal environment such

as the safety of neighborhoods or economic and social policies. Knowledge about how spatial division, schedules, routines, people, materials and activities can be arranged to produce specific effects can assist with the modification of settings that are contributing to problem behaviors and the design of interventions for individual childhood problems and disorders. It can inform clinical practice and add to clinical competency. Although attention to the organization of settings is not absent in the clinical literature, it is a topic that deserves much more specific focus.

As setting events, organizational variables can produce changes quickly because they depend upon previously acquired behavior for their effects and some of these changes may be broad in scope. However, this also means that they cannot substitute for the individualized therapeutic programming required to remediate well-established dysfunctional behavior or skill deficits. They can, however, be used in conjunction with and in support of such programs and can help insure that settings in which the child practices newly acquired skills provide opportunities and reinforcement for them, and that settings do not, themselves, promote the dysfunctional behavior that is the target of treatment. Modifying such variables often does not require the influx of additional resources but simply the rearrangement of what is already present in a setting.

20.5.2 Integrating Environmental Considerations into Clinical Practice

There are three broad questions that can guide clinicians and others involved in prevention and remediation as they consider the role of the immediate setting while working with the unfolding circumstances of a particular case. The first question is: *"Does the organization of the home, classroom, residential treatment center or other community-based setting generally promote children's safety, supervision, and productive engagement, minimize the occurrence of dangerous situations and dysfunctional behavior, and leave the adults with enough time and energy to participate in the therapeutic process?"* In extreme circumstances, of course, danger to children is addressed by removing them from the home or closing a group care setting. Disorganization coupled with desperate economic circumstances, family violence, or drug abuse can lead to referral to agencies concerned with family survival. In some cases of neglect or abuse, intensive training in basic household safety, cleanliness, healthcare, and parent–child interaction may be warranted, such as the in-home training provided by Project SafeCare (e.g., Lutzker & Bigelow, 2002; Lutzker, Bigelow, Doctor, & Kessler, 1998). Even if children are safe and supervised, they may be involved in so little productive engagement that it may be necessary to implement changes to the setting before or in conjunction with treatment for individual problems, just as adjunctive therapy for mental health problems or marital conflict might accompany parent training for the management of conduct disorder. For example, within a residential treatment program, clinical work to address the high and dangerous levels of aggression of one child could occur concurrently with modification of the schedule and activities of his living unit where there are low levels of productive engagement and many of the children are frequently aggressive.

Parents who are economically secure and who do not suffer from mental illness or marital strife may simply be overwhelmed with responsibilities that prevent them from completing treatment programs, despite the fact that they know a problem exists and desire assistance. For example, a mother with a preschool-aged child who is becoming increasingly noncompliant,

aggressive, and unhappy may be unable to handle the additional responsibility of learning how to implement contingency management procedures if she also has two other young children, a husband who works very long hours and is required to travel, and no relatives or friends nearby that she can rely upon for help. In addition, because she finds it impossible to set up and maintain a predictable schedule of daily routines, partly because of the child's noncompliant, disruptive, and aggressive behavior, the situation is rapidly becoming worse. Even if a mother in such circumstances manages to find a suitable treatment program, she may soon discontinue attending sessions, adding to the high dropout rates for behavioral parent training that are only partially understood (e.g., Barkley et al., 2000; Brinkmeyer & Eyberg, 2003). The stress she experiences just getting through each day would detract from learning new ways of responding to the child and simply getting to the clinic would be a challenge. It is unlikely that continued refinements in parent training methodology or high levels of approval from the therapist would be sufficient to overcome these obstacles; however, discussion and specific guidance about how to modify some of the organizational features of the home, including obtaining assistance from her husband or other sources, could make it easier for her to meet all of her responsibilities and make it more likely that she could implement contingency management procedures to address her child's noncompliant and aggressive behavior.

Another question that is helpful for guiding the use of this knowledge in clinical practice is: *"Can a change in some aspect of the organization of space, time, materials, activities, routines, or people constitute part of a treatment program for a childhood problem or disorder?"* In this case, the focus is on the individual problem rather than the setting as a whole, but changes in the way that some part of the setting is organized could contribute to the treatment, perhaps making it easier to implement or adding to its effectiveness. Evidence that spatial division, materials and activities, routines and schedules, and the characteristics and location of people can affect behavior has appeared throughout this chapter. The case examples provided below show how changes in these features can be tailored to contribute to the treatment for individual children.

A family sought clinical assistance because their 5-year-old daughter filled the time between dinner and bedtime with noncompliance, tantrums, and aggression toward parents, which made it very difficult for their school-aged son to complete his homework or interact with friends. Although it was agreed that contingency management would be a major part of treatment, it soon became clear that the absence of a predictable sequence of routines, including time shared with a parent doing a preferred activity, was probably contributing to the problem and would work against the implementation of treatment. Moreover, the setting was not structured to help produce compliance. Thus, in addition to training in contingency management, the clinician assisted the parents in using routines, scheduling, and materials to set the occasion for the desired behavior. They designed a predictable order of evening routines that culminated in reading to the child before bed. The preferred activity of reading followed cleaning up toys and taking a bath, which was resisted by the child. Adding toys to the tub was a technique used to make it more likely that the child would comply with the instruction to get in the tub and could then be praised by the parent. Although training in contingency management was still a critical component of intervention, it is likely that the reorganized evening routines and materials helped to produce the decrease in noncompliance and increase in cooperation that occurred.

Combining contingency management with modification of some of the organizational features of the home was also used with a mother who sought treatment because her 15-year-old

daughter would not do her homework and had begun to receive failing grades at school. This was one of several problems that had worsened after she and her husband divorced, and it added to their frequent arguments. The mother worked full-time and was taking two classes at night to earn a nursing degree but she was uncomfortable because she feared that her daughter's boyfriend was at the house in her absence. The mother reported that two previous attempts to obtain treatment had ended poorly. One clinician did talk with her about her concerns but did not provide suggestions for improving the problems. Another clinician recommended the use of a token economy at home and at school; however, the teachers refused to cooperate saying that this strategy did not work with adolescents.

Because the mother was under a great deal of stress and showed signs of depression, the therapist referred her to a psychiatrist who prescribed a mild antidepressant and provided cognitive therapy. The therapist also persuaded her to drop one of her evening classes and promised to assist her in obtaining a modified work schedule so that she could take a class during the day if her situation at home improved. Mother, daughter, and therapist collaborated to develop the following intervention. A homework chart was devised so that the daughter could record homework assignments and obtain teacher signatures. The consequence for not doing homework was loss of phone privileges until it was completed. In addition, a number of changes to the space, routines, and schedules of the home were implemented to set the occasion for homework completion and more pleasant interaction between the mother and daughter.

First, rather than beginning homework right after school as previously required, the schedule was changed so that the daughter could talk on the phone, listen to music, or engage in other preferred activities provided that friends did not come over. When the mother returned from work, they would prepare a meal or eat out and converse only about positive topics. This was perhaps easier to do now because there was no need to argue about why homework had not been done. Dinner was followed by a 1 hour study period that took place in the dining room rather than the daughter's bedroom. Small shelves were bought for books and supplies and the computer was set up on the table. Rather than doing her own studying late at night, the mother studied with the daughter. Phones and the TV were off, although music could be played if they both agreed. If homework was completed, the rest of the hour could be spent reading. Getting ready for bed was followed by another period of preferred activities. This schedule was followed from Sunday through Thursday, including the night the mother was in class.

This combination of procedures quickly produced very favorable outcomes in terms of homework completion, improvement in grades, a decrease in arguments, and discontinuation of the homework chart. Within 6 months, the mother was off the antidepressant and had obtained a change in her work schedule so that she could take a class during the day. It is important to note that changes to the setting were made without any visits to the home by the therapist. The therapist included a consideration of organizational variables in discussions with the mother and daughter about factors in the home that might be contributing to the problem, and how they might be changed as part of an intervention. Specific questions were asked about how space, time, materials and activities, routines, and the presence of people operated in that particular home.

The final question is: *"Does the organization of the immediate setting provide any specific supports for a planned intervention or are there any clear hindrances to its implementation?"*

Given that we often take the details of our immediate setting for granted and fail to appreciate the power they might have over our behavior, it is likely that parents, teachers, and staff do not realize what they have on hand to assist them in the implementation of treatment. Flexible space, predictable schedules, the willingness of both parents (or other adults in the household) to share responsibility for the children, well-established routines, and a network of relatives and friends who can be relied upon for help can obviously make it much easier for intervention to be implemented consistently (Dolezal-Sams, Nordquist, & Twardosz, in press). Some family members might also have particular characteristics or knowledge that would be useful for developing ties with a child's classroom teacher who might then be more willing to change some features of the classroom routine for a particular student. Similar supports could be listed for classrooms, residential treatment centers, and other community settings.

On the other hand, it is critical to take stock of the hindrances to treatment implementation that exist in the immediate setting, particularly those that are not amenable to change. Crowded space, lack of people who can be counted on for help, constant distractions, work schedules that do not permit family members to spend much time together, and economic circumstances that do not permit the purchase of materials are realities for many families and community settings that also face difficulties with an individual child who needs intervention. Other hindrances may be more specific to the problem that is being addressed with individual therapy, such as lack of space to exercise for children who are in treatment for obesity, or the lack of transportation that prevents a child from remaining after school for social activities that might contribute to some phases of therapy for social anxiety. Obtaining detailed information about potential hindrances and the supports that could compensate for them would contribute to the design of interventions that would fit into and take advantage of the child's setting.

20.6 Summary

The environment, broadly defined, has long been a concern for clinicians who work with children and their families because it can impact efforts to prevent and intervene with problems and disorders. Research on the environment, defined as the organization of space, time, materials, activities, routines, and people in the immediate setting of the individual, indicates that these variables not only affect behavior, but also are amenable to change in clinical situations. Knowledge about how they work together to promote productive engagement and help prevent problems, and how they can supplement and support interventions designed to treat the problems and disorders of individual children can inform clinical practice and add to clinical competency.

Clinicians can integrate existing knowledge about the organization of the immediate environment into prevention and remediation efforts by asking: (1) whether or not a setting generally promotes productive engagement and discourages dysfunctional behavior and if modification of the setting should be part of the intervention plan; (2) whether changes in the setting should be part of the intervention directed at the problem of an individual child; and (3) if specific supports or hindrances to intervention exist in the organization of a setting. The information gathered as a result of asking these questions will prove extremely useful for clinicians regardless of the setting in which they work.
