THE CIVIL ENGINEERING HANDBOOK

SECOND EDITION

New Directions in Civil Engineering

Series Editor
W. F. CHEN
Hawaii University

Published Titles

Advanced Analysis of Steel Frames: Theory, Software, and Applications
W.F. Chen and Shouji Toma

Analysis and Software of Cylindrical Members
W.F. Chen and Shouji Toma

Artificial Intelligence and Expert Systems for Engineers
C.S. Krishnamoorthy and S. Rajeev

The Civil Engineering Hanbook, Second Edtion
W.F. Chen and J.Y. Richard Liew

Cold Weather Concreting
Boris A. Krylov

Concrete Beams with Openings: Analysis and Design
M.A. Mansur and Kiang-Hwee Tan

Concrete Buildings: Analysis for Safe Construction
W.F. Chen and K.H. Mosallam

Earthquake Engineering Handbook
W.F. Chen and Charles Scawthorn

The Finite Strip Method
Y.K. Cheung and L.G. Tham

Flexural-Torsional Buckling of Structures
N.S. Trahair

Flood Frequency Analysis
Ramachandro A. Rao and Khaled Hamed

Fracture Processes of Concrete
Jan G.M. van Mier

Fracture and Size Effect in Concrete and Other Quasibrittle Materials
Zdeňek P. Bǎzant and Jaime Planas

Introduction to Environmental Geotechnology
Hsai-Yang Fang

Limit Analysis and Concrete Plasticity
M.P. Nielsen

LRFD Steel Design Using Advanced Analysis
W.F. Chen and Seung-Eock Kim

Response Spectrum Method in Seismic Analysis and Design of Structures
Ajaya Kumar Gupta

Simulation-Based Reliability Assessment for Structural Engineers
Pavel Marek, Milan Gustar, and Thalia Anagnos

Stability Design of Steel Frames
W.F. Chen and E.M. Lui

Stability and Ductility of Steel Structures under Cyclic Loading
Yuhshi Fukumoto and George C. Lee

Theory of Adaptive Structures: Incorporating Intelligence into Engineered Products
Senol Utku

Published Titles (Continued)

Unified Theory of Reinforced Concrete
Thomas T.C. Hsu

Water Treatment Processes: Simple Options
S. Vigneswaran and C. Visvanathan

Forthcoming Titles

Transportation Systems Planning: Methods and Applications
Konstandinos Goulias

Preface

The second edition of the *Civil Engineering Handbook* has been revised and updated to provide a comprehensive reference work and resource book covering the broad spectrum of civil engineering. This book has been written with the practicing civil engineer in mind. The ideal reader will be a BS- or MSc-level engineer with a need for a single reference source to use to keep abreast of new techniques and practices as well as to review standard practices.

The *Handbook* stresses professional applications, placing great emphasis on ready-to-use materials. It contains many formulas and tables that give immediate solutions to common questions and problems arising from practical work. It also contains a brief description of the essential elements of each subject, thus enabling the reader to understand the fundamental background of these results and to think beyond them. Traditional as well as new and innovative practices are covered.

As a result of rapid advances in computer technology and information technology, a revolution has occurred in civil engineering research and practice. A new aspect, *information technology and computing,* has been added to the theoretical and experimental aspects of the field to form the basis of civil engineering. Thorough coverage of computational and design methods is essential in a knowledge-based economy. Thus, computational aspects of civil engineering form the main focus of several chapters. The *Civil Engineering Handbook* is a comprehensive handbook, featuring a modern CAD/CAE approach in advancing civil engineers in the 21st century. The *Handbook* is organized into eight sections, covering the traditional areas of civil engineering: construction engineering, materials engineering, environmental engineering, structural engineering, geotechnical engineering, surveying engineering, hydraulic engineering, and transportation engineering.

The subdivision of each section into several chapters is made by the associate editors and is somewhat arbitrary, as the many subjects of the individual chapters are cross-linked in many ways and cannot be arranged in a definite sequence. To this end, in addition to the complete table of contents presented at the front of the book, an individual table of contents precedes each of the eight sections and gives a general outline of the scope of the subject area covered. Finally, each chapter begins with its own table of contents. The reader should look over these tables of contents to become familiar with the structure, organization, and content of the book. In this way, the book can also be used as a survey of the field of civil engineering, by the student or civil engineer, to find the topics that he or she wants to examine in depth. It can be used as an introduction to or a survey of a particular subject in the field, and the references at the end of each chapter can be consulted for more detailed studies.

The chapters of the *Handbook* have been written by many authors, all experts in their fields, and the eight sections have been carefully edited and integrated by the various associate editors in the School of Civil Engineering at Purdue University and the Department of Civil Engineering at the National University of Singapore. This *Handbook* is a testimonial to the dedication of the associate editors, the publisher, and the editorial associates. I wish to thank all of the authors for their contributions and the

reviewers for their constructive comments. I also wish to acknowledge at CRC Press, Helena Redshaw, Elizabeth Spangenberger, Susan Fox, and Cindy Carelli for their professional support in revising this handbook.

W. F. Chen
J. Y. Richard Liew
Editors-in-Chief

Editors-in-Chief

W. F. Chen is presently Dean of the College of Engineering at the University of Hawaii. He was a George E. Goodwin Distinguished Professor of Civil Engineering and Head of the Department of Structural Engineering at Purdue University from 1976 to 1999.

He received his B.S. in civil engineering from the National Cheng-Kung University, Taiwan, in 1959**,** M.S. in structural engineering from Lehigh University, PA, in 1963, and Ph.D. in solid mechanics from Brown University, RI, in 1966. He received the Distinguished Alumnus Award from the National Cheng-Kung University in 1988 and the Distinguished Engineering Alumnus Medal from Brown University in 1999.

Dr. Chen's research interests cover several areas, including constitutive modeling of engineering materials, soil and concrete plasticity, structural connections, and structural stability. He is the recipient of several national engineering awards, including the Raymond Reese Research Prize and the Shortridge Hardesty Award, both from the American Society of Civil Engineers, and the T. R. Higgins Lectureship Award from the American Institute of Steel Construction. In 1995, he was elected to the U.S. National Academy of Engineering. In 1997, he was awarded Honorary Membership by the American Society of Civil Engineers. In 1998, he was elected to the Academia Sinica (National Academy of Science) in Taiwan.

A widely respected author, Dr. Chen authored and coauthored more than 20 engineering books and 500 technical papers. His books include several classical works such as *Limit Analysis and Soil Plasticity* (Elsevier, 1975), the two-volume *Theory of Beam-Columns* (McGraw-Hill, 1976–77), *Plasticity in Reinforced Concrete* (McGraw-Hill, 1982), and the two-volume *Constitutive Equations for Engineering Materials* (Elsevier, 1994). He currently serves on the editorial boards of more than 10 technical journals. He has been listed in more than 20 *Who's Who* publications.

Dr. Chen is the editor-in-chief for the popular 1995 *Civil Engineering Handbook*, the 1997 *Handbook of Structural Engineering*, and the 1999 *Bridge Engineering Handbook*. He currently serves as the consulting editor for McGraw-Hill's *Encyclopedia of Science and Technology.*

He has been a longtime member of the Executive Committee of the Structural Stability Research Council and the Specification Committee of the American Institute of Steel Construction. He has been a consultant for Exxon Production Research on offshore structures, for Skidmore, Owings, and Merrill in Chicago on tall steel buildings, and for the World Bank on the Chinese University Development Projects, among many others.

Dr. Chen has taught at Lehigh University, Purdue University, and the University of Hawaii.

J. Y. Richard Liew is presently associate professor with the Department of Civil Engineering at the National University of Singapore. He received his B.Eng. and M.Eng in Civil Engineering from the National University of Singapore, in 1986 and 1988, respectively, and Ph.D. in Structural Engineering from Purdue University, West Lafayette, IN, in 1992.

Dr Liew published more than 100 papers covering topics such as steel design, frame stability, and steel-concrete composite structures. He is actively involved in research on innovative lightweight structures covering wide aspects of structural mechanics problems, including joint effects, composite actions between various materials, cable tensioning problems, and high temperature and high strain rate effects. He also worked on product development using fiber-reinforced polymer materials for structural applications. Dr. Liew authored and coauthored two books and more than ten engineering book chapters. He served on two editorial boards of technical journals related to steel and composite structures.

He is a member of the American Society of Civil Engineers and the Institute of Structural Engineers in the U.K. He is a Chartered Engineer of the U.K. He is currently (2002) the president of the Singapore Structural Steel Society. He has been serving as a specialist advisor to several national organizations on steel specifications and projects, to consultants and steel fabricators for special projects related to large span steel structures and high-rise steel buildings, among others.

7 Value Improvement Methods *David K. H. Chua*
Introduction • Value Engineering • Constructability • Quality Management • Conclusions

The construction industry is one of the largest segments of business in the United States, with the percentage of the gross national product spent in construction over the last several years averaging about 10%. For 2001, the total amount spent on new construction contracts in the U.S. is estimated at $481 billion [*Engineering News Record,* Nov. 19, 2001]. Of this total, about $214 billion is estimated for residential projects, $167 billion for nonresidential projects, and the rest for nonbuilding projects.

Construction is the realization phase of the civil engineering process, following conception and design. It is the role of the constructor to turn the ideas of the planner and the detailed plans of the designer into physical reality. The owner is the ultimate consumer of the product and is often the general public

for civil engineering projects. Not only does the constructor have an obligation to the contractual owner, or client, but also an ethical obligation to the general public to perform the work so that the final product will serve its function economically and safely.

The construction industry is typically divided into specialty areas, with each area requiring different skills, resources, and knowledge to participate effectively in it. The area classifications typically used are residential (single- and multifamily housing), building (all buildings other than housing), heavy/highway (dams, bridges, ports, sewage-treatment plants, highways), utility (sanitary and storm drainage, water lines, electrical and telephone lines, pumping stations), and industrial (refineries, mills, power plants, chemical plants, heavy manufacturing facilities). Civil engineers can be heavily involved in all of these areas of construction, although fewer are involved in residential. Due to the differences in each of these market areas, most engineers specialize in only one or two of the areas during their careers.

Construction projects are complex and time-consuming undertakings that require the interaction and cooperation of many different persons to accomplish. All projects must be completed in accordance with specific project plans and specifications, along with other contract restrictions that may be imposed on the production operations. Essentially, all civil engineering construction projects are unique. Regardless of the similarity to other projects, there are always distinguishing elements of each project that make it unique, such as the type of soil, the exposure to weather, the human resources assigned to the project, the social and political climate, and so on. In manufacturing, raw resources are brought to a factory with a fairly controlled environment; in construction, the "factory" is set up on site, and production is accomplished in an uncertain environment.

It is this diversity among projects that makes the preparation for a civil engineering project interesting and challenging. Although it is often difficult to control the environment of the project, it is the duty of the contractor to predict the possible situations that may be encountered and to develop contingency strategies accordingly. The dilemma of this situation is that the contractor who allows for contingencies in project cost estimates will have a difficult time competing against other less competent or less cautious contractors. The failure rate in the construction industry is the highest in the U.S.; one of the leading causes for failure is the inability to manage in such a highly competitive market and to realize a fair return on investment.

Participants in the Construction Process

There are several participants in the construction process, all with important roles in developing a successful project. The owner, either private or public, is the party that initiates the demand for the project and ultimately pays for its completion. The owner's role in the process varies considerably; however, the primary role of the owner is to effectively communicate the scope of work desired to the other parties. The designer is responsible for developing adequate working drawings and specifications, in accordance with current design practices and codes, to communicate the product desired by the owner upon completion of the project. The prime contractor is responsible for managing the resources needed to carry out the construction process in a manner that ensures the project will be conducted safely, within budget, and on schedule, and that it meets or exceeds the quality requirements of the plans and specifications. Subcontractors are specialty contractors who contract with the prime contractor to conduct a specific portion of the project within the overall project schedule. Suppliers are the vendors who contract to supply required materials for the project within the project specifications and schedule. The success of any project depends on the coordination of the efforts of all parties involved, hopefully to the financial advantage of all. In recent years, these relationships have become more adversarial, with much conflict and litigation, often to the detriment of the projects.

Construction Contracts

Construction projects are done under a variety of contract arrangements for each of the parties involved. They range from a single contract for a single element of the project to a single contract for the whole

project, including the financing, design, construction, and operation of the facility. Typical contract types include lump sum, unit price, cost plus, and construction management.

These contract systems can be used with either the competitive bidding process or with negotiated processes. A contract system becoming more popular with owners is design-build, in which all of the responsibilities can be placed with one party for the owner to deal with. Each type of contract impacts the roles and responsibilities of each of the parties on a project. It also impacts the management functions to be carried out by the contractor on the project, especially the cost engineering function.

A major development in business relationships in the construction industry is *partnering*. Partnering is an approach to conducting business that confronts the economic and technological challenges in industry in the 21st century. This new approach focuses on making long-term commitments with mutual goals for all parties involved to achieve mutual success. It requires changing traditional relationships to a shared culture without regard to normal organizational boundaries. Participants seek to avoid the adversarial problems typical for many business ventures. Most of all, a relationship must be based upon trust. Although partnering in its pure form relates to a long-term business relationship for multiple projects, many single-project partnering relationships have been developed, primarily for public owner projects. Partnering is an excellent vehicle to attain improved quality on construction projects and to avoid serious conflicts.

Partnering is not to be construed as a legal partnership with the associated joint liability. Great care should be taken to make this point clear to all parties involved in a partnering relationship.

Partnering is not a quick fix or panacea to be applied to all relationships. It requires total commitment, proper conditions, and the right chemistry between organizations for it to thrive and prosper. The relationship is based upon trust, dedication to common goals, and an understanding of each other's individual expectations and values. The partnering concept is intended to accentuate the strength of each partner and will be unable to overcome fundamental company weaknesses; in fact, weaknesses may be magnified. Expected benefits include improved efficiency and cost effectiveness, increased opportunity for innovation, and the continuous improvement of quality products and services. It can be used by either large or small businesses, and it can be used for either large or small projects. Relationships can develop among all participants in construction: owner-contractor, owner-supplier, contractor-supplier, contractor-contractor. (Contractor refers to either a design firm or a construction company.)

Goals of Project Management

Regardless of the project, most construction teams have the same performance goals:

Cost — Complete the project within the cost budget, including the budgeted costs of all change orders.
Time — Complete the project by the scheduled completion date or within the allowance for work days.
Quality — Perform all work on the project, meeting or exceeding the project plans and specifications.
Safety — Complete the project with zero lost-time accidents.
Conflict — Resolve disputes at the lowest practical level and have zero disputes.
Project startup — Successfully start up the completed project (by the owner) with zero rework.

Basic Functions of Construction Engineering

The activities involved in the construction engineering for projects include the following basic functions:

Cost engineering — The cost estimating, cost accounting, and cost-control activities related to a project, plus the development of cost databases.
Project planning and scheduling — The development of initial project plans and schedules, project monitoring and updating, and the development of as-built project schedules.
Equipment planning and management — The selection of needed equipment for projects, productivity planning to accomplish the project with the selected equipment in the required project schedule and estimate, and the management of the equipment fleet.

Design of temporary structures — The design of temporary structures required for the construction of the project, such as concrete formwork, scaffolding, shoring, and bracing.

Contract management — The management of the activities of the project to comply with contract provisions and document contract changes and to minimize contract disputes.

Human resource management — The selection, training, and supervision of the personnel needed to complete the project work within schedule.

Project safety — The establishment of safe working practices and conditions for the project, the communication of these safety requirements to all project personnel, the maintenance of safety records, and the enforcement of these requirements.

Innovations in Construction

There are several innovative developments in technological tools that have been implemented or are being considered for implementation for construction projects. New tools such as CAD systems, expert systems, bar coding, and automated equipment offer excellent potential for improved productivity and cost effectiveness in industry. Companies who ignore these new technologies will have difficulty competing in the future.

Scope of This Section of the Handbook

The scope of Section I, Construction, in this handbook is to present the reader with the essential information needed to perform the major construction engineering functions on today's construction projects. Examples are offered to illustrate the principles presented, and references are offered for further information on each of the topics covered.

Construction Estimating

1.1 Introduction
1.2 Estimating Defined
1.3 Estimating Terminology
1.4 Types of Estimates
Conceptual Estimates • Time and Location Adjustments • Detailed Estimates
1.5 Contracts
Method of Award • Method of Bidding/Payment
1.6 Computer-Assisted Estimating

James E. Rowings, Jr.
Peter Kiewit Sons', Inc.

1.1 Introduction

The preparation of estimates represents one of the most important functions performed in any business enterprise. In the construction industry, the quality of performance of this function is paramount to the success of the parties engaged in the overall management of capital expenditures for construction projects. The estimating process, in some form, is used as soon as the idea for a project is conceived. Estimates are prepared and updated continually as the project scope and definition develops and, in many cases, throughout construction of the project or facility.

The parties engaged in delivering the project continually ask themselves "What will it cost?" To answer this question, some type of estimate must be developed. Obviously, the precise answer to this question cannot be determined until the project is completed. Posing this type of question elicits a finite answer from the estimator. This answer, or estimate, represents only an approximation or expected value for the cost. The eventual accuracy of this approximation depends on how closely the actual conditions and specific details of the project match the expectations of the estimator.

Extreme care must be exercised by the estimator in the preparation of the estimate to subjectively weigh the potential variations in future conditions. The estimate should convey an assessment of the accuracy and risks.

1.2 Estimating Defined

Estimating is a complex process involving collection of available and pertinent information relating to the scope of a project, expected resource consumption, and future changes in resource costs. The process involves synthesis of this information through a mental process of visualization of the constructing process for the project. This visualization is mentally translated into an approximation of the final cost.

At the outset of a project, the estimate cannot be expected to carry a high degree of accuracy, because little information is known. As the design progresses, more information is known, and accuracy should improve.

Estimating at any stage of the project cycle involves considerable effort to gather information. The estimator must collect and review all of the detailed plans, specifications, available site data, available resource data (labor, materials, and equipment), contract documents, resource cost information, pertinent government regulations, and applicable owner requirements. Information gathering is a continual process by estimators due to the uniqueness of each project and constant changes in the industry environment.

Unlike the production from a manufacturing facility, each product of a construction firm represents a prototype. Considerable effort in planning is required before a cost estimate can be established. Most of the effort in establishing the estimate revolves around determining the approximation of the cost to produce the one-time product.

The estimator must systematically convert information into a forecast of the component and collective costs that will be incurred in delivering the project or facility. This synthesis of information is accomplished by mentally building the project from the ground up. Each step of the building process should be accounted for along with the necessary support activities and embedded temporary work items required for completion.

The estimator must have some form of systematic approach to ensure that all cost items have been incorporated and that none have been duplicated. Later in this chapter is a discussion of alternate systematic approaches that are used.

The quality of an estimate depends on the qualifications and abilities of the estimator. In general, an estimator must demonstrate the following capabilities and qualifications:

- Extensive knowledge of construction
- Knowledge of construction materials and methods
- Knowledge of construction practices and contracts
- Ability to read and write construction documents
- Ability to sketch construction details
- Ability to communicate graphically and verbally
- Strong background in business and economics
- Ability to visualize work items
- Broad background in design and code requirements

Obviously, from the qualifications cited, estimators are not born but are developed through years of formal or informal education and experience in the industry. The breadth and depth of the requirements for an estimator lend testimony to the importance and value of the individual in the firm.

1.3 Estimating Terminology

There are a number of terms used in the estimating process that should be understood. AACE International (formerly the American Association of Cost Engineers) developed a glossary of terms and definitions in order to have a uniform technical vocabulary. Several of the more common terms and definitions are given below.

1.4 Types of Estimates

There are two broad categories for estimates: conceptual (or approximate) estimates and detailed estimates. Classification of an estimate into one of these types depends on the available information, the extent of effort dedicated to preparation, and the use for the estimate. The classification of an estimate into one of these two categories is an expression of the relative confidence in the accuracy of the estimate.

Conceptual Estimates

At the outset of the project, when the scope and definition are in the early stages of development, little information is available, yet there is often a need for some assessment of the potential cost. The owner needs to have a rough or approximate value for the project's cost for purposes of determining the economic desirability of proceeding with design and construction. Special quick techniques are usually employed, utilizing minimal available information at this point to prepare a conceptual estimate. Little effort is expended to prepare this type of estimate, which often utilizes only a single project parameter, such as square feet of floor area, span length of a bridge, or barrels per day of output. Using available, historical cost information and applying like parameters, a quick and simple estimate can be prepared. These types of estimates are valuable in determining the order of magnitude of the cost for very rough comparisons and analysis but are not appropriate for critical decision making and commitment.

Many situations exist that do not warrant or allow expenditure of the time and effort required to produce a detailed estimate. Feasibility studies involve elimination of many alternatives prior to any detailed design work. Obviously, if detailed design were pursued prior to estimating, the cost of the feasibility study would be enormous. Time constraints may also limit the level of detail that can be employed. If an answer is required in a few minutes or a few hours, then the method must be a conceptual one, even if detailed design information is available.

Conceptual estimates have value, but they have many limitations as well. Care must be exercised to choose the appropriate method for conceptual estimating based on the available information. The estimator must be aware of the limitations of his estimate and communicate these limitations so that the estimate is not misused. Conceptual estimating relies heavily on past cost data, which is adjusted to reflect current trends and actual project economic conditions.

The accuracy of an estimate is a function of time spent in its preparation, the quantity of design data utilized in the evaluation, and the accuracy of the information used. In general, more effort and more money produce a better estimate, one in which the estimator has more confidence regarding the accuracy of his or her prediction. To achieve significant improvement in accuracy requires a larger-than-proportional increase in effort. Each of the three conceptual levels of estimating has several methods that are utilized, depending on the project type and the availability of time and information.

Order of Magnitude

The order-of-magnitude estimate is by far the most uncertain estimate level used. As the name implies, the objective is to establish the order of magnitude of the cost, or more precisely, the cost within a range of +30 to –50%.

Various techniques can be employed to develop an order-of-magnitude estimate for a project or portion of a project. Presented below are some examples and explanations of various methods used.

Rough Weight Check

When the object of the estimate is a single criterion, such as a piece of equipment, the order-of-magnitude cost can be estimated quickly based on the weight of the object. For the cost determination, equipment can be grouped into three broad categories:

1. Precision/computerized/electronic
2. Mechanical/electrical
3. Functional

Precision equipment includes electronic or optical equipment such as computers and surveying instruments. Mechanical/electrical equipment includes pumps and motors. Functional equipment might include heavy construction equipment, automobiles, and large power tools. Precision equipment tends to cost ten times more per pound than mechanical/electrical equipment, which in turn costs ten times per pound more than functional equipment. Obviously, if you know the average cost per pound for a particular class of equipment (e.g., pumps), this information is more useful than a broad category estimate. In any case, the estimator should have a feel for the approximate cost per pound for the three

categories so that quick checks can be made and order-of-magnitude estimates performed with minimal information available. Similar approaches using the capacity of equipment, such as flow rate, can be used for order-of-magnitude estimates.

Cost Capacity Factor

This quick method is tailored to the process industry. It represents a quick shortcut to establish an order-of-magnitude estimate of the cost. Application of the method involves four basic steps:

1. Obtain information concerning the cost (C_1 or C_2) and the input/output/throughput or holding capacity (Q_1 or Q_2) for a project similar in design or characteristics to the one being estimated.
2. Define the relative size of the two projects in the most appropriate common units of input, output, throughput, or holding capacity. As an example, a power plant is usually rated in kilowatts of output, a refinery in barrels per day of output, a sewage treatment plant in tons per day of input, and a storage tank in gallons or barrels of holding capacity.
3. Using the three known quantities (the sizes of the two similar plants in common units and the cost of the previously constructed plant), the following relationship can be developed:

$$C_1/C_2 = \left(Q_1/Q_2\right)^x$$

   where x is the appropriate cost capacity factor. With this relationship, the estimate of the cost of the new plant can be determined.
4. The cost determined in the third step is adjusted for time and location by applying the appropriate construction cost indices. (The use of indices is discussed later in this chapter.)

The cost capacity factor approach is also called the *six-tenths rule*, because in the original application of the exponential relationship, x was determined to be equal to about 0.6. In reality, the factors for various processes vary from 0.33 to 1.02 with the bulk of the values for x around 0.6.

Example 1

Assume that we have information on an old process plant that has the capacity to produce 10,000 gallons per day of a particular chemical. The cost today to build the plant would be $1,000,000. The appropriate cost factor for this type of plant is 0.6. An order-of-magnitude estimate of the cost is required for a plant with a capacity of 30,000 gallons per day.

$$C = \$1{,}000{,}000\left(30{,}000/10{,}000\right)^{0.6} = \$1{,}930{,}000$$

Comparative Cost of Structure

This method is readily adaptable to virtually every type of structure, including bridges, stadiums, schools, hospitals, and offices. Very little information is required about the planned structure except that the following general characteristics should be known:

1. Use — school, office, hospital, and so on
2. Kind of construction — wood, steel, concrete, and so on
3. Quality of construction — cheap, moderate, top grade
4. Locality — labor and material supply market area
5. Time of construction — year

By identifying a similar completed structure with nearly the same characteristics, an order-of-magnitude estimate can be determined by proportioning cost according to the appropriate unit for the structure. These units might be as follows:

1. Bridges — span in feet (adjustment for number of lands)
2. Schools — pupils

3. Stadium — seats
4. Hospital — beds
5. Offices — square feet
6. Warehouses — cubic feet

Example 2

Assume that the current cost for a 120-pupil school constructed of wood frame for a city is $1,800,000. We are asked to develop an order-of-magnitude estimate for a 90-pupil school.

Solution. The first step is to separate the per-pupil cost.

$$\$1{,}800{,}000/120 = \$15{,}000/\text{pupil}$$

Apply the unit cost to the new school.

$$\$15{,}000/\text{pupil} \times 90 \text{ pupils} = \$1{,}350{,}000$$

Feasibility Estimates

This level of conceptual estimate is more refined than the order-of-magnitude estimate and should provide a narrower range for the estimate. These estimates, if performed carefully, should be within ±20 to 30%. To achieve this increase in accuracy over the order-of-magnitude estimate requires substantially more effort and more knowledge about the project.

Plant Cost Ratio

This method utilizes the concept that the equipment proportion of the total cost of a process facility is about the same, regardless of the size or capacity of the plant, for the same basic process. Therefore, if the major fixed equipment cost can be estimated, the total plant cost can be determined by factor multiplication. The plant cost factor or multiplier is sometimes called the Lang factor (after the man who developed the concept for process plants).

Example 3

Assume that a historical plant with the same process cost $2.5 million, with the equipment portion of the plant costing $1 million. Determine the cost of a new plant if the equipment has been determined to cost $2.4 million.

$$C = 2.4/(1.0/2.5)$$

$$C = 6 \text{ million dollars}$$

Floor Area

This method is most appropriate for hospitals, stores, shopping centers, and residences. Floor area must be the dominant attribute of cost (or at least it is assumed to be by the estimator). There are several variations of this method, a few of which are explained below.

Total Horizontal Area

For this variation, it is assumed that cost is directly proportional to the development of horizontal surfaces. It is assumed that the cost of developing a square foot of ground-floor space will be the same as a square foot of third-floor space or a square foot of roof space. From historical data, a cost per square foot is determined and applied uniformly to the horizontal area that must be developed to arrive at the total cost.

Example 4

Assume that a historical file contains a warehouse building that cost $2.4 million that was 50 ft × 80 ft with a basement, three floors, and an attic. Determine the cost for a 60 ft × 30 ft warehouse building with no basement, two floors, and an attic.

Solution. Determine the historical cost per square foot.

Basement area	4000
1st floor	4000
2nd floor	4000
3rd floor	4000
Attic	4000
Roof	4000
TOTAL	24,000

$$\$2,400,000/24,000 = \$100/\text{ft}^2$$

Next, calculate the total cost for the new project.

1st floor	1800
2nd floor	1800
Attic	1800
Roof	1800
TOTAL	7200

$$7200\ \text{ft}^2 \times \$100/\text{ft}^2 = \$720,000$$

Finished Floor Area

This method is by far the most widely used approach for buildings. With this approach, only those floors that are finished are counted when developing the historical base cost and when applying the historical data to the new project area. With this method, the estimator must exercise extreme care to have the same relative proportions of area to height to avoid large errors.

Example 5

Same as the preceding example.

Solution. Determine historical base cost.

1st floor	4000
2nd floor	4000
3rd floor	4000
TOTAL	12,000 ft^2fa

$$\$2,400,000/12,000 = \$200/\text{ft}^2\text{fa}$$

where ft^2fa is square feet of finished floor area.

Next, determine the total cost for the new project.

1st floor	1800
2nd floor	1800
TOTAL	3600 ft^2fa

$$3600\ \text{ft}^2\text{fa} \times \$200/\text{ft}^2\text{fa} = \$720,000$$

As can be seen, little difference exists between the finished floor area and total horizontal area methods; however, if a gross variation in overall dimensions had existed between the historical structure and the new project, a wider discrepancy between the methods would have appeared.

Cubic Foot of Volume Method

This method accounts for an additional parameter that affects cost: floor-to-ceiling height.

Example 6

The same as the preceding two examples, except that the following ceiling heights are given:

	Old Structure	New Structure
1st floor	14	12
2nd floor	10	12
3rd floor	10	—

Solution. Determine the historical base cost.

$$\begin{aligned} 14 \times 4000 &= 56{,}000\ \text{ft}^3 \\ 10 \times 4000 &= 40{,}000\ \text{ft}^3 \\ 10 \times 4000 &= 40{,}000\ \text{ft}^3 \\ \text{TOTAL} &= 136{,}000\ \text{ft}^3 \end{aligned}$$

$$\$2{,}400{,}000 / 136{,}000\ \text{ft}^3 = \$17.65 / \text{ft}^3$$

Next, determine the total cost for the new warehouse structure.

$$\begin{aligned} 1^{st}\ \text{floor} \quad & 1800\ \text{ft}^2 \times 12\ \text{ft} = 21{,}600\ \text{ft}^3 \\ 2^{nd}\ \text{floor} \quad & 1800\ \text{ft}^2 \times 12\ \text{ft} = 21{,}600\ \text{ft}^3 \\ \text{TOTAL} \quad & = 43{,}200\ \text{ft}^3 \end{aligned}$$

$$43{,}200\ \text{ft}^3 \times \$17.65 / \text{ft}^3 = \$762{,}500$$

Appropriation Estimates

As a project scope is developed and refined, it progresses to a point where it is budgeted into a corporate capital building program budget. Assuming the potential benefits are greater than the estimated costs, a sum of money is set aside to cover the project expenses. From this process of appropriation comes the name of the most refined level of conceptual estimate. This level of estimate requires more knowledge and effort than the previously discussed estimates.

These estimating methods reflect a greater degree of accuracy. Appropriation estimates should be between ±10 to 20%. As with the other forms of conceptual estimates, several methods are available for preparing appropriation estimates.

Parametric Estimating/Panel Method

This method employs a database in which key project parameters, project systems, or panels (as in the case of buildings) that are priced from past projects using appropriate units are recorded. The costs of each parameter or panel are computed separately and multiplied by the number of panels of each kind. Major unique features are priced separately and included as separate line items. Numerous parametric systems exist for different types of projects. For process plants, the process systems and piping are the

parameters. For buildings, various approaches have been used, but one approach to illustrate the method is as follows:

Parameter	Unit of Measure
Site work	Square feet of site area
Foundations and columns	Building square feet
Floor system	Building square feet
Structural system	Building square feet
Roof system	Roof square feet
Exterior walls	Wall square feet minus exterior windows
Interior walls	Wall square feet (interior)
HVAC	Tons or Btu
Electrical	Building square feet
Conveying systems	Number of floor stops
Plumbing	Number of fixture units
Finishes	Building square feet

Each of these items would be estimated separately by applying the historical cost for the appropriate unit for similar construction and multiplying by the number of units for the current project. This same approach is used on projects such as roads. The units or parameters used are often the same as the bid items, and the historical prices are the average of the low-bid unit prices received in the last few contracts.

Bay Method

This method is appropriate for buildings or projects that consist of a number of repetitive or similar units. In the plan view of a warehouse building shown in Fig. 1.1, the building is made up of three types of bays. The only difference between them is the number of outside walls. By performing a definitive estimate of the cost of each of these bay types, an appropriation estimate can be made by multiplying this bay cost times the number of similar bays and totaling for the three bay types.

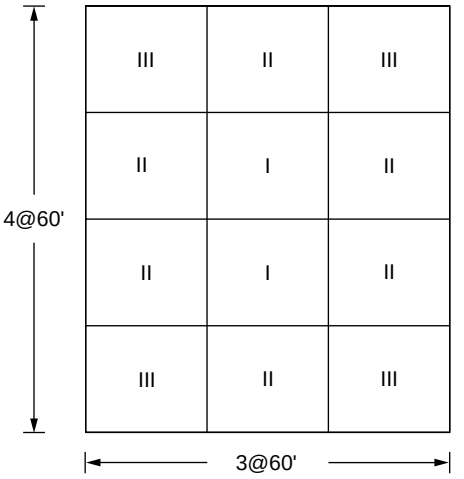

FIGURE 1.1 Plan view — warehouse building.

Example 7

We know from a definitive estimate that the cost of the three bay types is as follows:

Type I = $90,000
Type II = $120,000
Type III = $150,000

Determine the cost for the building structure and skin (outer surface).

Solution.

2 Type I @ 90,000	=	$180,000
6 Type II @ 120,000	=	$720,000
4 Type III @ 150,000	=	$600,000
TOTAL	=	$1,500,000

After applying the bay method for the overall project, the estimate is modified by making special allowances (add-ons) for end walls, entrances, stairs, elevators, and mechanical and electrical equipment.

Plant Component Ratio

This method requires a great deal more information than other methods used in the process industry. Definitive costs of the major pieces of equipment are needed. These can be determined from historical records or published data sources. Historical records also provide the data that identifies the relative percentage of all other items. The total project cost is then estimated as follows:

$$\text{TPC} = \frac{\text{ET}}{1 - \text{PT}}$$

where TPC = total plant cost
ET = total estimated equipment cost
PT = sum of percentages of other items or phases (major account divisions).

Example 8

The total equipment cost for a plant is estimated to be $500,000. The following percentages represent the average expenditures in other cost phases:

Engineering, overhead, and fees	22%
Warehousing	5%
Services	2%
Utilities	6%
Piping	20%
Instrumentation	5%
Electrical	6%
Buildings	4%
TOTAL	70% = PT

$$\frac{500{,}000}{(1.0 - 0.70)} = \$1{,}670{,}000$$

While the solution here appears simple, in fact, the majority of time and effort is spent collecting the equipment cost and choosing the appropriate percentages for application.

Time and Location Adjustments

It is often desirable when preparing conceptual estimates to utilize cost data from a different period of time or from a different location. Costs vary with time and location, and it is, therefore, necessary to adjust the conceptual estimate for the differences of time and location from the historical base. A construction cost-indexing system is used to identify the relative differences and permit adjustment.

Cost Indexing

A cost index is a dimensionless number associated with a point in time and/or location that illustrates the cost at that time or location relative to a base point in time or base location. The cost index provides a comparison of cost or cost change from year to year and/or location to location for a fixed quantity of services and commodities. The concept is to establish cost indices to avoid having to estimate all of the unique features of every project, when it is reasonable to assume that the application of relative quantities of resources is constant or will follow the use of historical data on a proportional basis without knowledge of all of the design details. If the cost index is developed correctly, the following simple relationship will exist:

$$\text{New cost}/\text{New index} = \text{Historical cost}/\text{Historical index}$$

An example of the way in which a cost index might be computed is given below. The cost elements used for developing a cost index for concrete in 1982 are as follows:

C_1 = four hours for a carpenter = \$240
C_2 = one cubic yard concrete = \$60
C_3 = three hours for laborer = \$66
C_4 = 100 fbm lumber (2 ¥ 10) = \$49
C_5 = 100 # rebar = \$35
C_6 = one hour from an ironworker = \$50

$$C_a = 240 + 60 + 66 + 49 + 35 + 50 = 500$$

Calculating C_b similarly for another time or location involves the following steps:

C_1 = four hours for a carpenter = \$200
C_2 = one cubic yard concrete = \$58
C_3 = three hours for laborer = \$90
C_4 = 100 fbm lumber (2 ¥ 10) = \$42
C_5 = 100 # rebar = \$36
C_6 = one hour from an ironworker = \$44

$$C_a = 200 + 58 + 90 + 42 + 36 + 44 = 470$$

Using the CI_a as the base with an index equal to 100, the CI_b index can be calculated as follows:

$$CI_b = \left(C_b / C_a\right) ¥ 100 = \left(470/500\right) ¥ 100 = 94$$

The key to creating an accurate and valid cost index is not the computational approach but the correct selection of the cost elements. If the index will be used for highway estimating, the cost elements should include items such as asphalt, fuel oil, paving equipment, and equipment operators. Appropriately, a housing cost index would include timber, concrete, carpenters, shingles, and other materials common to residential construction.

Most of the cost indices are normalized periodically to a base of 100. This is done by setting the base calculation of the cost for a location or time equal to 100 and converting all other indices to this base with the same divisor or multiplier.

While it is possible to develop specialized indices for special purposes, numerous indices have been published. These include several popular indices, such as the *Engineering News Record* building cost index and construction cost index and the *Means Building Construction Cost Data* construction cost index and historical cost index. These indices are developed using a wide range of cost elements. For example, the Means' construction cost index is composed of 84 construction materials, 24 building crafts' labor hours, and 9 different equipment rental charges that correspond to the labor and material items. These cost indices are tabulated for the major metropolitan areas four times each year and for the 16 major UCI construction divisions. Additionally, indices dating back to 1913 can be found to adjust costs from different periods of time. These are referred to as historical cost indices.

Application of Cost Indices

These cost indices can have several uses:

- Comparing costs from city to city (construction cost indices)
- Comparing costs from time to time (historical cost indices)

- Modifying costs for various cities and times (both)
- Estimating replacement costs (both)
- Forecasting construction costs (historical cost indices)

The cost index is only a tool and must be applied with sound judgment and common sense.

Comparing Costs from City to City

The construction cost indices can be used to compare costs between cities, because the index is developed identically for each city. The index is an indicator of the relative difference. The cost difference between cities for identical buildings or projects in a different city can be found by using the appropriate construction cost indices (CCI). The procedure is as follows:

$$\text{Cost, city A} = \frac{\text{CCI for city A}}{\text{CCI for city B}}\left(\text{Known cost, city B}\right)$$

$$\left(\text{Known cost, city B}\right) - \left(\text{Cost, city A}\right) = \text{Cost difference}$$

Comparing Costs from Time to Time

The cost indices can be used to compare costs for the same facility at different points in time. Using the historical cost indices of two points in time, one can calculate the difference in costs between the two points in time. It is necessary to know the cost and the historical index for time B and the historical cost index for time A.

$$\text{Cost, time A} = \frac{\text{HCI for time A}}{\text{HCI for time B}}\left(\text{Cost, time B}\right)$$

$$\left(\text{Known cost, time B}\right) - \left(\text{Cost, time A}\right) = \text{Cost difference}$$

Modifying Costs for Various Cities and Times

The two prior uses can be accomplished simultaneously, when it is desired to use cost information from another city and time for a second city and time estimate. Care must be exercised to establish the correct relationships. The following example illustrates the principle.

Example 9

A building cost $2,000,000 in 2000 in South Bend. How much will it cost to build in Boston in 2002?

Given: HCI, 2002 = 114.3
HCI, 2000 = 102.2
CCI, S. Bend = 123.4
CCI, Boston = 134.3

$$\frac{\left(\text{HCI, 2002}\right)\left(\text{CCI, Boston}\right)}{\left(\text{HCI, 2000}\right)\left(\text{CCI, S. Bend}\right)}\left(\text{Cost, S. Bend}\right) = \left(\text{Cost, Boston}\right)$$

$$\frac{\left(114.3\right)\left(134.3\right)}{\left(102.2\right)\left(123.4\right)}\left(2{,}000{,}000\right) = \$2{,}430{,}000$$

Estimating Replacement Costs

The historical cost index can be used to determine replacement cost for a facility built a number of years ago or one that was constructed in stages.

Example 10

A building was constructed in stages over the last 25 years. It is desired to know the 2002 replacement cost for insurance purposes. The building has had two additions since the original 1981, $300,000 portion was built. The first addition was in 1990 at a cost of $200,000, and the second addition came in 1994 at a cost of $300,000. The historical cost indices are as follows:

2002	100.0 = HCl
1994	49.8 = HCl
1990	34.6 = HCl
1981	23.9 = HCl

Solution. The cost of the original building is

$$\frac{100}{23.9}\,\$300{,}000 = \$1{,}255{,}000$$

The cost of addition A is

$$\frac{100}{34.6}\,\$200{,}000 = \$578{,}000$$

The cost of addition B is

$$\frac{100}{49.8}\,\$300{,}000 = \$602{,}000$$

So,

$$\text{Total replacement cost} = \$2{,}435{,}000$$

Construction Cost Forecasting

If it is assumed that the future changes in cost will be similar to the past changes, the indices can be used to predict future construction costs. By using these past indices, future indices can be forecast and, in turn, used to predict future costs. Several approaches are available for developing the future index. Only one will be presented here.

The simplest method is to examine the change in the last several historical cost indices and use an average value for the annual change in the future. This averaging process can be accomplished by determining the difference between historical indices each year and finding the average change by dividing by the number of years.

Detailed Estimates

Estimates classified as detailed estimates are prepared after the scope and definition of a project are essentially complete. To prepare a detailed estimate requires considerable effort in gathering information and systematically forecasting costs. These estimates are usually prepared for bid purposes or definitive budgeting. Because of the information available and the effort expended, detailed estimates are usually fairly accurate projections of the costs of construction. A much higher level of confidence in the accuracy of the estimate is gained through this increased effort and knowledge. These types of estimates are used for decision making and commitment.

The Estimating Process

Estimating to produce a detailed construction cost estimate follows a rigorous process made up of several key steps. These key steps are explained below.

Familiarization with Project Characteristics

The estimator must be familiar with the project and evaluate the project from three primary avenues: scope, constructibility, and risk. Having evaluated these three areas in a general way, the estimator will decide whether the effort to estimate and bid the work has a potential profit or other corporate goal potential (long-term business objective or client relations). In many cases, investigation of these three areas may lead to the conclusion that the project is not right for the contractor. The contractor must be convinced that the firm's competitive advantage will provide the needed margin to secure the work away from competitors.

Scope — Just because a project is available for bidding does not mean that the contractor should invest the time and expense required for the preparation of an estimate. The contractor must carefully scrutinize several issues of scope for the project in relation to the company's ability to perform. These scope issues include the following:

1. Technological requirements of the project
2. Stated milestone deadlines for the project
3. Required material and equipment availability
4. Staffing requirements
5. Stated contract terms and associated risk transfer
6. Nature of the competition and likelihood of an acceptable rate-of-return

The contractor must honestly assess the technological requirements of the project to be competitive and the internal or subcontractor technological capabilities that can be employed. This is especially true on projects requiring fleets of sophisticated or specialized equipment or on projects with duration times that dictate employment of particular techniques such as slipforming. On these types of projects, the contractor must have access to the fleet, as in the case of an interstate highway project, or access to a knowledgeable subcontractor, as in the case of high-rise slipforming.

The contractor must examine closely the completion date for the project as well as any intermediate contractual milestone dates for portions of the project. The contractor must feel comfortable that these dates are achievable and that there exists some degree of time allowance for contingencies that might arise. Failure to complete a project on time can seriously damage the reputation of a contractor and has the potential to inhibit future bidding opportunities with the client. If the contract time requirements are not reasonable in the contractor's mind after having estimated the required time by mentally sequencing the controlling work activities, two choices exist. The obvious first choice is to not bid the project. Alternatively, the contractor may choose to reexamine the project for other methods or sequences which will allow earlier completion. The contractor should not proceed with the estimate without a plan for timely completion of the project.

A third issue that must be examined in relation to the project's scope is availability to satisfy the requirements for major material commodities and equipment to support the project plan. Problems in obtaining structural steel, timber, quality concrete, or other materials can have pronounced effects on both the cost and schedule of a project. If these problems can be foreseen, solutions should be sought, or the project should not be considered for bidding.

Staffing requirements, including staffing qualifications as well as required numbers, must be evaluated to determine if sufficient levels of qualified manpower will be available when required to support project needs. This staffing evaluation must include supervisory and professional support and the various crafts that will be required. While the internal staffing (supervisory and professional support) is relatively simple to analyze, the craft availability is extremely uncertain and to some degree uncontrollable. With the craft labor in much of the construction industry (union sector) having no direct tie to any one construction company, it is difficult to predict how many workers of a particular craft will be available during a particular month or week. The ability to predict craft labor availability today is a function of construction economy prediction. When there is a booming construction market, some shortfalls in craft labor supply can be expected with a result of higher labor costs or longer project durations.

Constructibility — A knowledgeable contractor, having made a preliminary review of the project documents, can assess the constructibility of the project. Constructibility evaluations include examination of construction quality requirements, allowable tolerances, and the overall complexity of the project. The construction industry has general norms of quality requirements and tolerances for the various types of projects. Contractors tend to avoid bidding for projects for which the quality or tolerances specified are outside those norms. The alternative for the contractor is to overcompensate for the risk associated with achieving the requirements by increasing their expectation of cost.

Complexity of a project is viewed in terms of the relative technology requirement for the project execution compared with the technology in common practice in the given area. Where the project documents indicate an unusual method to the contractor, the contractor must choose to either accept the new technology or not bid. The complexity may also come about because of dictated logistical or scheduling requirements that must be met. Where the schedule does not allow flexibility in sequence or pace, the contractor may deem the project unsuitable to pursue through bidding.

The flexibility left to the contractor in choosing methods creates interest in bidding the project. The means and methods of work are the primary ways that contractors achieve competitive advantage. This flexibility challenges the contractor to develop a plan and estimate for the work that will be different and cheaper than the competition's.

Risk — The contractor must also evaluate the myriad of potential problems that might be encountered on the project. These risks can include the following:

- Material and workmanship requirements not specified
- Contradictory clauses interpreted incorrectly
- Impossible specifications
- Unknown or undiscovered site conditions
- Judgment error during the bidding process
- Assumption of timely performance of approvals and decisions by the owners
- Interpretation and compliance requirements with the contract documents
- Changes in cost
- Changes in sequence
- Subcontractor failure
- Suspension of work
- Weather variations
- Environmental issues
- Labor and craft availability
- Strikes and labor disputes
- Utility availability

This list represents a sample of the risks, rather than an inclusive listing. In general, a construction firm faces business risks, project risks, and operational risks, which must be offset in some way. Contract terms that transfer unmanageable risk or categories of risk that are not easily estimated discourage participation in bidding.

Contractors assess the likelihood of success in the bidding process by the number of potential competitors. Typically, more competition means lower markups. Lower markup reduces the probability for earning acceptable margins and rates of return associated with the project risks.

Examine the Project Design

Another aspect of the information important to the individual preparing the estimate is the specific design information that has been prepared. The estimator must be able to read, interpret, and understand the technical specifications, the referenced standards and any project drawings, and documents. The

estimator must closely examine material specifications so that an appropriate price for the quality and characteristics specified can be obtained. The estimator must use sound judgment when pricing substitute materials for providing an assumption of "or-equal" quality for a material to be used. A thorough familiarity and technical understanding is required for this judgment. The same is also true for equipment and furnishings that will be purchased. The estimator must have an understanding of referenced documents that are commonly identified in specifications. Standards of testing and performance are made a part of the specifications by a simple reference. These standards may be client standards or more universal standards, such as State Highway Specifications or ASTM (American Society for Testing and Materials) documents. If a specification is referenced that the estimator is not familiar with, he or she must make the effort to locate and examine it prior to bid submittal.

In some cases, the specifications will identify prescribed practices to be followed. The estimator must assess the degree to which these will be rigidly enforced and where allowances will be made or performance criteria will be substituted. Use of prescriptive specifications can choke innovation by the contractor but may also protect the contractor from performance risks. Where rigid enforcement can be expected, the estimator should follow the prescription precisely.

The drawings contain the physical elements, their location, and their relative orientation. These items and the specifications communicate the designer's concept. The estimator must be able to examine the drawings and mentally visualize the project as it will be constructed to completion. The estimator relies heavily on the information provided in the drawings for determination of the quantity of work required. The drawings provide the dimensions so that lengths, widths, heights, areas, volumes, and numbers of items can be developed for pricing the work. The drawings show the physical features that will be part of the completed project, but they do not show the items that may be required to achieve completion (such as formwork). It is also common that certain details are not shown on the drawings for the contractor but are developed by shop fabricators at a later time as shop drawings.

The estimator must keep a watchful eye for errors and omissions in the specifications and drawings. Discrepancies are often identified between drawings, between specifications, or between drawings and specifications. The discrepancies must be resolved either by acceptance of a risk or through communication with the designer. The best choice of solution depends on the specifics of the discrepancy and the process or the method for award of contract.

Structuring the Estimate

The estimator either reviews a plan or develops a plan for completing the project. This plan must be visualized during the estimating process; it provides the logical flow of the project from raw materials to a completed facility. Together with the technical specifications, the plan provides a structure for the preparation of the detailed estimate. Most estimators develop the estimate around the structure of the technical specifications. This increases the likelihood that items of work are covered without duplication in the estimate.

Determine the Elements of Cost

This step involves the development of the quantities of work (a quantity survey) to be performed and their translation into expected costs. Translating a design on paper into a functioning, completed project involves the transformation and consumption of a multitude of resources. These basic ingredients or resources utilized and incorporated in a project during construction can be classified into one of the following categories:

1. Labor
2. Material
3. Equipment
4. Capital
5. Time

Associated with the use or consumption of each of these resources is a cost. It is the objective of the estimator performing a detailed estimate to identify the specific types of resources that will be used, the

quantity of such resources, and the cost of the resources. Every cost item within an estimate is either one or a combination of these five basic resources. The common unit used to measure the different types of resources is dollars. Although overhead costs may not be broken down into the component resource costs, overhead items are a combination of several of these basic resources.

Labor Resources

Labor resources refer to the various human craft or skill resources that actually build a project. Through the years, large numbers of crafts have evolved to perform specialized functions and tasks in the construction industry. The specialties or crafts have been defined through a combination of collective bargaining agreements, negotiation and labor relations, and accepted extensions of trade practices. In most cases, the evolutionary process of definition of work jurisdiction has followed a logical progression; however, there are limited examples of bizarre craftwork assignment. In all, there are over 30 different crafts in the construction industry. Each group or craft is trained to perform a relatively narrow range of construction work differentiated by material type, construction process, or type of construction project. Where union construction is dominant, the assignment of work to a particular craft can become a significant issue with the potential for stopping or impeding progress. Usually in nonunion construction, jurisdictional disputes are nonexistent, and much more flexibility exists in the assignments of workers to tasks. In union construction, it is vital that the estimator acknowledge the proper craft for a task because labor wage rates can vary substantially between crafts. In nonunion construction, more managerial flexibility exists, and the critical concern to the estimator must be that a sufficient wage rate be used that will attract the more productive craftsworkers without hindering the chances of competitive award of the construction contract.

The source of construction labor varies between localities. In some cities, the only way of performing construction is through union construction. This, however, has been changing, and will most likely continue to change over the next few years. Open-shop or nonunion construction is the predominant form in many parts of the United States.

With union construction, the labor source is the hiring hall. The usual practice is for the superintendent to call the craft hiring hall for the type of labor needed and request the number of craftsworkers needed for the project. The craftsworkers are then assigned to projects in the order in which they became available for work (were released from other projects). This process, while fair to all craftsworkers, has some drawbacks for the contractor because the personnel cannot be selected based on particular past performance.

These union craftsworkers in construction have their primary affiliation with the union, and only temporarily are affiliated with a particular company, usually for the duration of a particular project. Training and qualifications for these craftsworkers must, therefore, be a responsibility of the union. This training effort provided through the union is financed through a training fund established in the collective bargaining agreement. Apprenticeship programs are conducted by union personnel to develop the skills needed by the particular craft. A second avenue for control is through admission into the union and acceptance after a trial period by the employer. The training for the craftsworker for this approach may have been in another vocational program, on-the-job experience, or a military training experience. The supply of craftsworkers in relation to the demands is thus controlled partially through admissions into the training or apprenticeship programs.

Open-shop or nonunion construction has some well-established training programs. The open-shop contractor may also rely on other training sources (union apprenticeship, vocational schools, and military training) for preparation of the craftsworker. The contractor must exercise considerable effort in screening and hiring qualified labor. Typically, craftsworkers are hired for primary skill areas but can be utilized on a much broader range of tasks. A trial period for new employees is used to screen craftsworkers for the desired level of skill required for the project. Considerably more effort is required for recruiting and maintaining a productive workforce in the open-shop mode, but the lower wage and greater flexibility in work assignments are advantages.

Cost of Labor

For a detailed estimate, it is imperative that the cost of labor resources be determined with precision. This is accomplished through a three-part process from data in the construction bidding documents that identify the nature of work and the physical quantity of work. The first step in the process involves identifying the craft that will be assigned the work and determining the hourly cost for that labor resource. This is termed the *labor rate*. The second part of the process involves estimation of the expected rate of work accomplishment by the chosen labor resource. This is termed the labor productivity. The third step involves combining this information by dividing the labor rate by the labor productivity to determine the labor resource cost per physical unit of work. The labor cost can be determined by multiplying the quantity of work by the unit labor resource cost. This entire process will be illustrated later in this chapter; however, an understanding of labor rate and labor productivity measurement must first be developed.

Labor Rate — The labor rate is the total hourly expense or cost to the contractor for providing the particular craft or labor resource for the project. This labor rate includes direct costs and indirect costs. Direct labor costs include all payments made directly to the craftsworkers. The following is a brief listing of direct labor cost components:

1. Wage rate
2. Overtime premium
3. Travel time allowance
4. Subsistence allowance
5. Show-up time allowance
6. Other work or performance premiums

The sum of these direct labor costs is sometimes referred to as the *effective wage rate*. Indirect labor costs include those costs incurred as a result of use of labor resources but which are not paid directly to the craftsworker. The components of indirect labor cost include the following:

1. Vacation fund contributions
2. Pension fund contributions
3. Group insurance premiums
4. Health and welfare contributions
5. Apprenticeship and training programs
6. Workers' compensation premiums
7. Unemployment insurance premiums
8. Social security contribution
9. Other voluntary contribution or payroll tax

It is the summation of direct and indirect labor costs that is termed the labor rate — the total hourly cost of providing a particular craft labor resource. Where a collective bargaining agreement is in force, most of these items can be readily determined on an hourly basis. Others are readily available from insurance companies or from local, state, and federal statutes. Several of the direct cost components must be estimated based on past records to determine the appropriate allowance to be included. These more difficult items include overtime, show-up time, and performance premiums. A percentage allowance is usually used to estimate the expected cost impact of such items.

Labor Productivity — Of all the cost elements that contribute to the total project construction cost, labor productivity ranks at the top for variability. Because labor costs represent a significant proportion of the total cost of construction, it is vital that good estimates of productivity be made relative to the productivity that will be experienced on the project. Productivity assessment is a complex process and not yet fully understood for the construction industry.

The following example illustrates the calculation of a unit price from productivity data.

Example 11

To form 100 square feet of wall requires 6 hours of carpenter time and 5 hours of common laborer time. This assumption is based on standards calculated as averages from historical data. The wage rate with burdens for carpenters is $60.00/h. The wage rate with burdens for common laborers is $22.00/h.

Solution. The unit cost may be calculated as follows:

Carpenter — 6 h at $60.00/h	= $360.00
Laborer — 5 h at $22.00/h	= $110.00
Total labor cost for 100 ft^2	= $470.00

$$\text{Labor cost per ft}^2 = \$470.00/100\ \text{ft}^2 = \$4.70/\text{ft}^2$$

This labor cost is adjusted for the following conditions:

Weather adjustment	1.05
Job complexity	1.04
Crew experience	0.95
Management	1.00

$$\text{Adjusted unit cost} = 4.70 \times 1.05 \times 1.04 \times 0.95 \times 1.00 = \$4.88/\text{ft}^2$$

Equipment Resources

One of the most important decisions a contractor makes involves the selection of construction equipment. Beyond simple construction projects, a significant number of the activities require some utilization of major pieces of equipment. This equipment may either be purchased by the contractor or leased for the particular project at hand. The decision for selection of a particular type of equipment may be the result of an optimization process or may be based solely on the fact that the contractor already owns a particular piece of equipment that should be put to use. This decision must be anticipated or made by the estimator, in most cases, to forecast the expected costs for equipment on a project being estimated.

Equipment Selection Criteria

It is important for the estimator to have a solid background in and understanding of various types of construction equipment. This understanding is most important when making decisions about equipment. The estimator, having recognized the work to be performed, must identify the most economical choice for equipment. There are four important criteria that must be examined to arrive at the best choice:

1. Functional performance
2. Project flexibility
3. Companywide operations
4. Economics

Functional performance is only one criterion, but an important one, for the selection of construction equipment. For each activity, there is usually a clear choice based on the most appropriate piece of equipment to perform the task. Functional performance is usually examined solely from the perspective of functional performance. The usual measures are capacity and speed. These two parameters also give rise to the calculation of production rates.

A second criterion that must be used is project flexibility. Although each task has an associated, appropriate piece of equipment based on functional performance, it would not be prudent to mobilize a different piece of equipment for each activity. Equipment selection decisions should consider the multiple uses the item of equipment possesses for the particular project. The trade-off between mobilization

expense and duration versus efficiency of the operation must be explored to select the best fleet of equipment for the project.

Companywide usage of equipment becomes an important factor when determining whether to purchase a particular piece of equipment for a project application. If the investment in the equipment cannot be fully justified for the particular project, then an assessment of future or concurrent usage of the equipment is necessary. This whole process necessarily influences selection decisions by the estimator because the project cost impacts must be evaluated. Equipment that can be utilized on many of the company projects will be favored over highly specialized single-project oriented equipment.

The fourth, and probably most important, criterion the estimator considers is the pure economics of the equipment selection choices. Production or hourly costs of the various equipment alternatives should be compared to determine the most economical choice for the major work tasks involving equipment. A later section in this chapter explains and illustrates the process of determining equipment costs that the estimator should follow.

Production Rates

Equipment production rates can be determined in a relatively simple fashion for the purposes of the estimator. Most manufacturers produce handbooks for their equipment that provide production rates for tasks under stated conditions.

Equipment Costs

Equipment costs represent a large percentage of the total cost for many construction projects. Equipment represents a major investment for contractors, and it is necessary that the investment generate a return to the contractor. The contractor must not only pay for the equipment purchased but also pay the many costs associated with the operation and maintenance of the equipment. Beyond the initial purchase price, taxes, and setup costs, the contractor has costs for fuel, lubricants, repairs, and so on, which must be properly estimated when preparing an estimate. A system must be established to measure equipment costs of various types to provide the estimator with a data source to use when establishing equipment costs.

The cost associated with equipment can be broadly classified as direct equipment costs and indirect equipment costs. Direct equipment costs include the ownership costs and operating expenses, while indirect equipment costs are the costs that occur in support of the overall fleet of equipment but which cannot be specifically assigned to a particular piece of equipment. Each of the broad cost categories will be discussed in greater detail in the following sections.

Direct Equipment Costs

Direct equipment expenses are costs that can be assigned to a particular piece of equipment and are usually divided into ownership and operating expenses for accounting and estimating. The concept behind this separation is that the ownership costs occur regardless of whether the equipment is used on a project.

Ownership Costs

Ownership costs include depreciation, interest, insurance, taxes, setup costs, and equipment enhancements. There are several views taken of ownership costs relating to loss in value or depreciation. One view is that income must be generated to build a sufficient reserve to replace the equipment at the new price, when it becomes obsolete or worn out. A second view is that ownership of a piece of equipment is an investment, and, as such, must generate a monetary return on that investment equal to or larger than the investment made. A third view is that the equipment ownership charge should represent the loss in value of the equipment from the original value due purely to ownership, assuming some arbitrary standard loss in value due to use. These three views can lead to substantially different ownership costs for the same piece of equipment, depending on the circumstances. For simplicity, ownership will be viewed as in the third view. The depreciation component of ownership cost will be discussed separately in the following section.

Depreciation Costs

Depreciation is the loss in value of the equipment due to use and/or obsolescence. There are several different approaches for calculating depreciation, based on hours of operation or on real-time years of ownership. In both cases, some arbitrary useful life is assumed for the particular piece of equipment based on experience with similar equipment under similar use conditions. The simplest approach for calculating depreciation is the straight-line method. Using the useful life, either hours of operation or years, the equipment is assumed to lose value uniformly over the useful life from its original value down to its salvage value. The salvage value is the expected market value of the equipment at the end of its useful life.

Operating Expenses

Operating costs are items of cost directly attributable to the use of the equipment. Operating costs include such items as fuel, lubricants, filters, repairs, tires, and sometimes operator's wages. Obviously, the specific project conditions will greatly influence the magnitude of the operating costs. It is, therefore, important that on projects where the equipment is a significant cost item, such as large civil works projects like dams or new highway projects, attention must be given to the job conditions and operating characteristics of the major pieces of equipment.

Equipment Rates

The equipment rates used in an estimate represent an attempt to combine the elements of equipment cost that have been explained above. The pricing of equipment in an estimate is also influenced by market conditions. On very competitive projects, the contractor will often discount the actual costs to win the project. In other cases, even though the equipment has been fully depreciated, a contractor may still include an ownership charge in the estimate, because the market conditions will allow the cost to be included in the estimate.

Materials Costs

Materials costs can represent the major portion of a construction estimate. The estimator must be able to read and interpret the drawings and specifications and develop a complete list of the materials required for the project. With this quantity takeoff, the estimator then identifies the cost of these materials. The materials costs include several components: the purchase price, shipping and packaging, handling, and taxes.

There are two types of materials: bulk materials and engineered materials. Bulk materials are materials that have been processed or manufactured to industry standards. Engineered materials have been processed or manufactured to project standards. Examples of bulk materials are sand backfill, pipe, and concrete. Examples of engineered materials are compressors, handrailing, and structural steel framing. The estimator must get unit price quotes on bulk materials and must get quotes on the engineered materials that include design costs as well as processing and other materials costs.

Subcontractor Costs

The construction industry continues to become more specialized. The building sector relies almost entirely on the use of specialty contractors to perform different trade work. The heavy/highway construction industry subcontracts a smaller percentage of work. The estimator must communicate clearly with the various subcontractors to define the scope of intended work. Each subcontractor furnishes the estimator with a quote for the defined scope of work with exceptions noted. The estimator must then adjust the numbers received for items that must be added in and items that will be deleted from their scope. The knowledge of the subcontractor and any associated risk on performance by the subcontractor must also be assessed by the estimator. The estimator often receives the subcontractor's best estimate only a few minutes before the overall bid is due. The estimator must have an organized method of adjusting the overall bid up to the last minute for changes in the subcontractor's prices.

Example 12

For use as structural fill, 15,000 cubic yards of material must be hauled onto a job site. As the material is excavated, it is expected to swell. The swell factor is 0.85. The material will be hauled by four 12-yd^3 capacity trucks. The trucks will be loaded by a 1.5-yd^3 excavator. Each cycle of the excavator will take about 30 sec. The hauling time will be 9 min, the dumping time 2 min, the return time 7 min, and the spotting time 1 min. The whole operation can be expected to operate 50 min out of every hour. The cost of the trucks is \$66/h and the excavator will cost about \$75/h. What is the cost per cubic yard for this operation?

Solution.

$$\text{Excavator capacity} = 1.5\ \text{yd}^3 \times 0.85 = 1.28\ \text{yd}^3/\text{cycle}$$

$$\text{Hauler capacity} = 12 \times 0.85 = 10.2\ \text{yd}^3/\text{cycle}$$

$$\text{Number of loading cycles} = 10.2/1.28 = 8\ \text{cycle}$$

Truck cycle time:

Load 8 cycles × 0.5 min =	4 min
Haul	9 min
Dump	2 min
Return	7 min
Spot	1 min
TOTAL	23 min

Fleet production:

$$4 \times (50/23) \times 10.2 = 89.75\ \text{yd}^3/\text{h}$$

$$15{,}000/89.75 = 168\ \text{h}$$

Cost:

168 × 66 × 4 =	\$44,352
168 × 75 =	\$12,600
TOTAL	\$56,952

$$56{,}952/15{,}000 = \$3.80/\text{yd}^3$$

Example 13

It is necessary to place 90 cubic yards of concrete. Site conditions dictate that the safest and best method of placement is to use a crane and a 2-cubic-yard bucket. It is determined that to perform the task efficiently, five laborers are needed — one at the concrete truck, three at the point of placement, and one on the vibrator. It is assumed that supervision is done by the superintendent.

The wage rate for laborers is \$22.00/h.

Time needed:	
Setup	30 min
Cycle:	
Load	3 min
Swing, dump, and return	6 min
TOTAL	9 min

No. of cycles	90/2 = 45 cycles
Total cycle time	45 ¥ 9 = 405 min
Disassembly subtotal	= 15 min
Inefficiency (labor, delays, etc.) 10% of cycle time	= 41 min
Total operation time	405 + 15 + 41 = 461 min
Amount of time needed (adjusted to workday)	= 8 h
Laborers — five for 8 hours at $22.00/h	= $880.00
Cost per 90 yd^3	= $880.00
Cost per cubic yard	$880/90 yd^3 = $9.78/$yd^3$

Example 14

A small steel-frame structure is to be erected, and you are to prepare an estimate of the cost based on the data given below and the assumptions provided. The unloading, erection, temporary bolting, and plumbing will be done by a crew of 1 foreman, 1 crane operator, and 4 structural steel workers with a 55-ton crawler crane. The bolting will be done by two structural-steel workers using power tools. The painting will be done by a crew of three painters (structural-steel) with spray equipment. For unloading at site, erection, temporary bolting, and plumbing, allow 7 labor-hours per ton for the roof trusses, and allow 5.6 labor-hours per ton for the remaining steel. Assume 60 crew hours will be required for bolting. Allow 1.11 labor-hours per ton for painting.

Materials:		
A 36 structural	Steel trusses	15 tons
	Columns, etc.	50 tons
Costs:		
Structural steel supply:		44¢/lb
Fabrication:		$800/ton — trusses
		$410/ton — other steel
Freight cost:		$2.65/100 lb
Field bolts:		250 @ $1.10 each
Paint:		41 gallons @ $30.00/gallon
Labor costs:	Assume payroll taxes and insurance are 80% of labor wage; use the following wages:	
	Foreman	$24.10
	Crane Operator	$21.20
	Structural steel worker	$22.10
	Painter	$20.20
Equipment costs:	Crane	$915.00/day
	Power tools	$23.40/day
	Paint equipment	$68.00/day
Move in/out:		$300.00
Overhead:		40% of field labor cost
Profit:		12% of all costs

Solution.

Materials:		
Structural steel: 65 ¥ 2000 ¥.44	=	$57,200
Freight: 65 ¥ 2000/100 ¥ 2.65	=	3445
Field bolts: 250 ¥ $1.10	=	275
Paint: 41 ¥ 30	=	1230
		$62,150

Fabrication:		
Truss: 15 ¥ 800	=	$12,000
Frame: 50 ¥ 410	=	20,500
		$32,500
Labor crew costs:		
Erection:		
1 foreman:		$24.10
1 crane operator:		21.20
4 structural steel workers:		88.40
		$133.70
Paint:		
3 painters:		$60.60
Bolting:		
2 structural steel workers:		$44.20
Erection:		
Frame:		
(50 ¥ 5.6)/6	=	46.7 crew hours — 6 days
		46.7 ¥ $133.40 = $6239
Trusses:		
(15 ¥ 7)/6	=	17.5 crew hours — 2 days
		17.5 ¥ 133.40 = $2340
Paint:		
(65 ¥ 1.11)/3	=	24 crew hours — 3 days
		24 ¥ 60.60 = $1455
Bolting:		60 ¥ 44.20 = $2652
		Total labor = $12,686
Equipment:		
Crane: 8 days ¥ 915/day	=	$7320
Power tools: 8 days ¥ 23.40/day	=	187
Paint equipment: 3 days ¥ 68/day	=	204
Move in/out	=	300
TOTAL		$8011

Summary

Materials:	$62,150
Fabrication:	32,500
Labor:	12,686
Equipment:	8011
Payroll taxes and insurance:	
80% of 12,686	10,149
Overhead:	
40% of (12,686 + 10,149)	9134
TOTAL	$134,630
Profit:	
12% of 90,781	16,156
Bid	= $150,786

Project Overhead

Each project requires certain items of cost that cannot be identified with a single item of work. These items are referred to as project overhead and are normally described in the general conditions of the contract. The items that are part of the project overhead include but are not limited to the following:

- Bonds
- Permits
- Mobilization
- Professional services (such as scheduling)
- Safety equipment
- Small tools
- Supervision
- Temporary facilities
- Travel and lodging
- Miscellaneous costs (e.g., cleanup, punch list)
- Demobilization

Each of these types of items should be estimated and included in the cost breakdown for a project.

Markup

Once the direct project costs are known, the estimator adds a sum of money to cover a portion of the general overhead for the firm and an allowance for the risk and investment made in the project — the profit. Each of these elements of markup is in large part determined by the competitive environment for bidding the project. The more competition, the less the markup.

General Overhead

Each business has certain expenses that are not variable with the amount of work they have under contract. These expenses must be spread across the projects. The typical method for spreading general overhead is to assign it proportionally according to the size of the project in relation to the expected total volume of work for the year. General overhead costs typically include the following:

- Salaries (home office)
- Employee benefits
- Professional fees
- Insurance
- Office lease or rent
- Office stationery and supplies
- Maintenance
- Job procurement and marketing
- Home office travel and entertainment
- Advertising

The only restriction on the items of general overhead is that they must have a legitimate business purpose. The estimator typically will start with the proportional amount and then add a percentage for profit.

Profit

The profit assigned to a project should recognize the nature of risk that the company is facing in the project and an appropriate return on the investment being made in the project. The reality is that the profit is limited by the competition. A larger number of bidders requires that a smaller profit be assigned to have a chance at having the low bid. This process of assigning profit is usually performed at the last minute by the senior management for the company submitting the bid.

1.5 Contracts

The estimator prepares the estimate in accordance with the instructions to bidders. There are numerous approaches for buying construction services that the estimator must respond to. These various approaches can be classified by three characteristics: the method of award, the method of bidding/payment, and incentives/disincentives that may be attached.

Method of Award

There are three ways in which construction contracts are awarded: competitive awards, negotiated awards, and combination competitive-negotiated awards. With a purely competitive award, the decision is made solely on the basis of price. The lowest bidder will be awarded the project. Usually, public work is awarded in this manner, and all who meet the minimum qualifications (financial) are allowed to compete. In private work, the competitive method of award is used extensively; however, more care is taken to screen potential selective bidders.

The term *selective bid process* describes this method of competitive award. At the opposite extreme from competitive awards are the negotiated awards. In a purely negotiated contract, the contractor is the only party asked to perform the work. Where a price is required prior to initiating work, this price is negotiated between the contractor and the client. Obviously, this lack of competition relieves some of the tension developed in the estimator through the competitive bid process because there is no need to be concerned with the price another contractor might submit. The contractor must still, if asked, provide a firm price that is acceptable to the client and may have to submit evidence of cost or allow an audit. As the purely competitive and purely negotiated method of contract awards represent the extremes, the combination competitive-negotiated award may fall anywhere in between. A common practice for relatively large jobs is to competitively evaluate the qualifications of several potential constructors and then select and negotiate with a single contractor a price for the work.

Method of Bidding/Payment

Several methods of payment are used to reimburse contractors for the construction services they provide. These methods of payment include lump sum or firm price, unit-price, and cost-plus. Each of these methods of payment requires an appropriate form of bidding that recognizes the unique incentive and risk associated with the method. The requirements for completeness of design and scope definition vary for the various types. The lump-sum or firm-price contract is widely used for well-defined projects with completed designs. This method allows purely competitive bidding. The contractor assumes nearly all of the risk, for quantity and quality. The comparison for bidding is based entirely on the total price submitted by the contractors, and payment for the work is limited to the agreed-upon contract price with some allowance for negotiated changes. The lump sum is the predominant form used for most building projects.

The unit-price contract is employed on highway projects, civil works projects, and pipelines. For these projects, the quality of the work is defined, but the exact quantity is not known at the time of bidding. The price per unit is agreed upon at the time of bidding, but the quantity is determined as work progresses and is completed. The contractor, therefore, assumes a risk for quality performance, but the quantity risk is borne by the owner. There is a strong tendency, by contractors, to overprice or front-load those bid items that will be accomplished first and compensate with lower pricing on items of work that will be performed later. This allows contractors to improve their cash flow and match their income closer to their expenses. Each unit-price given must include a portion of the indirect costs and profits that are part of the job. Usually, quantities are specified for bidding purposes so that the prices can be compared for competitive analysis. If contractors "unbalance" or front-load certain bid items to an extreme, they risk being excluded from consideration. The unit-price approach is appropriate for projects where the quantity of work is not known, yet where competitive bidding is desirable.

A third method, with many variations, is the cost-plus method of bidding/payment. With this method, the contractor is assured of being reimbursed for the costs involved with the project plus an additional amount to cover the cost of doing business and an allowance for profit. This additional amount may be calculated as a fixed fee, a percent of specified reimbursable costs, or a sliding-scale amount. The cost to the owner with this method of bidding/payment is open-ended; thus, the risks lie predominantly with the owner. This method is used in instances where it is desired to get the construction work underway prior to completion of design, or where it is desired to protect a proprietary process or production technology and design. Many of the major power plant projects, process facilities, and other long-term megaprojects have used this method in an attempt to shorten the overall design/construct time frame and realize earlier income from the project.

Of the several variations used, most relate to the method of compensation for the "plus" portion of the cost and the ceiling placed on the expenditures by the owner. One of the variations is the cost plus a fixed fee. With this approach, it is in the contractor's best interest to complete the project in the least time with the minimum nonreimbursable costs so that his profits during a given time period will be maximized. Where the scope, although not defined specifically, is generally understood, this method works well. The owner must still control and closely monitor actual direct costs. A second variation is the cost plus a percentage. This method offers little protection for the owner on the cost of the project or the length of performance. This method, in fact, may tempt the contractor to prolong project completion to continue a revenue stream at a set return. The sliding-scale approach is a third approach. This method of compensation is a combination of the two approaches described above. With this approach, a target amount for the project cost is identified. As costs exceed this amount, the fee portion decreases as a percentage of the reimbursable portion. If the costs are less than this target figure, there may be a sliding scale that offers the contractor an increased fee for good cost containment and management.

In addition to the method of calculations of the plus portion for a cost-plus method, there may be a number of incentives attached to the method. These typically take the form of bonuses and penalties for better time or cost performance. These incentives may be related to the calendar or working day allowed for completion in the form of an amount per day for early completion. Similarly, there may be a penalty for late completion. The owner may also impose or require submittal of a guaranteed maximum figure for a contract to protect the owner from excessive costs.

1.6 Computer-Assisted Estimating

The process of estimating has not changed, but the tools of the estimator are constantly evolving. The computer has become an important tool for estimators, allowing them to produce more estimates in the same amount of time and with improved accuracy.

Today, the computer is functioning as an aid to the estimator by using software and digitizers to read the architect/engineer's plans, by retrieving and sorting historical cost databases, by analyzing information and developing comparisons, and by performing numerous calculations without error and presenting the information in a variety of graphical and tabular ways.

The microcomputer is only as good as the programmer and data entry person. The estimator must still use imagination to create a competitive plan for accomplishing the work. The computer estimating tools assist and speed the estimator in accomplishing many of the more routine tasks.

Many commercially available programs and spreadsheets are used by estimators for developing their final estimates of cost. These are tools that calculate, sort, factor, and present data and information. The selection of a software program or system is a function of the approach used by the contractor and the particular work processes and cost elements encountered. The most widely used tool is still the spreadsheet because it gives the estimator a tool for flexible organization of data and information and the capacity to make quick and accurate calculations.

Defining Terms[1]

Bid — To submit a price for services; a proposition either verbal or written, for doing work and for supplying materials and/or equipment.

Bulk materials — Material bought in lots. These items can be purchased from a standard catalog description and are bought in quantity for distribution as required.

Cost — The amount measured in money, cash expended, or liability incurred, in consideration of goods and/or services received.

Direct cost — The cost of installed equipment, material, and labor directly involved in the physical construction of the permanent facility.

Indirect cost — All costs that do not become part of the final installation but which are required for the orderly completion of the installation.

Markup — Includes the percentage applications, such as general overhead, profit, and other indirect costs.

Productivity — Relative measure of labor efficiency, either good or bad, when compared to an established base or norm.

Quantity survey — Using standard methods to measure all labor and material required for a specific building or structure and itemizing these detailed quantities in a book or bill of quantities.

Scope — Defines the materials and equipment to be provided and the work to be done.

2.1 Introduction

One of the most important responsibilities of construction project management is the planning and scheduling of construction projects. The key to successful profit making in any construction company is to have successful projects. Therefore, for many years, efforts have been made to plan, direct, and control the numerous project activities to obtain optimum project performance. Because every construction project is a unique undertaking, project managers must plan and schedule their work utilizing their experience with similar projects and applying their judgment to the particular conditions of the current project.

Until just a few years ago, there was no generally accepted formal procedure to aid in the management of construction projects. Each project manager had a different system, which usually included the use of the Gantt chart, or bar chart. The bar chart was, and still is, quite useful for illustrating the various items of work, their estimated time durations, and their positions in the work schedule as of the report date represented by the bar chart. However, the relationship that exists between the identified work items is by implication only. On projects of any complexity, it is difficult, if not virtually impossible, to identify the interrelationships between the work items, and there is no indication of the criticality of the various activities in controlling the project duration. A sample bar chart for a construction project is shown in Fig. 2.1.

The development of the critical path method (CPM) in the late 1950s provided the basis for a more formal and systematic approach to project management. Critical path methods involve a graphical display (network diagram) of the activities on a project and their interrelationships and an arithmetic procedure

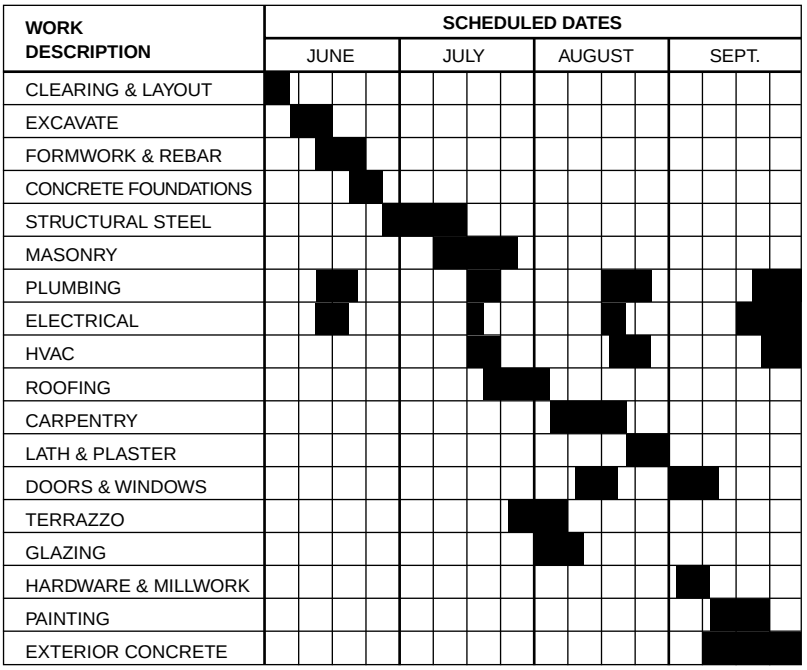

FIGURE 2.1 Sample Gantt or bar chart.

that identifies the relative importance of each activity in the overall project schedule. These methods have been applied with notable success to project management in the construction industry and several other industries, when applied earnestly as dynamic management tools. Also, they have provided a much-needed basis for performing some of the other vital tasks of the construction project manager, such as resource scheduling, financial planning, and cost control. Today's construction manager who ignores the use of critical path methods is ignoring a useful and practical management tool.

Planning and Scheduling

Planning for construction projects involves the logical analysis of a project, its requirements, and the plan (or plans) for its execution. This will also include consideration of the existing constraints and available resources that will affect the execution of the project. Considerable planning is required for the support functions for a project, material storage, worker facilities, office space, temporary utilities, and so on. Planning, with respect to the critical path method, involves the identification of the activities for a project, the ordering of these activities with respect to each other, and the development of a network logic diagram that graphically portrays the activity planning. Figure 2.2 is an I-J CPM logic diagram.

The planning phase of the critical path method is by far the most difficult but also the most important. It is here that the construction planner must actually build the project on paper. This can only be done by becoming totally familiar with the project plans, specifications, resources, and constraints, looking at various plans for feasibly performing the project, and selecting the best one.

The most difficult planning aspect to consider, especially for beginners, is the level of detail needed for the activities. The best answer is to develop the minimum level of detail required to enable the user to schedule the work efficiently. For instance, general contractors will normally consider two or three activities for mechanical work to be sufficient for their schedule. However, to mechanical contractors, this would be totally inadequate because they will need a more detailed breakdown of their activities in order to schedule their work. Therefore, the level of activity detail required depends on the needs of the user of the plan, and only the user can determine his or her needs after gaining experience in the use of critical path methods.

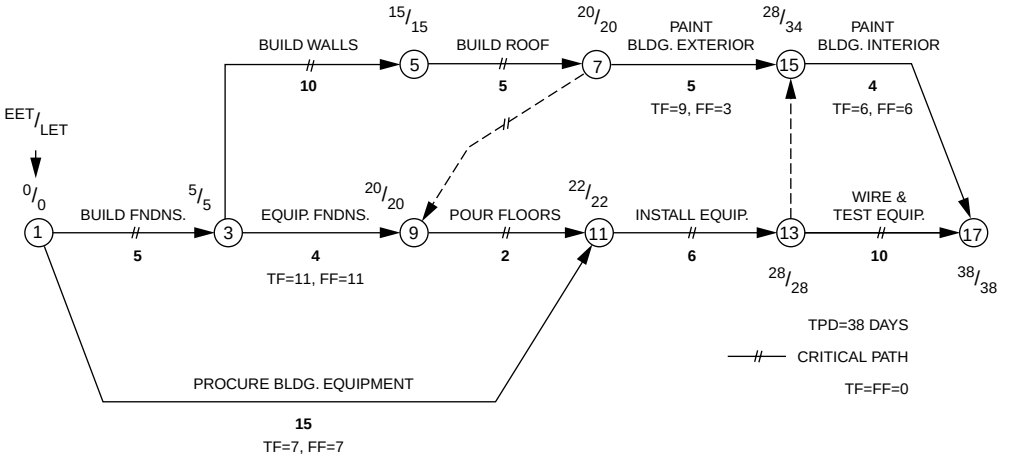

FIGURE 2.2 I-J CPM logic diagram.

Once the activities have been determined, they must be arranged into a working plan in the network logic diagram. Starting with an initial activity in the project, one can apply known constraints and reason that all remaining activities must fall into one of three categories:

1. They must precede the activity in question.
2. They must follow the activity in question.
3. They can be performed concurrently with the activity in question.

The remaining planning function is the estimation of the time durations for each activity shown on the logic diagram. The estimated activity time should reflect the proposed method for performing the activity, plus consider the levels at which required resources are supplied. The estimation of activity times is always a tough task for the beginner in construction because it requires a working knowledge of the production capabilities of the various crafts in the industry, which can only be acquired through many observations of actual construction work. Therefore, the beginner will have to rely on the advice of superiors for obtaining time estimates for work schedules.

Scheduling of construction projects involves the determination of the timing of each work item, or activity, in a project within the overall time span of the project. Scheduling, with respect to the critical path methods, involves the calculation of the starting and finishing times for each activity and the project duration, the evaluation of the available float for each activity, and the identification of the critical path or paths. In a broader sense, it also includes the more complicated areas of construction project management such as financial funds, flow analyses, resource scheduling and leveling, and inclement weather scheduling.

The planning and scheduling of construction projects using critical path methods have been discussed as two separate processes. Although the tasks performed are different, the planning and scheduling processes normally overlap. The ultimate objective of the project manager is to develop a working plan with a schedule that meets the completion date requirements for the project. This requires an interactive process of planning and replanning, and scheduling and rescheduling, until a satisfactory working plan is obtained.

Controlling

The controlling of construction projects involves the monitoring of the expenditure of time and money in accordance with the working plan for the project, as well as the resulting product quality or performance. When deviations from the project schedule occur, remedial actions must be determined that will allow the project to be finished on time and within budget, if at all possible. This will often require replanning the order of the remaining project activities.

If there is any one factor for the unsuccessful application of the critical path method to actual construction projects, it is the lack of project monitoring once the original schedule is developed. Construction is a dynamic process; conditions often change during a project. The main strength of the critical path method is that it provides a basis for evaluating the effects of unexpected occurrences (such as delivery delays) on the total project schedule. The frequency for performing updates of the schedule depends primarily on the job conditions, but updates are usually needed most as the project nears completion. For most projects, monthly updates of the schedule are adequate. At the point of 50% completion, a major update should be made to plan and schedule the remaining work. The control function is an essential part of successful CPM scheduling.

Critical Path Methods

The critical path technique was developed from 1956 to 1958 in two parallel but different problems of planning and control in projects in the U. S.

In one case, the U.S. Navy was concerned with the control of contracts for its Polaris missile program. These contracts compromised research and development work as well as the manufacture of component parts not previously made. Hence, neither cost nor time could be accurately estimated, and completion times, therefore, had to be based upon probability. Contractors were asked to estimate their operational time requirements on three bases: optimistic, pessimistic, and most likely dates. These estimates were then mathematically assessed to determine the probable completion date for each contract, and this procedure was referred to as the program evaluation and review technique (PERT). Therefore, it is important to understand that the PERT systems involve a probability approach to the problems of planning and control of projects and are best suited to reporting on works in which major uncertainties exist.

In the other case, the E.I. du Pont de Nemours Company was constructing major chemical plants in America. These projects required that time and cost be accurately estimated. The method of planning and control that was developed was originally called project planning and scheduling (PPS) and covered the design, construction, and maintenance work required for several large and complex jobs. PPS requires realistic estimates of cost and time and, thus, is a more definitive approach than PERT. It is this approach that was developed into the critical path method, which is frequently used in the construction industry. Although there are some uncertainties in any construction project, the cost and time required for each operation involved can be reasonably estimated. All operations may then be reviewed by CPM in accordance with the anticipated conditions and hazards that may be encountered on this site.

There are several variations of CPM used in planning and scheduling work, but these can be divided into two major classifications: (1) activity-on-arrows, or I-J CPM; and (2) activity-on-nodes, especially the precedence version. The original CPM system was I-J system, with all others evolving from it to suit the needs and desires of the users. There is a major difference of opinion as to which of the two systems is the best to use for construction planning and scheduling. There are pros and cons for both systems, and the systems do not have a significant edge over the other. The only important thing to consider is that both systems be evaluated thoroughly before deciding which one to use. This way, even though both systems will do a fine job, you will never have to wonder if your method is inadequate.

The two CPM techniques used most often for construction projects are the I-J and precedence techniques. As mentioned earlier, the I-J CPM technique was the first developed. It was, therefore, the technique used most widely in the construction industry until recent years. It is often called activity-on-arrows and sometimes referred to as PERT. This last reference is a misnomer, because PERT is a distinctly different technique, as noted previously; however, many people do not know the difference. An example of an I-J CPM diagram is shown in Fig. 2.2, complete with calculated event times.

The other CPM technique is the precedence method; it is used most often today for construction planning and scheduling. It is actually a more sophisticated version of the activity-on-nodes system, initiated by John W. Fondahl of Stanford University. A diagram of an activity-on-nodes system is shown in Fig. 2.3. Notice that the activities are now the nodes (or circles) on the diagram, and the arrows simply

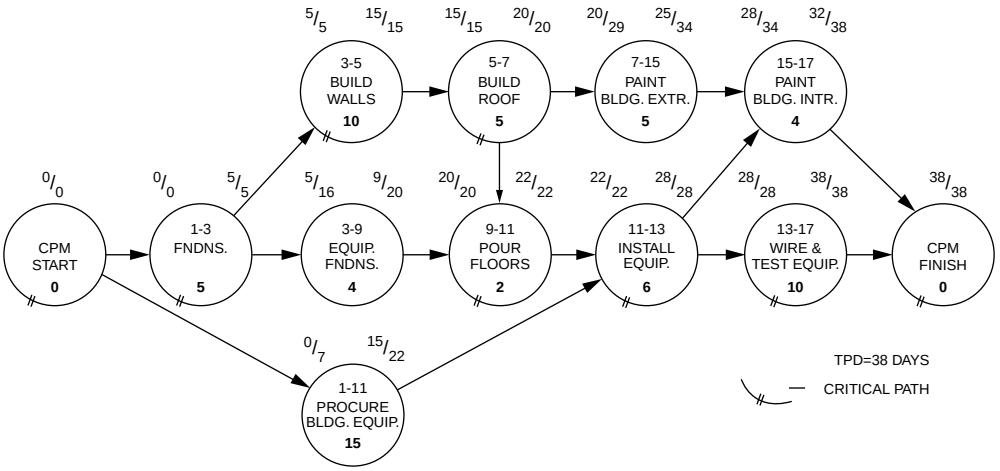

FIGURE 2.3 Activity-on-node CPM diagram.

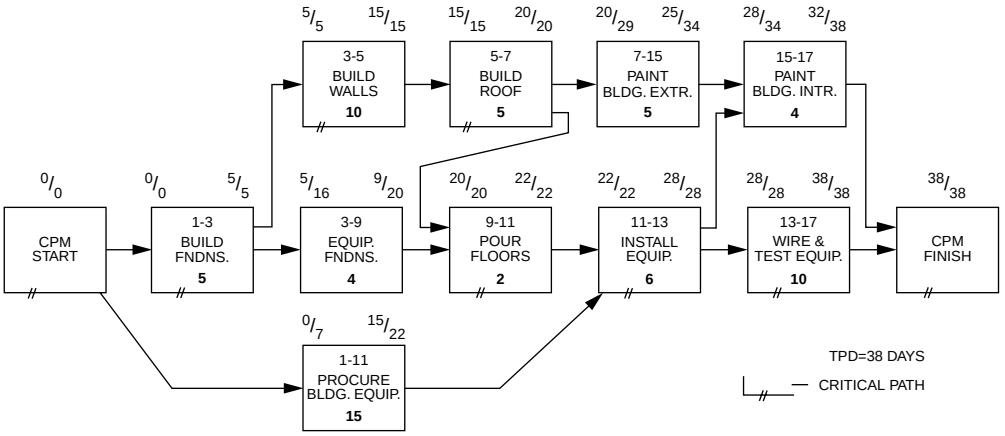

FIGURE 2.4 Precedence CPM logic diagram.

show the constraints that exist between the activities. The time calculations represent the activity's early and late start and finish times.

The precedence technique was developed to add flexibility to the activity-on-nodes system. The only constraint used for activity-on-nodes is the finish-to-start relationship, which implies that one activity must finish before its following activity can start. In the precedence system, there are four types of relationships that can be used; also, the activities are represented by rectangles instead of circles on the logic diagram. A complete precedence network plus calculations is shown in Fig. 2.4.

Advantages of CPM

The critical path methods have been used for planning and scheduling construction projects for over 20 years. The estimated worth of their use varies considerably from user to user, with some contractors feeling that CPM is a waste of time and money. It is difficult to believe that anyone would feel that detailed planning and scheduling work is a waste. Most likely, the unsuccessful applications of CPM resulted from trying to use a level of detail far too complicated for practical use, or the schedule was developed by an outside firm with no real input by the user, or the CPM diagram was not reviewed and updated during the project.

Regardless of past uses or misuses of CPM, the basic question is still the same: "What are the advantages of using CPM for construction planning and scheduling?" Experience with the application of CPM on several projects has revealed the following observations:

1. CPM encourages a logical discipline in the planning, scheduling, and control of projects.
2. CPM encourages more long-range and detailed planning of projects.
3. All project personnel get a complete overview of the total project.
4. CPM provides a standard method of documenting and communicating project plans, schedules, and time and cost performances.
5. CPM identifies the most critical elements in the plan, focusing management's attention to the 10 to 20% of the project that is most constraining on the scheduling.
6. CPM provides an easy method for evaluating the effects of technical and procedural changes that occur on the overall project schedule.
7. CPM enables the most economical planning of all operations to meet desirable project completion dates.

An important point to remember is that CPM is an open-ended process that permits different degrees of involvement by management to suit their various needs and objectives. In other words, you can use CPM at whatever level of detail you feel is necessary. However, one must always remember that you only get out of it what you put into it. It will be the responsibility of the user to choose the best technique. They are all good, and they can all be used effectively in the management of construction projects; just pick the one best liked and use it.

2.2 I-J Critical Path Method

The first CPM technique developed was the I-J CPM system, and therefore, it was widely used in the construction industry. It is often called activity-on-arrows and sometimes referred to as PERT (which is a misnomer). The objective of this section is to instruct the reader on how to draw I-J CPM diagrams, how to calculate the event times and activity and float times, and how to handle the overlapping work schedule.

Basic Terminology for I-J CPM

There are several basic terms used in I-J CPM that need to be defined before trying to explain how the system works. A sample I-J CPM diagram is shown in Fig. 2.5 and will be referred to while defining the basic terminology.

Event (node) — A point in time in a schedule, represented on the logic diagram by a circle, is an event. An event is used to signify the beginning or the end of an activity, and can be shared by several activities. An event can occur only after all the activities that terminate at the event have been completed. Each event has a unique number to identify it on the logic diagram.

Activity (A_{ij}) — A work item identified for the project being scheduled is an activity. The activities for I-J CPM are represented by the arrows on the logic diagram. Each activity has two events: a preceding event (i-node) that establishes its beginning and a following event (j-node) that establishes its end. It is the use of the i-node and j-node references that established the term I-J CPM. In Fig. 2.5, activity A, excavation, is referred to as activity 1–3.

Dummy — A fictitious activity used in I-J CPM to show a constraint between activities on the logic diagram when needed for clarity is called a dummy. It is represented as a dashed arrow and has a duration of zero. In Fig. 2.5, activity 3–5 is a dummy activity used to show that activity E cannot start until activity A is finished.

Activity duration (T_{ij}) — Duration of an activity is expressed in working days, usually eight-hour days, based on a five-day workweek.

ACTIVITY	DESCRIPTION	DURATION	PREDECESSOR
A	EXCAVATION	2	----
B	BUILD FORMS	3	----
C	PROCURE REINF. STEEL	1	----
D	FINE GRADING	2	A
E	ERECT FORMWORK	2	A, B
F	SET REINF. STEEL	2	D, E, C
G	PLACE/FINISH CONCRETE	1	F

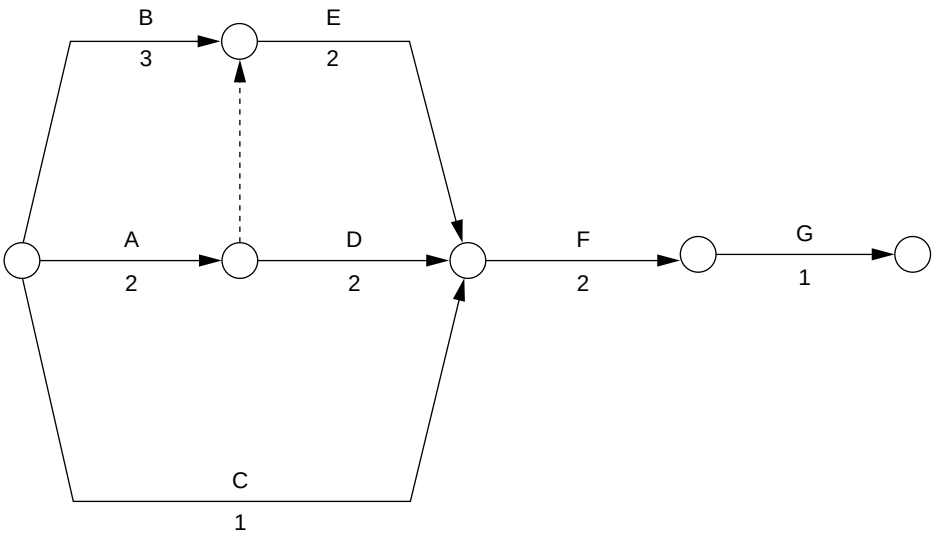

FIGURE 2.5 Sample I-J CPM activities and diagram.

EET_i — This is the earliest possible occurrence time for event *i*, expressed in project workdays, cumulative from the beginning of the project.

LET_i — This is the latest permissible occurrence time for event *i*, expressed in project workdays, cumulative from the end of the project.

Developing the I-J CPM Logic Diagram

The initial phase in the utilization of CPM for construction planning is the development of the CPM logic diagram, or *network model.* This will require that the preparer first become familiar with the work to be performed on the project and constraints, such as the resource limitations, which may govern the work sequence. It may be helpful to develop a list of the activities to be scheduled and their relationships to other activities. Then, draw the logic diagram. This is not an exact science but an interactive process of drawing and redrawing until a satisfactory diagram is attained.

A CPM diagram must be a closed network in order for the time and float calculations to be completed. Thus, there is a single starting node or event for each diagram and a single final node or event. In Fig. 2.5, the starting node is event 1, and the final node is event 11. Also, notice in Fig. 2.5 that event 11 is the only event which has no activities following it. If any other event in the network is left without an activity following it, then it is referred to as a *dangling node* and will need to be closed back into the network for proper time calculations to be made.

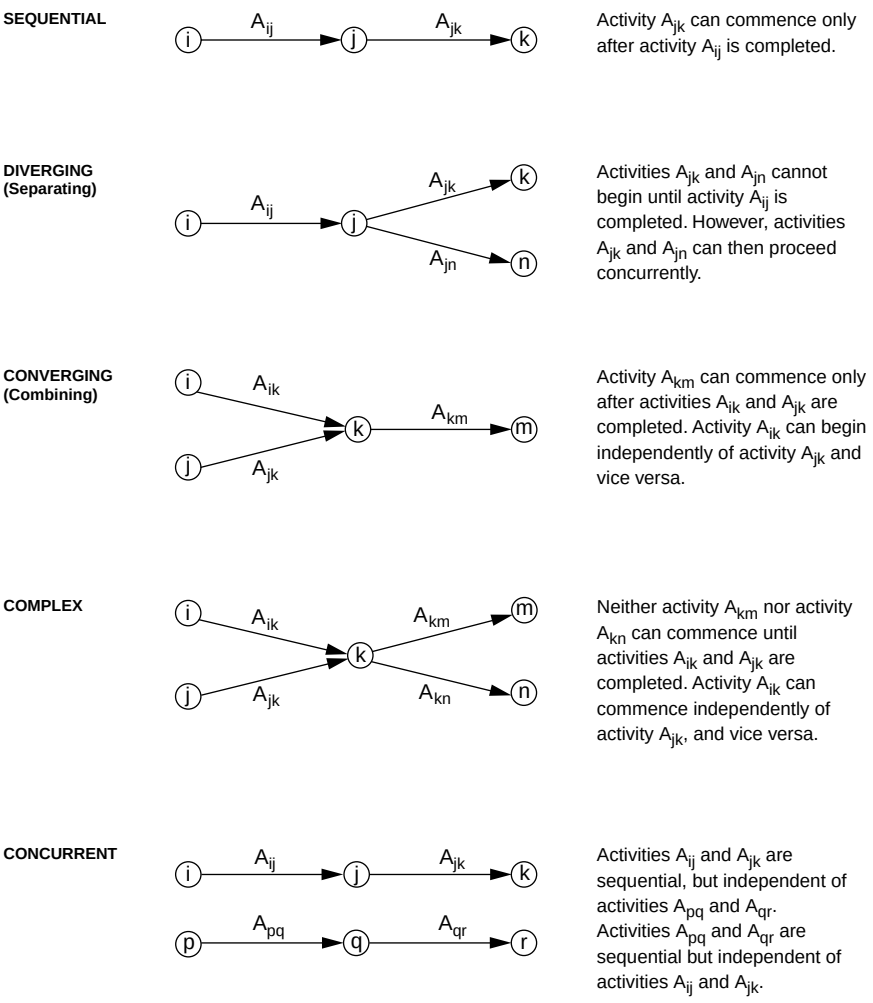

FIGURE 2.6 Typical I-J CPM activity relationships.

The key to successful development of CPM diagrams is to concentrate on the individual activities to be scheduled. By placing each activity on the diagram in the sequence desired with respect to all other activities in the network, the final logic of the network will be correct. Each activity has a variety of relationships to other activities on the diagram. Some activities must precede it, some must follow it, some may be scheduled concurrently, and others will have no relationship to it. Obviously, the major concern is to place the activity in a proper sequence with those that must precede it and those that must follow it. In I-J CPM, these relationships are established via the activity's preceding event (*i*-node) and following event (*j*-node).

The key controller of logic in I-J CPM is the event. Simply stated, all activities shown starting from an event are preceded by all activities that terminate at that event and cannot start until all preceding activities are completed. Therefore, one of the biggest concerns is to not carelessly construct the diagram and needlessly constrain activities when not necessary. There are several basic arrangements of activities in I-J CPM; some of the simple relationships are shown in Fig 2.6. Sequential relationships are the name of the game — it is just a matter of taking care to show the proper sequences.

The biggest problem for most beginners in I-J CPM is the use of the dummy activity. As defined earlier, the dummy activity is a special activity used to clarify logic in I-J CPM networks, is shown as a dashed line, and has a duration of zero workdays. The dummy is used primarily for two logic cases: the complex

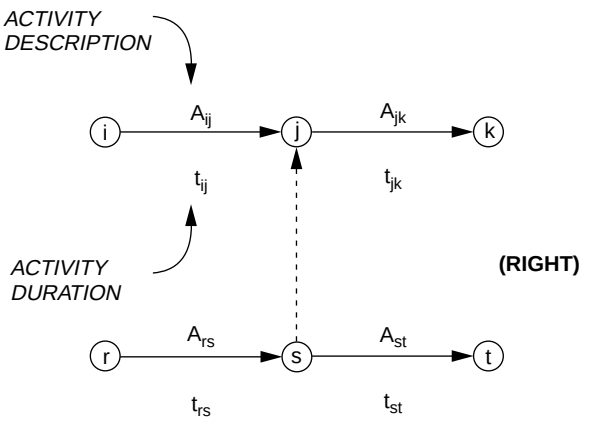

FIGURE 2.7 Correct use of I-J dummy activity.

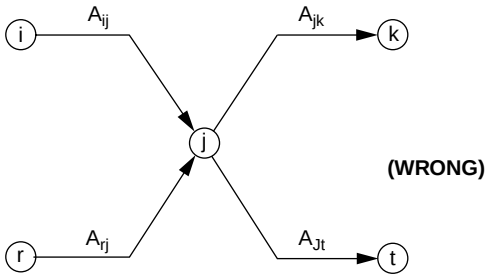

FIGURE 2.8 Incorrect use of I-J dummy activity.

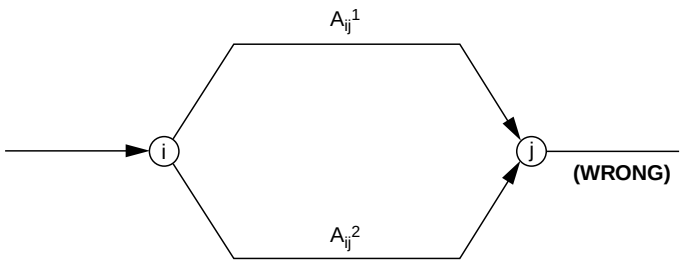

FIGURE 2.9 Incorrect nodes for parallel activities.

logic situation and the unique activity number problem. The complex logic situation is the most important use of the dummy activity to clarify the intended logic. The proper use of a dummy is depicted in Fig. 2.7, where it is desired to show that activity A_{rs} needs to be completed before both activities A_{st} and A_{jk}, and the activity A_{ij} precedes only A_{jk}. The incorrect way to show this logic is depicted in Fig. 2.8. It is true that this logic shows that A_{rs} precedes both A_{st} and A_{jk}, but it also implies that A_{ij} precedes both A_{jk} and A_{st}, which is not true. Essentially, the logic diagram in Fig. 2.7 was derived from the one in Fig. 2.8 by separating event *j* into two events, *j* and *s*, and connecting the two with the dummy activity A_{st}.

The other common use of the dummy activity is to ensure that each activity has a unique *i*-node and *j*-node. It is desirable in I-J CPM that any two events may not be connected by more than one activity. This situation is depicted in Fig. 2.9. This logic would result in two activities with the same identification number, *i-j*. This is not a fatal error in terms of reading the logic, but it is confusing and will cause

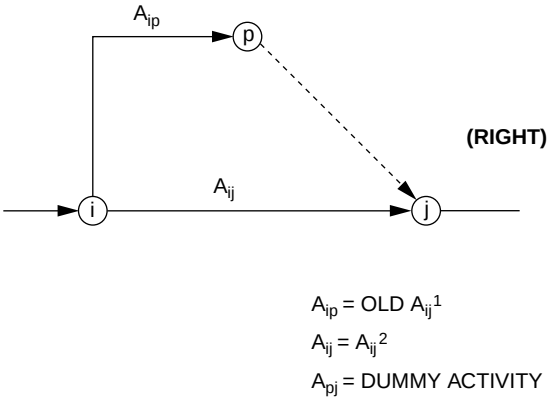

FIGURE 2.10 Correct nodes for parallel activities.

problems if utilizing a computer to analyze the schedule. This problem can be solved by inserting a dummy activity at the end of one of the activities, as shown in Fig. 2.10. It is also possible to add the dummy at the front of the activity, which is the same logic.

Each logic diagram prepared for a project will be unique if prepared independently. Even if the same group of activities is included, the layout of the diagram, the number of dummy activities, the event numbers used, and several other elements will differ from diagram to diagram. The truth is that they are all correct if the logic is correct. When preparing a diagram for a project, the scheduler should not worry about being too neat on the first draft but should try to include all activities in the proper order. The diagram can be fine-tuned after the original schedule is checked.

I-J Network Time Calculations

An important task in the development of a construction schedule is the calculation of the network times. In I-J CPM, this involves the calculation of the event times, from which the activity times of interest are then determined. Each event on a diagram has two event times: the early event time (EET) and the late event time (LET), which are depicted in Fig. 2.11. Each activity has two events: the preceding event, or the *i*-node, and the following event, or the *j*-node. Therefore, each activity has four associated event times: EET_i, LET_i, EET_j, and LET_j. A convenient methodology for determining these event times involves a forward pass to determine the early event times and a reverse pass to determine the late event times.

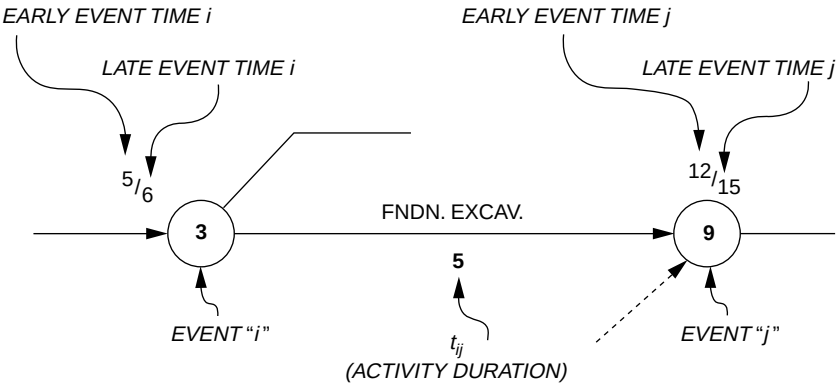

FIGURE 2.11 Terminology for I-J CPM activities.

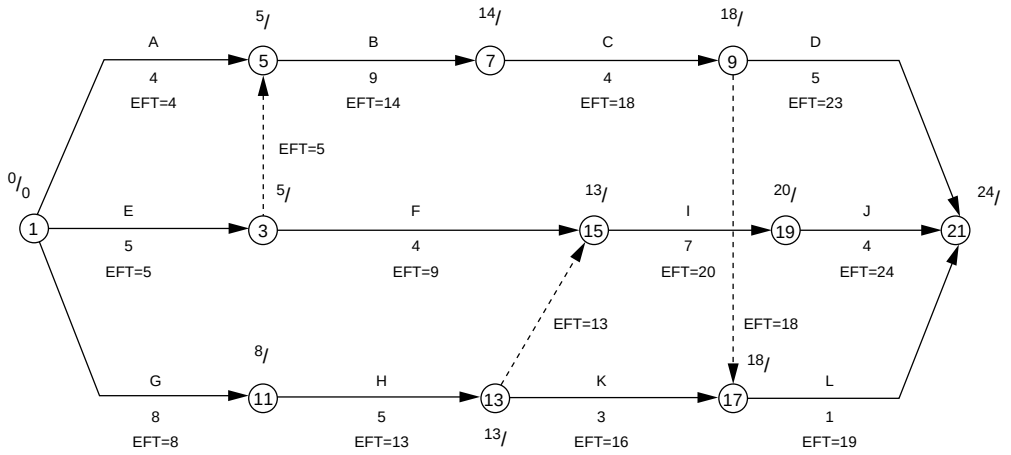

FIGURE 2.12 Forward pass calculations for I-J CPM.

Forward Pass

The objective of the forward pass is to determine the early event times for each of the events on the I-J diagram. The process is started by setting the early event time of the initial event on the diagram (there is to be only one initial event) equal to zero (0). Once this is done, all other early event times can be calculated; this will be explained by the use of Fig. 2.12. The early event time of all other events is determined as the maximum of all the early finish times of all activities that terminate at an event in question. Therefore, an event should not be considered until the early finish times of all activities that terminate at the event have been calculated. The forward pass is analogous to trying all the paths on a road network, finding the maximum time that it takes to get each node. The calculations for the forward pass can be summarized as follows:

1. The earliest possible occurrence time for the initial event is taken as zero [$EET_i = 0 = EST_{ij}$ (i = initial event)].
2. Each activity can begin as soon as its preceding event (i-node) occurs ($EST_{ij} = EET_i$, $EFT_{ij} = EET_i + T_{ij}$).
3. The earliest possible occurrence time for an event is the largest of the early finish times for those activities that terminate at the event [$EET_j = \max EFT_{pj}$ (p = all events that precede event j)].
4. The total project duration is the earliest possible occurrence time for the last event on the diagram [TPD = EET_j (j = terminal event on diagram)].

The early event time of event 1 in Fig. 2.12 was set equal to 0; i.e., EET(1) = 0. It is then possible to calculate the early finish times for activities 1–5, 1–3, and 1–11, as noted. Activity early finish times are not normally shown on an I-J CPM diagram but are shown here to help explain the process. Since both events 3 and 11 have only a single activity preceding them, their early event times can be established as five and eight, respectively. Event 5 has two preceding activities; therefore, the early finish times for both activities 1–5 (4) and 3–5 (5) must be found before establishing that its early event time equals 5. Note that dummy activities are treated as regular activities for calculations. Likewise, the early finish time for event 15 cannot be determined until the early finish times for activities 3–15 (9) and 13–15 (13) have been calculated. EET(15) is then set as 13. The rest of the early event times on the diagram are, thus, similarly calculated, resulting in an estimated total project duration of 24 days.

Reverse Pass

The objective of the reverse pass is to determine the late event time for each event on the I-J diagram. This process is started by setting the late event time of the terminal, or last, event on the diagram (there

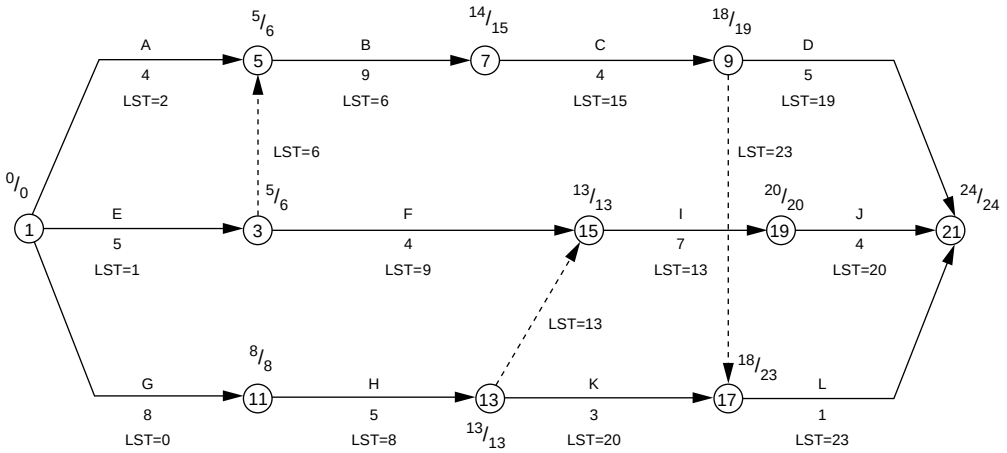

FIGURE 2.13 Reverse pass calculations for I-J CPM.

is to be only one terminal event) equal to the early event time of the event; i.e., $LET_j = EET_j$. Once this is done, then all other late event times can be calculated; this will be explained by the use of Fig. 2.13. The late event time of all other events is determined as the minimum of all the late start times of all activities that originate at an event in question. Therefore, an event should not be considered until the late event times of all activities that originate at the event have been calculated. The calculations for the reverse pass can be summarized as follows:

1. The latest permissible occurrence time for the terminal event is set equal to the early event time of the terminal event. This also equals the estimated project duration [$LET_j = EET_j$ = TPD (j = terminal event on diagram)].
2. The latest permissible finish time for an activity is the latest permissible occurrence time for its following event (j-node) ($LFT_{ij} = LET_j$; $LST_{ij} = LET_j - T_{ij}$).
3. The latest permissible occurrence time for an event is the minimum (earliest) of the latest start times for those activities that originate at the event [LET_i = min LST_{ip} (p = all events that follow event i)].
4. The latest permissible occurrence time of the initial event should equal its earliest permissible occurrence time (zero). This provides a numerical check [$LET_i = EET_i = 0$ (i = initial event on diagram)].

The late event time of event 21 in Fig. 2.13 was set equal to 24. It is then possible to calculate the late start times for activities 9–21, 19–21, and 17–21, as noted. Activity late start times are not normally shown on I-J CPM diagram but are shown here to help explain the reverse pass process. Since both events 17 and 19 have only a single activity that originates from them, their late event times can be established as 23 and 20, respectively. Event 9 has two originating activities; therefore, the late start times for activities 9–17 (23) and 9–21 (19) must be found before establishing that its late event time equals 19. Note that dummy activities are treated as regular activities for calculations. Likewise, the late event time for event 3 cannot be determined until the late start times for activities 3–5 (6) and 3–15 (9) have been calculated. LET(3) is then set as 6. The rest of the late event times on the diagram are thus calculated, resulting in the late event time of event 1 checking in as zero.

Activity Float Times

One of the primary benefits of the critical path methods is the ability to evaluate the relative importance of each activity in the network by its calculated float, or slack, time. In the calculation procedures for CPM, an allowable time span is determined for each activity; the boundaries of this time span are

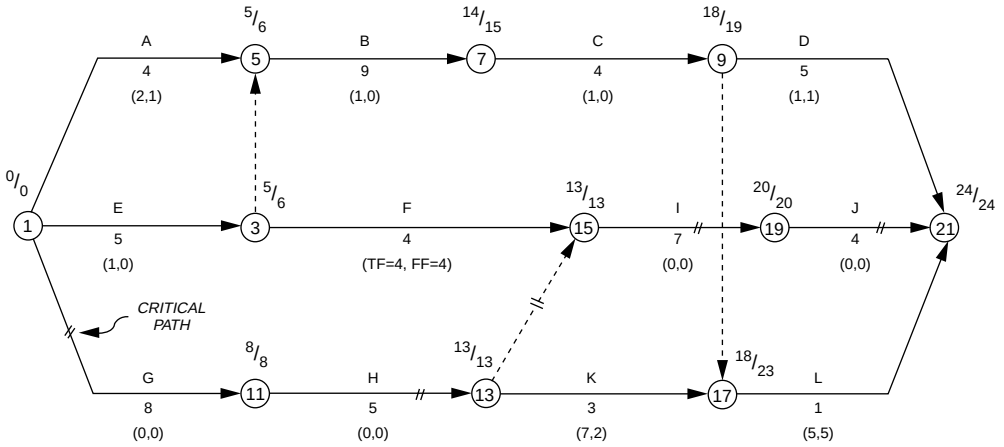

FIGURE 2.14 I-J CPM diagram with float times.

established by the activity's early start time and late finish time. When this bounded time span exceeds the activity's duration, the excess time is referred to as float time. Float time can exist only for noncritical activities. Activities with zero float are *critical activities* and make up the critical path(s) on the network. There are three basic float times for each activity: total float, free float, and interfering float. It should be noted that once an activity is delayed to finish beyond its early finish time, then the network event times must be recalculated for all following activities before evaluating their float times.

Total Float

The total float for an activity is the total amount of time that the activity can be delayed beyond its early finish time, before it delays the overall project completion time. This delay will occur if the activity is not completed by its late finish time. Therefore, the total float is equal to the time difference between the activity's late finish time and its early finish time. The total float for an activity can be calculated by the following expression:

$$TF_{ij} = LET_j - EETI - T_{ij}$$

Since the LET_j for any activity is its late finish time, and the EET_i plus the duration, T_{ij}, equals the early finish time, then the above expression for the total float of an activity reduces to:

$$TF_{ij} = LFT_{ij} - EFT_{ij}$$

The calculation of the total float can be illustrated by referring to Fig. 2.14, where the total float and free float for each activity are shown below the activity. For activity B, the total float = 15 – 5 – 9 = 1, and for activity K, the total float = 23 – 13 – 3 = 7. The total float for activities G, H, I, and J is zero; thus, these activities make up the critical path for this diagram. Float times are not usually noted on dummy activities; however, dummies have float because they are activities. Activity 13–15 connects two critical activities and has zero total float; thus, it is on the critical path and should be marked as such.

One of the biggest problems in the use of CPM for scheduling is the misunderstanding of float. Although the total float for each activity is determined independently, it is not an independent property but is shared with other activities that precede or follow it. The float value calculated is good only for the event times on the diagram. If any of the event times for a diagram change, then the float times must be recalculated for all activities affected. For example, activity B has a total float = 1; however, if activity A or E is not completed until CPM day 6, then the EET(5) must be changed to 6, and the total float for activity B then equals zero. Since activity B had one day of float originally, then the project duration is not affected. However, if the EET(5) becomes greater than 6, then the project duration will be increased.

A chain of activities is a series of activities linked sequentially in a CPM network. Obviously, there are many different possible chains of activities for a given network. Often, a short chain will have the same total float, such as the chain formed by activities B, C, and D in Fig. 2.14. The total float for each of these activities is 1 day. Note that if the total float is used up by an earlier activity in a chain, then it will not be available for following activities. For instance, if activity B is not finished until day 15, then the total float for both activities C and D becomes zero, making them both critical. Thus, one should be very careful when discussing the float time available for an activity with persons not familiar with CPM. This problem can be avoided if it is always a goal to start all activities by their early start time, if feasible, and save the float for activities that may need it when problems arise.

Free Float

Free float is the total amount of time that an activity can be delayed beyond its early finish time, before it delays the early start time of a following activity. This means that the activity must be finished by the early event time of its *j*-node; thus, the free float is equal to the time difference between the EET_j and its early finish time. The free float can be calculated by the following expressions:

$$FF_{ij} = EET_j - EET_i - T_{ij} \quad \text{or} \quad FF_{ij} = EET_j - EFT_{ij}$$

The calculation of free float can be illustrated by referring to Fig. 2.14, where the total float and free float for each activity are shown below the activity. For activity A, the free float = 14 – 5 – 9 = 0, and for activity D, the free float = 24 – 18 – 5 = 1.

The free float for most activities on a CPM diagram will be zero, as can be seen in Fig. 2.14. This is because free float occurs only when two or more activities merge into an event, such as event 5. The activity that controls the early event time of the event will, by definition, have a free float of zero, while the other activities will have free float values greater than zero. Of course, if two activities tie in the determination of the early event time, then both will have zero free float. This characteristic can be illustrated by noting that activities 1–5 and 3–5 merge at event 5, with activity 3–5 controlling the EET = 5. Thus, the free float for activity 3–5 will be zero, and the free float for activity 1–5 is equal to one. Any time you have a single activity preceding another activity, then the free float for the preceding activity is immediately known to be zero, because it must control the early start time of the following activity. Free float can be used up without hurting the scheduling of a following activity, but this cannot be said for total float.

Interfering Float

Interfering float for a CPM activity is the difference between the total float and the free float for the activity. The expression for interfering float is:

$$IF_{ij} = LET_j - EET_j \quad \text{or} \quad IF_{ij} = TF_{ij} - FF_{ij}$$

The concept of interfering float comes from the fact that if one uses the free float for an activity, then the following activity can still start on its early start time, so there is no real interference. However, if any additional float is used, then the following activity's early start time will be delayed. In practice, the value of interfering float is seldom used; it is presented here because it helps one to better comprehend the overall system or float for CPM activities. The reader is encouraged to carefully review the sections on activity float, and refer to Figs. 2.14 and 2.15 for graphic illustrations.

Activity Start and Finish Times

One of the major reasons for the utilization of CPM in the planning of construction projects is to estimate the schedule for conducting various phases (activities) of the project. Thus, it is essential that one know how to determine the starting and finishing times for each activity on a CPM diagram. Before explaining

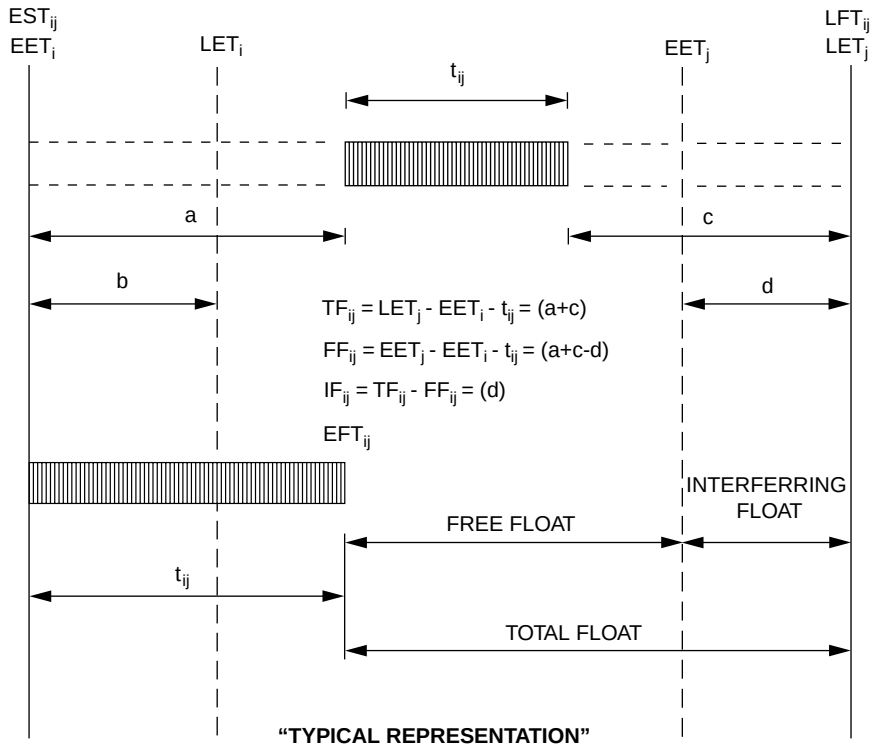

FIGURE 2.15 Graphic representation of I-J CPM float.

how to do this, it is important to note that any starting or finish time determined is only as good as the CPM diagram and will not be realistic if the diagram is not kept up to date as the project progresses. If one is interested only in general milestone planning, this is not as critical. However, if one is using the diagram to determine detailed work schedules and delivery dates, then updating is essential. This topic will be discussed in "Updating the CPM Network" later in this chapter.

The determination of the early and late starting and finishing times for I-J CPM activities will be illustrated by reference to Fig. 2.14. There are four basic times to determine for each activity: early start time, late start time, early finish time, and late finish time. Activity F in Fig. 2.14, as for all other activities on an I-J CPM diagram, has four event times:

$$EET_i = 5, \quad LET_i = 6, \quad EET_j = 13, \quad LET_j = 13$$

A common mistake is to refer to these four times as the early start time, late start time, early finish time, and late finish time for activity F, or activity 3–15. Although this is true for all critical activities and may be true of some other activities, this is not true of many of the activities on an I-J diagram, and this procedure should not be used.

The basic activity times can be determined by the following four relationships:

Early start time, $EST_{ij} = EET_i$	(5 for activity F)
Late start time, $LST_{ij} = LET_j - T_{ij}$	(13 – 4 = 9 for activity F)
Early finish time, $EFT_{ij} = EST_{ij} + T_{ij}$	(5 + 4 = 9 for activity F)
Late finish time, $LFT_{ij} = LET_j$	(13 for activity F)

As can be seen, the early finish time for activity F is 9, not 13, and the late start time is 9, not 6. The four basic activity times can be found quickly and easily but cannot be read directly off the diagram. For

many construction projects today, the starting and finishing times for all activities are shown on a computer printout, not only in CPM days, but in calendar days also. As a further example, the EST, LST, EFT, and LFT of activity A in Fig. 2.14 are 0, 2, 4, and 6, respectively. These times are in terms of CPM days; instructions will be given later for converting activity times in CPM days into calendar dates.

Overlapping Work Items in I-J CPM

One of the most difficult scheduling problems encountered is the overlapping work items problem. This occurs often in construction and requires careful thought by the scheduler, whether using I-J CPM or the precedence CPM technique (precedence will be discussed in the following section). The overlapping work situation occurs when two or more work items that must be sequenced will take too long to perform end to end, and thus, the following items are started before their preceding work items are completed. Obviously, the preceding work items must be started and worked on sufficiently in order for the following work items to begin. This situation occurs often with construction work such as concrete wall (form, pour, cure, strip, finish) and underground utilities (excavate, lay pipe, test pipe, backfill). Special care must be taken to show the correct logic to follow on the I-J diagram, while not restricting the flow of work, as the field forces use the CPM schedule.

The overlapping work item problem is also encountered for several other reasons in construction scheduling. A major reason is the scheduling required to optimize scarce or expensive resources, such as concrete forms. It is usually too expensive or impractical to purchase enough forms to form an entire concrete structure at one time; therefore, the work must be broken down into segments and scheduled with the resource constraints identified. Another reason for overlapping work items could be for safety or for practicality. For instance, in utilities work, the entire pipeline could be excavated well ahead of the pipe-laying operation. However, this would expose the pipe trench to weather or construction traffic that could result in the collapse of the trench, thus requiring expensive rework. Therefore, the excavation work is closely coordinated with the pipe-laying work in selected segments to develop a more logical schedule.

The scheduling of overlapping work items will be further explained by the use of an example. Assume that a schedule is to be developed for a small building foundation. The work has been broken down into four separate phases: excavation, formwork, concrete placement, and stripping and backfilling. A preliminary analysis of the work has determined the following workday durations of the four work activities: 4, 8, 2, and 4, respectively. If the work items are scheduled sequentially, end to start, the I-J CPM diagram for this work would appear as depicted in Fig. 2.16. Notice that the duration for the completion of all the work items is 18 workdays.

A more efficient schedule can be developed for the work depicted in Fig. 2.16. Assume that the work is to be divided into two halves, with the work to be overlapped instead of done sequentially. A bar chart schedule for this work is shown in Fig. 2.17. The work items have been abbreviated as E1 (start excavation), E2 (complete excavation), and so on, to simplify the diagrams. Because there is some float available for some of the work items, there are actually several alternatives possible. Notice that the work scheduled on the bar chart will result in a total project duration of 13 workdays, which is five days shorter than the CPM schedule of Fig. 2.16.

An I-J CPM schedule has been developed for the work shown on the bar chart of Fig. 2.17 and is depicted in Fig. 2.18. At first glance, the diagram looks fine except for one obvious difference: the project duration is 14 days, instead of 13 days for the bar chart schedule. Closer review reveals that there are

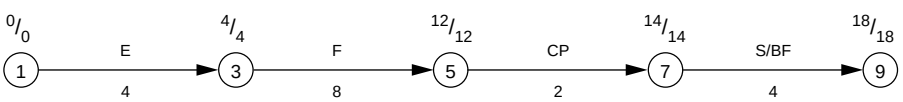

FIGURE 2.16 I-J CPM for sequential activities.

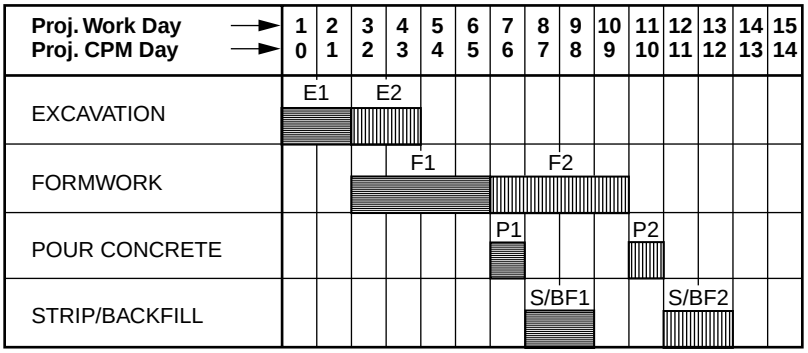

FIGURE 2.17 Bar chart for overlapping work items.

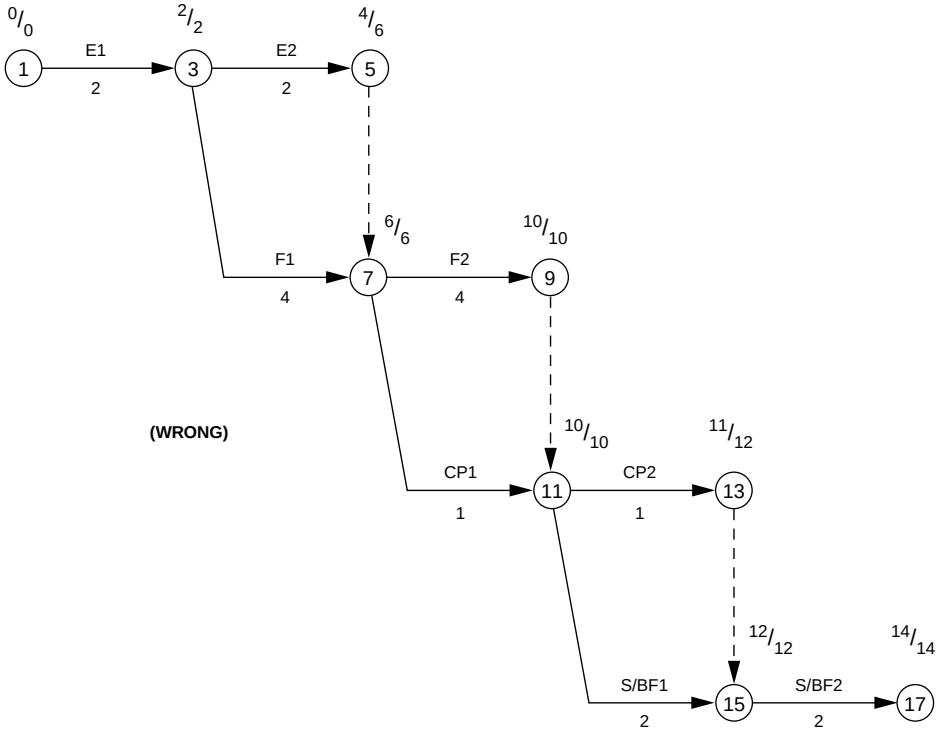

FIGURE 2.18 I-J CPM No. 1 for overlapping work items.

serious logic errors in the CPM diagram at events 7 and 11. As drawn, the second half of the excavation (E2) must be completed before the first concrete placement (CP1) can start. Likewise, the first wall pour cannot be stripped and backfilled (S/BF1) until the second half of the formwork is completed (F2). These are common logic errors caused by the poor development of I-J activities interrelationships. The diagram shown in Fig.2.19 is a revised version of the I-J CPM diagram of Fig. 2.18 with the logic errors at events 7 and 11 corrected. Notice that the project duration is now 13 days, as for the bar chart.

Great care must be taken to show the correct logic for a project when developing any CPM diagram. One should always review a diagram when it is completed to see if any unnecessary or incorrect constraints have been developed by improper drawing of the activities and their relationships to each other. This is especially true for I-J CPM diagrams where great care must be taken to develop a sufficient number of

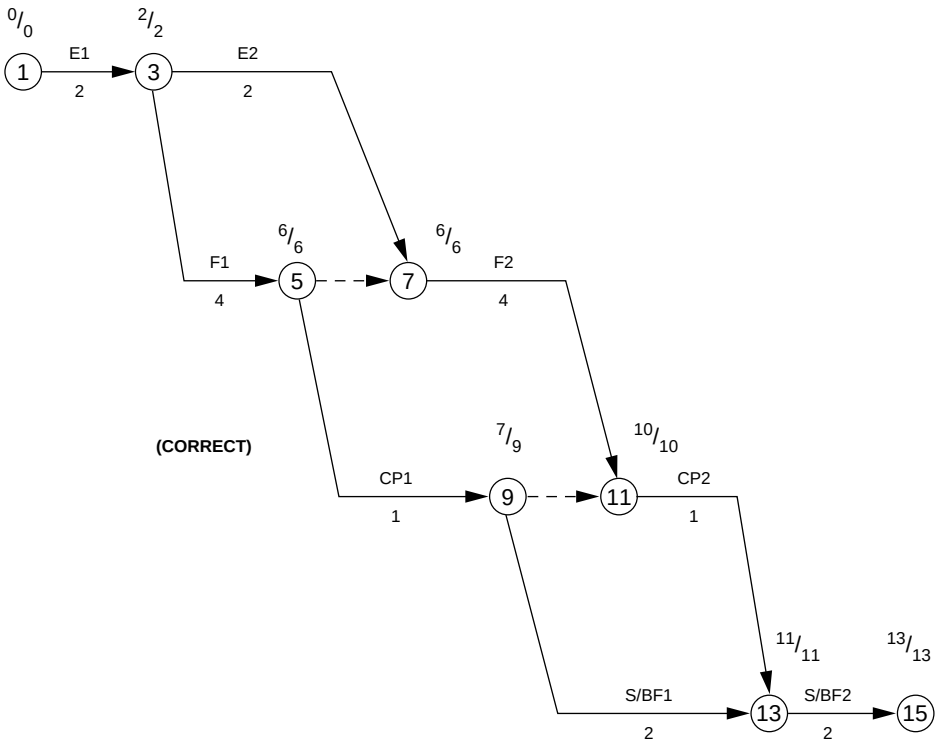

FIGURE 2.19 I-J CPM No. 2 for overlapping work items.

events and dummy activities to show the desired construction work item sequences. The scheduling of overlapping work items often involves more complicated logic and should be done with care. Although beginning users of I-J CPM tend to have such difficulties, they can learn to handle such scheduling problems in a short time period.

2.3 Precedence Critical Path Method

The critical path method used most widely in the construction industry is the precedence method. This planning and scheduling system was developed by modifying the activity-on-node method discussed earlier and was depicted in Fig. 2.3. In activity-on-node networks, each node or circle represents a work activity. The arrows between the activities are all finish-to-start relationships; that is, the preceding activity must finish before the following activity can start. The four times shown on each node represent the early start time/late start time and early finish time/late finish time for the activity. In the precedence system (see Fig. 2.20), there are several types of relationships that can exist between activities, allowing for greater flexibility in developing the CPM network.

The construction activity on a precedence diagram is typically represented as a rectangle (see Fig. 2.21). There are usually three items of information placed within the activity's box: the activity number, the activity description, and the activity time (or duration). The activity number is usually an integer, although alphabetical characters are often added to denote the group responsible for management of the activity's work scope. The activity time represents the number of workdays required to perform the activity's work scope, unless otherwise noted.

There are two other important items of information concerning the activity shown on a precedence diagram. First, the point at which the relationship arrows touch the activity's box is important. The left edge of the box is called the *start edge;* therefore, any arrow contacting this edge is associated with the

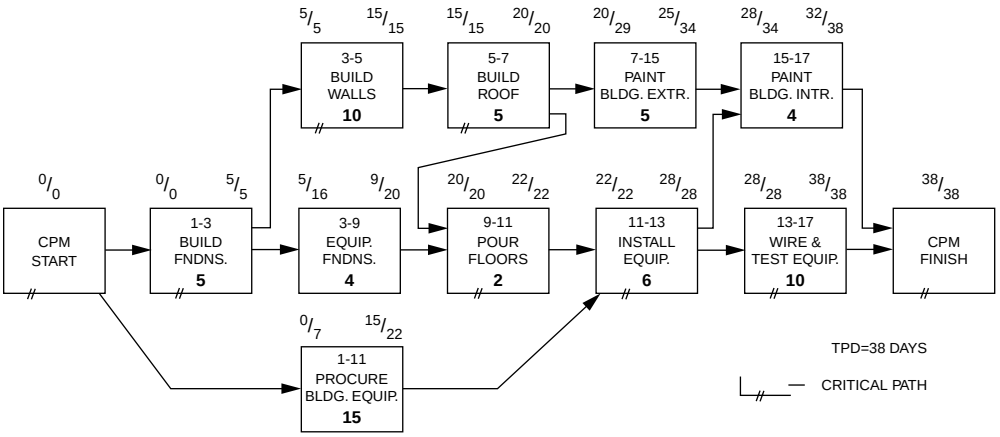

FIGURE 2.20 Precedence CPM diagram.

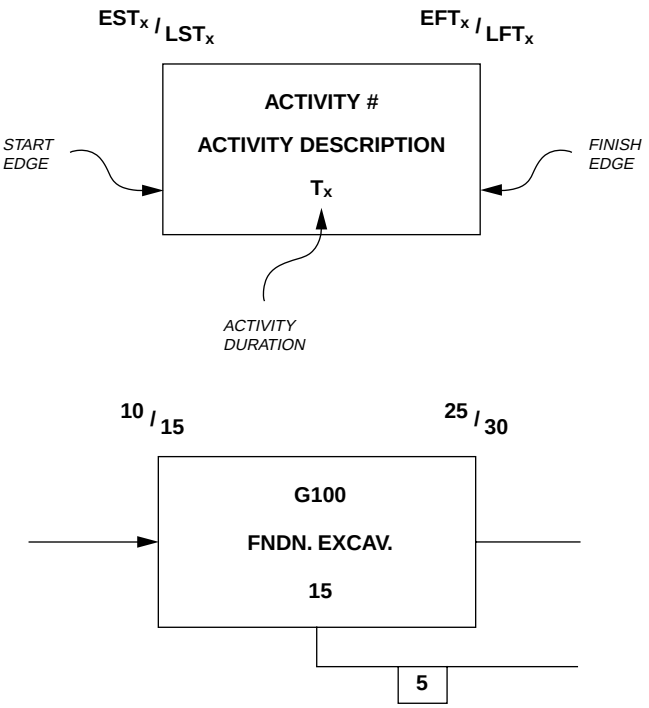

FIGURE 2.21 Precedence CPM activity information.

activity's start time. The right edge of the box is called the *finish edge;* therefore, any arrow contacting this edge is associated with the activity's finish time. Second, the calculated numbers shown above the box on the left represent the early start time and the late start time of the activity, and the numbers above the box on the right represent the early finish time and the late finish time of the activity. This is different from I-J CPM, where the calculated times represent the event times, not the activity times.

Precedence Relationships

The arrows on a precedence diagram represent the relationships that exist between different activities. There are four basic relationships used, as depicted in Fig. 2.22. The *start-to-start* relationship states that

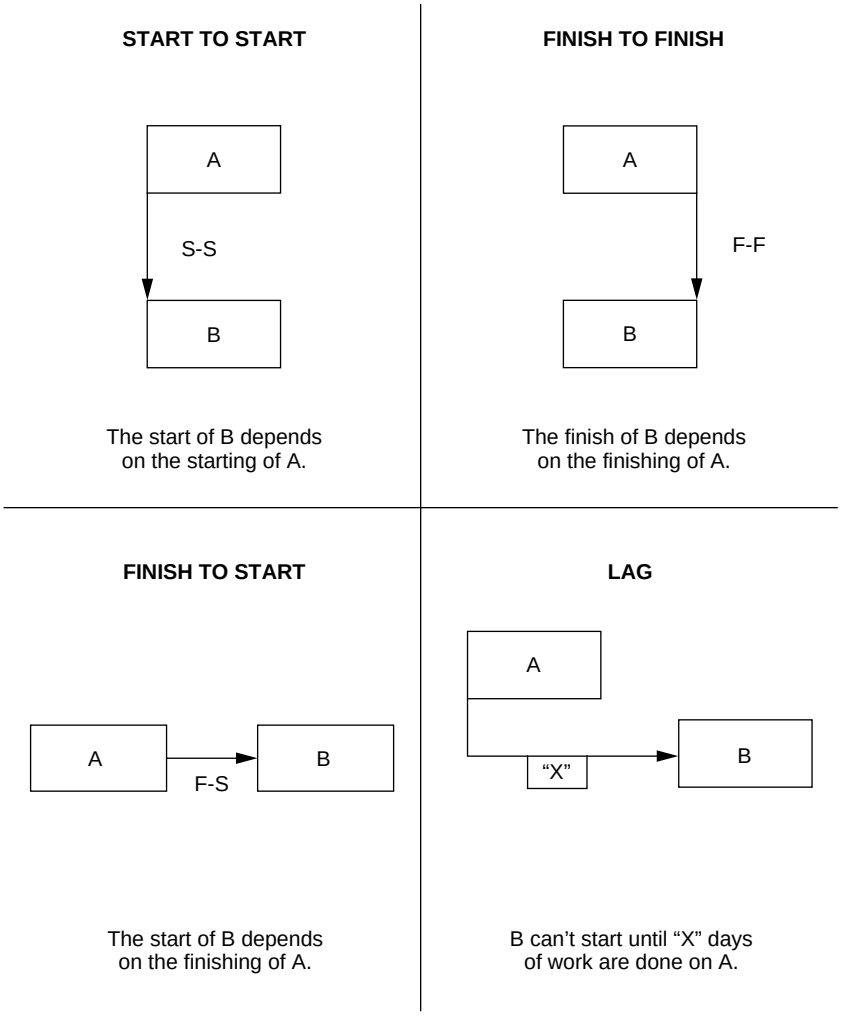

FIGURE 2.22 Precedence CPM activity relationships.

activity B cannot start before activity A starts; that is, EST(B) is greater than or equal to EST(A). The greater-than situation will occur when another activity that precedes activity B has a greater time constraint than EST(A).

The *finish-to-start* relationship states that activity B cannot start before activity A is finished; that is, EST(B) is greater than or equal to EFT(A). This relationship is the one most commonly used on a precedence diagram. The *finish-to-finish* relationship states that activity B cannot finish before activity A finishes; that is, EFT(B) is greater than or equal to EFT(A). This relationship is used mostly in precedence networks to show the finish-to-finish relationships between overlapping work activities.

The fourth basic relationship is the lag relationship. Lag can be shown for any of the three normal precedence relationships and represents a time lag between the two activities. The lag relationship shown in Fig. 2.22 is a start-to-start (S-S) lag. It means that activity B cannot start until *X* days of work are done on activity A. Often when there is an S-S lag between two activities, there is a corresponding F-F lag, because the following activity will require *X* days of work to complete after the preceding activity is completed. The use of lag time on the relationships allows greater flexibility in scheduling delays between activities (such as curing time) and for scheduling overlapping work items (such as excavation, laying pipe, and backfilling). A precedence with all three basic relationships and three lags is shown in Fig. 2.23.

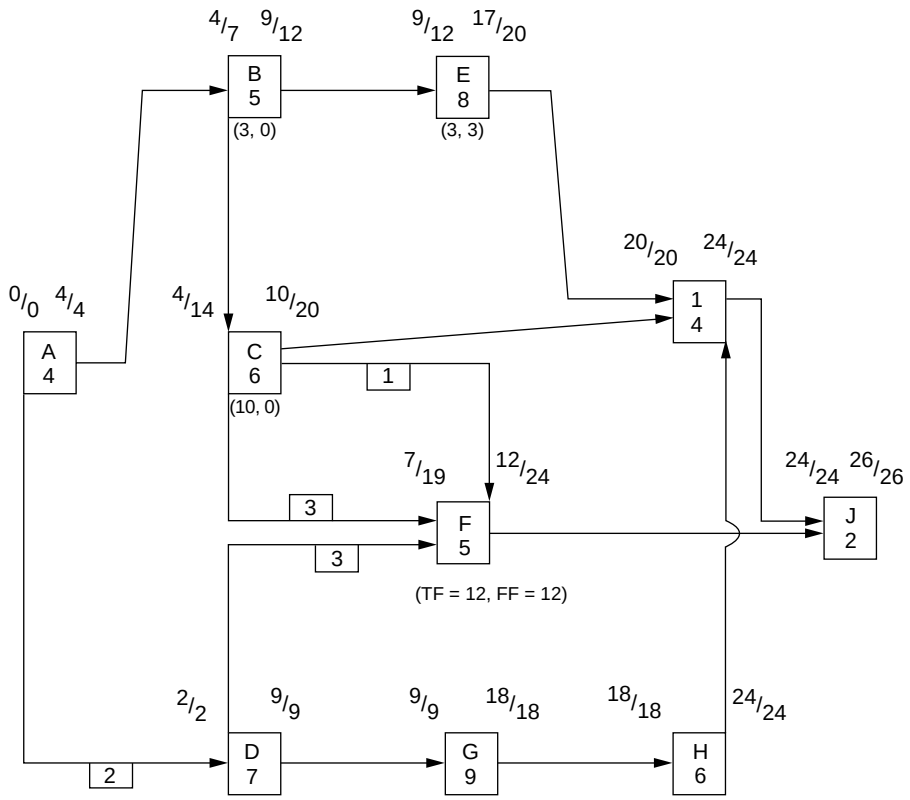

FIGURE 2.23 Precedence diagram with activity times and float times on non-critical activities.

Precedence Time Calculations

The time calculations for precedence are somewhat more complex than for I-J CPM. The time calculation rules for precedence networks are shown in Fig. 2.24. These rules are based on the assumption that all activities are continuous in time; that is, once started, they are worked through to completion. In reality, this assumption simplifies interpretation of the network and the activity float times. It ensures that the EFT equals the EST plus the duration for a given activity.

The time calculations involve a forward pass and a reverse pass, as in I-J CPM. However, for precedence, one is calculating activity start and finish times directly and not event times as in I-J. In the forward pass, one evaluates all activities preceding a given activity to determine its EST.

For activity F in Fig. 2.23, there are three choices: C-to-F (start-to-start), EST(F) = 4 + 3 = 7; C-to-F (finish-to-finish), EST(F) = 10 + 1 – 5 = 6; D-to-F (finish-to-start), EST(F) = 2 + 3 = 5. Since 7 is the largest EST, the C-to-F (S-S) relationship controls. The EFT is then determined as the EST plus the duration; for activity F, the EFT = 12.

For the reverse pass in precedence, one evaluates all activities following a given activity to determine its LFT. For activity F, the only following activity is activity J; therefore, the LFT(F) is 24 – 0 = 24. For activity D, there are two choices for LFT: D-to-F (start-to-start, with lag), LFT(D) = 19 – 3 + 7 = 23; D-to-G (finish-to-start), LFT(D) = 9 – 0 = 9. Since 9 is the smallest LFT, the D-to-G relationship controls. The LST is then determined as the LFT minus the duration; for activity D, the LST is 2.

A major advantage of the precedence system is that the times shown on a precedence activity represent actual start and finish times for the activity. Thus, less-trained personnel can more quickly read these times from the precedence network than from an I-J network. As for I-J CPM, the activity times represent

I. EARLIEST START TIME

A. EST of first Work Item (W.I.) is zero (by definition).

B. EST of all other W.I.'s is the **greater** of these times:

1) EST of a preceding W.I. if start-start relation.

2) EFT of a preceding W.I. if finish-start relation.

3) EFT of a preceding W.I., less the duration of the W.I. itself, if finish-finish relation.

4) EST of a preceding W.I., plus the lag, if there is a lag relation.

II. EARLIEST FINISH TIME

A. For first Work Item, EFT = EST + Duration.

B. EFT of all other W.I.'s is the **greater** of these times:

1) EST of W.I. plus its duration.

2) EFT of preceding W.I. if finish-finish relation.

III. LATEST FINISH TIME

A. LFT for last Work Item is set equal to its EFT.

B. LFT for all other W.I.'s is the **lesser** of these items:

1) LST of following W.I. if finish-start relation.

2) LFT of following W.I. if finish-finish relation.

3) LST of following W.I., plus the duration of the W.I. itself, if there is a start-start relation.

4) LST of following W.I., less the lag, plus the duration of the W.I. itself, if there is a lag relation.

IV. LATEST START TIME

A. LST of first Work Item = LFT - Duration.

B. LST of all other W.I.'s is the **lesser** of these items:

1) LFT of W.I. less its duration.

2) LST of following W.I. if start-start relation.

3) LST of following W.I. if less the lag, if there is a lag relation.

EST = Early Start Time LST = Late Start Time

EFT = Early Finish Time LFT = Late Finish Time

Lag = Number of days of lag time associated with a relationship.

FIGURE 2.24 Precedence activity times calculation rules.

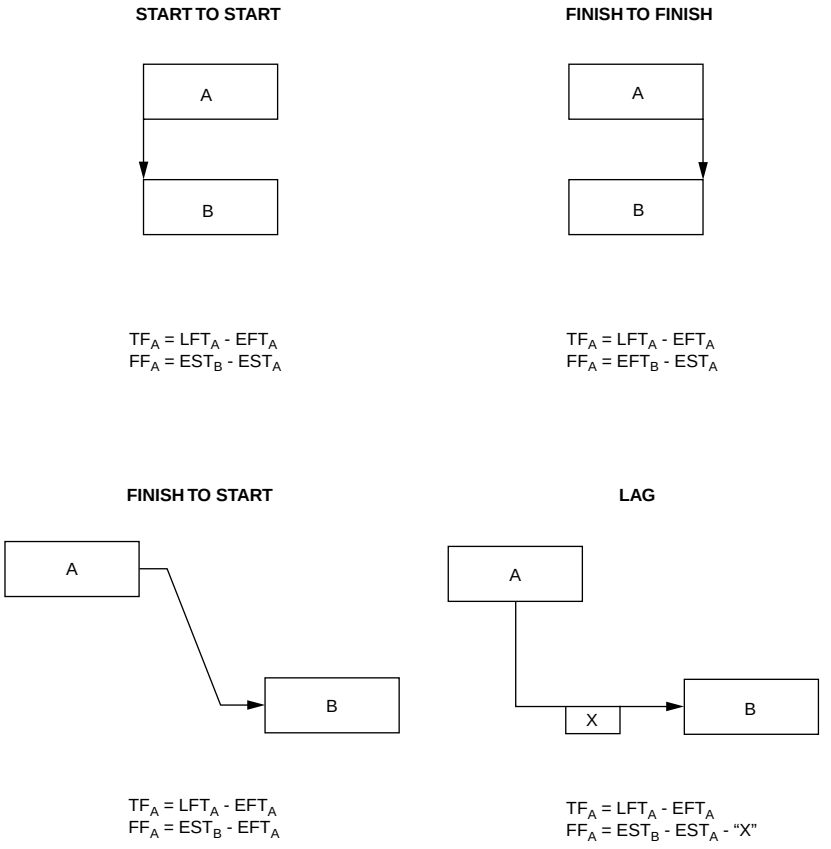
CPM days, which relate to workdays on the project. The conversion from CPM days to calendar dates will be covered in the next section.

Precedence Float Calculations

The float times for precedence activities have the same meaning as for I-J activities; however, the calculations are different. Before float calculations can be made, all activity start and finish times must be calculated as just described. Remember again that all activities are assumed to be continuous in duration. The float calculations for precedence networks are depicted in Fig. 2.25.

The total float of an activity is the total amount of time that an activity can be delayed before it affects the total project duration. This means that the activity must be completed by its late finish time; therefore, the total float for any precedence activity is equal to its LFT minus its EFT. For activity F in Fig. 2.23, its total float is 24 – 12 = 12.

The free float of an activity is the total amount of time that an activity can be delayed beyond its EFT before it delays the EST of a following activity. In I-J CPM, this is a simple calculation equal to the EET of its *j*-node minus the EET of its *i*-node minus its duration. However, for a precedence activity, it is necessary to check the free float existing between it and each of the activities that follows it, as depicted in Fig. 2.25. The actual free float for the activity is then determined as the minimum of all free float options calculated for the following activities. For most precedence activities, as for I-J, the free float



NOTES:

(1) All activities assumed continuous in duration.

(2) The Total Float for all activities is always equal to their Late Finish Time minus their Early Finish Time.

(3) The Free Float calculations shown are for each type of relationship. If an activity has several following activities, then the Free Float for the activity is the **smallest** of the Free Float calculations made for each following activity.

FIGURE 2.25 Precedence float calculation rules.

time is normally equal to zero. For activity C in Fig. 2.23, there are three choices: C-to-F (start-to-start), FF = 7 – 4 – 3 = 0; C-to-F (finish-to-finish), FF = 12 – 10 – 1 = 1; C-to-I (finish-to-start), FF = 20 – 10 = 10. Since the smallest is 0, then the C-to-F (S-S) relationship controls, and the FF = 0.

Overlapping Work Items

A major reason that many persons like to use the precedence CPM system for construction scheduling is its flexibility for overlapping work items. Figure 2.26 depicts the comparable I-J and precedence diagrams necessary to show the logic and time constraints shown in the bar chart at the top of the figure. Although the precedence version is somewhat easier to draw, one has to be careful in calculating the activity times. There is also a tendency for all of the precedence activities to be critical, due to the continuous time constraint for the activities. If one understands how to use either CPM system, the network development will not be difficult; therefore, it is mostly a matter of preference.

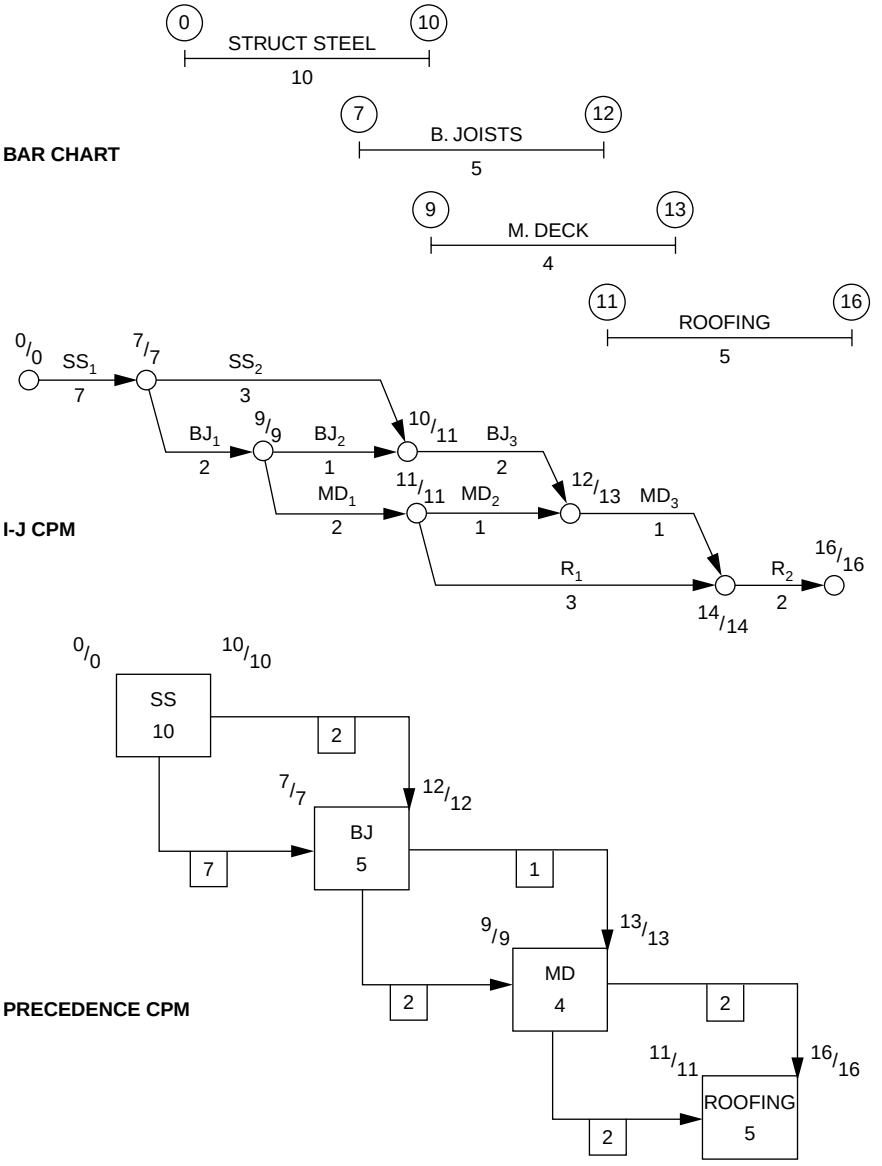


FIGURE 2.26 Precedence overlapping work schedules.

2.4 CPM Day to Calendar Day Conversion

All CPM times on the logic diagrams are noted in CPM days, which are somewhat different from project workdays and decidedly different from calendar days or dates. Because most persons utilizing the activity times from a CPM diagram need to know the starting and finishing time requirements in calendar dates, one needs to know how to convert from CPM days to calendar dates. To illustrate this relationship, refer to Fig. 2.27 that depicts a typical activity from an I-J CPM activity, plus a CPM day to CAL day conversion chart.

The CPM/CAL conversion table represents CPM days on the left and regular calendar days on the right. For the sample project shown, the project start date is February 3, 1993. Accordingly, the first CPM

(i.e. CPM Day 0 = Project Work Day 1)

FIGURE 2.27 CPM/CAL conversion chart.

day is 0 and is shown on the left side. CPM days are then noted consecutively, skipping weekends, holidays, and other nonworkdays for the project. CPM days are referenced to the morning of a workday; therefore, CPM day 0 is equal to the morning of project workday 1 and also equal to the morning of February 3, 1993.

Activity start dates are read directly from the conversion table, because they start in the morning. For instance, if an activity has an early start on CPM day 5, then it would start on February 10, 1993. This is also the morning of workday 6. Finish times can also be read directly from the table, but one must remember that the date is referenced to the morning of the day. For instance, if an activity has an early finish of CPM day 8, then it must finish on the morning of February 13. However, most persons are familiar with finish times referenced to the end of the day; therefore, unless the project crew is working 24-hour days, one must back off by one CPM day to give the finish date of the evening of the workday before. This means the finish time for the activity finishing by the morning of February 12 would be given as February 12, 1993. This process is followed for the early finish time and the late finish time for an activity.

The activity shown in Fig. 2.27 has the following activity times:

Early start time = CPM day 5
Late start time = 15 – 5 = CPM day 10
Early finish time = 5 + 5 = CPM day 10 (morning) or CPM day 9 (evening)
Late finish time = 15 = CPM day 15 (morning) or CPM day 14 (evening)

The activity time in calendar dates can be obtained for the activity depicted in Fig. 2.27 using the CPM/CAL conversion table:

Early start time = February 10, 1993
Late start time = February 17, 1993
Early finish time = February 17 (morning) or February 14 (evening) (February 14 would be the date typically given)
Late finish time = February 24 (morning) or February 21 (evening) (February 21 would be the date typically given)

The conversion of CPM activity start and finish times to calendar dates is the same process for I-J CPM and precedence CPM. The CPM/CAL conversion table should be made when developing the original CPM schedule, because it is necessary to convert all project constraint dates, such as delivery times, to CPM days for inclusion into the CPM logic diagram. The charts can be made up for several years, and only the project start date is needed to show the CPM days.

2.5 Updating the CPM Network

Updating the network is the process of revising the logic diagram to reflect project changes and actual progress on the work activities. A CPM diagram is a dynamic model that can be used to monitor the project schedule if the diagram is kept current, or up to date. One of the major reasons for dissatisfaction with the use of CPM for project planning occurs when the original schedule is never revised to reflect actual progress. Thus, after some time, the schedule is no longer valid and is discarded. If it is kept up to date, it will be a dynamic and useful management tool.

There are several causes for changes in a project CPM diagram, including the following:

1. Revised project completion date
2. Changes in project plans, specifications, or site conditions
3. Activity durations not equal to the estimated durations
4. Construction delays (e.g., weather, delivery problems, subcontractor delays, labor problems, natural disasters, owner indecision)

In order to track such occurrences, the project schedule should be monitored and the following information collected for all activities underway and those just completed or soon to start:

1. Actual start and finish dates, including actual workdays completed
2. If not finished, workdays left to complete and estimated finish date
3. Reasons for any delays or quick completion times
4. Lost project workdays and the reasons for the work loss

Frequency of Updating

A major concern is the frequency of updates required for a project schedule. The obvious answer is that updates should be frequent enough to control the project. The major factor is probably cost, because monitoring and updating are expensive and cause disturbances, no matter how slight, for the project staff. Other factors are the management level of concern, the average duration of most activities, total project duration, and the amount of critical activities. Some general practices followed for updating frequencies include the following:

1. Updates may be made at uniform intervals (daily, weekly, monthly).
2. Updates may be made only when significant changes occur on the project schedule.
3. Updates may be made more frequently as the project completion draws near.
4. Updates may be made at well-defined milestones in the project schedule.

In addition to keeping up with the actual project progress, there are other reasons that make it beneficial to revise the original project network:

1. To provide a record for legal action or for future schedule estimates
2. To illustrate the impact of changes in project scope or design on the schedule
3. To determine the impact of delays on the project schedule
4. To correct errors or make changes as the work becomes better defined

Methods for Revising the Project Network

If it is determined that the current project network is too far off the actual progress on a project, then there are three basic methods to modify the network. These methods will be illustrated for a small network, where the original schedule is as shown in Fig. 2.28, and the project's progress is evaluated at the end of CPM day 10.

I. Revise existing network (see Fig. 2.29).
   A. Correct diagram to reflect actual duration and logic changes for the work completed on the project schedule.
   B. Revise logic and duration estimates on current and future activities as needed to reflect known project conditions.

II. Revise existing network (see Fig. 2.30).
   A. Set durations equal to zero for all work completed and set the EET (first event) equal to the CPM day of the schedule update.
   B. Revise logic and duration estimates on current and future activities as needed to reflect known project conditions.

III. Develop a totally new network for the remainder of project work if extensive revisions are required of the current CPM schedule.

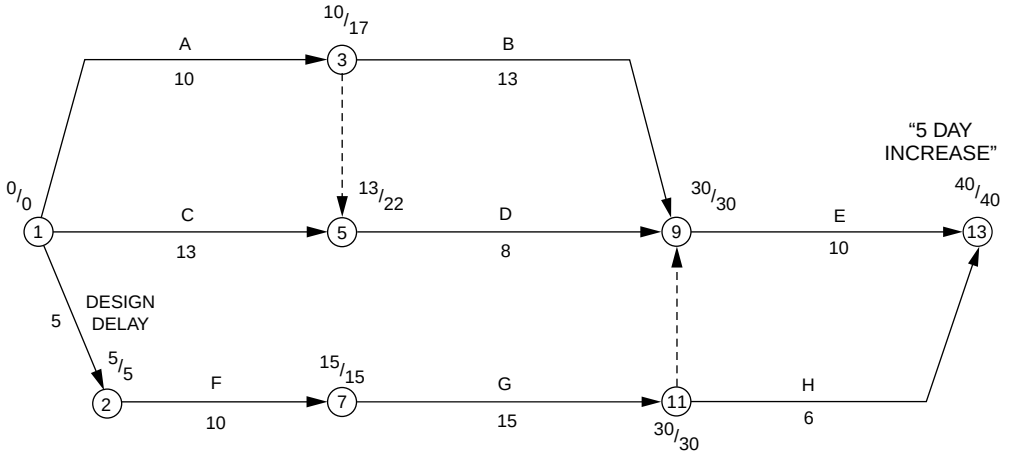

FIGURE 2.29 Updated I-J CPM diagram (Version I).

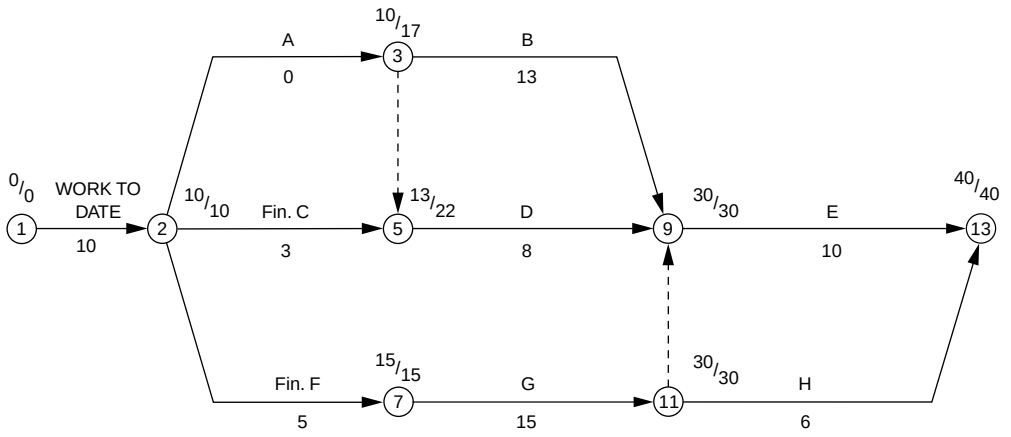

FIGURE 2.30 Updated I-J CPM diagram (Version II).

2.6 Other Applications of CPM

Once the CPM schedule has been developed for a construction project (or any type of project, for that matter), there are several other applications that can be made of the schedule for management of the project. Since complete coverage of these applications is beyond the scope of this handbook, the applications are only mentioned here. The methodologies for using these applications are covered in most textbooks on construction planning and scheduling, if the reader is interested. Major applications include the following:

Funds flow analysis — The flow of funds on a construction project (expenditures, progress billings and payments, supplier payments, retainages, etc.) are of great concern to contractors and owners for their financing projections for projects. CPM activities can be costed and used, along with other project cost conditions, to predict the flow of funds over the life of the project.

Resource allocation and analysis — The efficient utilization of resources is an important problem in construction project management, especially for the scheduling of scarce resources. By identifying the resource requirements of all activities on a CPM network, the network provides the basis for

evaluating the resource allocation needs of a project. If the demand is unsatisfactory over time, then several methods are available with which to seek a more feasible project schedule to minimize the resource problem. The controlling factor in most cases is the desire to minimize project cost.

Network compression — This process is sometimes referred to as the *time-cost trade-off problem*. In many projects, the need arises to reduce the project duration to comply with a project requirement. This can be planned by revising the CPM network for the project to achieve the desired date. This is accomplished by reducing the durations of critical activities on the network and is usually a random process with minimal evaluation of the cost impact. By developing a cost utility curve for the network's activities, especially the critical or near-critical activities, the network compression algorithm can be used to seek the desired reduced project duration at minimal increased cost.

2.7 Summary

Construction project planning and scheduling are key elements of successful project management. Time spent in planning prior to a project start, or early in the project, will most always pay dividends for all participants on the project. There are several methods available to utilize for such planning, including the bar chart and the critical path methods. Key information on these methods has been presented in this chapter of the *Handbook*. Use of any of the methods presented will make project planning an easier and more logical process. They also provide the basis for other management applications on the project. The reader is encouraged to seek more information on the methods presented and investigate other methods available. Finally, there are many computer software packages available to facilitate the planning process. The use of these systems is encouraged, but the reader should take care to purchase a system that provides the services desired at a reasonable cost. Take time to investigate several systems before selecting one, and be sure to pick a reliable source that is likely to be in business for some time in the future.

Defining Terms

Activity — A distinct and identifiable operation within a project that will consume one or more resources during its performance is an activity. The concept of the distinct activity is fundamental in network analysis. The level of detail at which distinct activities are identified in planning depends largely on the objectives of the analysis. An activity may also be referred to as an operation, or work item. A dummy activity, which does not consume a resource, can be used to identify a constraint that is not otherwise apparent.

Activity duration — The estimated time required to perform the activity and the allocation of the time resource to each activity define activity duration. It is customary to express the activity duration in work-time units; that is, workday, shift, week, and so on. An estimate of activity duration implies some definite allocation of other resources (labor, materials, equipment, capital) necessary to the performance of the activity in question.

Constraints — Limitations placed on the allocation of one or several resources are constraints.

Critical activities — Activities that have zero float time are critical. This includes all activities on the critical path.

Critical path — The connected chain, or chains, of critical activities (zero float), extending from the beginning of the project to the end of the project make up the critical path. Its summed activity duration gives the minimum project duration. Several may exist in parallel.

Float (slack) — In the calculation procedures for any of the critical path methods, an allowable time span is determined for each activity to be performed within. The boundaries of this time span for an activity are established by its early start time and late finish time. When this bounded time span exceeds the duration of the activity, the excess time is referred to as float time. Float can be classified according to the delayed finish time available to an activity before it affects the starting time of its following activities. It should be noted that once an activity is delayed to

finish beyond its early finish time, then the network calculations must be redone for all following activities before evaluating their float times.

Free float — The number of days that an activity can be delayed beyond its early finish time without causing any activity that follows it to be delayed beyond its early start time is called free float. The free float for many activities will be zero, because it only exists when an activity does not control the early start time of any of the activities that follow it.

Management constraints — Constraints on the ordering of activities due to the wishes of management are management constraints. For instance, which do you install first, toilet partitions or toilet fixtures? It does not usually matter, but they cannot be easily installed at the same time. Therefore, one will be scheduled first and the other constrained to follow; this is a management constraint.

Monitoring — The periodic updating of the network schedule as the project progresses is called monitoring. For activities already performed, estimated durations can be replaced by actual durations. The network can then be recalculated. It will often be necessary to replan and reschedule the remaining activities, as necessary, to comply with the requirement that the project duration remain the same.

Network model — The graphical display of interrelated activities on a project, showing resource requirements and constraints or a mathematical model of the project and the proposed methods for its execution. A network model is actually a logic diagram prepared in accordance with established diagramming conventions.

Physical constraints — Constraints on the ordering of activities due to physical requirements are termed physical constraints. For instance, the foundation footings cannot be completed until the footing excavation work is done.

Planning — The selection of the methods and the order of work for performing the project is planning. (Note that there may be feasible methods and, perhaps, more than one possible ordering for the work. Each feasible solution represents a plan.) The required sequence of activities (preceding, concurrent, or following) is portrayed graphically on the network diagram.

Project — Any undertaking with a definite point of beginning and a definite point of ending, requiring one or more resources for its execution is a project. It must also be capable of being divided into interrelated component tasks.

Project duration — The total duration of the project, based on the network assumptions of methods and resource allocations. It is obtained as the linear sum of activity durations along the critical path.

Resource constraints — Constraints on the ordering of activities due to an overlapping demand for resources that exceeds the available supply of the resources. For instance, if two activities can be performed concurrently but each requires a crane, and only one crane is available, then one will have to be done after the other.

Resources — These are things that must be supplied as input to the project. They are broadly categorized as manpower, material, equipment, money, time, and so on. It is frequently necessary to identify them in greater detail (draftsmen, carpenters, cranes, etc.).

Scheduling — The process of determining the time of a work item or activity within the overall time span of the construction project. It also involves the allocation of resources (men, material, machinery, money, time) to each activity, according to its anticipated requirements.

Total float — The total time available between an activity's early finish time and late finish time as determined by the time calculations for the network diagram. If the activity's finish is delayed more than its number of days of total float, then its late finish time will be exceeded, and the total project duration will be delayed. Total float also includes any free float available for the activity.

Further Information

There are hundreds of books, papers, and reports available on the subject of construction planning and scheduling in the U.S.. The two references cited above are only two such publications often used by the author. In addition, there are many computer software packages available that give in-depth details of basic and advanced applications of planning and scheduling techniques for construction project management. Some of the commonly used packages are Primavera, Open Plan, Harvard Project Manager, and Microsoft Project. Another excellent source of information on new developments in scheduling is the *ASCE Journal of Construction Engineering and Management*, which is published quarterly.

3.1 Introduction

Whether a construction contract is unit price, lump sum, or cost-plus; whether the construction project is to be linear (i.e., concept Æ design Æ procurement Æ construction) or fast-track (i.e., design/build), the cost of construction is a major factor in all projects. The major factors that impact construction costs are materials, labor, equipment, overhead, and profit. The cost of equipment for civil engineering construction projects can range from 25 to 40% of the total project cost.

Figure 3.1 illustrates the ability to influence the construction cost of a project. The greatest influence to construction cost occurs at the front end of the project. Assumptions made by design engineers during the conceptual and design phases of a project dictate the choice of equipment that will be used for the particular project, just as it will dictate the choice of materials used in construction. Thus, sometimes the design may, in fact, restrict the best and most cost-effective solutions from being utilized. For example, many sewer projects are designed on the basis of traditional specifications, materials, and equipment, when more advanced materials, techniques, and equipment may, in fact, be safer, more environmentally and socially acceptable, and more cost-effective. This is especially true of sewer projects in urban areas, where modern construction techniques, such as microtunneling and pipebursting, utilizing new pipe materials such as glass fiber-reinforced polymers (GRP) and high-density polyethylene (HDPE), are replacing the traditional dig and replace methods of sewer construction.

It is important for design engineers and construction engineers to be knowledgeable about construction equipment. Construction equipment is an integral part of the construction process. The cost of construction is a function of the design of the construction operation.

This chapter will provide an overview of construction equipment selection and utilization processes. It will describe typical equipment spreads associated with two major classifications of civil engineering construction projects: heavy/highway and municipal/utility. Methods for determining equipment productivity and cost will be discussed.

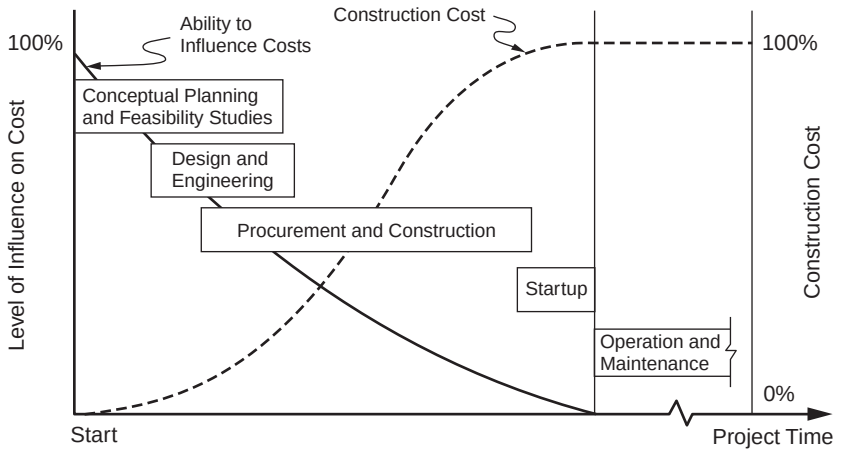

FIGURE 3.1 Ability to influence construction cost over time. (*Source:* Hendrickson, C. and Au, T. *Project Management for Construction.* Prentice Hall, Englewood Cliffs, NJ.)

3.2 Heavy/Highway Construction Projects

These projects include new road construction, dams, airports, waterways, rehabilitation of existing roadways, marine construction, bridges, and so on. Each project can be segmented into various phases or operations. The equipment spread selected for a specific construction operation is critical to the success of the project.

Figure 3.2(a) illustrates a typical sequence of activities for the construction of a new highway. This highway project contains culverts and a bridge. While there will be some overlap in equipment utilization, each activity must be evaluated carefully to identify all operations in the activity and to ensure that the equipment selected for each operation is compatible with the tasks to be completed. Figure 3.2(b) lists the activities associated with the project, the duration of each, and whether the activities are critical or noncritical. The intent is not to provide a detailed description of each activity but to illustrate how equipment selection and utilization are a function of the associated variables. For example, the first activity (clearing and grubbing) is critical, as no activity can begin until the project site is cleared. Even though clearing land is often considered to be a basic, straightforward activity, it is still more an art than a science. The production rates of clearing land are difficult to forecast, because they depend on the following factors:

- The quantity and type of vegetation
- Purpose of the project
- Soil conditions
- Topography
- Climatic conditions
- Local regulations
- Project specifications
- Selection of equipment
- Skill of operators

To properly address these variables requires research and a thorough evaluation of the site to determine the following:

- Density of vegetation
- Percent of hardwood present

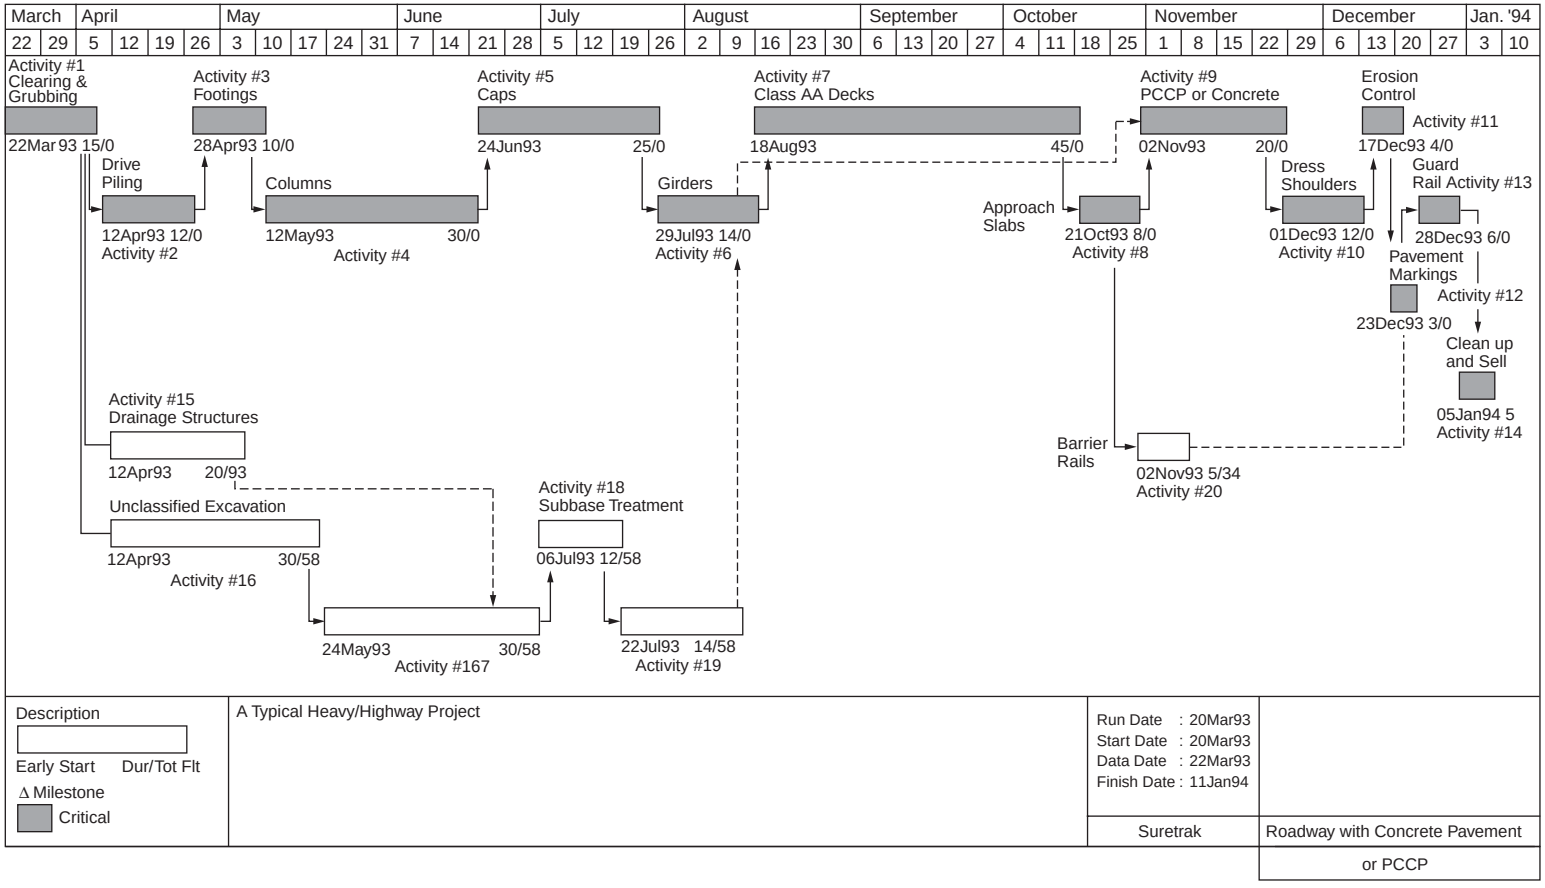

FIGURE 3.2 (a) Typical sequence of activities for a new highway project; (b) activities associated with a new highway project.

Activity Number	Activities on Critical Path	Duration (Days)
1.	Clearing and Grubbing	15
2.	Drive Piling for Bridge	12

FIGURE 3.2 (continued).

- Presence of heavy vines
- Average number of trees by size category
- Total number of trees

A method for quantifying the density of vegetation and the average number of trees per size category is described in Caterpillar [1993] and Peurifoy and Schexnayder [2002, p. 179].

The most common type of construction equipment used for clearing and grubbing activities is a bulldozer. The term *bulldozer* is used to define a tractor mounted with a dozing blade. Tractor size can vary from less than 70 flywheel horsepower (FWHP) to more than 775 FWHP. Dozing blades are available in many types. The appropriate blade depends on the job to be accomplished. For example, types of blades include the following:

U — universal
SU — semiuniversal
S — straight
P — power angle and tilt
A — angling
V — tree cutter

Caterpillar [1993, pp. 1–39–1–41] provides a detailed description and illustration of various blades commonly used. To maximize production, it is important to ensure that the tractor and dozer blade are

properly matched. The two major factors to be considered in selecting the proper blade and tractor are material to be moved and tractor limitations. For example, weight and horsepower of the tractor determine its ability to move material. Particle size, particle shape, voids, and water content are the main factors affecting the level of difficulty of moving material.

Caterpillar [1993] and Peurifoy and Schexnayder [2002] utilize the following relationship to estimate the time required to perform various operations, such as felling trees with bulldozers and piling in windows with bulldozers:

$$T = B + M_1N_1 + M_2N_2 + M_3N_3 + M_4N_4 + DF \tag{3.1}$$

where T = time required per acre, minutes
B = base time required for a bulldozer to cover an acre with no trees requiring splitting or individual treatment, minutes
M = time required per tree in each diameter range, minutes
N = number of trees per acre in each diameter range, obtained from field survey
D = sum of diameter in feet of all trees per acre, if any, larger than 6 ft in diameter at ground level
F = time required per foot of diameter for trees larger than 6 ft in diameter, minutes

While industry average data exist for the variables in Eq. (3.1), which correlate operation duration with FWHP of bulldozers, a firm's historic database should provide improved accuracy in forecasting production. Such a database can be developed by project owner representatives and constructors. This database could then be used for future projects and comparison with industry averages.

Many large constructors do not maintain such detailed databases. For example, the equipment selected for the clearing and grubbing activities for the project illustrated in Fig. 3.2 was based on estimator experience. When questioned about the selection process, the estimator stated that he made his selection based on the fact that the project consisted of more than 25 acres of timber with trees larger than 24 in. diameter. If there had been less than 25 acres with less than 24-in. in diameter trees, he would have selected smaller equipment.

The type of production estimating used by this constructor is extremely effective when experienced estimators are responsible for making the necessary decisions. However, a more detailed database would permit decisions to be made at a lower level by less experienced people without sacrificing accuracy. This would allow the more experienced estimator to utilize his or her time more effectively. In addition, a more detailed database would provide better information to substantiate the impact if a change in conditions should develop.

Table 3.1 illustrates major equipment requirements for each activity shown in Fig. 3.2. The equipment listed can be categorized as follows: bulldozers, excavators, compactors, graders, scrapers, spreaders, cranes, loaders, trucks, and miscellaneous (asphalt spreaders, screeds, water trucks, power brooms, farm tractors, generators).

Although it is beyond the scope of this chapter to provide an in-depth analysis of the estimated productivity of each of the above classes of equipment, this analysis is provided in the references cited at the end of this chapter. Several categories of machines are discussed in general terms. Equipment manufacturers also provide reliable productivity information.

It is important to be able to segment a project into its basic activities, as illustrated in Fig. 3.2. Each activity must then be further segmented into its basic operations. Individual operations within an activity are unique and require specific combinations of equipment to be executed in a cost-effective manner. Each machine selected will have a unique operation within an activity; the operation is a function of the cycle time of the machines needed to execute it. The machines must be selected so that their productivities balance. The durations of the activities listed in Fig. 3.2 are a function of the operations necessary to accomplish the activity.

Duration estimating is extremely important, but, because of the many variables involved, it is not an easy task. Excellent simulation methods and computer software programs are available to help project managers evaluate more precisely the impact of variables of operations and processes [Halpin and Riggs, 1992].

TABLE 3.1 Equipment Selected for Typical Heavy/Highway Project (See Fig. 3.2)

Activity Number	Equipment Description				
	No. of Units	Size	Type	Equipment Cost/Unit	Remarks
1	2	285–340 FWHP	Bulldozers	$424,000	Provide: Track-type
					2 — U blades
					1 — Rake
	1	160–180 FWHP	Bulldozer	$157,000	Provider: Track-type w/P blade
	1	140–160 FWHP	Hydraulic excavator	$440,000	
2	1	65–75 ton	Crane	$343,000	Provide: 1 — pile-driving hammer
				$83,000	1 — set of cable leads
				$44,000	1 — drill and power pack
				$132,000	
3,4,5	1	50–75 ton	Crane	$314,000	
	1	Small	Generator	$33,000	50 KW
6	2	75–100 ton	Cranes	$660,000	
7	1	50–75 ton	Crane	$313,000	
	1	Medium	Generator	$110,000	150 KW
	1	150 CFM	Air compressor	$13,000	
	1		Bridge screed	$44,000	
	1		Concrete pump truck	$192,000	
8	1	140–160 FWHP	Hydraulic excavator	$440,000	
	1		Clarey screed	$8,500	
	1	63–70 FWHP	Bulldozer	$72,000	
9	1		Compactor	$82,000	Smooth Drum roller
	1		Compactor	$66,000	Pneumatic roller
	1		Power broom	$20,000	Broce model T-20
	1		Asphalt spreader	$193,000	Barber-Green BFS-185
10	1	75–90 FWHP	Bulldozer	$83,000	Track-type
	1	135–145 FWHP	Motor grader	$126,000	12G
	1	175–180 FWHP	Scraper	$237,000	Provide: elevating equipment/model 615
11	3	50–70 FWHP	Farm tractors	$44,000	Provide: miscellaneous attachments
	2	1800–3000 gal	Water trucks	$4,000	
12					Subcontract work
13					Subcontract work
14	1	135–145 FWHP	Motor grader	$127,000	
	1	75–90 FWHP	Bulldozer	$83,000	Track-type
	1	118–133 FWHP	Hydraulic excavator	$176,000	
	1		Dump truck	$68,000	
15	1	118–133 FWHP	Hydraulic excavator	$176,000	
	1	75–90 FWHP	Bulldozer	$82,000	Track-type
	1	145–170 FWHP	Front-end loader	$82,000	Provide: rubber-tired type
	4		Compactors	$82,000	Provide: vibra-plate tamps
	1	Small	Compactor	$22,000	Provide: self-propelled roller
16, 17	6	350–450 FWHP	Scrapers	$330,000	Model 631E
16, 17	1	320–370 FWHP	Bulldozer	$605,000	Push tractor for scrapers
	2	120–140 FWHP	Bulldozers	$82,000	To level and spread material
	1	140–160 FWHP	Hydraulic excavator	$440,000	
	1	180–200 FWHP	Motor grader	$247,000	16G
	1	175–215 FWHP	Compactor	$198,000	Provide: self-propelled roller
	1	10,000 gal	Water truck	$44,000	
	1	250–300 FWHP	Farm tractor	$116,000	Provide: 24–28 in plow
18	3		Soil stabilizers	$165,000	Type: Raygo
	4	1800–3000 gal	Water trucks	$28,000	
	1		Compactor	$165,000	Provide: self-propelled
	1		Compactor	$82,000	Sheep-foot roller
	2	135–145 FWHP	Motor graders	$82,000	Provide: pneumatic roller
			Truck	$44,000	

TABLE 3.1 (continued) Equipment Selected for Typical Heavy/Highway Project (See Fig. 3.2)

Activity Number	Equipment Description				
	No. of Units	Size	Type	Equipment Cost/Unit	Remarks
19	1		Compactor	$82,000	Smooth drum roller
	1		Compactor	$66,000	Pneumatic roller
	1		Power broom	$20,000	Broce model T-20
	1		Asphalt spreader	$192,000	Barber Green BFS-185

Note: Equipment costs represent estimated market value. They illustrate the size of investment that must be recovered.

It is important to ensure that the project is designed for constructibility. Project designers must be knowledgeable concerning construction processes and the variables impacting total life-cycle costs.

Equipment Productivity

Once the equipment needs for an activity have been identified, the next step is to conduct an equipment productivity analysis to select the optimum size. The objective is to determine the number of units and the size of equipment that would permit the constructor to accomplish the activity with a duration resulting in the lowest cost.

Because most civil engineering construction projects are awarded based on lowest cost, it is of utmost importance to the constructor to select the proper equipment spread providing the lowest construction cost for the project. The project is segmented into various activities; therefore, the lowest cost must be determined for each activity.

Bulldozer Productivity

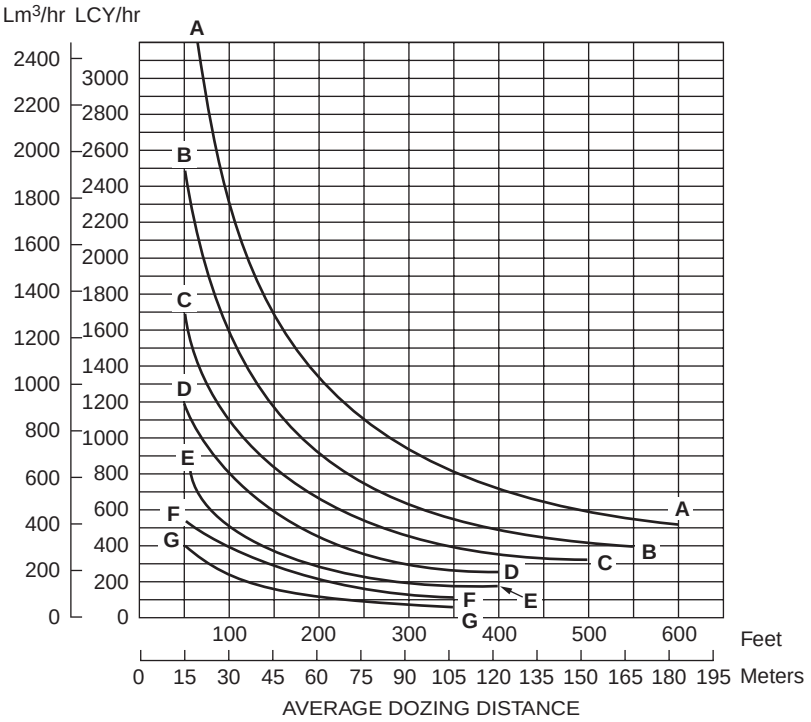
When a constructor lacks reliable historical data, most bulldozer equipment manufacturers will provide production information. Manufacturer's production information is useful in conducting a comparative analysis when developing a conceptual estimate or schedule. Production data provided by manufacturers (or any other source) must be applicable to a particular situation.

For example, Caterpillar [1993] contains excellent production curves for estimating dozing production in units of loose cubic yards (LCY) of materials per hour (LCY/h). Figure 3.3 illustrates a typical production curve from Caterpillar [1993, p. 1–58]. This information is based on numerous field studies made under varying job conditions. These production curves provide the maximum uncorrected production based on the following conditions:

1. 100% efficiency (60-min hour — level cycle)
2. Power shift machines with 0.05 min fixed times
3. Machine cuts for 50 ft (15 m), then drifts blade load to dump over a high wall. (Dump time — 0 sec)
4. Soil density of 2300 lb/LCY (1370 kg/m^3)
5. Coefficient of traction: track machines — 0.5 or better, wheel machines — 0.4 or better
6. Hydraulic-controlled blades are used
7. Dig 1F; carry 2F; return 2R (1F — first forward gear, etc.)

As long as the conditions that the production curves are based on are understood, they can be used for other conditions by applying the appropriate correction factors using the following relationship:

$$\text{Production (LCY/hr)} = \text{Maximum production (from production curve)} \times \text{Correction factor} \tag{3.2}$$



KEY

A — D11N-11SU
B — D10N-10SU
C — D9N-9SU
D — D8N-8SU
E — D7H-7SU
F — D6H-6SU
G — D5H XL-5SU XL

FIGURE 3.3 Typical production curve for estimation of dozing production. A-D11N-11SU, a bulldozer as manufactured by Caterpillar, Inc. with a model number D11N utilizing an SU-type blade designed for use with a D11 machine can be expected to move the volume of earth per hour as indicated by the A curve on this chart for a specific distance. For comparative purposes, the FWHP of each machine is D11N — 770, D10N — 520, D9N — 370, D8N — 285, D7H — 215, and D6H — 165. (*Source: Caterpillar Performance Handbook,* 24th ed., 1993. Caterpillar, Peoria, IL, p. 1–58.)

Common correction factors are provided for such variables as operator skill, type of material being handled, method of dozing [i.e., dozing in a slot or side-by-side dozing, visibility, time efficiency (actual minutes per hour of production), transmission type, dozer blade capacity, and grades]. Caterpillar [1993, pp. 1–59–1–60] is an excellent source for correction factors and provides an excellent example of how to use production curves and correction factors.

When easy-to-use production curves do not apply to a particular situation, the basic performance curves must be utilized. Manufacturers provide a performance curve for each machine. Track-type tractor performance curves are in the form of drawbar pull (DBP) versus ground speed, and rubber-tired-type machine performance curves are in the form of rimpull (RP) versus ground speed.

The DBP vs. speed curves will be discussed in this section, and the RP vs. speed curves will be discussed later in connection with rubber-tired scrapers.

Drawbar horsepower is the power available at the tractor drawbar for moving the tractor and its towed load forward. Figure 3.4 illustrates the transfer of power from the flywheel to the drawbar.

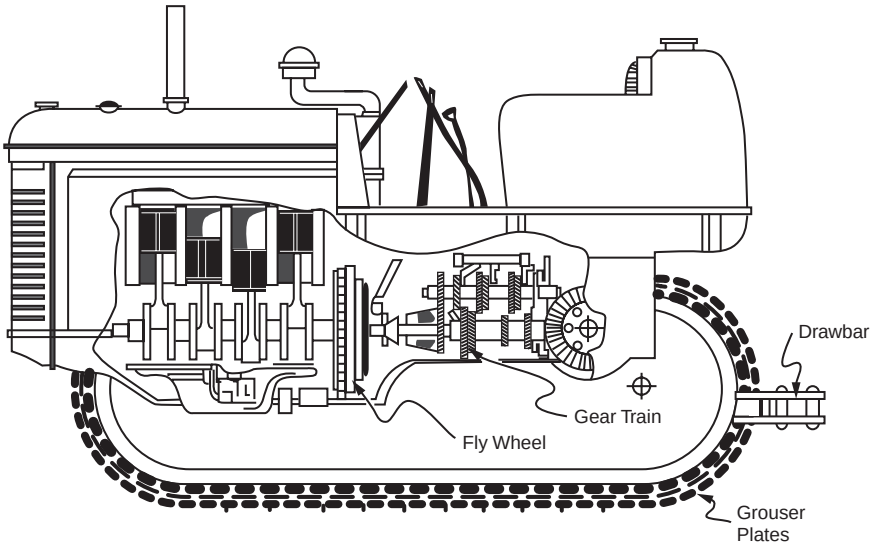


FIGURE 3.4 Characteristics of typical crawler tractors. (*Source:* Carson, A.B. 1961. *General Excavation Methods*. McGraw-Hill, New York.)

The relationship between DB horsepower, DB pull, and speed can be expressed as follows:

$$\text{DBHP} = \frac{\text{DBP}(\text{lb}) \times \text{speed}(\text{mph})}{375} \tag{3.3}$$

where DBHP = drawbar horsepower
DBP = drawbar pull (pounds)
Speed = ground speed (miles per hour)
375 = conversion factor

For example, to obtain the compaction required in activity 17 in Fig. 3.2, tillage may be necessary to accelerate drying of the soil. This tillage could be accomplished with a 24 to 28 in. agricultural plow pulled behind a track-type tractor. Production requirements could demand that this tillage operation needs to move at a speed of 3 mph and would impose a 22,000 lb DBP. Thus, the tractor must be able to apply at least

$$\frac{22{,}000 \text{ lb DBP} \times 3 \text{ mph}}{375} = 176 \text{ DBHP}$$

However, as can be seen in Table 3.1, for activity 17, a 250 to 300 FWHP rubber-tired farm tractor was selected by the constructor. Obviously, this decision for a more powerful, rubber-tired machine was made because a higher production rate was needed to keep all operations in balance.

Figure 3.5 is a DBP vs. speed performance curve for model D8N track-type tractor as manufactured by Caterpillar, Inc. The same type curves are available from all other manufacturers, whether domestic or foreign. As illustrated, once the demand has been defined in terms of the necessary DBP required to perform the task, the gear range and ground speed are determined for a specific machine. Obviously, this speed is critical information when trying to determine the cycle times for each machine at work. The cycle times are essential in determining how long each operation will take, and the length of each operation defines the duration of each activity shown in Fig. 3.2.

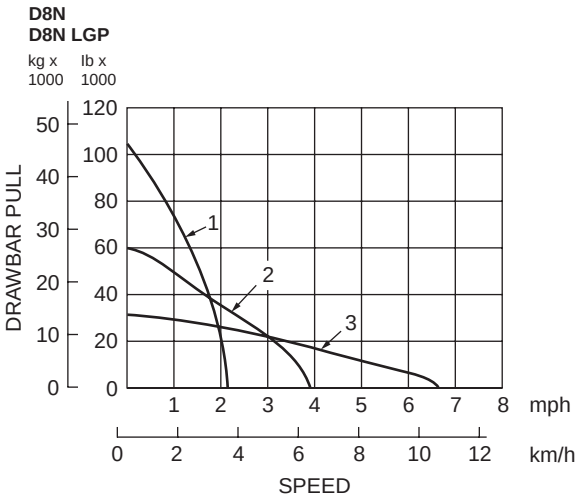

FIGURE 3.5 Drawbar pull vs. ground speed power shift. 1 — 1st gear, 2 — 2nd gear, 3 — 3rd gear. (*Source: Caterpillar Performance Handbook*, 24th ed., 1993. Caterpillar, Peoria, IL, p. 1–58.)

Excavator Productivity

Excavators are a common and versatile type of heavy construction equipment. As in the project illustrated by Fig. 3.2, excavators are used to accomplish many activities, such as lifting objects, excavating for trenches and mass excavation, loading trucks and scrapers, and digging out stumps and other buried objects.

The production of an excavator is a function of the digging cycle, which can be divided into the following segments:

1. Time required to load the bucket
2. Time required to swing with a loaded bucket
3. Time to dump the bucket
4. Time to swing with an empty bucket

This cycle time depends on machine size and job conditions. For example, a small excavator can usually cycle faster than a large one, but it will handle less payload per cycle. As the job conditions become more severe, the excavator will slow. As the soil gets harder and as the trench gets deeper, it takes longer to fill the bucket.

Other factors that greatly impact excavator production are digging around obstacles such as existing utilities, having to excavate inside a trench shield, or digging in an area occupied by workers.

Many excavator manufacturers provide cycle time estimating data for their equipment. This information is an excellent source when reliable historical data are not available. If an estimator can accurately predict the excavator cycle time and the average bucket payload, the overall production can be calculated as follows:

$$\frac{\text{Production}}{(\text{LCY/hr})} = \frac{\text{Cycles}}{\text{hr}} \times \frac{\text{Average bucket payload (LCY)}}{\text{Cycle}} \tag{3.4}$$

Caterpillar [1993, pp. 4–106–4–107] provides estimated cycle times for common excavators with bucket size variations. These values are based on no obstructions, above average job conditions, above average operator skill, and a 60 to 90° angle of swing. Correction factors must be applied for other operating conditions.

TABLE 3.2 Cycle Estimating Chart for Excavators

Model	E70B	311	312	E140	320	E240C	325	330	235D	350	375

Table 3.2 illustrates the level of detailed information available from manufacturers on specific machines. This table presents information on four Caterpillar excavators commonly used on civil engineering projects.

Once the cycle time is determined, either by measuring or estimating, the production can be determined by the following relationship:

$$\text{LCY/60-min hr} = \text{Cycles/60-min hr} \times \text{Average bucket payload (LCY)} \tag{3.5}$$

where,

$$\text{Average bucket payload} = \text{Heaped bucket capacity} \times \text{Bucket fill factor} \tag{3.6}$$

This production is still based on production occurring the full 60 min of each hour. Since this does not occur over the long term, job efficiency factors are presented at the lower left corner of Table 3.3 and applied as follows:

$$\text{Actual Production (LCY/hr)} = \text{LCY/60-min hr} \times \text{Job efficiency factor} \tag{3.7}$$

Example 1

Determine the actual production rate for a Cat 225D hydraulic excavator (150 FWHP) as required for activity 16, unclassified excavation, for the project represented in Fig. 3.2. It is estimated that the realistic productive time for the excavator will be 50 min/hr. Thus, the job efficiency factor will be 50/60 = 0.83. The soil type is a hard clay.

Solution.

$$\text{Average bucket payload} = \text{Heaped bucket capacity} \times \text{Bucket fill factor}$$

Enter Table 3.2 and select

1. 1.78 LCY bucket capacity for a Cat 225D
2. 0.25 min total cycle time

$$1.51 \text{ LCY} = 1.78 \text{ LCY} \times 0.85$$

TABLE 3.3 Cubic Yards per 60-Minute Hour

Source: Caterpillar. 1993. *Caterpillar Performance Handbook*, 24th ed. Caterpillar, Peoria, IL.

Enter Table 3.3 and select an average production rate based on a work time of 60 min/hr. Select the column headed by a 1.5 LCY bucket payload and the row that represents a 0.25 min cycle time. From this, the average production is determined to be 360 LCY per 60-min hr.

$$\text{Actual production} = \text{LCY/60-min hr} \times \text{Job efficiency factor}$$

$$299 \text{ LCY/hr} = 360 \text{ LCY/60-min hr} \times 0.83$$

When an excavator is used for trenching, the desired rate of production often needs to be expressed in lineal feet excavated per hour. The trenching rate depends on the earth-moving production of the excavator being used and the size of the trench to be excavated.

Scraper Production

Scrapers provide the unique capability to excavate, load, haul, and dump materials. Scrapers are available in various capacities by a number of manufacturers, with options such as self-loading with elevators, twin engines, or push-pull capability.

Scrapers are usually cost-effective earthmovers when the haul distance is too long for bulldozers yet too short for trucks. This distance typically ranges from 400 to 4000 ft; however, the economics should be evaluated for each project.

The production rate of a scraper is a function of the cycle time required to load, haul the load, dump the load, and return to the load station. The times required to load and dump are usually uniform once established for a specific project, while travel times can vary a significant amount during the project due to variation of the travel distance. The load time can be decreased by prewetting the soil and designing the operation to load downgrade.

It is common practice for a push tractor during the loading operation to add the necessary extra power. The pattern selected for the tractor-assisted loading operation is important in the design of the operation to maximize production. The standard patterns are back tracking, chain, and shuttle. A thorough description of these patterns is provided in Peurifoy and Schexnayder [2002, p. 222].

The performance of a scraper is the function of the power required for the machine to negotiate the job site conditions and the power that is available by the machine. The power required is a function of rolling resistance (RR) and the effect of grade (EOG). RR is the force that must be exerted to roll or pull a wheel over the ground. It is a function of the internal friction of bearings, tire flexing, tire penetration into the surface, and the weight on the wheels.

Each ground-surface type has a rolling resistance factor (RR_F) associated with it. However, as a general rule, the RR_F consists of two parts. First, it takes at least a 40 lb force per each ton of weight just to move a machine. Second, it takes at least a 30 lb force per each ton of weight for each inch of tire penetration. Therefore, the RR_F can be determined as follows:

$$RR_F = 40 \text{ lb/ton} + 30 \text{ lb/ton/inch of penetration} \tag{3.8}$$

Rolling resistance is then calculated by using the RR_F and the gross vehicle weight (GVW) in tons:

$$RR = RR_F \times GVW \tag{3.9}$$

RR can be expressed in terms of pounds or percent. For example, a resistance of 40 lb/ton of equipment weight is equal to a 2% RR.

The EOG is a measure of the force due to gravity, which must be overcome as the machine moves up an incline, but is recognized as grade assistance when moving downhill. Grades are generally measured in percent slope. It has been found that for each 1% increment of adverse grade, an additional 20 lb of resistance must be overcome for each ton of machine weight. Therefore, the effect of grade factor (EOG_F) can be determined by:

$$EOG_F = (20 \text{ lb/ton/\% grade}) \times (\% \text{ of grade}) \tag{3.10}$$

The EOG is then calculated by:

$$EOG = EOG_F \times GVW \tag{3.11}$$

The total resistance (TR) associated with a job site can be calculated by:

$$\text{Machine moving uphill: } TR = RR + EOG \tag{3.12}$$

$$\text{Machine moving on level ground: } TR = RR \tag{3.13}$$

$$\text{Machine moving downhill: } TR = RR - EOG \tag{3.14}$$

Once the power requirements are determined for a specific job site, a machine must be selected that has adequate power available. Available power is a function of horsepower and operating speed. Most equipment manufacturers provide user-friendly performance charts to assist with evaluating the influence of GVW, TR, speed, and rimpull. Rimpull is the force available between the tire and the ground to propel the machine.

The relationship of the power train to rimpull for a rubber-tired tractor can be expressed as follows:

$$\text{Rimpull} = \frac{375 \times HP \times \text{Efficiency}}{\text{Speed (mph)}} \tag{3.15}$$

Figure 3.6 illustrates information available from a typical performance chart. The following example illustrates how this information can be utilized.

Example 2

A scraper with an estimated payload of 34,020 kg (75,000 lb) is operating on a total effective grade of 10%. Find the available rimpull and maximum attainable speed.

$$\text{Empty weight} + \text{payload} = \text{Gross weight}$$

$$43{,}945 \text{ kg} + 34{,}020 \text{ kg} = 77{,}965 \text{ kg}$$

$$(96{,}880 \text{ lb} + 75{,}000 \text{ lb} = 171{,}880 \text{ lb})$$

Solution. Using Fig. 3.6, read from 77,965 kg (171,880 lb) on top of the gross weight scale down (line B) to the intersection of the 10% total resistance line (point *C*).

Go across horizontally from *C* to the Rimpull Scale on the left (point *D*). This gives the required rimpull: 7593 kg (16,740 lb).

Where the line *CD* cuts the speed curve, read down vertically (point *E*) to obtain the maximum speed attainable for the 10% effective grade: 13.3 km/h (8.3 mph).

The vehicle will climb the 10% effective grade at a maximum speed of 13.3 km/h (8.3 mph) in fourth gear. Available rimpull is 7593 kg (16,740 lb).

3.3 Municipal/Utility Construction Projects

Municipal/utility construction involves projects that are typically financed with public funds and include such things as water and sewer pipelines, storm drainage systems, water and wastewater treatment facilities, streets, curbs and gutters, and so on. Much of the same equipment listed in Fig. 3.2 is utilized for this type of construction. The productivity rates are determined the same way.

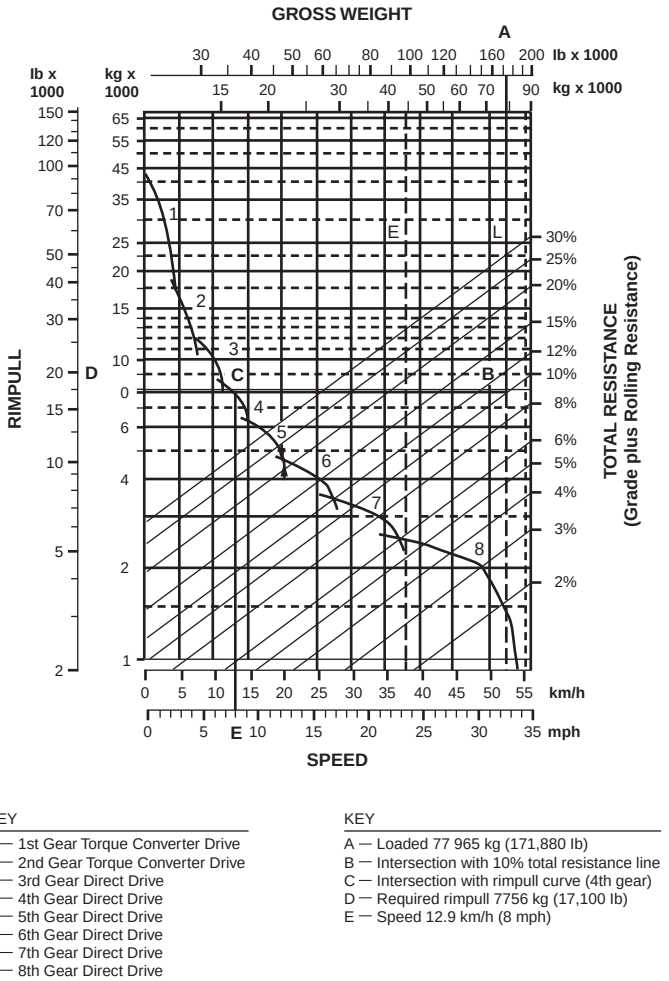

FIGURE 3.6 Rimpull-speed-gradeability curves. (*Source: Caterpillar Performance Handbook*, 24th ed., 1993. Caterpillar, Peoria, IL.)

It is beyond the scope of this chapter to attempt a descriptive comparison of the various types of construction and equipment in this division. In the preceding section, a typical heavy/highway project was presented with an itemized list of the typical equipment associated with each activity. In this segment, the emphasis will be placed on advanced technology, while the emphasis in the section on heavy/highway equipment was on traditional equipment. In recent years, more concern has been placed on the impact of construction activities on society. As a result, the trenchless technology industry has expanded greatly. Trenchless technology includes all methods, equipment, and materials utilized to install new or rehabilitate existing underground infrastructure systems.

While *trenchless technology* is a relatively recent expression (it was coined in the mid-1980s), the ability to install pipe without trenching is not new. Methods such as auger boring and slurry boring have been used since the early 1940s. Until recently, these methods were used primarily to cross under roadways and railroads. The trend today is to utilize the trenchless concept to install complete underground utility and piping systems with minimum disruption and destruction to society and the environment, safely, and at the lowest total life-cycle cost.

Figure 3.7 is a classification system of the trenchless methods available to install new systems. Each method involves unique specialized equipment. The methods are described in detail in Iseley and Tanwani

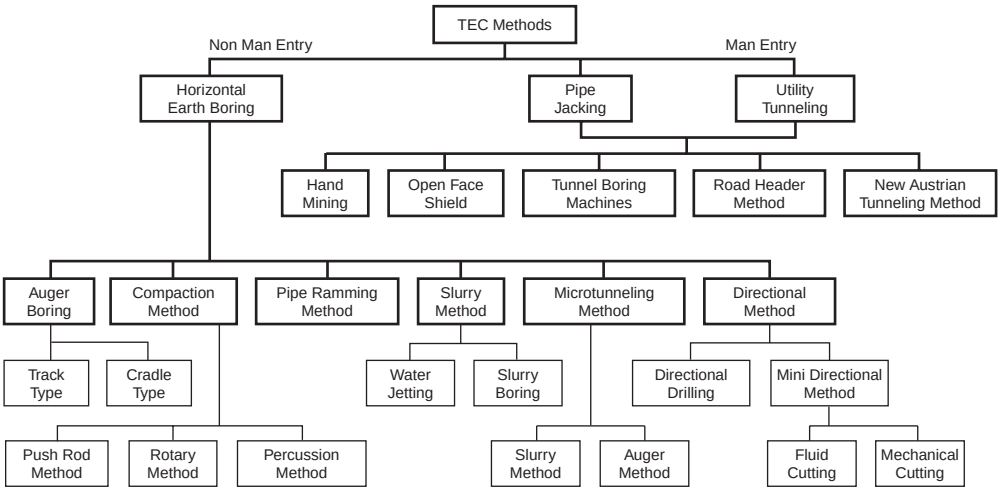

FIGURE 3.7 Trenchless excavation construction (TEC) classification system.

[1993]. No one method is compatible with all installations. Each project should be evaluated separately; the method selected should be compatible, safe, and cost-effective and should provide a high probability of success.

Only the microtunneling technique will be described in this chapter. This technique is well suited for installing sanitary and storm sewer pipelines, which require high degrees of accuracy for alignment and grade. For an excellent introduction to some of the other more common trenchless techniques used to install underground pipelines, the reader is referred to Iseley and Gokhale [1997].

Microtunneling systems are laser-guided, remote-controlled, pipe-jacking systems. In most instances, because of their high accuracy, the product pipe is installed in one pass. Most machines have the capability to counterbalance the earth pressure at the work face continuously, so that dewatering is not required.

These systems were developed in Japan in the mid-1970s, introduced in Germany in the early 1980s, and first used in the U.S. in 1984. Figure 3.8 shows the growth of the microtunneling industry in the

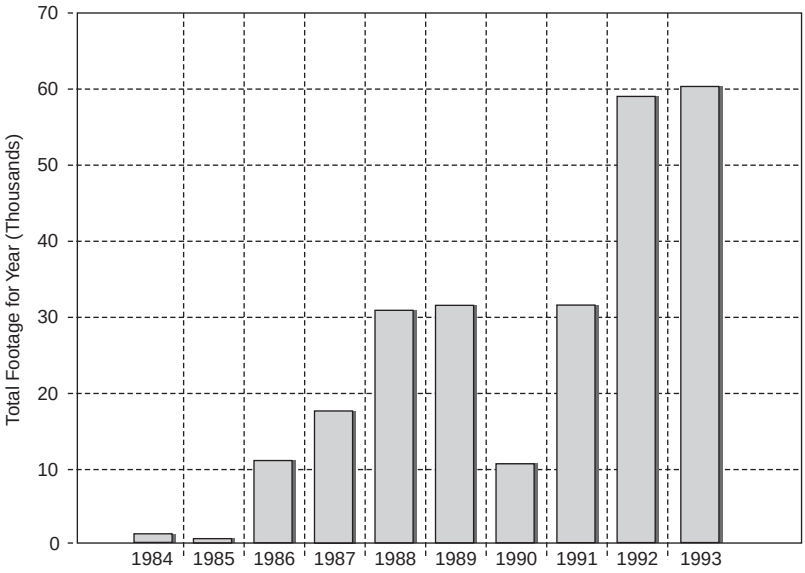

FIGURE 3.8 Total U.S. microtunneling footage by year.

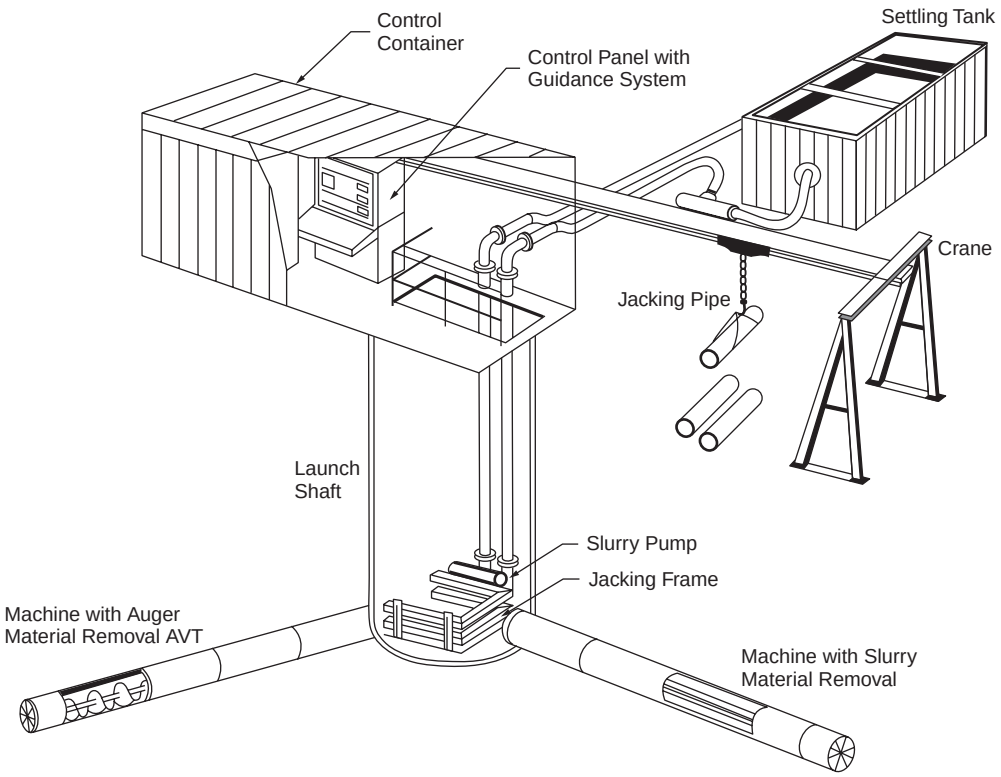

FIGURE 3.9 Auger and slurry microtunneling systems.

U.S. By mid-1993, more than 50 mi of pipe had been installed by this method. The industry continues to grow in demand because of its extraordinary capability. For example, in a residential Houston, TX area, microtunneling was used in 1987 to install almost 4 mi of gravity sewer lines (10 to 24 in. diameter), because the residents did not want their neighborhood torn apart by traditional methods. In 1989, in Staten Island, NY, this method was used to install a 5-ft diameter gravity sewer at a depth of 80 ft, under 60 ft of groundwater, with the longest single drive 1600 linear feet. It was installed at an accuracy of ±1 in. horizontal and vertical. In 1992–93, two raw water intake lines were installed, one above the other, in Jordan Lake, near Carey, NC. These examples and many others are helping engineers realize the unique capability of microtunneling to solve complex problems safely, cost-effectively, and with minimum environmental impact.

Figure 3.9 illustrates the two basic types of systems. They provide similar capabilities but are differentiated by their spoil removal systems. One provides a slurry spoil transportation system, and the other provides an auger spoil removal system.

Figure 3.10 is a schematic drawing that illustrates the basic components and systems of the microtunneling methods.

The microtunneling process consists of five independent systems: the mechanized excavation system, the propulsion system, the spoil removal system, the guidance control system, and the pipe lubrication system.

The Mechanized Excavation System

The cutter head is mounted on the face of the microtunnel boring machine and is powered by electric or hydraulic motors located inside the machine. Cutting heads are available for a variety of soil conditions, ranging from soft soils to rock, including mixed-face conditions and boulders. The microtunnel machines

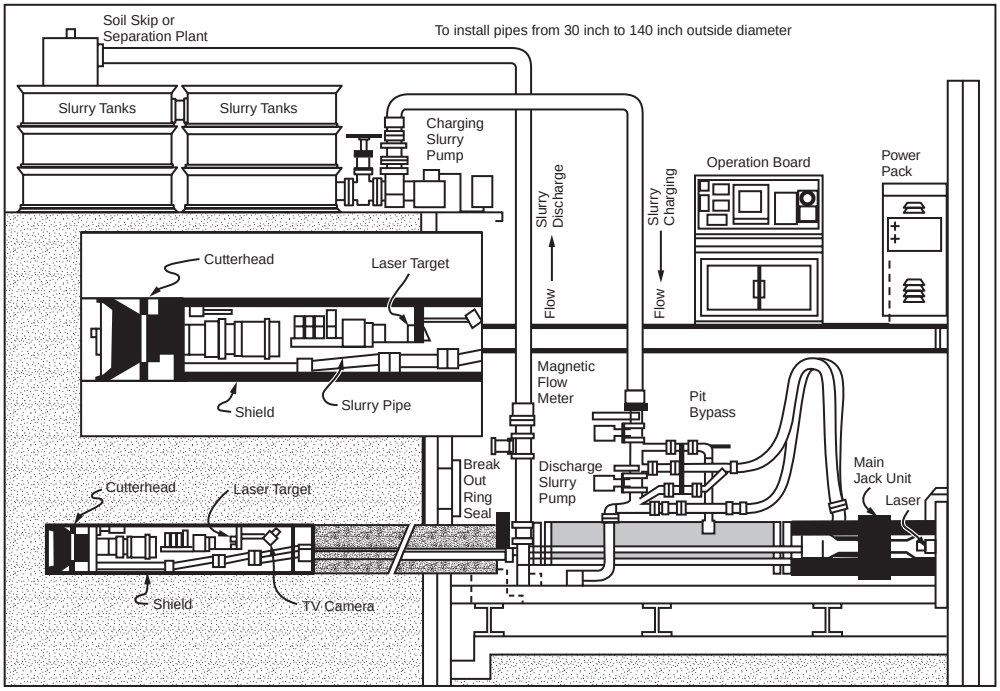

FIGURE 3.10 Slurry microtunneling system.

may operate above or below the groundwater. Each manufacturer produces unique cutting heads. These machines have been used successfully on projects where rock is encountered with unconfined compressive strength up to 30,000 psi. Also, they can handle boulders and other obstructions that are up to 30% of the diameter of the machine by incorporating crushing capability in the head. This crushing mechanism reduces the boulder to 1 in. particles that can be removed by an auger or by the slurry spoil removal system.

The boring machine also houses the articulating steering unit with steering jacks and the laser control target. Additional components that may be located in the microtunnel boring machine, depending on the type of machine, include the rock crusher, mixing chamber, pressure gauges, flow meters, and control valves.

Most machines have the capability of counterbalancing the actual earth pressure and the hydrostatic pressure independently. The actual earth pressure is counterbalanced by careful control over the propulsion system and spoil removal system. This force is carefully regulated to stay higher than the actual earth pressure but lower than the passive earth pressure so that subsidence and heave are avoided. The groundwater can be maintained at its original level by counterbalancing with slurry pressure or compressed air.

The Guidance Control System

The heart of the guidance control system is the laser. The laser provides the alignment and grade information for the machine to follow. The laser beam must have an unobstructed pathway from the drive shaft to the target located in the machine. The laser must be supported in the drive shaft so that it is independent of any movement that may take place as a result of forces being created by the propulsion system. The target receiving the laser information can be an active or passive system. The passive system consists of a target that receives the light beam from the laser; the target is monitored by a closed-circuit TV system. This information is then transferred to the operator's control panel so that any necessary

adjustments can be made. The active system consists of photosensitive cells that convert information from the laser into digital data. The data are electronically transmitted to the control panel so that the operator is provided with a digital readout pinpointing the target the laser beam is hitting. Both active and passive systems have been used extensively in the U.S. and around the world; both systems have been found to be reliable.

The Propulsion System

The microtunneling process is a pipe-jacking process. The propulsion system for the microtunneling machine and the pipe string consists of a jacking frame and jacks in the drive shaft. The jacking units have been specifically designed for the microtunneling process, offering compactness of design and high thrust capacity. That capacity ranges from approximately 100 tons to well over 1000 tons, depending on the soil resistance that must be overcome. The soil resistance includes resistance from face pressure and resistance from friction and adhesion along the length of the steering head and the pipe string. Jacking force estimates may be based on drive length, ground conditions, pipe characteristics, and machine operating characteristics, specifically on overcut and lubrication. A reliable estimate of the required jacking force is important to ensure that the needed thrust capacity will be available and that the pipe will not be overloaded.

The propulsion system provides two major pieces of information to the operator: the total force or pressure being exerted by the propulsion system and the penetration rate of the pipe being pushed through the ground. The penetration rate and the total jacking pressure generated are important for controlling the counterbalancing forces of the tunnel boring machine to maintain safe limits.

The types of pipe typically used for microtunneling include concrete, clay, steel, PVC, and centrifugally cast fiberglass-reinforced polyester pipe (GRP).

The Spoil Removal System

Microtunneling spoil removal systems can be divided into the slurry transportation system and the auger transportation system. Both systems have been used extensively in this country and abroad and have been successful. In the slurry system, the spoil is mixed into the slurry in a chamber located behind the cutting head of the tunnel-boring machine. The spoil is hydraulically removed through the slurry discharge pipes installed inside the product pipe. This material is then discharged into a separation system. The degree of sophistication of the spoil separation system is a function of the type of spoil being removed. The effluent of the separation system becomes the charging slurry for the microtunneling system; thus, the system is closed loop.

Because the slurry chamber pressure is used to counterbalance the groundwater pressure, it is important that the velocity of the flow as well as the pressure be closely regulated and monitored. Regulation is accomplished by variable speed charging and discharging pumps, bypass piping, and control valves. As a result of this capability to counterbalance the hydrostatic head accurately, these machines have worked successfully in situations with extremely high hydrostatic pressures. The machine can be completely sealed off from external water pressure, allowing underwater retrieval, as was successfully accomplished on two recent projects at Corps of Engineer's lakes. The auger spoil removal system utilizes an independent auger system in an enclosed casing inside the product pipe for spoil removal. The spoil is augered to the drive shaft, collected in a skip, and hoisted to a surface storage facility near the shaft. Water may be added to the spoil in the machine to facilitate spoil removal. However, one of the advantages of the auger system is that the spoil does not have to reach pumping consistency for removal.

The Control System

All microtunneling systems rely on remote control capability, allowing operators to be located in a safe and comfortable control cabin, typically at the surface, immediately adjacent to the drive shaft, so the

operator can visually monitor activities in the shaft. If the control cabin cannot be set up adjacent to the drive shaft for visual monitoring, a closed-circuit TV system can be set up in the shaft to allow the operator to monitor activities using a TV monitor. A key ingredient to a successful project is the operator's skill. The operator must monitor numerous bits of information continuously fed to the control panel, evaluate this information, and make decisions regarding future actions. Information relayed to the control panel is audible as well as visual, as sounds generated in the microtunneling machine are sent to the operator. Other information that must be monitored includes the line and grade of the machine, cutterhead torque, jacking thrust, steering pressures, slurry flow rates and pressures for slurry systems, and rate of advancement.

The sophistication of the control system varies from totally manual to completely automatic. With the manual system, the operator evaluates all information and makes necessary decisions regarding correcting actions. It is the responsibility of the operator to record all information at appropriate intervals during the pipe-jacking procedure. All monitoring and recording of data is automated; the computer provides a printout on the condition of the various systems at selected time intervals. Systems using fuzzy logic are available for making necessary corrections in the operational process. This allows the machine to automatically acquire, evaluate, and compare the data to corrections typically utilized for the existing condition. The machine will then make those corrections. With this system, the operator monitors the actions to ensure that the automatic corrections are those that the operator thinks are appropriate. Manual override of the automatic corrections is also possible.

The Pipe Lubrication System

The pipe lubrication system consists of a mixing tank and the necessary pumping equipment, which transmits the lubricant from a reservoir near the shaft to the application points inside the machine or along the inside barrel of the pipe. Pipe lubrication is optional but recommended for most installations, particularly for lines of substantial length. The lubricant can be a bentonite or polymer-based material. For pipe systems less than 36 in. diameter, the application point is at the machine steering head at the face of the tunnel. For sizes greater than 36 in., application points can be installed at intervals throughout the pipe. Lubrication can substantially reduce the total thrust required to jack the pipe.

Equipment Cost

The cost of the project must include the cost of equipment needed to build the project. The constructor must be able to determine, as accurately as possible, the duration of each piece of equipment required for each activity of the project. He or she must then be able to apply cost factors to this time commitment. The cost factor should represent the actual equipment cost experienced by the constructor. If the cost is too low, the equipment will not pay for itself. If the rate is too high, it may result in not being competitive. To know the true equipment cost requires accurate record keeping.

The constructor can lease equipment or purchase equipment. If equipment is leased, determining equipment cost is straightforward, because the rental rate will be established. If the equipment is to be purchased, the anticipated owing and operating (O&O) cost will need to be determined.

Associated Equipment Distributors publishes an annual compilation of nationally averaged rental rates for construction equipment. The following need to be taken into consideration when considering the leasing option:

1. **Time basis of the rates quoted —** It is common practice in the industry to base rates on one shift of 8 h/d, 40 h/week, or 176 hr/month. If these hours are exceeded, an extra fee can be charged.
2. **Cost of repairs —** The lessor usually bears the cost of repairs due to normal wear and tear, and the lessee bears all other costs. Normal wear and tear would be expected to result from the use of the equipment under normal circumstances. This can lead to disputes, because in many cases, normal wear and tear is difficult to distinguish.

3. **Operator —** Unless specifically stated otherwise, the operator is not included in the rental rates.
4. **Fuel and lubricants —** Unless specifically stated otherwise, the lessee is responsible for the cost of fuel, lubricants, and all preventive maintenance work while the equipment is being rented.
5. **Condition of equipment —** It is standard practice for the equipment to be delivered to the lessee in good operational condition and to be returned to the lessor in the same condition less normal wear and tear.
6. **Freight charges —** Unless specifically stated otherwise, the rental rates are f.o.b. the lessor's shipping point.
7. **Payment and taxes —** Normally, rental rates are payable in advance, and no license, sale, or use taxes are included in the rates.
8. **Insurance —** It is standard practice for the lessee to furnish the lessor a certificate of insurance prior to equipment delivery.

The factors influencing the calculation of owning and operating costs are investment and depreciation (ownership costs) and maintenance, repairs, lubrication, and fuel (operating costs). If a firm has similar equipment, they should have reliable historical data to help forecast the cost that should be applied to a specific piece of equipment. Many times, however, this is not the case. Therefore, the constructor must use an approximation based on assumed cost factors. Most equipment manufacturers can provide valuable assistance in selecting cost factors that should apply to the type of work being considered.

Whether rental rates or O&O costs are being utilized, they should eventually be expressed as total hourly equipment cost without operator cost. This facilitates the determination of machine performance in terms of cost per units of material. For example,

$$\text{Top machine performance} = \frac{\text{Lowest possible equipment hourly cost}}{\text{Highest possible hourly productivity}}$$

$$\text{Top machine performance} = \frac{\text{Cost/hr}}{\text{Units of material/hr}} = \frac{\text{Cost(\$)}}{\text{Units of material}}$$

Caterpillar [1993], Peurifoy and Schexnayder [2002], and *Production and Cost Estimating* [1981] contain detailed information on how to develop O&O costs. These references contain numerous examples that show how to apply specific factors.

The following is a summary of the principles presented in Peurifoy and Schexnayder [2002]:

I. Ownership costs (incurred regardless of the operational status)
   A. Investment costs
      1. Interest (money spent on equipment that could have been invested at some minimum rate of return)
      2. Taxes (property, etc.)
      3. Equipment productivity
      4. Insurance storage

Investment costs can be expressed as a percentage of an average annual value of the equipment ($\bar{p}$). For equipment with no salvage value:

$$\bar{p} = \frac{p(N+1)}{2N}$$

where p is the total initial cost and N is the useful life in years. For equipment with salvage value:

$$\bar{p} = \frac{p(N+1) + S(N-1)}{2N}$$

Example 3

Interest on borrowed money	= 12%
Tax, insurance, storage	= 8%
Total	= 20%
Investment cost	= $0.20\overline{P}$

B. Depreciation (the loss in value of a piece of equipment over time due to wear, tear, deterioration, obsolescence, etc.)

II. Operation costs
   A. Maintenance and repair
      1. Depends on type of equipment, service, care
      2. Usually taken into consideration as a ratio or percentage of the depreciation cost
   B. Fuel consumed
      1. Gas engine = 0.06 gal/FWHP-h
      2. Diesel engine = 0.04 gal/FWHP-h
   C. Lubricating oil

FWHP-h is the measure of work performed by an engine based on average power generated and duration. Two major factors that impact the FWHP-h are the extent to which the engine will operate at full power and the actual time the unit will operate in an hour.

$$\text{TF} = \text{Time factor} = \frac{50 \text{ min}}{60} \times 100 = 83.3\%$$

$$\text{EF} = \text{Engine factor} = \frac{\%\text{ of time at full load}}{\%\text{ of time at less than full load}}$$

$$\text{OF} = \text{Operating factor} = \text{TF} \times \text{EF}$$

$$\text{Fuel consumed} = \text{OF} \times \text{Rate of consumption}$$

The amount of lubricating oil consumed includes the amount used during oil changes plus oil required between changes.

$$q = \frac{\text{FWHP} \times \text{OF} \times 0.006 \text{ \#/FWHP-hr}}{7.4 \text{ \#/gal}} = \frac{c}{t} = \frac{\text{gal}}{\text{hr}}$$

where OF is the operating factor, c is the crankcase capacity in gallons, t is the number of hours between changes, and # is pound.

Example 4

Hydraulic excavator.

160 FWHP — diesel engine
Cycle time = 20 s
Filling the dipper = 5 s at full power
Remainder of time = 15 s at half power
Assume shovel operates 50 min/h

$$\text{TF} = \frac{50}{60} \times 100 - 83.3\%$$

Engine factor:

$$\begin{aligned} \text{Filling} \quad & 5/20 \times 1 = 0.25 \\ \text{Rest of Cycle} \quad & 15/20 \times .50 = \underline{0.375} \\ \text{TOTAL} \quad & 0.625 \end{aligned}$$

$$OF = TF \times EF \times 0.625 \times 0.833 = 0.520$$

$$\frac{\text{Fuel consumed}}{\text{hr}} = 0.52 \times 160 \times 0.04 = 3.33 \text{ gal / hr}$$

3.4 Preventive Maintenance

Preventive maintenance (PM) is necessary for sound equipment management and protection of a company's assets. Minimum corporate PM standards should be established. Specific maintenance procedures should be available from the equipment department on most major pieces of equipment. If specific standards are not available, the manufacturer's minimum maintenance recommendations need to be used. A functioning PM program will comprise the following:

1. The PM program will be written and have specific responsibilities assigned. Company, division, and/or area managers will have the responsibility of seeing that the program works as designed.
2. Periodic service and inspections on all equipment in operation will be performed, documented, and reported (in writing). Each division/area will implement the service and inspection using the equipment manufacturers' recommendations as guidelines. For major pieces of equipment, this will be defined by the equipment department.
3. A systematic method of scheduling and performing equipment repairs will be implemented.
4. A fluid analysis program with regular sampling (including, but not limited to, testing for aluminum, chromium, copper, iron, sodium, silicon, plus water and fuel dilution) will be implemented.
5. All necessary permits will be acquired.
6. Federal, state, and local laws that affect the trucking industry will be followed.

3.5 Mobilization of Equipment

The following are factors that should be taken into consideration to facilitate and expedite mobilization of equipment:

1. Type and size of equipment
2. Number of trucks and trailers needed to make the move
3. Rates (company charges or rental charges)
4. Equipment measurements (weight, height, width, length)
5. Permits (vary with state)
6. Federal, state, and local laws affecting the trucking industry

The purpose of mobilization is to maximize efficiency and minimize cost by using rental or company trucks. This requires research on the above items by using equipment dealer support, appropriate law enforcement agencies, and so on.

Acknowledgments

The author would like to express his sincere appreciation to Danny A. Lott for his input. He has over 18 years of professional management experience with two leading corporations in construction and

communications. For the past eight years he has been the equipment maintenance and truck operations manager for T. L. James and Company, Inc., Ruston, LA. He provided a wealth of insight into the approach and substance of this chapter.

5.1 Introduction

Engineers and architects excel in their mastery of the technical aspects of planning and design, while contractors are highly proficient in identifying cost-effective process to build complex modern structures. However, when evaluated on the basis of their knowledge of contracts, many of these professionals do not understand the importance of the contract language that forms the basis for their relationship with the owner or with each other. Even small contracts have complex contract relationships, due to increased regulation of the environment and safety. Few would argue that the proliferation of contract claims consultants and attorneys reflects positively on the ability of designers and contractors to deliver quality products without litigation. While it is commonly heard that contractors actively seek claims for profit, few reputable contractors would pursue a claim that is frivolous or subjective. Owners and design professionals reflect their heightened awareness of the potential for claims by using restrictive contract language.

This section will focus on the basics: elements of contracts, contract administration, interpretation of some key clauses, the common causes of claims, and resolution alternatives. The type of contract is an important indication of how the contracting parties wish to distribute the financial risks in the project. The discussion on interpretation of contracts presents common interpretation practices and is not intended to replace competent legal advice. Good contract administration and interpretation practices are needed to ensure proper execution of the project contract requirements. In the event that circumstances do not

evolve as anticipated, a claim may be filed to settle disputed accounts. Owners and engineers often view claims as the contractor's strategy to cover bidding errors or omissions. Those who have successfully litigated a claim are not likely to agree that claims are "profitable" undertakings. A claim is a formalized complaint by the contractor, and the contractor's right to file for the claim is an important element of contract law. In many situations, court decisions related to unresolved claims help to define new areas of contract interpretation. These disputes often relate to some particularly troublesome clause interpretation and serve to provide contract administrators additional guidance on contract interpretation.

5.2 Contracts

Sweet [1989, p. 4] describes contract formation as follows:

Generally, American law gives autonomy to contracting parties to choose the substantive content of their contracts. Because most contracts are economic exchanges, giving parties autonomy allows each to value the other's performance. To a large degree, autonomy assumes and supports a marketplace where participants are free to pick the parties with whom they deal and the terms upon which they will deal.

The terms of a contract will be enforced, no matter how harshly some language treats one of the parties. Equity or fairness is occasionally used as the basis for a claim, but the courts seldom use equity to settle a dispute ensuing from a contract relationship. The most common contract relationships created by modern construction projects are:

- The owner and contractor(s)
- The owner and design professional
- The contractor and subcontractor(s)
- The contractor and the *surety*

If the owner hires a construction manager, this creates an additional contract layer between the owner and the designer or contractor. These contracts form the primary basis of the relationship among the parties. It is important that project-level personnel as well as corporate managers understand the importance of the contract and how properly to interpret the contract as a whole.

A contract is a binding agreement between the parties to exchange something of value. Contracts are generally written, but unless there is a statutory requirement that prohibits their use, oral contracts are valid agreements. The basic elements of a valid contract are:

- Competent parties
- Offer and acceptance
- Reasonable certainty of terms
- Proper subject matter
- Consideration

Competent parties must be of a proper age to enter into a contract and must have sufficient mental capacity to understand the nature of the agreement. *Offer and acceptance* indicates that there has been a meeting of the minds or mutual assent. A contract cannot be formed if there is economic duress, fraud, or mutual mistakes. The *terms* of the contract should be clear enough that an independent third party can determine whether the two parties performed as promised. While this is rarely a problem in public construction contracts, the private industry sector has a greater potential for problems, due to more informal exchanges in determining boundaries of a contract. Contract *subject matter* must not be something that is illegal.

The last element of a valid contract is *consideration*. Contracts are generally economic exchanges; therefore, something of value must be exchanged. Consideration need not be an equal exchange. Courts will uphold seemingly unbalanced consideration if all the elements of a contract are met, and there is no evidence of fraud or similar problems.

Form of Agreement

The actual form of agreement, which describes the contracting parties' authority, the work in general, the consideration to be paid, penalties or bonuses, and time for performance, is often a brief document containing under a dozen pages. This document is seldom the issue of concern in a dispute. More commonly, the documents that detail the relationships and project requirements are the source of disagreement. Primarily, these documents for a construction project are the general conditions, special conditions, technical specifications, and plans.

Contract types can be separated according to a variety of methods. In keeping with the concept of a contract being an economic exchange, contracts can be identified as either *fixed price* or *cost reimbursable*. Fixed price contracts establish a fixed sum of money for the execution of a defined quantity of work. These contracts are often termed *hard dollar contracts*. Fixed price contracts fall into two major categories: lump sum and unit price. *Lump sum contracts* require the contractor to assume all risks assigned by the contract for their stated price. Adjustments to costs and extensions of time require a modification to the original agreement. *Unit price contracts* permit more flexibility by establishing costs relative to measurable work unit (cubic yards and square feet are examples of work units).

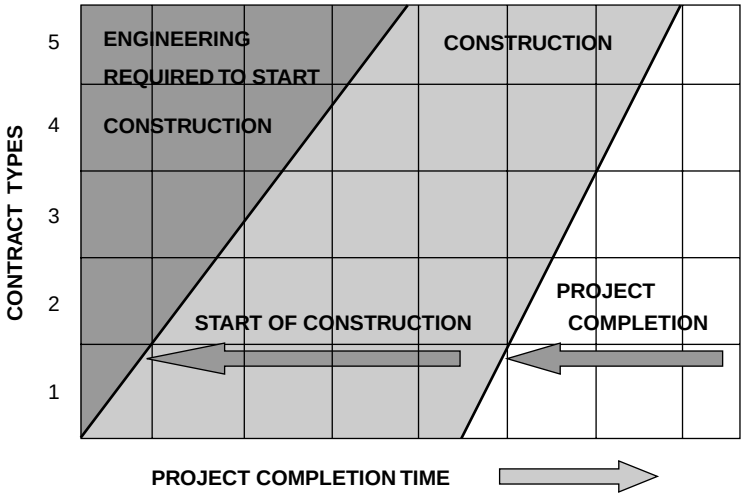
Reimbursable contracts allow for contract adjustments relative to overall project scope as determined by the cost and do not, generally, address a final fixed price. Fixed price contracts allocate more risk to the contractor and thus require more effort, money, and time on design documentation before construction is initiated. Cost-reimbursable contracts require greater risk sharing between the owner and contractor and often require more owner personnel for contract administration during the construction phase to enforce cost and schedule. Cost reimbursable contracts are more easily used for fast-tracking of design and construction. Reimbursable contracts are also flexible for changing design or scope of work and establish the basis for a less adversarial relationship between the owner and contractor [Contracts Task Force, 1986, p. 8]. Figure 5.1, from the *Construction Industry Cost Effectiveness (CICE) Project Report* portrays the time advantages associated with cost reimbursable contracts when the owner has a demand for a facility that is highly schedule-driven [CICE, 1982, p. 9]. Often, both forms of contracts exist on a project simultaneously. Prime contractors will often have cost reimbursable contracts with the owner and fixed price contracts with their subcontractors.

5.3 Contract Administration

The contractor must concentrate on constructing the project and concurrently attend to the terms of the contract documents. Contract administration involves numerous daily decisions based on interpretation of the contract documents. A record of these deliberations is important to both parties. The primary tools for controlling a project contract are the cost and schedule report updates. In addition, quality and safety reports are indicative of project administration success. Administration of the contract requires that accurate records be maintained as a permanent record of the contract process. In the event that the project manager would need to negotiate a change order, prepare a claim, or reconstruct specific events, the project data from records and correspondence are often needed. Figure 5.2 [Richter and Mitchell, 1982] emphasizes the importance of accurate records and documents. The relative priority of documents would be determined by the nature of the dispute.

Trauner [1993] places emphasis on professional information management as a necessary and cost-effective measure for reducing risk on the project. The following list highlights the importance of information management in contract management:

1. Appropriate documentation permits future users to verify how the project was built.
2. Lessons learned on the project are recorded for the benefit of future projects.
3. Continuous, contemporaneous documentation reduces the chance of misunderstanding day-to-day concerns.
4. Records prevent the loss of information otherwise left to memory.



CONTRACT TYPES

1 COST REIMBURSABLE WITH % FEE

2 COST REIMBURSABLE WITH FIXED FEE

3 TARGET PRICE

4 GUARANTEED MAXIMUM PRICE

5 LUMP SUM FIXED PRICE

FIGURE 5.1 Contract time and type comparison. *Source:* CICE (Construction Industry Cost Effectiveness Project Report). 1982. *Contractual Arrangement, Report A-7.* The Business Round Table, New York, p. 9.

5. Project personnel turnover problems can be reduced with a complete project history.
6. Written reports are the best means of keeping multiple parties informed of project progress.
7. Written reports reduce oral communications and the number of meetings.
8. Information management supports documentation and monitoring of the project.
9. Establishing defined documentation requirements assists the manager in focusing on the most important aspects of the project.

Progress Reports

Performance documentation covers a wide variety of reports and charts. The project schedule is essential for determining the status of the project at any given point in time, and it can also be used to estimate the time impact of disruptions at the project site. It is important, therefore, that the schedule be updated at frequent intervals to ensure that the actual start dates, finish dates, and percent complete are recorded.

Progress should be recorded in daily and weekly reports. Daily reports should be prepared by personnel who can report on field and office activities. Weather information, subcontractor performance, workforce data, equipment use, visitor data, meeting notations, and special or unusual occurrences are entered into a standard diary form, which is filed on-site and in the home office.

Progress reporting should include a photographic progress journal. A log of photograph dates and locations is needed to preserve the specific nature of the photograph. Photographs provide strong visual evidence of the site conditions reported in the progress reports.

The personal project diaries of superintendents also record daily activity. These records summarize key events of the day including meetings, oral agreements or disagreements, telephone discussions, and similar events. Diaries also record drawing errors, provide notations on differing conditions observed on the site, and other discrepancies. Personal project diaries should be collected at the end of the project and stored with project records.

Quality Records

Complete records of all quality tests performed on materials and reports from inspections should be retained. In addition to test results, plots or statistical analyses performed on the data should also be stored for later use. Inspection reports should be retained as an integral part of the quality recordation and documentation. Rework should be noted, and the retest results should be noted. Problems with quality and notes on corrective procedures applied should be evident in the records.

Change Order Records

Changes should be tracked by a change order record system separate from other project records. Careful attention is needed to ensure compliance with notice requirements, proper documentation of costs, and estimation of the anticipated time impact. An understanding beforehand of the change order process

and the required documentation will reduce the risk of a change order request not being approved. Change orders can have a significant impact on the progress of remaining work as well as on the changed work. Typical information included in a change request includes the specification and drawings affected, the contract clauses that are appropriate for filing the change, and related correspondence. Once approved, the change order tracking system resembles traditional cost and schedule control.

Correspondence Files

Correspondence files should be maintained in chronological order. The files may cover the contract, material suppliers, subcontracts, minutes of meetings, and agreements made subsequent to meetings. It is important that all correspondence, letters, and memorandums be used to clarify issues, not for the self-serving purpose of preparing a claim position. If the wrong approach in communications is employed, the communications may work against the author in the eventual testimony on their content. Oral communications should be followed by a memorandum to file or to the other party to ensure that the oral communication was correctly understood. Telephone logs, fax transmissions, or other information exchanges also need to be recorded and filed.

Drawings

Copies of the drawings released for bidding and those ultimately released for construction should be archived for the permanent project records. A change log should be maintained to record the issuance or receipt of revised drawings. Obsolete drawings should be properly stamped and all copies recovered. Without a master distribution list, it is not always possible to maintain control of drawing distribution. Shop drawings should also be filed and tracked in a similar manner. Approval dates, release dates, and other timing elements are important to establishing the status of the project design and fabrication process.

5.4 Reasoning with Contracts

The contract determines the basic rules that will apply to the contract. However, unlike many other contracts, construction contracts usually anticipate that there will be changes. Changes or field variations are created from many different circumstances. Most of these variations are successfully negotiated in the field, and once a determination is made on the cost and time impact, the contracting parties modify the original agreement to accommodate the change. When the change order negotiation process fails, the change effectively becomes a dispute. The contractor will commonly perform a more formal analysis of the items under dispute and present a formal claim document to the owner to move the negotiations forward. When the formal claim analysis fails to yield results, the last resort is to file the claim for litigation. Even during this stage, negotiations often continue in an effort to avoid the time and cost of litigation. Unfortunately, during the maturation from a dispute to a claim, the parties in the dispute often become entrenched in positions and feelings and lose their ability to negotiate on the facts alone. Contract wording is critical, and fortunately, most standard contracts have similar language. It is important to understand the type of dispute that has developed. Figure 5.3 was developed to aid in understanding the basic relationships among the major types of changes.

5.5 Changes

Cardinal and bilateral changes are beyond the scope of the contract. Cardinal changes describe either a single change or an accumulation of changes that are beyond the general scope of the contract. Exactly what is beyond the scope of a particular contract is a case-specific determination based on circumstances and the contract; there is no quick solution or formula to determine what constitutes a cardinal change. Cardinal changes require thorough claim development.

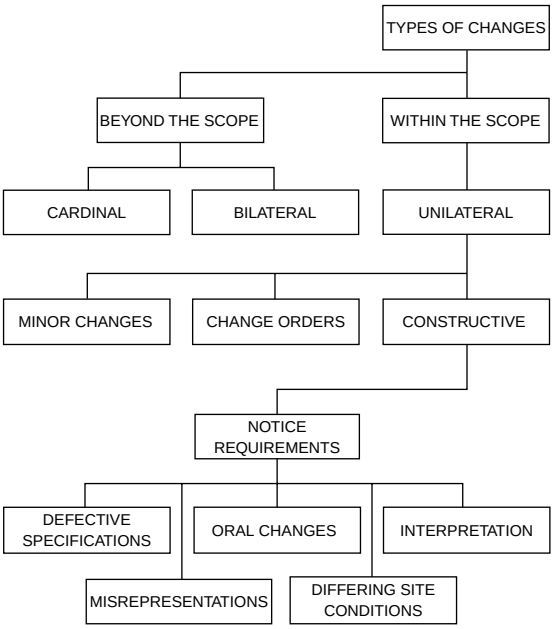

FIGURE 5.3 Types of changes.

A bilateral change is generated by the need for a change that is recognized as being outside the contract scope and, therefore, beyond the owner's capability to issue a unilateral change. A bilateral change permits the contractor to consent to performing the work required by the change or to reject the change and not perform the additional work. Bilateral changes are also called contract modifications. Obviously, the gray area between what qualifies as a unilateral change and a bilateral change requires competent legal advice before a contractor refuses to perform the work.

Several distinctions can be made among unilateral changes. Minor changes that do not involve increased cost or time can be ordered by the owner or the owner's representative. Disputes occasionally arise when the owner believes that the request is a minor change, but the contractor believes that additional time and/or money is needed. Minor changes are also determined by specific circumstances. Change orders are those changes conducted in accordance with the change order clause of the contract, and unless the change can be categorized as a cardinal change, the contractor is obligated to perform the requested work. Constructive changes are unilateral changes not considered in the changes clause; they can be classified as oral changes, defective specifications, misrepresentation, contract interpretation, and differing site conditions. However, before constructive changes can be considered in more detail, contract notice requirements must be satisfied.

5.6 Notice Requirements

All contracts require the contractor to notify the owner as a precondition to claiming additional work. The reason for a written notice requirement is that the owner has the right to know the extent of the liabilities accompanying the bargained-for project. Various courts that have reviewed notice cases agree that the notice should allow the owner to investigate the situation to determine the character and scope of the problem, develop appropriate strategies to resolve the problem, monitor the effort, document the contractor resources used to perform the work, and remove interferences that may limit the contractor in performing the work.

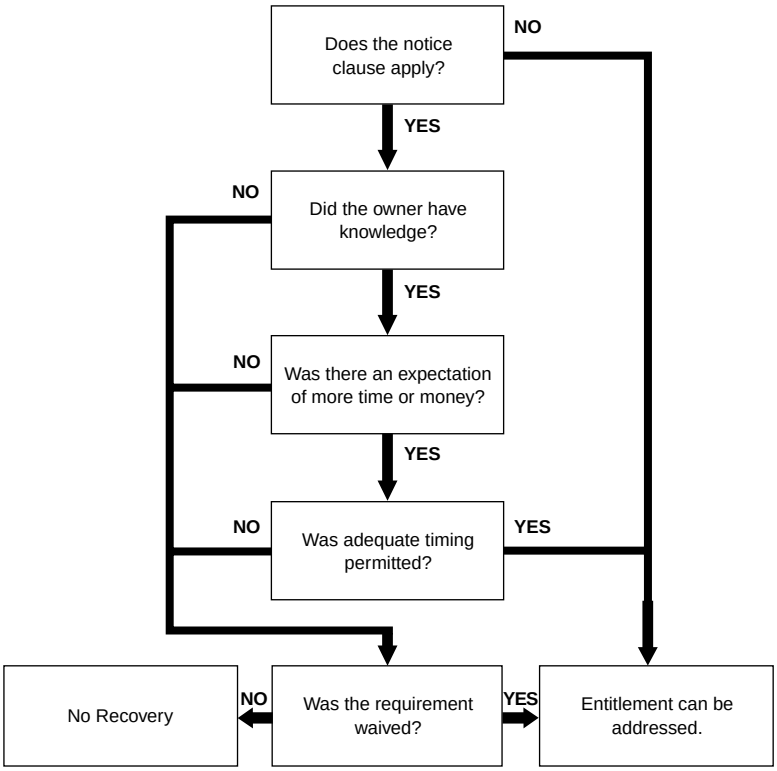

FIGURE 5.4 Notice disputes flowchart.

Contracts often have several procedural requirements for filing the notice. Strict interpretation of the notice requirements would suggest that where the contract requires a written notice, only a formal writing will satisfy the requirement. The basic elements in most contracts' change order clauses are the following:

- Only persons with proper authority can direct changes.
- The directive must be in writing.
- The directive must be signed by a person with proper authority.
- Procedures for communicating the change are stated.
- Procedures for the contractor response are defined.

Figure 5.4 is a decision analysis diagram for disputes involving notice requirements.

The applicability of the clause should be at issue only if the contract has been written such that the notice clause is only effective for specific situations. Written notice implies that a formal letter has been delivered that clearly defines the problem, refers to the applicable contract provisions, and states that the contractor expects to be compensated for additional work and possibly given additional time to complete the work. However, notice can also be delivered in other ways. Verbal statements have been found to constitute notice to satisfy this requirement. The principal issues are owner knowledge of events and circumstances, owner knowledge that the contractor expects compensation or a time extension under some provision of the contract, and timing of the communication.

Owner knowledge is further divided into actual knowledge and constructive knowledge. Actual knowledge is clear, definite, and unmistakable. Constructive knowledge can be divided into implied knowledge and imputed knowledge. Implied knowledge is communicated by deduction from the circumstances, job site correspondence, or conduct of the parties. While this may not be complete, it is generally sufficient to alert the owner that additional investigation is warranted. Evidence of owner knowledge is more

compelling if it involves a problem caused by the owner or within the owner's control. Imputed knowledge refers to situations in which proper notice is given to an individual who has the duty to report it to the person affected.

Knowledge that the contractor is incurring additional expense is not sufficient to make the owner liable for the costs. If the owner is unaware that the contractor expects payment for the additional cost, the owner may not be held liable for payment.

Notice Timing

Timing of the notice is important. If the notice is given too late for the owner to control the extent of its liability for additional costs, the court may not find that the notice requirement was satisfied. Generally, contracts will specify a time limit for submission of the notice. Slippage of time may not be meaningful if the character of the problem cannot be ascertained without passage of time. However, in some cases, the passage of time obscures some of the information, which will prevent the owner from verifying information or controlling costs.

Form of Notice

If notice was not given and evidence of constructive notice is not clear, the remaining recourse is for the contractor to show that the requirement was waived. The owner cannot insist on compliance with the contract in situations where the owner's actions have conflicted with the same requirements. If a statute requires written notice, the requirement cannot be waived. Waiver can only occur by the owner or the owner's representative.

The form of communication is usually a formal letter. Notice can occur in job site correspondence, letters, memos, and other site documents. Project meeting minutes that summarize discussions about project situations may be sufficient, provided they are accurately drafted. In some instances, CPM (critical path method) updates that show delay responsibilities have been found to constitute notice of delay because they kept the owner fully informed of progress.

5.7 Oral Changes

Oral communication is very common on construction projects. In most cases, the oral instructions are clearly understood, and no problems result from the exchange. Oral modifications may be valid even though there may be specific contract language prohibiting oral change orders. Through their consent or mutual conduct, the parties to a contract may waive the written change requirement. Therefore, the owner must be consistent in requiring that all changes be written. The contractor must also be consistent if submitting written changes; failure to provide the written change may indicate that it was a minor change and therefore no additional time or payment was expected. Any inconsistent conduct in the handling of changes will often eliminate the written requirement.

While the actions of the parties may waive a contract clause, the requirement will be upheld when there are statutory requirements for written directives. The owner must be aware of incurring additional liability. The owner may understand that the contractor is accruing additional cost but may not know the contractor is expecting the owner to pay for the additional cost. This may happen when the contractor, in some fashion, indicates that the work is being completed on a voluntary basis. However, when the owner has made an express or implied promise to pay the contractor for the work, recovery is likely. The contractor must make the owner aware at the time of the change that the owner will be expected to pay for additional costs. Acceptance of completed work is not sufficient to show that the owner agreed to pay for the work.

The person approving the change must also have the authority to act for the owner and incur the liability for the owner on the extra work. Generally, the authority is clearly written, but there are cases in which the conduct of an individual implies that he or she has authority. Contractors need to know

who has the authority to direct changes at the site. Owners, on the other hand, may appear to extend authority to someone they know does not have explicit authority, but fail to correct the action directed by the unauthorized person. Waiver of the requirements is caused by works, actions, or inactions of the owner that result in abandonment of a contract requirement. The owner must consistently require that the changes be in writing; any deviation from this requirement will result in abandonment of the clause that specifies that all changes be in writing.

5.8 Contract Interpretation

The rules for contract interpretation are well established in common law. The rules are split into two major divisions: procedural and operational. Procedural rules are the rules within which the court must operate. Operational rules are applied to assist in the interpretation of the facts in the case.

Procedural rules establish the objective of interpretation, measures for the admissibility of evidence, controls on what interpretation can be adopted, and standards for evaluating interpretations. The objective of interpretation focuses on determining the intent of the parties in the contract. Courts will not uphold hidden agendas or secret intentions. The admissibility of evidence provides the court the opportunity to look at separate contracts, referenced documents, oral agreements, and parol evidence (oral evidence provided to establish the meaning of a word or term). Courts have no right to modify the contract of the parties, and they cannot enforce contracts or provisions that are illegal or against public policy or where there is evidence of fraud [Thomas and Smith, 1993]. The last function of interpretation controls is to incorporate existing law. Generally, the laws where the contract was made will govern the contract. However, in the construction business, the performance of the contract is governed by the law where the contracted work is performed.

Operational interpretation rules are primarily those applied to ascertain the meaning of the contract. The "plain meaning rule" establishes the meaning of words or phrases that appear to have an ambiguous or unclear meaning. Generally, the words will be assigned their common meaning unless the contracting parties had intended to use them differently. A patent ambiguity is an obvious conflict within the provisions of the contract. When a patent ambiguity exists, the court will look to the parties for good faith and fair dealing. Where one of the parties recognizes an ambiguity, a duty to inquire about the ambiguity is imposed on the discovering party. Practical construction of a contract's terms is based on the concept that the intentions of the contracting parties are best demonstrated by their actions during the course of the contract.

Another common rule is to interpret the contact as a whole. A frequent mistake made by contract administrators in contract interpretation is to look too closely at a specific clause to support their position. The court is not likely to approach the contract with the same narrow viewpoint. All provisions of the contract should be read in a manner that promotes harmony among the provisions. Isolation of specific clauses may work in a fashion to render a part of the clause or another clause inoperable. When a provision may lead to more than one reasonable interpretation, the court must have a tiebreaker rule. A common tiebreaker is for the court to rule against the party that wrote the contract because they failed to clearly state their intent.

When the primary rules of interpretation are not sufficient to interpret a contract, additional rules can be applied. When language is ambiguous, the additional interpretation guides suggest that technical words be given their technical meaning with the viewpoint of a person in the profession and that all words be given consistent meaning throughout the agreement. The meaning of the word may also be determined from the words associated with it.

In the case of ambiguities occurring because of a physical defect in the structure of the contract document, the court can reconcile the differences looking at the entire contract; interpret the contract so that no provision will be treated as useless; and where a necessary term was omitted inadvertently, supply it to aid in determining the meaning of the contract. Some additional guidance can be gained by providing that specific terms govern over general terms, written words prevail over printed words, and written words are chosen over figures. Generally, where words conflict with drawings, words will normally

govern. It is possible, in some cases, that the drawings will be interpreted as more specific if they provide more specific information to the solution of the ambiguity.

The standards of interpretation for choosing between meanings are the following:

- A reasonable interpretation is favored over an unreasonable one.
- An equitable interpretation is favored over an inequitable one.
- A liberal interpretation is favored over a strict one.
- An interpretation that promotes the legality of a contract is favored.
- An interpretation that upholds the validity of a contract is favored.
- An interpretation that promotes good faith and fair dealing is favored.
- An interpretation that promotes performance is favored over one that would hinder performance.

5.9 Defective Specifications

Defective specifications are not a subject area of the contract like a differing site condition or notice requirement. However, there is an important area of the law that considers the impact of defective specifications under implied warranties. The theory of implied warranty can be used to resolve disputes originating in the specifications or the plans; the term defective specification will refer to both. The contract contemplates defects in the plans and specifications and requires the contractor to notify the designer when errors, inconsistencies, or omissions are discovered.

Defective specifications occur most frequently when the contractor is provided a method specification. A method specification implies that the information or method is sufficient to achieve the desired result. Because many clauses are mixtures, it is imperative to identify what caused the failure. For example, was the failure caused by a poor concrete specification or poor workmanship? Another consideration in isolating the cause of the failure is to identify who had control over the aspect of performance that failed. When the contractor has a performance specification, the contractor controls all aspects of the work. If a method specification was used, it must be determined that the contractor satisfactorily followed the specifications and did not deviate from the work. If the specification is shown to be commercially impractical, the contractor may not be able to recover if it can be shown that the contractor assumed the risk of impossibility. Defective specifications are a complex area of the law, and competent legal advice is needed to evaluate all of the possibilities.

5.10 Misrepresentation

Misrepresentation is often used in subsurface or differing site condition claims, when the contract does not have a differing site conditions clause. In the absence of a differing site conditions clause, the owner assigns the risk for unknown subsurface conditions to the contractor [Jervis and Levin, 1988]. To prove misrepresentation, the contractor must demonstrate that he or she was justified in relying on the information, the conditions were materially different from conditions indicated in the contract documents, the owner erroneously concealed information that was material to the contractor's performance, and the contractor had an increase in cost due to the conditions encountered. More commonly, a differing site condition clause is included in the contract.

5.11 Differing Site Conditions

One of the more common areas of dispute involves differing site conditions. However, it is also an area in which many disputes escalate due to misunderstandings of the roles of the soil report, disclaimers, and site visit requirements. The differing site condition clause theoretically reduces the cost of construction, because the contractors do not have to include contingency funds to cover the cost of hidden or latent subsurface conditions [Stokes and Finuf, 1986]. The federal differing site conditions (DSC) clause,

or a slightly modified version, is used in most construction contracts. The clause is divided into two parts, commonly called Type I and Type II conditions. A Type I condition allows additional cost recovery if the conditions differ materially from those indicated in the contract documents. A Type II condition allows the contractor additional cost recovery if the actual conditions differ from what could have been reasonably expected for the work contemplated in the contract. Courts have ruled that when the wording is similar to the federal clause, federal precedent will be used to decide the dispute. More detailed discussions of the clause can be found elsewhere [Parvin and Araps, 1982; Currie et al., 1971].

Type I Conditions

A Type I condition occurs when site conditions differ materially from those indicated in the contract documents. With a DSC clause, the standard of proof is an indication or suggestion that may be established through association and inference. Contract indications are normally found in the plans and specifications and may be found in borings, profiles, design details, contract clauses, and sometimes in the soil report. Information about borings, included in the contract documents, is a particularly valuable source because they are commonly held to be the most reliable reflection of the subsurface conditions. While the role of the soil report is not consistent, the courts are often willing to go beyond the contract document boundaries to examine the soil report when a DSC clause is present. This situation arises when the soil report is referred to in the contract documents but not made part of the contract documents. Groundwater is a common problem condition in DSC disputes, particularly where the water table is not indicated in the drawings. Failure to indicate the groundwater level has been interpreted as an indication that the water table exists below the level of the borings or that it is low enough not to affect the anticipated site activities.

The contractor must demonstrate, in a DSC dispute, that he or she was misled by the information. To show that he or she was misled, the contractor must show where his or her bid incorporated the incorrect information and how the bid would have been different if the information had been correct. These proofs are not difficult for the contractor to demonstrate. However, the contractor must also reasonably interpret the contract indications. The contractor's reliance on the information may be reduced by other contract language, site visit data, other data known to the contractor, and previous experience of the contractor in the area. If these reduce the contractor's reliance on the indications, the contractor will experience more difficulty in proving the interpretation.

Owners seek to reduce their exposure to unforeseen conditions by disclaiming responsibility for the accuracy of the soil report and related information. Generally, this type of disclaimer will not be effective. The disclaimers are often too general and nonspecific to be effective in overriding the DSC clause — particularly when the DSC clause serves to reduce the contractor's bid.

Type II Conditions

A Type II DSC occurs when the physical conditions at the site are of an unusual nature, differing materially from those ordinarily encountered and generally recognized as inherent in work. The conditions need not be bizarre but simply unknown and unusual for the work contemplated. A Type II condition would be beyond the conditions anticipated or contemplated by either the owner or the contractor. As in the Type I DSC, the contractor must show that he or she was reasonably misled by the information provided. The timing of the DSC may also be evaluated in Type II conditions. The contractor must establish that the DSC was discovered after contract award.

5.12 Claim Preparation

Claim preparation involves the sequential arrangement of project information and data to the extent that the issues and costs of the dispute are defined. There are many methods to approach development and cost of a claim, but all require a methodical organization of the project documents and analysis.

Assuming that it has been determined that there is entitlement to a recovery, as determined by consideration of interpretation guidelines, the feasibility of recovery should be determined. Once these determinations are complete, claims are generally prepared by using either a total-cost approach or an actual-cost approach.

An actual-cost approach, also called a discrete approach, will allocate costs to specific instances of modifications, delays, revisions, and additions where the contractor can demonstrate a cost increase. Actual costs are considered to be the most reliable method for evaluating a claim. Permissible costs are direct labor, payroll burden costs, materials, equipment, bond and insurance premiums, and subcontractor costs. Indirect costs that are recoverable include labor inefficiency, interest and financing costs, and profit. Impact costs include time impact costs, field overhead costs, home office overheads, and wage and material escalation costs. Pricing the claim requires identification and pricing of recoverable costs. The recoverable costs depend primarily on the type of claim and the specific causes of unanticipated expenses. Increased labor costs and losses of productivity can occur under a wide variety of circumstances. Increased costs for bonding and insurance may be included when the project has been delayed in completion or the scope has changed. Material price escalation may occur in some circumstances. In addition, increased storage costs or delivery costs can be associated with many of the common disputes. Equipment pricing can be complicated if a common schedule of values cannot be determined.

Total cost is often used when the cost overrun is large, but no specific items or areas can be identified as independently responsible for the increase. Stacked changes and delays often leave a contractor in a position of being unable to fully relate specific costs to a particular cause. The total-cost approach is not a preferred approach for demonstrating costs. A contractor must demonstrate that the bid and actual costs incurred were reasonable, costs increased because of actions by the defendant, and the nature of the losses make it impossible or highly impractical to determine costs accurately. Good project information management will improve the likelihood that the contractor can submit an actual-cost claim rather than a total-cost claim. However, due to the complexity of some projects, the total-cost approach may be the most appropriate method.

5.13 Dispute Resolution

Alternate dispute resolution (ADR) techniques have slowly gained in popularity. High cost, lost time, marred relationships, and work disruptions characterize the traditional litigation process. However, many disputes follow the litigation route as the main recourse if a significant portion of the claim involves legal issues. The alternatives — dispute review boards, arbitration, mediation**,** and minitrials — are usually established in the contract development phase of the project.

The traditional litigation process is the primary solution mechanism for many construction claims. This is particularly important if the dispute involves precedent-setting issues and is not strictly a factual dispute. The large expense of trial solutions is often associated with the cost of recreating the events on the project that created the original dispute. Proof is sought from a myriad of documents and records kept by contractors, engineers, subcontractors, and suppliers, in some cases. Once filing requirements have been met, a pretrial hearing is set to clarify the issues of the case and to establish facts agreeable to the parties.

The discovery phase of litigation is the time-consuming data-gathering phase. Requests for and exchange of documents, depositions, and interrogatories are completed during this time period. Evidence is typically presented in a chronological fashion with varying levels of detail, depending on the item's importance to the case. The witnesses are examined and cross-examined by the lawyers conducting the trial portion of the claim. Once all testimony has been presented, each side is permitted to make a summary statement. The trier of the case, a judge or jury, deliberates on the evidence and testimony and prepares the decision. Appeals may result if either party feels there is an error in the decision. Construction projects present difficult cases because they involve technological issues and terminology issues for the lay jury or judge. The actual trial time may last less than a week after several years of preparation. Due

to the high cost of this procedure, the alternative dispute resolution methods have continued to gain in popularity.

Dispute review boards have gained an excellent reputation for resolving complex disputes without litigation. Review boards are a real-time, project-devoted dispute resolution system. The board, usually consisting of three members, is expected to stay up-to-date with project progress. This alone relieves the time and expense of the traditional document requests and timeline reconstruction process of traditional discovery and analysis. The owner and contractor each appoint one member of the dispute review board. The two appointees select the third member, who typically acts as the chairman. The cost of the board is shared equally. Typically, board members are highly recognized experts in the type of work covered by the contract or design. The experience of the board members is valuable, because they quickly grasp the scope of a dispute and can provide their opinion on liability. Damage estimates are usually left to the parties to work out together. However, the board may make recommendations on settlement figures as well. Board recommendations are not binding but are admissible as evidence in further litigation.

Arbitration hearings are held before a single arbitrator or, more commonly, before an arbitration panel. A panel of three arbitrators is commonly used for more complex cases. Arbitration hearings are usually held in a private setting over a period of one or two days. Lengthy arbitrations meet at convenient intervals when the arbitrators' schedules permit the parties to meet; this often delays the overall schedule of an arbitration. Information is usually presented to the arbitration panel by lawyers, although this is not always the case. Evidence is usually submitted under the same administrative rules the courts use. Unless established in the contract or by a separate agreement, most arbitration decisions are binding. An arbitrator, however, has no power to enforce the award. The advantages of arbitration are that the hearings are private, small claims can be cost-effectively heard, knowledge of the arbitrator assists in resolution, the proceedings are flexible, and results are quickly obtained.

Mediation is essentially a third-party-assisted negotiation. The neutral third party meets separately with the disputing parties to hear their arguments and meets jointly with the parties to point out areas of agreement where no dispute exists. A mediator may point out weaknesses and unfounded issues that the parties have not clarified or that may be dropped from the discussion. The mediator does not participate in settlements but acts to keep the negotiations progressing to settlement.

Mediators, like all good negotiators, recognize resistance points of the parties. A primary role of a mediator is to determine whether there is an area of commonality where agreement may be reached. The mediator does not design the agreement. Confidentiality of the mediator's discussions with the parties is an important part of the process. If the parties do agree on a settlement, they sign an agreement contract. The mediator does not maintain records of the process or provide a report to the parties on the process.

A major concern that can be expressed about the ADR system is that it promotes a private legal system specifically for business, where few if any records of decisions are maintained, yet decisions may affect people beyond those involved in the dispute. ADR may also be viewed as a cure-all. Each form is appropriate for certain forms of disputes. However, when the basic issues are legal interpretations, perhaps the traditional litigation process will best match the needs of both sides.

5.14 Summary

Contract documents are the framework of the working relationship of all parties to a project. The contracts detail technical as well as business relationships. Claims evolve when either the relationship or the technical portion of the contract fails. While it is desirable to negotiate settlement, disputes often cannot be settled, and a formal resolution is necessary. If the contracting managers had a better understanding of the issues considered by the law in contract interpretation, perhaps there would be less of a need to litigate.

Defining Terms

Arbitration — The settlement of a dispute by a person or persons chosen to hear both sides and come to a decision.

Bilateral — Involving two sides, halves, factions; affecting both sides equally.

Consideration — Something of value given or done in exchange for something of value given or done by another, in order to make a binding contract; inducement for a contract.

Contract — An agreement between two or more people to do something, especially, one formally set forth in writing and enforceable by law.

Equity — Resort to general principles of fairness and justice whenever existing law is inadequate; a system of rules and doctrines, as in the U.S., supplementing common and statute law and superseding such law when it proves inadequate for just settlement.

Mediation — The process on intervention, usually by consent or invitation, for settling differences between persons, companies, etc.

Parol — Spoken evidence given in court by a witness.

Surety — A person who takes responsibility for another; one who accepts liability for another's debts, defaults, or obligations.

University of Wisconsin-Madison

6.1 Introduction

In the U.S., the construction industry is one of the largest industrial sectors. The expenditure on construction between 1996 and 1999 was estimated at $416.4 billion dollars, which amounts to about 4.5% of the U.S. Gross Domestic Product (GDP) [Lum and Moyer, 2000]. The construction industry's share increased from 4 to 4.5% between 1996 and 1999. In addition, over 6.8 million people are employed in the construction industry, including design, construction, remodeling, maintenance, and equipment and materials suppliers. This number represents 5.2% of the nonagricultural labor force of the U.S. [BLS, 2001]. Clearly, this enormous capital investment and expenditure and large number of employees highlight the crucial role that the construction industry plays to enhance the overall national economy of the U.S.

Despite its importance to the national economy, the U.S. construction industry faces a number of problems in safety, quality, productivity, technology, and foreign competition. To overcome these problems, automation and robotic technologies are often considered solutions [Everett and Saito, 1996; Cousineau and Miura, 1998; Warszawski and Navon, 1998]. Since 1980, significant efforts have been made to introduce automation and robotic technologies into construction. However, only specialized applications of automation and robotics have been implemented due to economic and technical considerations.

In many cases, the work site poses a significant health hazard to humans involved. Hazards are associated with work in undersea areas, underground, at high elevations, on chemically or radioactively

contaminated sites, and in regions with prevailing harsh temperatures. The U.S. construction industry continues to be the industrial sector responsible for the most occupational accidents, injuries, and fatalities. Hinze [1997] mentioned that the construction sector has generally accounted for nearly 20% of all industry worker deaths. There were 1190 fatal occupational injuries and 501,400 nonfatal injuries and illnesses in construction in 1999. Incidence rates for nonfatal injuries and illnesses were 8.6 per 100 full-time equivalent workers in construction and 6.3 per 100 full-time equivalent workers in all private industry. The accidents in the construction industry alone cost over $17 billion annually [Levitt and Samelson, 1993; BLS, 2000a, b]. Even though the incidence of injuries and fatalities has reduced by about 50% during the last three decades, the number of accidents, injuries, and deaths remains high when compared to other industries [Smallwood and Haupt, 2000]. Consequently, liability insurance for most types of construction work is costly. Replacing humans with robots for dangerous construction tasks can contribute to the reduction of these costs.

Decline in construction productivity has been reported by many studies conducted throughout the world. In the U.S., construction productivity, defined as gross product originating per person-hour in the construction industry, has shown an average annual net decrease of nearly 1.7% since 1969. The average of all industries for the same period has been a net annual increase of 0.9%, while the manufacturing industry has posted an increase of 1.7% [Groover et al., 1989]. The Bureau of Labor Statistics' (BLS) productivity index also shows the declining tendency of construction productivity. This decline in construction productivity is a matter of global concern, because of its impact on the economy's health. Recent trends have made availability of capital and innovation through the application of automated technologies the defining parameters of competitiveness in today's global economy. These trends enable projects to be constructed with improved quality, shorter construction schedules, increased site safety, and lower construction costs.

Much of the increase in productivity in the manufacturing industry can be attributed to the development and application of automated manufacturing technologies. This, combined with concern about declining construction productivity, has motivated many industry professionals and researchers to investigate the application of automation technology to construction. As a practical matter, these efforts have recognized that complete automation of construction works is not presently technically and economically feasible. Because of frequently reconfigured operations, often under severe environmental conditions, the construction industry has been slower than the manufacturing industry to adopt automation technology [Paulson, 1985].

Tucker [1990] mentioned that complaints of poor construction quality have long been traditional in the U.S. construction industry. Quality is defined as the conformance to requirements that are described in contract documents such as specifications. To meet requirements, things should be done right the first time, and rework should be avoided. Nonconformation will result in extra cost and project delay. There are several major barriers to successful quality work, such as lack of skilled workers, poorly installed equipment, poor plans and specifications, poorly defined work scope, etc. Among them, the skilled worker shortage problem is most critical. Many industrial nations, including Japan, France, Germany, and to some extent the U.S., suffer from a shortage of skilled construction labor. This trend of worker shortages in many traditional construction trades will most likely continue into the future. This will result, as it has over the past two decades, in an increase in the real cost of construction labor. These facts, together with the rapid advancement in automation and robotics technology, indicate promising potential for gradual automation and robotization of construction work.

Many experts stress that the future success of the construction industry may depend on the widespread implementation of advanced technologies. However, the construction industry is among the least advanced industries in the use of advanced technologies available for the performance of industrial processes and has lagged behind the manufacturing industry in technological improvement, innovation, and adoption. The physical nature of any construction project is a primary obstacle to meaningful work automation. In batch manufacturing, the work object is mobile though the production facility, and work tools can be stationary. The manufacturing industry is similar in size to construction, is better coordinated, and is controlled by larger corporations with in-house management, planning, design, and production

capabilities [Sanvido and Medeiros, 1990]. By contrast, in construction, the "work object" is stationary, of large dimensions, and constantly changing as work progresses, while tools are mobile, whether handheld or mechanized. In addition, construction processes are usually performed in dusty and noisy environments, preventing the use of fragile, high-precision, and sensitive electronic devices. Most construction jobs require a certain amount of on-site judgment, which automated equipment or robots cannot provide. In addition, there are many uncontrolled environmental factors on the construction site.

The investment in research and development of the U.S. construction industry is less than 0.5% of sales volume. In Japan, the largest construction companies such as Shumizu, Taisei, Kajima, Obayashi, and Takenaka invest about 1% of annual gross revenue in research and development [Cousineau and Miura, 1998]. Questions have arisen regarding the construction industry's ability to meet the demands for construction in the 21st century. To remain competitive in today's construction marketplace, the U.S. construction industry must introduce advanced technologies, in particular, construction automation and robotics technologies, in order to solve the problems mentioned above.

Construction has traditionally been resistant to technical innovation. Past efforts to industrialize construction in the U.S. were undertaken at the time when industrial automation technology was at its infancy. Additionally, engineering and economic analyses of prefabrication processes and systems were lacking. On the other hand, numerous construction tasks have or will become more attracted to automated technologies based upon the following characteristics: (1) repetitive, (2) tedious and boring, (3) hazardous to health, (4) physically dangerous, (5) unpleasant and dirty, (6) labor intensive, (7) vanishing skill area, (8) high skill requirement, (9) precision dexterity requirement, and (10) critical to productivity [Kangari and Halpin, 1989]. For example, some construction tasks have been historically noted for their arduous, repetitive nature, with relatively little dynamic decision making required on the part of a human laborer. Such tasks may include placing of concrete, placing of drywall screws, finishing of concrete, and placing of masonry block, among others. The work involved in these tasks is rather unattractive for humans. Robots, however, are applicable to these types of work tasks provided that the technology and economics are feasible.

There have been increasing demands to enhance intelligence of construction equipment and systems. Many researchers have investigated the addition of sensors and control systems to existing construction equipment. A limited amount of research, however, has been conducted in developing intelligent construction equipment and systems. For semiautonomous and autonomous equipment with great potential for impact on the construction industry, artificial intelligence (AI) is required to generate instructions and plans necessary to perform tasks in dynamically changing environments on their own.

Construction automation refers to the use of a mechanical, electrical, and computer-based system to operate and control construction equipment and devices. There are two types of construction automation:

1. Fixed construction automation
2. Programmable construction automation

Fixed construction automation involves a sequence of operations performed by equipment fixed in their locations. In other words, an automated facility, whether it is permanently indoors or temporarily on the construction site, is set up specifically to perform only one function or produce one product. In programmable construction automation, equipment has the ability to change its sequence of operations easily to accommodate a wide variety of products.

6.2 Fixed Construction Automation

Fixed construction automation is useful in mass production or prefabrication of building components such as:

1. Reinforcing steel
2. Structural steel
3. Exterior building components (e.g., masonry, granite stone, precast concrete)

Examples of Fixed Construction Automation

In this section, selected examples of fixed construction automation are highlighted.

Automated Rebar Prefabrication System

The automated rebar prefabrication system places reinforcing bars for concrete slab construction. The system consists of a NEC PC98000XL high-resolution-mode personal computer that uses AutoCAD™, DBASE III Plus™, and BASIC™ software. The information regarding number, spacing, grade and dimension, and bending shapes of rebars is found from the database generated from an AutoCAD file. This information is used by an automatic assembly system to fabricate the rebar units.

The assembly system consists of two vehicles and a steel rebar arrangement support base. Of the two vehicles, one moves in the longitudinal direction and the other in the transverse direction. The longitudinally moving vehicle carries the rebars forward until it reaches the preset position. Then, it moves backward and places the rebars one by one at preset intervals on the support base. Upon completion of placement of the rebars by the longitudinally moving vehicle, the transversely moving vehicle places the rebars in a similar manner. The mesh unit formed by such a placement of rebars is tied together automatically [Miyatake and Kangari, 1993].

Automated Brick Masonry

The automated brick masonry system, shown in Fig. 6.1, is designed to spread mortar and place bricks for masonry wall construction. The system consists of:

1. Mortar-spreading module
2. Brick-laying station

The controls of the system are centered around three personal computers responsible for:

1. Collecting and storing date in real time
2. Interfacing a stepping-motor controller and a robot controller
3. Controlling the mortar-spreading robot

A Lord 15/50 force-torque sensor is used to determine the placing force of each brick. The system is provided with an integrated control structure that includes a conveyor for handling the masonry bricks [Bernold et al., 1992].

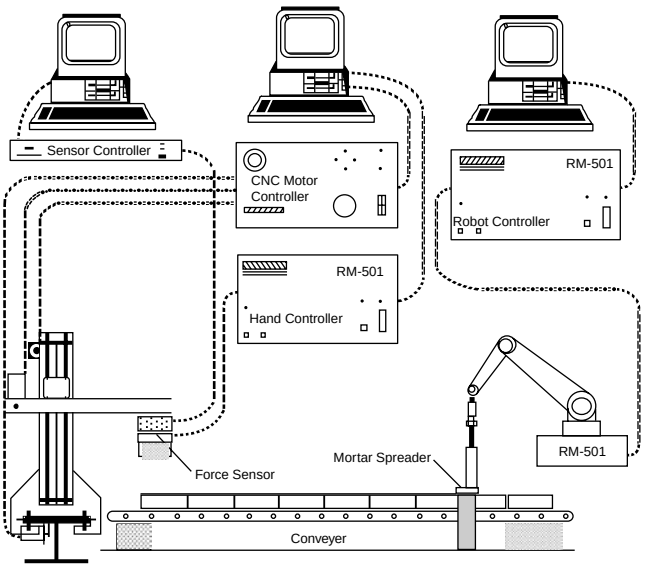

FIGURE 6.1 Automated brick masonry. (*Source:* Bernold et al. 1992. Computer-Controlled Brick Masonry. *Journal of Computing in Civil Engineering, ASCE.* 6(2):147–161. Reproduced by permission of ASCE.)

Fully Automated Masonry Plant

The fully automated masonry plant is designed to produce different brick types with the production capacity of 300 m^2 wall elements per shift. The system consists of several components: a master computer, a database server, a file server, stone cutters, masonry robots, pallet rotation systems, refinement systems, storage systems, transversal platforms, a disposition management system, an inventory management system, and a CAD system.

Two individual brick types can be managed in parallel by unloading the gripper and the cutter-system consisting of two stone saws. By conveyer systems, stone units and fitting stones are transported to the masonry robot system. The masonry robots move two bricks at each cycle to the growing wall after a mortar robot puts a layer of mortar on it. A pallet rotation system carries the wall to the drying chamber. After 48 hours, the wall is transported to destacking stations to group the wall elements of the same order. Finally, grouped wall elements are transported to the construction site [Hanser, 1999].

Automated Stone Cutting

The purpose of the automated stone-cutting facility is to precut stone elements for exterior wall facings. The facility consists of the following subsystems:

1. Raw materials storage
2. Loading
3. Primary workstation
4. Detail workstation
5. Inspection station
6. End-product inventory

A special lifting device has been provided for automated materials handling. The boom's rigidity enables the computation of exact location and orientation of the hook. Designs for the pallets, the primary saw table, the vacuum lift assembly, and the detail workstation have also been proposed [Bernold et al., 1992].

6.3 Programmable Construction Automation

Programmable construction automation includes the application of the construction robots and numerical control machines described below.

Construction Robots

The International Standards Organization (ISO) defines a robot as "an automatically controlled, reprogrammable, multi-purpose, manipulative machine with several reprogrammable axes, which may be either fixed in place or mobile for use in industrial automation applications" [Rehg, 1992]. For construction applications, robots have been categorized into three types [Hendrickson and Au, 1988]:

1. Tele-operated robots in hazardous or inaccessible environments
2. Programmed robots as commonly seen in industrial applications
3. Cognitive or intelligent robots that can sense, model the world, plan, and act to achieve working goals

The important attributes of robots from a construction point of view are their (1) manipulators, (2) end effectors, (3) electronic controls, (4) sensors, and (5) motion systems [Warszawski, 1990]. For further explanation of these attributes, refer to the definitions section at the end of this chapter.

Applications of Construction Robots

Table 6.1 presents a partial list of construction robot prototypes developed in the U.S. and in other countries. Brief summaries of several of these prototypes are provided below. Several of these descriptions have been adapted from Skibniewski and Russell [1989].

John Deere 690C Excavator

The John Deere 690C excavator is a tele-operated machine; that is, it is fully controlled by a human operating from a remote site. It is equipped with a model 60466T, six-cylinder, four-stroke turbocharged diesel engine, producing a maximum net torque of 450 ft-lb (62.2 kgf-m) at 1300 revolutions per minute (rpm) [*Technical Specifications*, 1985]. The engine propels the excavator at traveling speeds ranging from 0 to 9.8 mph (15.8 km/h).

The arm on the 690C excavator has a lifting capacity of 11,560 lb (5243 kgf) over side and 10,700 lb (4853 kgf) over end. The rated arm force is 15,900 lb (7211 kgf), and the bucket digging force is 25,230 lb (11,442 kgf) [*Technical Specifications*, 1985].

The John Deere 690C excavator has been implemented in a cooperative development program with the U.S. Air Force within the Rapid Runway Repair (RRR) project. The major task of the RRR is the repair of runways damaged during bombing raids. The Air Force is currently investigating other areas in which the 690C could be implemented, including heavy construction work, combat earthmoving in forward areas, mine-field clearing, and hazardous-material handling.

Robot Excavator (REX)

The primary task of the robot excavator (REX) is to remove pipelines in areas where explosive gases may be present. This robot is an autonomous machine able to sense and adjust to its environment. REX achieves its autonomous functions by incorporating three elements into its programming [Whittaker, 1985a]:

1. Subsurface premapping of pipes, structures, and other objects is possible using available utility records and ground-penetrating sensors. Magnetic sensing is the leading candidate for premapping metallic pipes.
2. Primary excavation for gross access near target pipes is possible. Trenching and augering are the leading candidates for this operation.
3. Secondary excavation, the fine and benign digging that progresses from the primary excavation to clear piping, can be accomplished with the use of a supersonic air jet.

The hardware that REX uses for primary excavation is a conventional backhoe retrofitted with servo valves and joint resolvers that allow the computer to calculate arm positions within a three-dimensional space. The manipulator arm can lift a 300 lb (136 kg) payload at full extension and over 1000 lb (454 kg) in its optimal lifting position.

REX uses two primary sensor modes: tactile and acoustic. The tactile sensor is an instrumented compliant nozzle. The instrumentation on the nozzle is an embedded tape switch that is activated when the nozzle is bent. The second sensor employed in excavation is an acoustical sensor, allowing for three-dimensional imaging.

Haz-Trak

Haz-Trak, developed by Kraft Telerobotics, is a remotely controlled excavator that can be fitted with a bulldozer blade for grading, backfilling, and leveling operations [Jaselskis and Anderson, 1994]. Haz-Trak uses force feedback technology, allowing the operator to actually feel objects held by the robot's manipulator. The operator controls the robot's arm, wrist, and grip movements through devices attached to his or her own arm. Thus, the robot arm instantly follows the operator's movements.

Pile-Driving Robot

The Hitachi RX2000 is a pile-driving machine directed by a computer-assisted guiding system. It consists of a piling attachment (such as an earth auger or a vibratory hammer) directly connected to the tip of a multijointed pile driver arm. The pile driver arm uses a computer-assisted guiding system called an "arm tip locus control." Coordinates of arm positions are calculated using feedback from angle sensors positioned at joints along the arm. A control lever operation system is provided to increase efficiency. The compactness of the RX2000 and its leaderless front attachment enable efficient piling work even in congested locations with little ground stabilization. Further, the vibratory hammer has a center hole

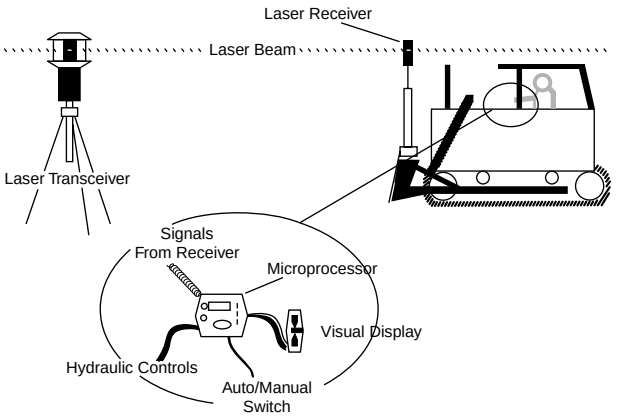

FIGURE 6.2 Laser-aided grading system. (*Source:* Tatum, C. B., and Funke, A. T. 1988. Partially Automated Grading: Construction Process Innovation. *Journal of Construction Engineering and Management, ASCE*. 114(1):19–35. Reproduced by permission of ASCE.)

chuck that firmly chucks the middle part of a sheet pile or an H-steel pile. Hence, pile length is not limited by the base machine's dump height [Uchino et al., 1993].

Laser-Aided Grading System

Spectra-Physics of Dayton, OH, developed a microcomputer-controlled, laser-guided soil-grading machine (see Fig. 6.2). A laser transmitter creates a plane of light over the job site. Laser light receptors mounted on the equipment measure the height of the blade relative to the laser plane. Data from the receiver are then sent to the microcomputer that controls the height of the blade through electronically activated valves installed in the machine's hydraulic system. A similar device has been developed by Agtek Company in cooperation with a construction contractor in California [Paulson, 1985]. An automated soil-grading process implemented by these machines relieves the operator from having to manually position and control the grading blades, thus increasing the speed and quality of grading, as well as work productivity [Tatum and Funke, 1988].

Automatic Slipform Machines

Miller Formless Systems Company developed four automatic slipform machines — M1000, M7500, M8100, and M9000 — for sidewalk and curb and gutter construction [*Technical Specifications,* 1988]. All machines are able to pour concrete closer to obstacles than is possible with alternative forming techniques. They can be custom-assembled for the construction of bridge parapet walls, monolithic sidewalk, curb and gutter, barrier walls, and other continuously formed elements commonly used in road construction.

The M1000 machine is suitable for midrange jobs, such as the forming of standard curb and gutter, sidewalks to 4 ft, and cul-de-sacs. The M7500 is a sidemount-design machine for pouring barrier walls, paved ditches, bridge parapets, bifurcated walls, and other types of light forming jobs. The M8100 is a midsize system with a sidemount design combined with straddle-paving capabilities. The machine can be extended to 16-ft (4.88-m) slab widths with added bolt-on expansion sections. The M9000 multidirectional paver is designed for larger-volume construction projects. It can perform an 18-ft (5.49-m) wide paving in a straddle position. Options are available for wider pours, plus a variety of jobs from curbs to irrigation ditches, in its sidemount mode.

Horizontal Concrete Distributor

The HCD, developed by Takenaka Company, is a hydraulically driven, three-boom telescopic arm that cantilevers from a steel column. The boom can extend 66 ft (20 m) in all directions over an 11,000-ft (1000-m) surface area. A cockpit located at the end of the distributor houses the controls for an operator

to manipulate the boom direction and flow of concrete. The weight of the robot is 4.97 tons (4508 kgf), and it can be raised along the column by jacks for the next concrete pour. On average, the relocation procedure takes only 1.5 h [Sherman, 1988].

Shotcrete Robot

Traditionally, in tunneling work, a skilled operator has been needed to regulate the amount of concrete to be sprayed on a tunnel surface and the quality of the hardening agent to be added, both of which depend on the consistency of the concrete. Kajima Construction Company of Japan developed and implemented a semiautonomous robotic applicator by which high-quality shotcrete placement can be achieved [Sagawa and Nakahara, 1985].

Slab-Finishing Robot

The robot designed for finishing cast-in-place concrete slabs by Kajima Construction Company, shown in Fig. 6.3, is mounted on a computer-controlled mobile platform and equipped with mechanical trowels that produce a smooth, flat surface [Saito, 1985]. By means of a gyrocompass and a linear distance sensor, the machine navigates itself and automatically corrects any deviation from its prescheduled path. This mobile floor-finishing robot is able to work to within 1 m of walls. It is designed to perform the work of at least six skilled workers.

Auto-Claw and Auto-Clamp

Two robotic devices used for steel beam and column erection on construction sites have been developed by Obayashi Construction Company of Japan. Both construction robots have been developed to speed up erection time and to minimize the risks incurred by steelworkers. Both have been implemented on real job sites.

The auto-claw consists of two steel clamps extended from a steel-encased unit containing a DC battery pack, electrical panel, and microprocessor unit, which is in turn suspended from a standard crane. The two clamps have a rated capacity of two tons (1.824 kgf) each and can be adjusted to fit beam flanges from 8 to 12 in. (203.2 to 304.8 mm). The clamps are automatically released by remote radio control once the beam is securely in place. Fail-safe electronic circuitry prevents the accidental release of the clamps during erection by keeping the circuit broken at such times. The steel beams require no special preparation for using this robot.

The auto-clamp's essential purpose and mechanics are the same as for the auto-claw, except that the auto-clamp uses a special electrosteel cylinder tube to secure and erect columns. A steel appendage plate with a hole in the center must be welded to one end of the column. The steel cylinder is electrically inserted and locked into the hole by remote control, whereupon the column can be erected. The auto-clamp has a rated lifting capacity of 15 tons (13,605 kg). The appendage plates must be removed after the columns are erected. Like the auto-claw, the auto-clamp is equipped with a fail-safe system preventing the cylinder from retracting from the hole during erection [Sherman, 1988].

Automated Pipe Construction

Research into automated pipe construction is under way at the University of Texas at Austin [O'Connor et al., 1987]. Research efforts are focused on developing and integrating three pipe production technologies: bending, manipulation, and welding. The pipe manipulator, shown in Fig. 6.4, was adapted from a 20-ton rough-terrain hydraulic crane with an attachment to the main boom [Hughes et al., 1989]. The attachment includes an elevating, telescoping, auxiliary boom with a wrist and pipe-gripping jaws. Associated research has concentrated on improving productivity through automated lifting and manipulating of horizontal piping [Fisher and O'Connor, 1991].

Blockbots

Another application involves the design, development, and testing of the "blockbot" robot intended to automate the placement of masonry blocks to form walls. The complete wall assembly consists of four major components [Slocum et al., 1987]:

1. A six-axis "head" that will actually place the blocks on the wall
2. A 20- to 30-ft (6- to 9.1-m) hydraulic scissors lift used to roughly position the placement head vertically and longitudinally
3. A large-scale metrology system, sensors, and other related computer control equipment
4. A block-feeding system/conveyor to continually supply the placement head

To facilitate construction, the blocks are stacked upon each other with no mortar between the levels. The wall is then surface-bonded using Surewall™, a commercial fiberglass-reinforced bonding cement. This process produces a wall with strength comparable to that of a traditional mortar wall.

Wallbots

Researchers at the Massachusetts Institute of Technology (MIT) are engaged in the Integrated Construction Automation Design Methodology (ICADM) project [Slocum et al., 1987]. This work attempts to integrate the efforts of material suppliers, architects, contractors, and automated construction equipment designers.

The process of building interior wall partitions is divided between two separate robots: a trackbot and a studbot. Circumventing the need for complex navigational systems, the trackbot is guided by a laser beacon aligned manually by a construction worker. The trackbot is separated into two parallel workstations: an upper station for the ceiling track and a lower station for the floor track. Detectors are mounted on the ends of the effector arms to ensure that the laser guidance system achieves the necessary precision. The placement of the track consists of four steps: (1) the effector arm grabs a piece of track, (2) the effector arm positions the track, (3) two pneumatic nail guns fasten the track, and (4) the trackbot moves forward, stopping twice to add additional fasteners.

Once the trackbot has completed a run of track, the studbot can begin placing studs. Location assessment is made by following the track and employing an encoding wheel or an electronic distance measuring (EDM) instrument. The studbot then references a previously sorted floor plan to ascertain locations of studs to be placed. The stud is removed from its bin and placed into position. The positioning arm then spot-welds the stud into place.

Interior Finishing Robot

An interior finishing robot, shown in Fig. 6.5, can execute the following tasks: (1) building walls and partitions, (2) plastering walls and ceilings, (3) painting walls and ceilings, and (4) tiling walls. The arm of the robot has six degrees of freedom with a nominal reach of 5.3 ft (1.6 m) and a lifting capacity of 66 lb (145 kgf). The robot is designed to perform interior finishing work in residential and commercial buildings with single or multiple floor levels and interior heights of 8.5 to 8.8 ft (2.60 to 2.70 m). A three-wheel mobile carriage measuring 2.8 ¥ 2.8 ft (0.85 ¥ 0.85 m) enables motion of the robot between static workstations [Warszawski and Navon, 1991; Warszawski and Rosenfeld, 1993].

Fireproofing Spray Robot

Shimizu Company has developed two robot systems for spraying fireproofing material on structural steel [Yoshida and Ueno, 1985]. The first version, the SSR-1, was built to (1) use the same materials as in conventional fireproofing, (2) work sequentially and continuously with human help, (3) travel and position itself, and (4) have sufficient safety functions for the protection of human workers and of building components. The second robot version, the SSR-2, was developed to improve some of the job site functions of SSR-1. The SSR-2 can spray faster than a human worker but requires time for transportation and setup. The SSR-2 takes about 22 min for one work unit, whereas a human worker takes about 51 min. The SSR-2 requires relatively little manpower for the spraying preparation — only some 2.1 person-days compared with 11.5 for the SSR-1. As the positional precision of the robot and supply of the rock wool feeder were improved, the SSR-2 could achieve the same quality of dispersion of spray thickness as for that applied by a human worker.

Exterior Wall Painting Robot

The exterior wall painting robot, shown in Fig. 6.6, paints walls of high-rise buildings, including walls with indentations and protrusions. The robot is mounted on mobile equipment that permits translational motion along the exterior wall of a building. The robot consists of the following:

1. Main body that sprays paint
2. Moving equipment to carry the robot main body to the proper work position
3. Paint supply equipment
4. A controller

The robot main body consists of the following:

1. Main frame
2. Painting gun
3. Gun driver
4. Control unit

The painting gun is driven in three principal translational directions (x, y, and z). The painting gun is also provided with two rotational degrees of freedom. The robot moving equipment consists of the following:

1. A transporter that propels the moving equipment along the outside of the building being painted
2. A work stage on which the robot main body is mounted
3. A mast that serves as a guide for raising and lowering the work stage

The top of the mast is attached to a travel fitting, and the fitting moves along a guide rail mounted on the top of the building [Terauchi et al., 1993].

Integrated Surface Patcher (ISP)

Secmar Company of France developed a prototype of the integrated surface patcher (ISP) [Point, 1988]. The unit consists of the following components:

1. A 19-ton (17,234-kgf) carrier with rear-wheel steering
2. A 3.9-yd^3 (3-m^3) emulsion tank
3. A 5.2-yd^3 (4-m^3) aggregate container
4. A built-in spreader working from the tipper tailboard (a pneumatic chip spreader with 10 flaps and a 10-nozzle pressurized bar)
5. A compaction unit

The ISP unit has a compressor to pressurize the emulsion tank and operate the chip-spreading flaps. The machine uses a hydraulic system driven by an additional motor to operate its functional modules. The electronic valve controls are operated with power supplied by the vehicle battery.

The ISP is used primarily for hot resurfacing repairs, including surface cutting, blowing and tack coating with emulsion, as well as for repairs requiring continuous treated or nontreated granular materials. The unit is suitable for deep repairs using aggregate-bitumen mix, cement-bound granular materials, and untreated well-graded aggregate, as well as for sealing wearing courses with granulates.

The current design of the ISP allows only carriageway surface sealing. It is thus not well suited for surface reshaping or pothole filling. It is used only for routine maintenance tasks. In operational terms, ISP is not capable of on-line decision making on how to proceed in the case of an irregular crack or other nonpredetermined task. However, automated patching can be started manually or automatically, depending on the presence of optical readers mounted on the equipment that read the delimiters of the work area, and on the mode of action chosen by the operator.

Autonomous Pipe Mapping

Another application is the development of an automated pipe-mapping system. Current manual methods are slow, inefficient, qualitative, and nonrepetitive. The intention of the system is to autonomously

TABLE 6.1 Example Construction Robotic Prototypes

System Description	Application	Research Center
	Excavation	
John Deere 690C	Tele-operated excavation machine	John Deere, Inc., Moline, IL
Robot excavator (REX)	Autonomous excavation, sandblasting, spray washing, and wall finishing	The Robotics Institute, Carnegie-Mellon Univ., Pittsburgh, PA
Super hydrofraise excavation control system	Excavate earth	Obayashi Co., Japan
Haz-Trak	Remotely controlled excavation	Kraft Telerobotics
Hitachi RX2000	Pile driving	Hitachi Construction Machinery Co., Japan
Remote core sampler (RCS)	Concrete core sampling for radiated settings	The Robotics Institute, Carnegie-Mellon Univ., Pittsburgh, PA
Laser-aided grading system	Automatic grading control for earthwork	Gradeway Const. Co. and Agtek Dev. Co., San Francisco, CA; Spectra-Physics, Dayton, OH
	Tunneling	
Shield machine control sytem	Collect and analyze data for controlling tunneling machine	Obayashi Co. and Kajima Co., Japan
Microtunneling machine	Tele-operated microtunneling	American Augers, Wooster, OH
Tunnel wall lining robot	Assemble wall liner segments in tunnels for sewer systems and power cables	Ishikawajima-Harima Heavy Industries, Japan; Electric Power Co., Japan; Kajima Co., Japan
	Concrete	
Automatic concrete distribution system	Carry concrete from batching plant to the cable crane	Obayashi Co., Japan
Automatic slipform machines	Placement of concrete sidewalks, curbs, and gutters	Miller Formless Systems Co., McHenry, IL; Gomaco, Ida Grove, IA
Concrete placing robot for slurry walls	Place and withdraw tremie pipes and sense upper level of concrete as it is poured	Obayashi Co., Japan
Shotcrete robot	Spray concrete tunnel liner	Kajima Co., Japan; Obayashi Co., Japan
HMC handling robot	Transport and place HMC concrete forms	Taisei Co., Japan
Rebar bending robot	Bend rebar	Obayashi Co., Japan
Rebar preassembly robot	Place and tie rebar	Shimizu Co., Japan
Rebar fabricating robot	Fabricate beam rebar, place and tie rebar	Taisei Co., Japan
Automatic concrete vibrator tamper	Vibrate cast-in-place concrete	Obayashi Co., Japan
Automatic laser beam-guided floor robot	Finish surface of cast-in-place concrete	Obayashi Co., Japan
Slab-finishing robot	Finish surface of cast-in-place concrete	Kajima Co., Japan
Rebar placing robot	Place heavy rebar	Kajima Co., Japan
Rebar installation crane	Place heavy rebar	Takenaka Co., Japan
Horizontal concrete distributor (HCD)	Place concrete for horizontal slabs	Takenaka Komuten Co., Japan
Mobile concrete distributor	Concrete distribution	Tokyu Co., Japan
CONDIS	Concrete distribution	Takenaka Co., Japan
ACSUS	Concrete distribution	Konoike Construction, Japan
CALM	Concrete leveling	Fujita Co., Japan
Mobile screeding robot	Level fresh concrete	Shimizu Co., Japan; Yanmar Diesel, Japan
Screed Robo	Level fresh concrete	Takenaka Co., Japan
Kote-King	Finish large floor areas	Kajima Co., Japan
Surf-Robo	Finish large floor areas	Takenaka Komuten Co., Japan
Flat-kun	Finish large floor areas	Shimuzu Co., Japan
Concrete floor finishing robot	Finish large floor areas	Hazama Co., Japan; Mitubishi Co., Japan; Eroika Co., Japan
Water removing robot	Remove surface water	Takenaka Co., Japan

TABLE 6.1 Example Construction Robotic Prototypes

System Description	Application	Research Center
	Structural Members	
Auto-claw, auto-clamp	Erect structural steel beams and columns	Obayashi Co., Japan
Mighty shackle ace	Handle structural steel	Shimizu Co., Japan
Structural element placement	Place reinforcing steel	Kajima Co., Japan
TAP system	Straighten structural steel	Taisei Co., Japan
Structural element welding	Weld large structural blocks for cranes and bridges	Mitsubishi Heavy Industries Co., Japan
Fujita welding robot	Weld structural steel columns	Fujita Co., Japan
Obayashi welding robot	Weld structural steel columns	Obayashi Co., Japan
Shimizu welding robot	Weld structural steel columns	Shimizu Co., Japan
Taisei welding robot	Weld structural steel columns	Taisei Co., Japan
Takenaka welding robot	Weld structural steel columns	Takenaka Co., Japan
Welding robot	Weld structural steel columns	Kajima Co., Japan; Mitsubishi Heavy Industry, Japan
Shear stud welder	Weld shear connectors in composite steel/concrete construction	Massachusetts Institute of Technology, Cambridge
Automatic carbon fiber wrapper	Wrap existing structures with carbon steel	Obayashi Co., Japan
SSR-1, SSR-2, and SSR-3	Spray fireproofing material on steel structure	Shimizu Co., Japan
Fireproof spray robot	Spray fireproofing material on steel structure	Fijita Co., Japan; Shimizu Co., Japan; Nichias Co., Japan
Automated pipe construction	Pipe bending, pipe manipulation, and pipe welding	University of Texas, Austin
Blockbots	Construction of concrete masonry walls	Massachusetts Institute of Technology, Cambridge
Wallbots	Construction of interior partitions, metal track studs	Massachusetts Institute of Technology, Cambridge
Interior finishing	Building walls and partitions, plastering, painting, and tiling walls and ceilings	Israel Institute of Technology, National Building Research Institute
	Non-concrete Spraying	
Paint-spraying robot	Paint balcony rails in high-rise buildings	Shimizu Co., Fijita Co., Kajima Co., and Taisei Co., Japan
KFR-2	Spray paint	Kumagai Co., Japan
SB Multi Coater	Spray paint	
OSR-1	Spray paint	Shimizu Co., Japan
TPR-02	Spray paint	Taisei Co., Japan
	Inspection	
Wall inspection robot (Kabedohda I and II)	Inspect reinforced concrete walls Inspect façade	Obayashi Co., Japan Kajima Co., Shimizu Construction Co., Takenaka Co., and Taisei Co., Japan
Bridge inspection robot	Inspect structural surface of a bridge	University of Wales
GEO robot	Finish façade/surface	Eureka, France
Kajima tile inspection robot	Detect bonding condition of both tile and mortar	Kajima Co., Japan
Kumagai tile inspection robot	Detect bonding condition of both tile and mortar	Kumagai Co., Japan
Takenaka	Detect bonding condition of both tile and mortar	Takenaka Co., Japan
TG-02	Detect bonding condition of both tile and mortar	Taisei Co., Japan
Pipe inspection robot	Measure pipe thickness	Mitsui Construction, Japan
Pipero	Measure pipe thickness	Obayashi Co., Japan

	Other	
Clean room inspection and monitoring robot (CRIMRO)	Inspect and monitor the amount of particles in the air	Obayashi Co., Japan
K-Creitor	Inspect clean room	Kumagai Gumi, Japan
Leak robo	Inspect clean room	Hazama Gumi, Japan
Integrated surface patcher (ISP) material handling	Hot resurfacing on highways, pick and distribute construction materials (e.g., prefabricated concrete materials and pipe)	Secmar Co., France; Tokyo Construction Co., Japan; Hitachi Construction Co., Japan
Autonomous pipe mapping	Mapping subsurface pipes	The Robotics Institute, Carnegie-Mellon Univ., Pittsburgh, PA
Terregator	Autonomous navigation	The Robotics Institute, Carnegie-Mellon Univ., Pittsburgh, PA
Remote work vehicle (RWV)	Nuclear accident recovery work, wash contaminated surfaces, remove sediments, demolish radiation sources, apply surface treatment, package and transport materials	The Robotics Institute, Carnegie-Mellon Univ., Pittsburgh, PA
ODEX III	Inspection, surveillance, material transport	Odetics, Inc., French Commissariat a l'Energie Atomique, France
CFR1	Material transport (ceiling board)	Shimizu Co., Japan
Boardman-100	Material transport (plaster board)	Taisei Co., Japan
Mighty hand	Material transport	Kajima Co., Japan
Sky hand	Material transport	Komatsu Co., Japan
Balance hand	Material transport	Komatsu Co., Japan
Lady bug	Detect underground	Tokyo Construction, Japan

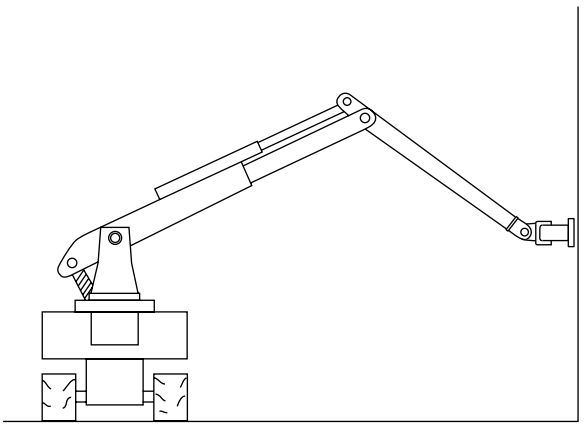

FIGURE 6.5 Interior finishing robot. (*Source:* Warszawski, A. and Navon, R. 1991. Robot for Interior-Finishing Works. *Journal of Construction Engineering and Management, ASCE.* 117(3):402–422.)

establish size, depth, and orientation of buried pipes. This knowledge is extremely valuable in guiding excavation, validating as-built drawings, and building databases of piping details [Motazed and Whittaker, 1987].

The system is composed of a computer-controlled Cartesian *x-y* table that allows various sensors to be swept across an arid area. The primary mapping is completed by a magnetic sensor that reads and records magnetic field intensities. These intensities are manipulated and interpreted, resulting in a line drawing representing the pipe locations. Higher-level processing estimates the depth of pipes and identifies interconnections such as elbows, tees, and crosses.

Terregator

A machine that may be used to transport the autonomous pipe mapping system is the terregator. Designed for autonomous outdoor navigation, it can be directly applied on a construction site. The terregator has been specifically designed to be extremely durable and powerful in order to prevent problems that inhibit machines designed for interior use. Its gearing is adjustable to allow it to be configured as a low-speed, high-torque machine or as a high-speed, low-torque machine. The terregator has a six-wheel-drive design to ensure mobility on rough terrain.

The terregator is also designed as a fully enclosed modular system to facilitate repairs, additions, or system improvements. The subsystems include locomotion, power, backup power, computer and controls, serial links, sensors, and a video link [Whittaker, 1985b].

ODEX

ODEX III, developed by Odetics, Inc., is a six-legged, tele-operated, high-strength robot designed for inspection, surveillance, and material handling in nuclear power plants and outdoor hazardous environments

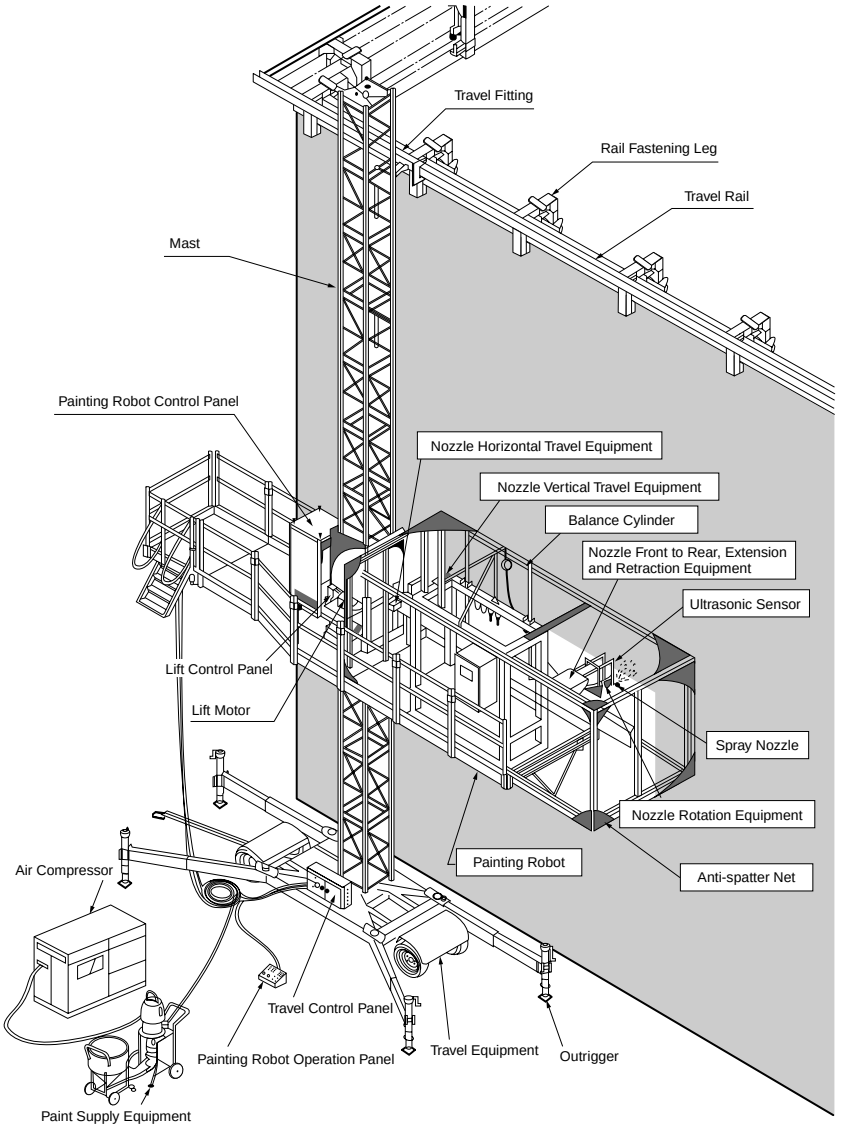

FIGURE 6.6 Exterior wall painting robot. (*Source:* Terauchi et al. 1993. Development of an Exterior Wall Painting Robot — Capable of Painting Walls with Indentations and Protrusions. *Proceedings, Tenth International Symposium on Automation and Robotics for Construction.* Houston, TX, pp. 363–370.)

[Jaselskis and Anderson, 1994]. ODEX III has telescoping legs that can extend it to a full height of 7.9 ft (2.4 m), a manipulator arm, and sensors on each foot to determine proper foot placement.

Numerical Control

Numerical control refers to control of construction equipment using numbers [Luggen, 1984]. Questions such as "What numbers are used to control a piece of equipment?" and "In what format are they presented to the equipment?" are basic to understanding numerical control. Numerically controlled equipment consists of a machine control unit (MCU) and a machine tool (such as an end effector). The MCU cannot think, judge, or reason in relation to the environment in which it works. The machine accepts and responds to commands from the control unit [Luggen, 1984]. For example, a numerically controlled

pumped-concrete placement system may use numbers corresponding to (1) position (x, y, z) of the discharging end of the placement pipe, (2) pumping pressure, and (3) the speed at which the discharging end of the placement pipe travels.

Numerical Control (NC) Programs

The numerically controlled tool concept is based on textual programming methods to describe the structural components with the help of control surfaces. The description of the structural component is taken from the architectural drawing, converted to a code, and entered on a code carrier such as a computer disk. The format of the control data and the equipment commands need to be defined in detail. The control program consists of a sequence of commands in standardized symbolic format. The control program is transferred to the MCU, which translates the program to equipment-level instructions. The equipment-level instruction may be coded on perforated paper tape (NC tape), computer cards, magnetic tape, or floppy disks [Rembold et al., 1985].

Computers are used to derive equipment-level instructions using information from the control program. For a computer to accept and process the NC program data, the input programs must conform to the exacting requirements of the programming language of the computer. Hence, the general-purpose computer must be primed to handle the specific input program. The general-purpose computer is converted to a special-purpose computer through insertion of the NC program [Maynard, 1971].

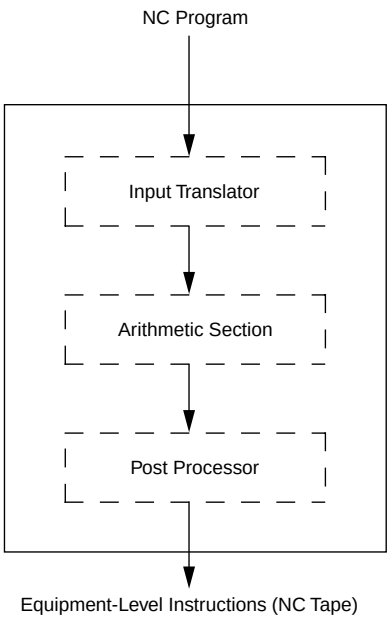

FIGURE 6.7 Software sections for NC programming processing.

The NC program, when processed by a computer, passes through three modules, as shown in Fig. 6.7. The input translator converts the NC program into a binary-coded system called machine language. Next, the machine language instructions are passed to the arithmetic section, which performs the required mathematical and geometric computations to calculate the path of the numerically controlled equipment. The post-processor checks the limitations of a particular piece of equipment (such as maximum pumping pressure or maximum velocity of the placing boom). The final output corresponds to the equipment-level instructions [Maynard, 1971].

Computer Numerical Control (CNC)

A CNC system performs control functions similar to those of the NC system. However, CNC systems can have a microcomputer or multiprocessor architecture that is highly flexible. Logic control, geometric data processing, and NC program executions are supervised by a central processing unit (CPU). Hence, CNC is a software control system that performs the following tasks using a microcomputer: (1) system management, (2) data input/output, (3) data correction, (4) control of the NC program, (5) processing of operator commands, and (6) output of the NC process variables to the display [Rembold et al., 1985].

6.4 Computer-Integrated Construction (CIC)

Computer-integrated construction (CIC) is defined as "a strategy for linking existing and emerging technologies and people in order to optimize marketing, sales, accounting, planning, management, engineering, design, procurement and contracting, construction, operation and maintenance, and support functions" [Miyatake and Kangari, 1993]. Computer-aided design/computer-aided construction (CAD/CAC) systems are a major subset of CIC that focus on design and construction issues [Kunigahalli

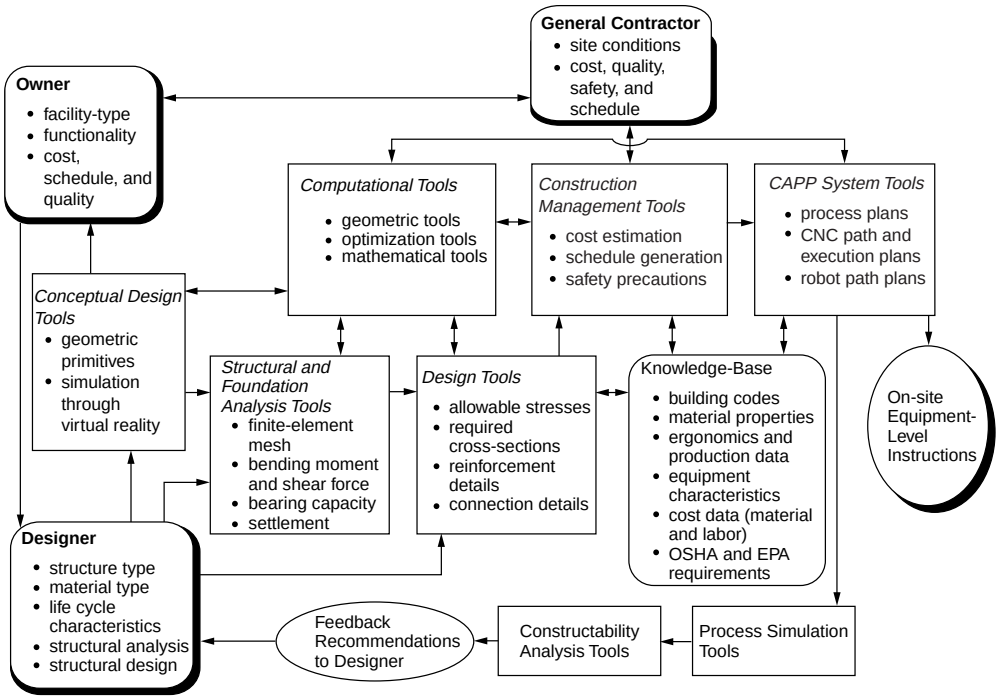

FIGURE 6.8 Framework of CAD/CAC systems.

and Russell, 1995]. Figure 6.8 presents the architecture of CAD/CAC systems. The development of CAD/CAC systems requires multidisciplinary research efforts in a variety of areas such as:

1. Computer-aided design (CAD) and geometric modeling
2. Algorithms and data structures
3. Artificial intelligence
4. Computer numerical control (CNC) and robotics
5. Group technology (GT)
6. Computer-aided process planning (CAPP)

Veeramani et al. [1998] draw attention to some of the significant research opportunities and challenges that exist in the areas of collaborative design and computer-integrated construction.

The implementation of CIC requires technologies related to (1) computer-aided engineering, (2) automatic material handling and data-identification systems, (3) network communications, (4) object-oriented programming, (5) knowledge-based systems (KBS), and (6) database management systems [Miyatake and Kangari, 1993]. Three of these areas are discussed below, followed by an example application of CIC.

Computer-Aided Design (CAD) and Geometric Modeling

Computer-aided design (CAD) can be described as using a computer in the design process. A CAD model requires graphical data processing that comprises many techniques to process and generate data in the form of lines and figures. Thus, the input representation of textual or pictorial data is performed with techniques of character and pattern recognition [Rembold et al., 1985].

Models are used to represent physical abstract entities and phenomena, not just for the purpose of making pictures (creating sectional views), but to represent their structure and behavior [Foley and Van Dam, 1982]. CAD software modeling can be classified into the following three categories: (1) basic two-dimensional and three-dimensional wire-frame modeling, (2) surface modeling, and (3) solid modeling.

Basic Two-Dimensional and Three-Dimensional Wire-Frame Modeling

In two-dimensional and three-dimensional wire-frame models, lines are stored as edges in an edge table, with each line pointing to its two end vertices stored in a vertex table. Wire-frame CAD models are not capable of recognizing the faces delineated by lines and vertices of the object being represented. Wire-frame CAD models are generally used as a substitute for manual drafting.

Surface Modeling

Surface modeling allows users to add faces to geometric models. Hence, hidden surface removal is possible in surface models. However, surface models do not contain information on the interior and exterior of the object.

Solid Modeling

A solid geometric model is an unambiguous and informationally complete mathematical representation of the physical shape of an object in a form that a computer can easily process [Mortenson, 1985]. Topology and algebraic geometry provide the mathematical foundation for solid modeling. Solid modeling's computational aspects include data structures and algorithms from computer science and application considerations from design and construction of engineering projects.

The following techniques are available for solid modeling of civil engineering facilities [Requicha, 1980]:

1. Primitive instancing
2. Cell decompositions
3. Spatial occupancy enumeration (SOE)
4. Constructive solid geometry (CSG)
5. Sweep representations
6. Boundary representation (B-Rep)

Primitive Instancing

The primitive instancing modeling technique consists of an independent approach to solid-object representation in the context of the group technology (GT) paradigm. The modeling approach is based on the notion of families of objects, with each member of the family being distinguishable by a few parameters. For example, columns, beams, and slabs can be grouped as separate families in the case of general buildings. Each object family is called a generic primitive, and individual objects within a family are referred to as primitive instances [Requicha, 1980].

Cell Decompositions

Cell decompositions are generalizations of triangulations. Using the cell decomposition modeling technique, a solid may be represented by decomposing it into cells and representing each cell in the decomposition. This modeling technique can be used for analysis of trusses and frames in industrial and general buildings, bridges, and other civil engineering facilities. In fact, the cell decomposition technique is the basis for finite-element modeling [Mortenson, 1985].

Spatial Occupancy Enumeration (SOE)

The spatial occupancy enumeration (SOE) technique is a special case of the cell decomposition technique. A solid in the SOE scheme is represented using a list of spatial cells occupied by the solid. The spatial cells, called *voxels,* are cubes of a fixed size lying in a fixed spatial grid. Each cell may be represented by the coordinates of its centroid. Cell size determines the maximum resolution. This modeling technique requires large memory space, leading to inefficient space complexity. However, this technique may be used for motion planning of automated construction equipment under complete-information models [Requicha, 1980].

Constructive Solid Geometry (CSG)

Constructive solid geometry (CSG), often referred to as building-block geometry, is a modeling technique that defines a complex solid as a composition of simpler primitives. Boolean operators are used to execute the composition. CSG concepts include regularized Boolean operators, primitives, boundary evaluation

procedures, and point membership classification. CSG representations are ordered binary trees. Operators specify either rigid motion, regularized union, intersection, or difference and are represented by nonterminal nodes. Terminal nodes are either primitive leaves that represent subsets of three-dimensional Euclidean space or transformation leaves that contain the defining arguments of rigid motions. Each subtree that is not a transformation leaf represents a set resulting from the application of the motional and combinational operators to the sets represented by the primitive leaves.

The CSG modeling technique can be adopted to develop computer-aided design and drafting (CADD) systems for civil engineering structures. It can be combined with primitive instancing that incorporates the group technology paradigm to assist the designer. Although CSG technique is most suitable for design engineering applications, it is not suitable for construction engineering applications, as it does not store topological relationships required for construction process planning [Requicha, 1980].

Sweep Representation

The sweep representation technique is based on the idea of moving a point, curve, or surface along a given path; the locus of points generated by this process results in one-dimensional, two-dimensional, and three-dimensional objects, respectively. Two basic ingredients are required for sweep representation: an object to be moved and a trajectory to move it along. The object can be a curve, surface, or solid. The trajectory is always an analytically definable path. There are two major types of trajectories: translational and rotational [Mortenson, 1985].

Boundary Representation (B-Rep)

The boundary representation modeling technique involves representing a solid's boundary by decomposing it into a set of faces. Each face is then represented by its bounding edges and the surface in which it lies. Edges are often defined in the two-dimensional parametric space of the surface as segments of piecewise polynomial curves. A simple enumeration of a solid's faces is sufficient to unambiguously separate the solid from its complement. However, most boundary representation schemes store additional information to aid feature extraction and determine topological relationships. The additional information enables intelligent evaluation of CAD models for construction process planning and automated equipment path planning required in CAD/CAC systems [Requicha and Rossignac, 1992; Kunigahalli et al., 1995; Kunigahalli and Russell, 1995].

The boundary representation technique, storing topological relationships among geometric entities, is most suitable for computer-aided generation of construction process plans. However, primitive instancing, sweep representation, and CSG techniques are useful in developing user friendly CAD software systems for the design of civil engineering structures. Hence, CAD systems that incorporate CSG or primitive instancing techniques during interactive design processes and that employ boundary representation techniques for internal storage of design information are efficient for use in CAD/CAC systems [Kunigahalli and Russell, 1995].

CAD Applications in Civil Engineering

AutoCAD

AutoCAD is the most widely used CAD software in civil engineering applications. In an effort toward computer-integrated construction (CIC), researchers have developed a link between AutoCAD and a knowledge-based planning program [Cherneff et al., 1991].

CATIA

CATIA is a three-dimensional solid modeling software marketed by IBM Corporation. Stone & Webster Engineering Corporation, in cooperation with IBM, developed an integrated database for engineering, design, construction, and facilities management. The system uses the DB2 relational database management system and the CATIA computer-aided-design software system [Reinschmidt et al., 1991].

Walkthrough™

Bechtel Corporation developed a three-dimensional simulation system called Walkthrough to aid in marketing, planning, and scheduling of construction projects. Walkthrough was developed to replace the

use of plastic models as a design tool [Cleveland and Francisco, 1988]. It was designed to allow users to interact with a three-dimensional computer model as they would with a plastic model. The system uses three-dimensional, real-time animation that lets the user visually move through the computer model and observe visual objects. Graphics of the system are presented such that objects are recognizable to users not accustomed to typical CAD images. This includes the use of multiple colors and shading. Walkthrough uses a Silicon Graphics IRIS workstation with specialized processors facilitating the high-speed graphics required for real-time animation. This visualization and simulation system supports files from IGDS (Intergraph CAD system) and 3DM [Morad et al., 1992].

Object-Oriented CAD Model

An object-oriented CAD model for the design of concrete structures that uses EUROCODE2, a European standard for concrete structures, has been developed by German researchers. The primitive instancing solid-modeling technique was employed in the development of this object-oriented model [Reymendt and Worner, 1993]. A committee, entitled "NEW TECCMAR," formed under the Japanese construction ministry, developed a three-dimensional finite-element method (FEM) program with an extended graphical interface to analyze general buildings [Horning and Kinura, 1993].

Automated Material Management

Automated material management systems are another important function of CIC. They comprise automated material identification systems and automated material handling systems.

Automated Material Identification Systems

When construction materials arrive at CIC job sites, they are identified at the unloading area, and the job site inventory database in the central computer is updated. CIC requires tight control on inventory and integrated operation of automated equipment. Further, all construction materials must be tracked from the time of their arrival at the job site to their final position in the finished facility. Such tracking of construction materials may be done by employing automated identification systems.

There are two means of tracking construction materials: direct and indirect. Direct tracking involves identifying a construction material by a unique code on its surface. This method of tracking can be employed with the use of large prefabricated components. Indirect tracking involves identifying construction material by a unique code on the material handling equipment. This method of tracking can be employed for tracking bulk materials such as paints [Rembold et al., 1985]. Select automatic identification systems for construction materials are described below.

Bar Coding

The U.S. Department of Defense (DOD) was the first organization to implement bar coding technology. The Joint Steering Group for Logistics Applications of Automated Marking and Reading Symbols (LOGMARS) spearheaded the DOD's effort in the implementation of bar coding technology. The symbology of bar codes conveys information through the placement of wide or narrow dark bars that create narrow or wide white bars. With the rise of the LOGMARS project, code 39 (also called "3 of 9" coding) has become a standard for bar coding. To date, most construction bar code applications have used the code 39 symbology [Teicholz and Orr, 1987; Bell and McCullough, 1988].

Laser beams and magnetic foil code readers are two basic technologies available for reading bar codes. Lasers offer the ability to read bar codes that move rapidly. Magnetic code readers are among the most reliable identification systems. It is possible to transmit the code without direct contact between the code reader and the write head on the code carrier. When the workpiece passes the read head, the code is identified by the code reader [Teicholz and Orr, 1987; Rembold et al., 1985].

Voice Recognition

Voice recognition provides computers the capability of recognizing spoken words, translating them into character strings, and sending these strings to the central processing unit (CPU) of a computer. The objective of voice recognition is to obtain an input pattern of voice waveforms and classify it as one of

a set of words, phrases, or sentences. This requires two steps: (1) analyze the voice signal to extract certain features and characteristics sequentially in time and (2) compare the sequence of features with the machine knowledge of a voice, and apply a decision rule to arrive at a transcription of the spoken command [Stukhart and Berry, 1992].

Vision Systems

A vision system takes a two-dimensional picture by either the vector or the matrix method. The picture is divided into individual grid elements called pixels. From the varying gray levels of these pixels, the binary information needed for determining the picture parameters is extracted. This information allows the system, in essence, to see and recognize objects.

The vector method is the only method that yields a high picture resolution with currently available cameras. The vector method involves taking picture vectors of the scanned object and storing them at constant time intervals. After the entire cycle is completed, a preprocessor evaluates the recomposed picture information and extracts the parameters of interest [Rembold et al., 1985].

Automated Material Handling Systems

Automated material handling systems play an important role in CIC. Efficient handling of construction materials, such as prefabricated and precast components, is possible through an effective automated material handling system operating in conjunction with an automated material identification system.

Towlines

A towline consists of a simple track with a powered chain that moves carts of other carriers from pickup points to assigned destinations. Towlines can be controlled by sophisticated computer electronic techniques. Towlines interface efficiently with other automated material handling systems. Automated material identification systems can be easily integrated with towline material handling systems. Optical scanners or photoelectric readers can be used at important locations and intersections along the track to read the bar-coded information attached to the cart and relay signals to the control system. The control system then routes the cart to its destination [Considine and Considine, 1986].

Underhang Cranes

There are two types of motor-driven underhang cranes: (1) single-bridge overhead cranes that can operate on multiple runways and (2) double-bridge overhead cranes that can achieve higher hook lifts with greater load-carrying capacity. A motor-driven crane consists of a track used for crane runways and bridge girders, the end trucks, the control package, a drive assembly, drive wheels, a drive line shaft, a traveling pushbutton control, and runway and cross-bridge electrification.

Power and Free Conveyor Systems

Conveyor systems allow precast or prefabricated components to be carried on a trolley or on multiple trolleys propelled by conveyors through some part of the system and by gravity or manual means through another part of the system. Conveyor systems provide the high weight capacities that are normally required in construction.

Inverted Power and Free Conveyor Systems

An inverted power and free conveyor system is an upside-down configuration of the power and free conveyor system. The load is supported on a pedestal-type carrier for complete access.

Track and Drive Tube Conveyors

Track and drive tube conveyors can be employed to transport components for prefabrication. This conveyor system consists of a spinning tube (drive tube) mounted between two rails. Carriers of prefabricated units need to be equipped with a drive wheel capable of moving between 0 and 45°. This drive wheel is positioned against the spinning drive tube. Speed of the moving component can be controlled by varying the angle of the drive wheel. When the drive wheel is in the 0° position, the carrier remains stationary. As the angle between the drive wheel and the drive tube is increased, the carrier accelerates forward.

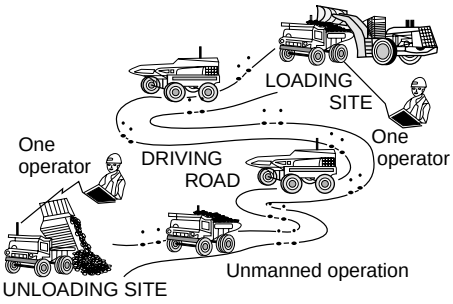

FIGURE 6.9 Autonomous dump truck system. (*Source:* Sugiyura et al. 1993. Autonomous Dump Truck Systems for Transporting and Positioning Heavy-Duty Materials in Heavy Construction Sites. *Proceedings, Tenth International Symposium on Automation and Robotics for Construction.* Houston, TX, pp. 253–260.)

Automatic Vertical Transport System (AVTS)

Fujita Corp.'s AVTS is a system under development that is designed to deliver material throughout the job site. The system uses an automated elevator system that automatically loads material onto a lift, hoists the material to the designated floor, and automatically unloads the lift [Webster, 1993].

Interlocks

Interlocks allow transfer of hoist carriers between adjacent crane runways, thereby maximizing the area covered by the overhead material handling systems. Interlocks also eliminate duplicate handling. Cross-connected, double-locking pins help to ensure that the safety stops will not operate until the crane and connecting track are in proper alignment.

Automatically Guided Vehicles

Automatically guided vehicles (AGVs) are the most flexible of all material handling equipment. AGVs can be controlled by programmable controllers, on-board microprocessors, or a central computer. Because of their lack of dependence on manual guidance and intervention, AGVs can also be categorized as construction robots. AGVs have their own motive power aboard. The steering system is controlled by signals emanating from a buried wire [Considine and Considine, 1986].

Autonomous Dump Truck System

The autonomous dump truck system, shown in Fig. 6.9, enables driverless hauling operations, such as hauling of earth and gravel by dump trucks, on heavy construction sites. The two major functions of this system are autonomous driving function and advanced measurement function.

The driving distance and velocity of the vehicle are detected by encoder sensors attached to the truck tires. Direction of the vehicle is detected by a fiber-optic gyroscope. Positions of the vehicle are determined using data from the encoder sensors and fiber-optic gyroscope.

A laser transmitter/receiver is equipped at the left side of the test vehicle, and laser reflectors are installed along the driving route at a spacing of approximately 50 m. Positional errors accumulated in long-distance driving are corrected using the feedback information from the laser transmitter/receiver. The autonomous vehicle system recognizes the workers wearing helmets by utilizing a color image processor [Sugiyura et al., 1993].

Network Communication

Communication technology, transferring information from one person or computer system to another, plays a vital role in the implementation of CIC. Establishment of an effective communications network such that originating messages receive the correct priority and accurate data arrive at the final destination is a difficult task [Miyatake and Kangari, 1993]. To ensure smooth operations in CIC, many automated devices and computers must be linked. Computer networking techniques enable a large number of computers to be connected. Computer networks can be classified as wide-area networks (WANs), which

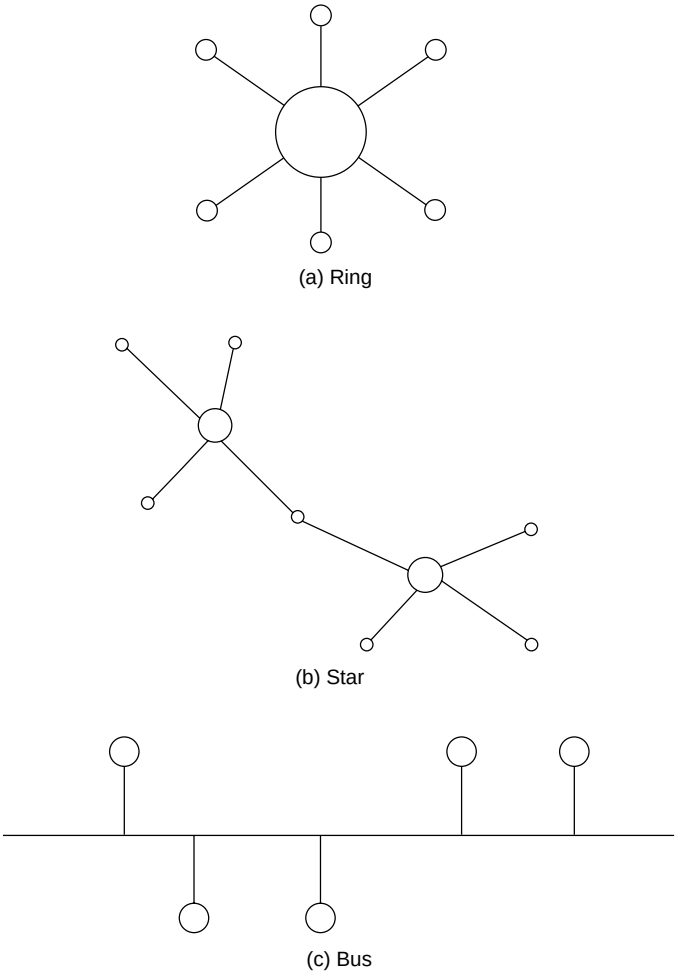

FIGURE 6.10 Three common network arrangements.

serve geometric areas larger than 10 km; local-area networks (LANs), which are confined to a 10-km distance; and high-speed local networks (HSLNs), which are confined to a distance less than 1 km.

Wide-area networks such as APPANET can be employed to connect the construction company's corporate office to various automated project sites. LANs combined with HSLNs can be employed to facilitate efficient data exchange among automated construction equipment (such as a CNC concrete placement machine, floor-leveling robots, and wall-painting robots) operating on job sites. Various gateways (computers that transfer a message from one network to another) can be used to link networks.

Three types of commonly used network arrangements — ring, star, and bus — are shown in Fig. 6.10. In a ring network arrangement, the connecting coaxial cable must be routed back to where it begins. This results in network breakdown whenever the ring breaks. The star network arrangement is easily expanded, but the network relies on a server at the center of the star. Further, all communications between nodes must pass through the center. The bus network arrangement is open-ended, and hence, a node can be added easily to the network [Chang et al., 1991].

The efficiency of a network system depends on the following parameters [Rembold et al., 1985]:

1. Transmission speed and maximum transmission distance
2. Time delay necessary to respond to interrupts and data requests
3. Additional hardware and software needed for expansion

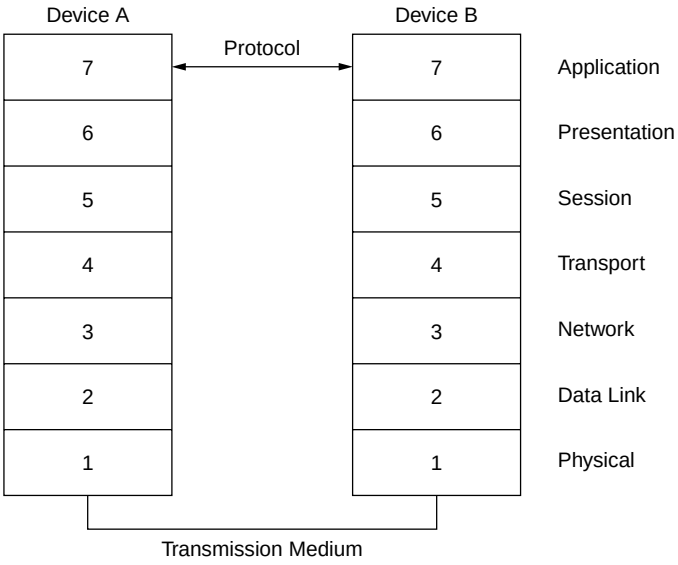

FIGURE 6.11 Open Systems Interconnect (OSI) model developed by ISO.

4. Reliability, fault tolerance, and availability
5. Unique logic structure
6. Standard plug-in principle
7. Possible geographic distribution of communication processes
8. Cost of the system components

In an attempt to enable network communications using computers and devices from different vendors, the International Standards Organization (ISO) developed a model for LANs called the Open System Interconnect (OSI) model, which is shown in Fig. 6.11. The OSI splits the communication process into seven layers as described below:

1. **Physical layer —** The physical layer corresponds to electrical and mechanical means of data transmission. It includes coaxial cable, connectors, fiber optics, and satellite links.
2. **Data link layer —** Functions of this layer include resolution of contention for use of the shared transmission medium, delineation and selection of data addressed to this node, detection of noise, and error correction.
3. **Network layer —** This layer is responsible for establishing, maintaining, and terminating connections. Further, this layer enables internetwork routing using a global standard for assigning addresses to nodes.
4. **Transport layer —** This layer provides a network-independent service to the session, presentation, and application layers. Loss or duplication of information is also checked by this layer.
5. **Session layer —** This layer controls the dialogue between applications and provides a checkpoint and resynchronizing capability. In case of network interruptions during the communication session, this layer provides a means to recover from the failure.
6. **Presentation layer —** This layer is responsible for verifying the syntax of data exchanged between applications. Thus, it enables data exchanges between devices using different data encoding systems.
7. **Application layer —** This layer corresponds to a number of applications such as CAD/CAC systems, construction robots, NC or CNC machines, and computer graphic interfaces. This is the most complex layer and ensures that data transferred between any two applications are clearly understood [Chang et al., 1991].

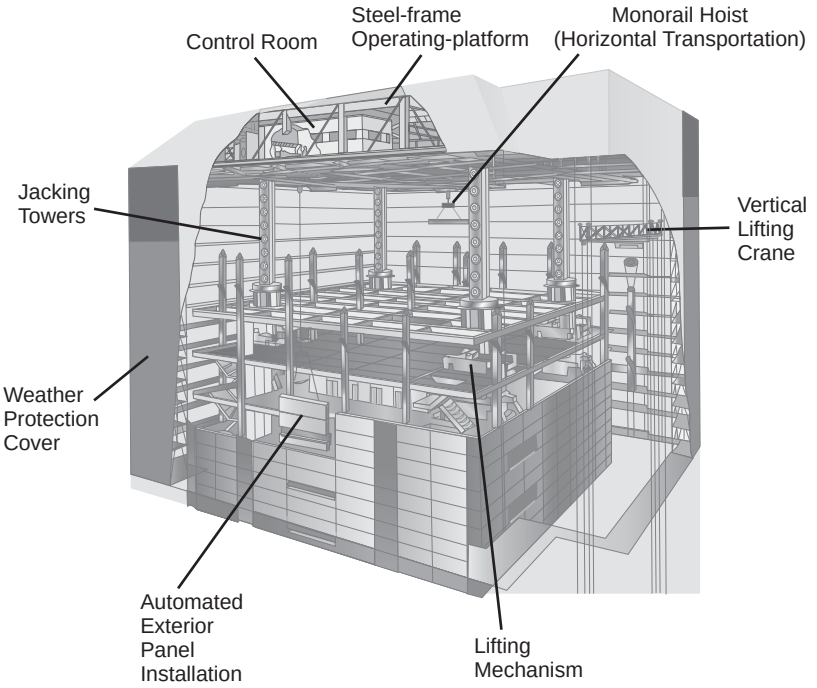

FIGURE 6.12 Shimizu's Manufacturing by Advanced Robotic Technology (SMART) system. (*Source:* Miyatake, Y. and Kangari, R. 1993. Experiencing Computer Integrated Construction. *Journal of Construction Engineering and Management, ASCE*. 119(2):307–323. Reproduced by permission of ASCE.)

Example Application of Computer-Integrated Construction

The SMART system, shown in Fig. 6.12, is part of an overall CIC strategy. The SMART system integrates high-rise construction processes such as erection and welding of steel frames, placement of precast concrete floor slabs, and exterior and interior wall panel installation.

In the SMART system, steel-frame columns and beams are automatically conveyed to designated locations. Assembly of these structural components is greatly simplified by using specially designed joints.

The SMART system consists of an operating platform, jacking towers, a vertical lifting crane, and weather protection cover. The operating platform is an automated assembly system and consists of a computer-control room, monorail hoists for automated material handling, and a structural steel frame that eventually becomes the top roof of the building. Upon completion of the foundation activity, the operating platform is assembled and mounted on top of the four jacking towers of the lifting mechanism. After completion of construction work in each floor of the building, the entire automated system is lifted by vertical jacks. Thus, the automated construction work is performed, floor by floor, until the entire building is completed [Miyatake and Kangari, 1993].

6.5 Toward Advanced Construction Automation

In this section, four emerging technologies and equipment path planning, which can be adapted to implement cognitive or intelligent construction robots and systems, are described. Selected examples of recent applications and research on automation and robotic technologies in building construction and civil engineering works are also presented.

Emerging Technologies

There are several emerging technologies that can be adapted to implement cognitive or intelligent construction robots and systems. The intelligent construction robots and systems cannot be successful without efficient and proper real-time monitoring and controlling of inputs and outputs about environment and construction equipment itself [Kim and Russell, 2001]. Other industries, such as the mechanical and manufacturing industries, are the valuable sources of these technologies. Although some technologies from other industries are not directly suitable for the construction industry, a little modification will satisfy the needs. This section will briefly review four technologies, namely, (1) distributed artificial intelligence, (2) global positioning system (GPS), (3) sensor and sensing technology, and (4) wireless communication technology.

Distributed Artificial Intelligence

DAI is a subfield of artificial intelligence (AI). It is concerned with solving problems by applying both artificial intelligence techniques and multiple problem solvers [Decker, 1987]. The world of DAI can be divided into two primary arenas: Distributed Problem Solving (DPS) and Multi-Agent System (MAS). Research in DPS considers how the work of solving a particular problem can be divided among a number of modules, or nodes, that cooperate at the level of dividing and sharing knowledge about the problem and about the developing solution [Smith and Davis, 1981]. In MAS, research is concerned with coordinating intelligent behavior among a collection of autonomous intelligent agents and with how they can coordinate their knowledge, goals, skills, and plans jointly to take action or to solve problems.

There are some reasons why the DAI concept is appropriate for intelligent construction systems. First, due to possible changes in the initial conditions, the replanning of almost all task execution is often necessary. Equipment breakdowns, accidents, and other unexpected conditions are some causes of changing the initial plan. DAI can provide an effective way to deal with these kinds of changes. Second, several agents that have distributed and heterogeneous functions are involved in field operation at the same time. They should perform tasks in a cooperative manner. DAI can provide insights and understanding about interaction among agents in the construction site in order to solve problems. In addition, data from these agents should be interpreted and integrated. Third, every agent has different capacity and capability. This implies that there are a great number of possible agent combinations that are time and cost effective to perform given tasks. Fourth, it is easy to decompose tasks for field operations. An example of tasks involved in earthwork operations are stripping, hauling, spreading, and compacting.

Global Positioning System (GPS)

The global positioning system (GPS) is a worldwide satellite-based navigation system operated and maintained by the U.S. Department of Defense. GPS provides several important features, including its high position accuracy and velocity determination in three dimensions, global coverage, all-weather capability, continuous availability to an unlimited number of users, accurate timing capability, ability to meet the needs of a broad spectrum of users, and jam resistance [Leick, 1990].

Currently, GPS is used in various fields ranging from avionics, military, mapping, mining, and land surveying, to construction. One example of construction application is SiteVision™ GPS system, which is an earthmoving control system developed by Trimble Navigation Ltd. With horizontal and vertical accuracies better than 30 mm, it allows the machine operator to work to design specifications without the use of pegs, boards, or strings. This system can give the operators all the necessary direction for precise grade, slope, and path control. Planned grade is achieved in fewer passes with less rework. With the SiteVision™ GPS system, accurate earthmoving operations take less time with lower fuel and maintenance costs on large-scale earthmoving projects [Phair, 2000; Trimble Navigation Ltd., 2001]. There is another possible application for construction equipment. An equipment motion strategy for the efficient and exact path for earthwork operations can be determined by GPS position data with preplanned motion models.

Sensor and Sensing Technology

A sensor is a device or transducer that receives information about various physical effects, such as mechanical, optical, electrical, acoustic, and magnetic effects and converts that information into electrical signals. These electrical signals can be acted upon by the control unit [Warszawski and Sangrey, 1985]. Construction equipment's ability to sense its environment and change its behavior on that basis is important for an automated system. Without sensing ability, construction equipment would be nothing more than a construction tool, going through the same task again and again in a human-controlled environment. Such a construction tool is commonly used for construction operation currently, and certainly has its place and is often the right economic solution. With smart sensors, however, construction equipment has the potential to do much more. It can perform given tasks in unstructured environments and adapt as the environment changes around it. It can work in dirty and dangerous environments where humans cannot work safely. The sensor technologies are used for real-time positioning, real-time data collection during operation, equipment health monitoring, work quality verification and remediation, collision-free path planning, and equipment performance measurement.

Wireless Communication Technology

Wireless communication can be defined as a form of communication without using wires or fiber optic cables over distance by the use of arbitrary codes. Information is transmitted in the form of radio spectrum, not in the form of speech. So, information can be available to users at all time, in all places. The data transmitted can represent various types of information such as multivoice channels, full-motion video, and computer data [IBM Corp., 1995].

Wireless communication technology is important for the intelligent construction systems, because equipment moves from place to place on a construction site, and data and information needed should be exchanged between construction equipment agents in real time. With wireless communication technology, communication is not restricted by harsh construction environments due to remote data connection, and construction equipment agents and human operators can expect and receive the delivery information and services no matter where they are on the construction site, even around the construction site.

Construction Robot Path Planning

The purpose of a path planning method for a construction robot is to find a continuous collision-free path from the initial position of the robot to its target position. Several path-planning approaches have been suggested and applied to automated navigation of construction robots.

The research on robot path planning can be categorized into two models that are based on different assumptions about the available information for planning: path planning with complete information and path planning with incomplete information. The first model assumes that a construction robot has perfect information about itself and its environment. Information, which fully describes the sizes, shapes, positions, and orientations of all obstacles in two-dimensional or three-dimensional space, is known. Because complete information is assumed, path planning is a one-time and off-line operation [Lumelsky and Stepanov, 1987; Lumelsky and Skewis, 1988]. Latombe [1991] categorizes path planning with complete information into three general approaches: road map, cell decomposition, and potential field method.

In the second model, an element of uncertainty is present, and the missing data is typically provided by some source of local information through sensory feedback using an ultrasound range or a vision module [Lumelsky and Skewis, 1988]. A robot has no information on its environment except a start position and a target position. The sensory information is used to build a global model for path planning in real time. The path planning is a continuous on-line process. The construction and maintenance of the global model based on sensory information requires heavy computation, which is a burden on the robot [Kamon and Rivlin, 1997].

There are two approaches for path planning with incomplete information based on the way the sensory information is incorporated in the path planning. One approach separates path planning from the functions of scene reconstruction. Another approach, called dynamic path planning, integrates sensory ability into the path planning function [Lumelsky and Skewis, 1988].

In the first approach, the whole environment or a part of it is reconstructed based on the sensor data, and then a path is generated using a path-planning algorithm. However, this approach requires large computational load to reconstruct and maintain the environmental model. Thus, it is difficult to implement.

Under the dynamic planning approach, the mobile robot makes a decision on its next step at each point based on the sensory information. Initially, the mobile robot moves toward the target. When the robot encounters an object, it follows the boundary of the obstacle. If a leaving condition holds, it leaves the boundary of the obstacle and resumes its movement to the target [Kamon and Rivlin, 1997]. This approach minimizes the computational load, because the robot memorizes some points such as the start, current, hit, and target points to generate its next path. Table 6.2 shows the dynamic path planning algorithms that are mostly Bug algorithm based.

TABLE 6.2 Algorithms for Path Planning in an Unknown Environment

Researchers	Algorithms

The performance of algorithms can be measured by two evaluation criteria: the total path length and path safety. Kamon and Rivlin [1997] state that path safety should be considered while evaluating path quality. They suggest that minimal distance between the robot and the surrounding obstacles from every location along the path can be used for measuring path safety. The bigger the average distance, the safer the path. However, it is difficult to do a direct comparison between algorithms, because the performance changes based on different environments.

Examples of Recent Research and Applications

Building Construction Domain

From the late 1980s, Japanese contractors began to explore the application of manufacturing principles to construction, because they began to understand that single-task automation could not provide big payoffs. By 1991, they achieved the first full-scale application of construction automation for building construction [Cousineau and Miura, 1998]. Some construction automation systems are listed in Table 6.3. These systems adapt the just-in-time principle for material delivery, bar-coding technology for tracking and placing delivered materials, and information technology for monitoring and coordinating construction processes. In these systems, the numbers of single-task robots are used, efforts for integrating single-task robots are made, and more construction processes are automated. These construction systems have four fundamental elements: an on-site factory protected by an all-weather enclosure, an automated jacking system, an automated material-conveying system, and a centralized information-control system [Cousineau and Miura, 1998].

Civil Engineering Works Domain

Many of the recently developed systems for civil works are intelligent assistant tools that enhance operators' ability to sense, plan, and monitor their works in real time. These tools integrate human operators and construction machines into a whole effective construction system. Tele or automated systems may be the only feasible alternative, when construction operations are performed in hazardous environments. In many cases, the cost of protecting human operators or workers may exceed the cost of developing tele or automated systems.

TABLE 6.3 Construction Automation Systems for Building Construction

System Description	Project Year	Company
Push-Up	1989–91, 1993–95	Takenaka Co., Japan
SMART (Shimizu Manufacturing System by Advanced Robotics Technology)	1991–94, 1994–97	Shimizu Co., Japan
ABCS (Automated Building Construction System)	1991–94	Obayashi Co., Japan
T-Up (Totally Mechanized Construction System)	1992–94	Taisei Co., Japan
MCCS (Mast Climbing Construction System)	1992–94, 1995–98	Maeda Co., Japan
AKWTSUKI 21 (Automated weather-unaffected building construction system)	1994–96	Fujita Co., Japan
AMURAD (Automatic Up-Rising Construction by Advanced Technique)	1995–96	Kajima Co., Japan
Big Canopy	1995–97	Obayashi Co., Japan

Source: Modified from Cousineau and Miura, 1998.

Semiautonomous Dump Truck System

To overcome worker shortage problems and to prevent accidents on heavy construction sites, an autonomous dump truck system was developed by Saito et al. [1995]. The aim of HIVACS is to develop a semiautonomous dump truck system that has adaptability for changing surroundings such as long-distance driving, high-speed driving, driving within road width, and change of route, etc., with comprehensive peripheral facilities. According to the report, this system enables two operators to manage five dump trucks without truck drivers and results in a labor saving 17% at the studied dam construction site.

Tele-Earthwork System

Sakoh et al. [1996] developed the Tele-Earthwork System to provide a fail-safe, automated system to assist both older and unskilled laborers, and to save labor. It is a remote-control system that can perform a series of earthwork functions such as digging, loading, transporting, and disposal. In this system, an earthwork equipment control room is installed at a safe location away from the harmful and dangerous environment. An operator performs a series of earthwork tasks in the control room while observing equipment status and in-process tasks through three-dimensional images on the screen. All information is transmitted via a mobile radio relay car. This proposed system was applied to a full-scale earthwork project.

Automated Landfill System

A conceptual framework for an automated landfill system (ALS) was developed by Tserng et al. [1996], Tserng [1997], and Tserng et al. [2000]. The research focused on space model development and management, mapping and positioning methods, and equipment motion planning. The properties and location of job-site space are recorded into nodes of the quadtree data structure. In order to avoid collision with obstacles and other equipment, which are transformed to represent the locus of forbidden positions, the equipment becomes a point in the transformed geometric model called configuration space (CSpace). The quadtree-cube geometric model is employed for recording several CSpace in one quadtree structure. After the quadtree-cube system is established, the specific quadtree network is extracted for each piece of equipment. Then, this system uses the k-shortest path algorithm to traverse the quadtree network.

Autonomous Excavator

A pure autonomous excavator is being developed by Carnegie Mellon University. The range of automation covers the whole excavation process from bucket path planning to material dump on a truck. It has a high-level planner that determines where and how to excavate, and a local-optimal planner that decides the shape of each dig [Stentz et al., 1998].

GPS-Based Guiding System

Pampagnin et al. [1998] developed an operator-aiding system for the real-time control of the positioning of road construction compactors. The main goal of this system was to assist the compactor operator in the road compaction task, by helping him to perform the exact number of passes, at the right speed,

everywhere on the surface to be compacted. GPS, optical fiber gyrometer, and advanced filtering techniques were used for a civil engineering machine for the first time.

Computer Integrated Road Construction

Peyret [1999] and Peyret et al. [2000] conducted a study on the computer integrated road construction (CIRC) project that aims to develop CIC systems for the real-time control and monitoring of task operations performed by road construction equipment. These systems mainly rely on CAD data established during the design phase and during the construction in real time. CIRC products, the one for the compactors and the one for the asphalt pavers, can provide good tools for operator assistance, machine control, and quality assessment and ensuring. They showed the benefits of new technologies applied to road construction works.

Laser-Based System

Haoud [1999] described a laser-based system for earthwork applications. On the construction machine and on both sides of the blade, electric receivers are installed on two guide masts that send signals to the control system to notify the status of the blade. The construction machine is equipped with a manual checking device, which is used for machine calibration and checking operation results, and a swivel-head laser emitter, which defines a virtual plane. This virtual plane is parallel to the future plane for the pavement. The laser-based system offers the quality improvement of the end result due to lower tolerance levels and better evenness of the surface. With this system, it is possible to save manpower significantly and increase productivity greatly.

Automated System for Quality Control of Compaction Operations

In road construction, the number of passes of compactors will directly affect the density of asphalt pavement, when roller frequency, wheel load, and compactor speed are kept constant. For this reason, monitoring the exact number of passes over the entire surface of pavement is important. An automated system for mapping compaction equipment using GPS technology and an algorithm was developed. It can find the exact number of passes at each point in the roadway and graphically depict the number of passes of compactors (Oloufa et al., 1999).

Automated Earthmoving Status Determination

Present research conducted by the National Institute of Standards and Technology (NIST) is focused on developing automated, nonintrusive production-measurement systems and procedures for monitoring the status of general earthmoving operations. The effort of the research includes the development of methods for automated registration of 2–1/two-dimensional range data, for automated volume calculation, and for web-based three-dimensional site simulators. Information on terrain changes in one location is sent via wireless Ethernet to another location to display the instant terrain geometry and to perform cut and fill calculations [Stone et al., 2000].

Open Communication System

Recently, information technology and communication technology have been rapidly expanding and growing. They offer better possibilities for automation and robotization in earthmoving and road construction. The effective and efficient automation with mobile construction equipment can be possible by effective data communication between electronic components and systems equipped with mobile construction machines. The University of Magdeburg, Germany, conducted a study on an open communication system (CANopen) for mobile construction equipment, which offers higher flexibility and extensive safety and control mechanisms. As a result of the integrated connection among sensors, actuators, and electronic systems, new possibilities are created for automation and robotization in construction [Poppy and Unger, 2000].

Computer Aided Earthmoving System (CAES)

There is a commercially available system for assisting human operators, a Computer Aided Earthmoving System (CAES) introduced by Caterpillar Inc. (2001). CAES integrates planning and design operations.

CAES consists of on-board computers, software, GPS, and data radios and receivers, which replace the manpower and time-intensive processes associated with conventional surveying. CAES allows engineers to transmit planning and designs wirelessly to the machine's on-board computer. The machine operator can get information on where the machine is in the design area, what the current surface is, and where the final surface is. The operator uses this information to see where to cut and fill and by how much. The machine progress is measured and recorded to update information for the operator and is transmitted to the office for analysis and documentation. Caterpillar is continuing to develop advanced technology products. These products include radio data communications, machine monitoring, diagnostics, job and business-management software, and machine control that can be used for automated construction systems.

Intelligent Earthwork System

Kim [2001] developed a framework for an intelligent earthwork system (IES). This framework defines the architecture and methodologies to serve as the foundation for developing an IES. The IES enables multiple pieces of equipment to automatically generate earthwork plans for construction robots and perform the given operations. The proposed framework defines the architecture and methodologies to serve as the foundation for developing an IES, such as a construction agent model for IES, a task identification and planning method for effective task execution, a resource allocation method in order to maximize equipment utilization, and a dynamic path planning algorithm to avoid collisions in the construction site.

6.6 Economics

Three major factors contributing to economic benefits of construction automation are productivity, quality, and savings in skilled labor [Kangari and Halpin, 1989]. These benefits must be weighed against the costs of automation, including initial investment and operating costs; these are further described in Table 6.4. Economic data resulting from analyses of several robot applications and automated systems are described below.

Automated Stone Cutting

Benefits of a partially automated stone-cutting mill were assessed through computer simulation [Hijazi et al., 1988]. In comparison to traditional stone-cutting methods, simulation of the automated system resulted in a 74% increase in productivity and 42% less time to process identical orders.

Steel Bridge Deck Welding

The economic implications of using robot welders in steel bridge deck fabrication were studied by Touran and Ladick [1988]. Using the robot welders in the fabrication shop was predicted to reduce fabrication costs by 5.6%.

TABLE 6.4 Costs Associated with Construction Robotics

Initial Investment Costs	Robot Operating Costs
Research and development	On-site programming
Engineering personnel	Software adaptation
Product testing	Labor cost (technicians)
Robot components	Electricity
Control hardware	System dismantling and re-setup
	Robot transporting costs
	Maintenance and repair

Excavation

Most reports related to construction automation indicate improvement in productivity and quality. In one particular instance, the development and use of partially automated laser-guided grading equipment not only improved productivity of fine grading operations, but also increased the contractor's flexibility in managing its fleet. The contractor gained a major competitive advantage that contributed to the contractor's growth from an annual volume of $500,000 in 1976 to over $50,000,000 in 1984 [Tatum and Funke, 1988].

Large-Scale Manipulators

Use of large-scale manipulators (LSMs) can reduce the amount of non-value-added tasks and increase productivity. According to a case study by the Construction Industry Institute, LSMs have high potential for industrial construction. They can be used for elevated concrete placement, painting, and sandblasting, as well as pipe, cable tray, and structural steel erection. These tasks on average constitute 33% of total project work-hours [Hsieh and Haas, 1993].

Results from a productivity analysis performed by videotaping identical pipe-handling operations by a pipe manipulator and a telescopic rough-terrain crane indicate a shorter cycle time for the pipe manipulator [Hsieh et al., 1993].

Interior Finishing Robot

A performance study of an interior-finishing robot indicated that the net productivity of the robot can reach 10–19 m^2/h in a one-layer coating and 8–8.5 m^2/h in a dry (mortarless) building. These figures are four to five times higher than for an average construction worker. Wages of $25 per hour, 1500 to 2000 hours of robot usage per year, suitable site conditions, and proper organization of material packaging can result in savings of 20 to 50% in the cost of interior finishing work [Warszawski and Navon, 1991; Warszawski and Rosenfeld, 1993].

Exterior Building Finishers

Results from an outdoor experiment using a tile-setting robot indicate a setting efficiency of 14 m^2/day, with an average adhesive strength of 17.2 kg/cm, representing improved productivity and quality [Kikawada et al., 1993].

Automated Slab Placing and Finishing

According to a study on automated concrete placement and finishing [Moselhi et al., 1992], automation of placing and finishing concrete slabs would require a minimum annual work volume of 144,321 m^2 (1,600,000 ft^2) of pavement in order to be more economical than the conventional manual process. Thus, at present, the sizable capital cost of the initial investment precludes smaller paving contractors from considering automation.

Shimizu's SMART System

Shimizu Corporation's experience with the SMART system includes improved productivity, attractive working environment, all-weather protection, higher quality and durability, reduced construction schedule duration, and reduced amount of waste and damage to materials. Upon further advancement of the SMART system, a 50% reduction in construction duration is expected [Miyatake and Kangari, 1993].

Obayashi's ABCS

The evaluation of ABCS system shows that when cranes were operated automatically, a 30% reduction in power was achieved. During construction, sound measurement indicated a marked improvement in

the work environment at the factory floor level. The work environment was also improved by the all-weather sheeting [Cousineau and Miura, 1998].

Maeda's MCCS

Observations made during construction included 30% reduction in manpower, significant reduction in waste, and 20% reduction in the cycle time to complete one story. As workers learn how to use the MCCS, more reduction in manpower and schedule is expected [Cousineau and Miura, 1998].

Obayashi's Big Canopy

Big Canopy is the first automated system to improve overall productivity. Use of this system resulted in 60% reduction in labor for frame election and reduction in material cost [Cousineau and Miura, 1998].

Kajima's AMURAD

According to observations on the use of AMURAD, significant improvement is achieved: (1) 30% reduction in construction time, (2) 50% reduction in manpower, (3) 50% reduction in waste, (4) more predictable schedule by using the all-weather protective sheeting, and (5) more comfortable environment for workers [Kajima Corporation, 1996].

6.7 Summary

A brief description of construction industry characteristics followed a discussion on the importance of construction automation. Fixed construction automation was defined, and selected examples of fixed construction automation were provided. Following this, programmable automation including robotic and numerical control applications were described. Computer-integrated construction (CIC), which provides an intelligent approach to planning, design, construction, and management of facilities, requires emerging technology that encompasses research efforts from a variety of engineering and computer science disciplines. A detailed description of CIC and supporting areas that play important roles in implementing CIC was provided. Some emerging technologies and equipment path planning, which can be adapted to implement cognitive or intelligent construction robots and systems, are described. Finally, selected examples of recent applications and research on automation and robotic technologies in building construction and civil engineering works are presented.

Defining Terms[1]

Electronic controls — Computer-based hardware units designated to control and coordinate the positions and motions of manipulator arms and effectors. A controller is always equipped with manipulator control software, enabling an operator to record a sequence of manipulator motions and subsequently play back these motions a desired number of times. More sophisticated controllers may plan entire sequences of motions and tool activators given a desired work task.

End effectors — Tools and devices on automated construction equipment, including discharge nozzles, sprayers, scrapers, grippers, and sensors. The robot tools are usually modified compared with tools used by human workers or even specially designed to accommodate unique characteristics of the working machine.

Manipulators — Stationary, articulated arms that are essential components of industrial robotics. The role of a manipulator arm is to move an effector tool to the proper location and orientation

[1] *Source:* Adapted from Hunt, V.D. 1983. *Industrial Robotics Handbook*. Industrial Press, New York.

relative to a work object. To achieve sufficient dexterity, arms typically require six axes of motions (i.e., six degrees of freedom), three translational motions (right/left, forward/back, up/down), and three rotational motions (pitch, roll, and yaw).

Motion systems — Systems that enable the essential features of mobility and locomotion for construction equipment. A variety of mobile platforms can support stationary manipulator arms for performance of required tasks. An example selection of automatically guided vehicle (AGV) platforms is presented in Skibniewski [1988]. However, most automated tasks supported by AGVs in construction will require modified control systems and larger payloads than those in automated factories.

Sensors — A device for converting environmental conditions into electrical signals. An environmental condition might be a mechanical, optical, electrical, acoustic, magnetic, or other physical effect. These effects may occur with various levels of intensity and can be assessed quantitatively by more sophisticated sensors. These measurements are used to control robot movements and, in advanced robots, to plan operations. Sensors are important to robotics in construction because they instantaneously convey elements of the building environment to the control unit.

7.1 Introduction

This chapter deals with several concepts that will help improve value in the design and construction phases of a project. These are value engineering, constructability, and quality management. The essence of each of these concepts is as follows:

- **Value engineering** — To deliver the required functions of a component or product at lowest cost while meeting quality, performance, and reliability specifications
- **Constructability** — To integrate construction knowledge and experience in project planning, design, and execution to better achieve project outcomes
- **Quality management** — To deliver quality with the view of customer satisfaction in all operations

Each of these concepts involves systematic approaches and will require some changes in management perspectives to fully realize the benefits from their implementation. The key principles for each of these concepts will be elaborated in turn. Their methodologies will also be presented.

7.2 Value Engineering

Basic Concepts

The concept of value engineering (VE) was born out of necessity almost immediately after World War II when, as a result of wartime shortages, substitute materials were used in innovative designs that offered better performance at lower costs. Much of this happened in the General Electric Company under the attention of Harry Erlicher, the Vice President of Manufacturing. Eventually, in 1947, Lawrence Miles, a staff engineer with the company, was assigned to formalize the approach. The program saved millions

of dollars for the company. To replicate the success, value engineering became a mandatory requirement in the Armed Services Procurement Regulations (ASPR) in 1962. Subsequently, it was introduced to two of the largest contracting companies in the U.S., namely, the U.S. Army Corps of Engineers and the U.S. Navy Bureau of Yards. Eventually, its use spread to other companies and contracting agencies posing similar successes.

Essentially, VE is a systematic approach to eliminate any unnecessary cost of an item that does not add to its required function. It does not simply reduce cost by using cheaper substitutes or lesser quantities. Instead, its methodology centers on the following questions: What must it do? What alternative material or method can perform the same function equally well? This is function analysis: the principal component in VE. Thus, in a construction project, VE involves analyzing the functional requirements of components, subsystems, and even construction methods.

The other aspects of VE are cost and worth. Total cost is the objective to be minimized in any value engineering exercise, while worth represents the minimum costs to achieve the required functions. Worth forms the means for generating alternatives and serves as the baseline against which various alternatives can be compared. Any reduction in unnecessary cost represents the savings achieved.

Methodology

The formal approach for value engineering is often referred to as the job plan. The VE job plan comprises several phases. Generally, although there are possible variations, the following five form the essence of the job plan (see Fig. 7.1):

1. **Information phase** — Getting the facts
2. **Speculation phase** — Brainstorming for alternatives
3. **Analysis phase** — Evaluating the alternatives
4. **Development phase** — Developing the program
5. **Recommendation phase** — Selling the recommendations

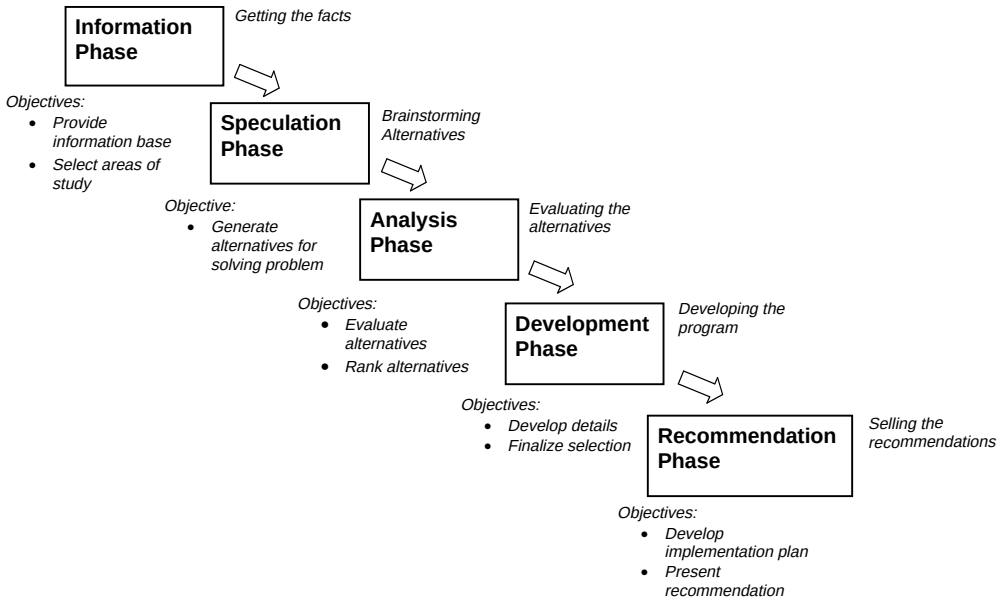

FIGURE 7.1 Phases in the value engineering job plan.

Information Phase

One objective of this phase is to determine and evaluate the function(s) of the items that have the greatest potential for eliminating unnecessary cost. This answers the question "what *must it do?*." The function analysis approach is one method to achieve this (Dell'Isola, 1982). It employs a verb-noun description of the function, for example, the function of a non-load-bearing wall may be defined to be "*enclose space*," where *enclose* is the verb and *space* the noun. In function analysis, the focus is on why an item is necessary (i.e., its function performance) rather than on the item per se. This paves the way for substituting with cheaper alternative ways to achieve the same function(s) in the latter phases.

All the functions identified are classified as either basic or secondary. The basic function of an item is the primary purpose the item must achieve to fulfill the owner's requirement. A secondary function, on the other hand, is not an essential feature to the owner and usually arises from a particular design configuration that makes the item look better. Sometimes, however, a secondary function may be required by regulatory or building codes. In this case, it is still a critical function essential to the performance of the item. The categorization of the functions enables costs incurred for the nonessential secondary functions to be isolated from those required to provide the basic functional performance. In this way, the number of secondary functions with its associated costs can be reduced (or eliminated) without compromising required owner's functions. Moreover, focus can be placed on alternatives to reduce the cost of providing the basic functions.

The next objective is to determine the cost and worth of the various functions identified. The worth of an item is the lowest cost to perform the basic and required secondary functions, while nonessential secondary functions are not assigned any worth. The cost/worth ratio is an indication of the functional efficiency of the item. A high cost/worth is also indicative of the potential for reaping improvements in value.

The Function Analysis Systems Technique (FAST) originally developed by Charles Bytherway in 1965, has been widely used to determine the relationship between functions of an entire system, process, or complicated assembly. A FAST diagram gives graphical representation of the interrelation of functions and their costs and is an excellent technique to use for this phase.

Other information required at this stage may include the following:

- Constraints that still apply at this stage
- Constraints that are unique to the system
- Frequency of use of item
- Alternative designs considered in the earlier concept

Speculation Phase

The sole objective in this phase is to generate various alternative methods of achieving the same functions, answering the question "*what else will satisfy the same needed functions?*" Creative thinking techniques are used to produce as many ideas as possible. The idea in this stage is not to leave out any possible solution. Alternatives will only be evaluated in the next phase.

There are several techniques that can be adopted in this process. Brainstorming is the most popular of these. It is based on the principle that ideas are generated in large numbers if the group is diversified. With a large number of ideas, there is an increased probability of getting good ideas. Some of these may arise spontaneously, whereas others may be derived from building upon those already proposed. At all times, no criticism or evaluation can be offered. All ideas are documented and categorized for later evaluation.

Other group techniques (Jagannathan, 1992) that can be used include:

- **Checklist** — The checklist comprises a set of questions or points. They provide idea clues to the VE team. For example, can the material of the item be changed?
- **Morphological analysis technique** — There are two steps in the technique. The first is to identify all the parameters or characteristics of the item. The next step is to seek alternatives in each

characteristic. These characteristics can then be blended in a variety of ways to improve the basic performance of the item.

- **Delphi method** — This technique uses written questionnaires. It is advantageous in cases where participants find it difficult to attend any VE workshop session.

Analysis Phase

The objective here is to evaluate the alternatives generated in the preceding phase and select the best cost-saving alternative. This process can be difficult if there are too many alternatives in the first place. The number of alternatives can be reduced to a manageable size using filtering (Jagannathan, 1992), where the initial ideas can be rapidly evaluated against the criteria in such filters. For example, one important filter is "safety." Thus, if an alternative is perceived to affect safety levels adversely, it can be filtered out for later consideration. "Technology" can be another filter to defer alternatives that require technology not available in the organization and may require considerable R&D efforts.

The remaining alternatives are then ranked in order of their effectiveness. Their effectiveness is evaluated based on some weighted criteria measure. The decision matrix in Table 7.1 shows a comparison of various alternatives brainstormed for sealing the joints between pipe sections belonging to a 2400 ft, 8-ft diameter storm sewer line. The problem arose when it was observed that the ground surface along the corridor of the pipeline had large differential settlements. The City Engineers had attributed these settlements to sand being washed down the pipe through joint openings between pipe sections. Due to tidal movement, the ground beneath the pipeline settled, resulting in differential settlement of the 30-ft long pipe sections, breaking the cement mortar that was initially placed between the joints. The list of

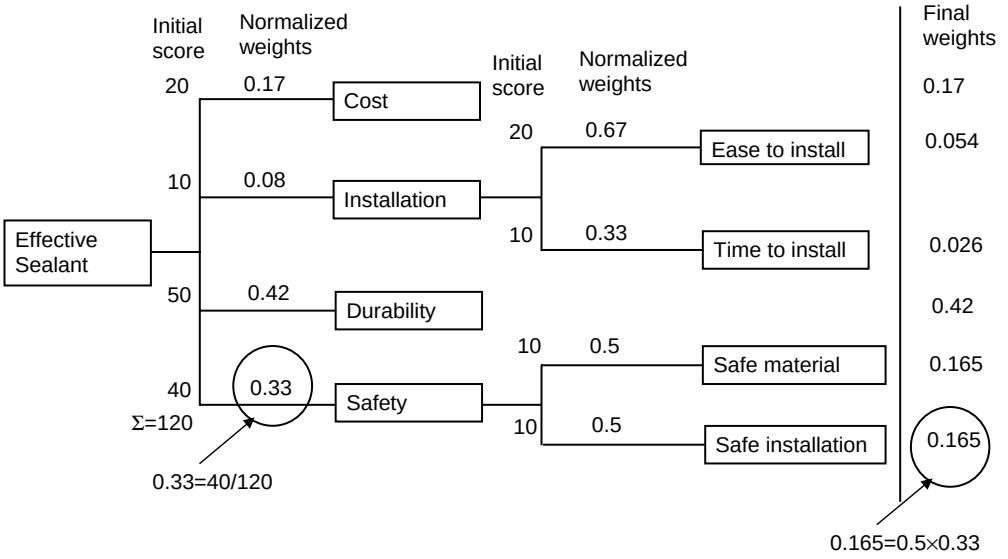

FIGURE 7.2 Value hierarchy.

criteria used to evaluate the performance of the various methods proposed includes cost, safety in installation, time and ease of installation, durability against further differential settlement of pipeline, and safe materials. Scoring of the alternatives is based on a simple scale ranging from 1 (poor) to 4 (excellent) for each criterion. The best alternative is the method with the highest overall score.

For more complex value criteria, a value hierarchy (Green, 1992) can be employed to structure the criteria. The top of the hierarchy comprises the primary objective of the problem. This is progressively broken down to subcriteria by way of a "means-ends" analysis, where the lower-order criterion is a means to the immediate higher criterion. Using the above example, a value hierarchy is developed following similar criteria attributes given in Table 7.1, and depicted as shown in Fig. 7.2. The weighting of each criterion is first obtained by normalizing the initial score of degree of importance (based on a 10 for the least important in the group). The final weighting for the lowest-level criterion is computed as the product of the criterion in the path of the tree to the top. The criteria in the lowest level of each branch with their final weights are used in the evaluation of the alternatives. The analytical hierarchical procedure (AHP) can also be adopted to derive the final weightings of the criteria (Saaty, 1980). The AHP approach has been employed to rank success factors (Chua et al., 1999) and criteria for the selection of design/build proposals (Paek, Lee, and Napier, 1992).

Development Phase

This is the phase when a limited number of the ranked alternatives are taken forward for development. The alternatives are designed in greater detail so that a better appraisal of their cost, performance, and implementation can be made. The cost should be computed based on life-cycle costing. At this stage, it may be necessary to conduct a trial or prepare a model or prototype to test the concept before recommending them to the decision makers.

Recommendation Phase

In this phase, a sound proposal is made to management. The effort in this phase can be crucial because all the good work done thus far could be aborted at this final stage if the proposal is not effectively presented. The presentation must also include the implementation plan so that management can be fully convinced that the change can be made effectively and successfully without detriment to the overall project.

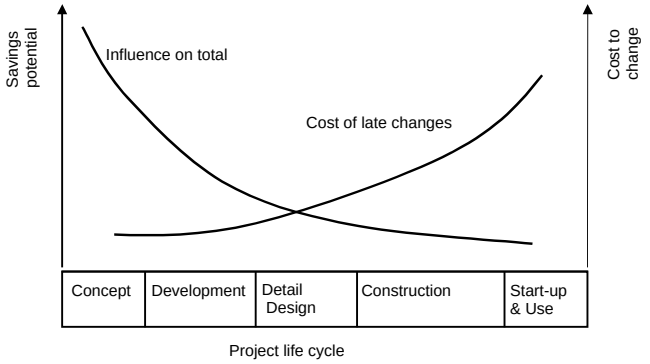

FIGURE 7.3 Cost savings potential over project duration.

Implementation

Value engineering can be applied at any stage of a project. It must, however, be borne in mind that greater benefits can be reaped when it is implemented in the earlier stages of the project. Figure 7.3 shows the drastic decline in cost savings potential over time. In the earlier stages of the project, there are less hard constraints, so there can be greater flexibility for adopting innovative alternatives. As the project proceeds, more constraints are added. Then, there is less flexibility for change, and greater costs will have to be incurred to make the necessary design changes.

Another consideration applies to the level of effort in the program. It is possible to apply VE extensively to every item in a project, but the amount of effort may not be recompensed in the same measure. Alternatively, the 20 to 80% rule should direct the VE efforts. The rule is generally also applicable to the costs of a system or facility, meaning that 20% of the items of a facility contribute to about 80% of its total costs. By the same token, a large proportion of unnecessary costs is contributed by only a few items. Thus, the efforts of VE should be directed at these few items to yield significant cost savings.

It is traditional practice that designers adopt without challenge the owner's requirements and architect's specifications as given constraints from which they will begin to optimize their designs. These constraints, however, can lead to poor cost and value ratios, and if left unchallenged, can lead only to suboptimal solutions. Similarly, in a process-type facility, the owner's and process engineer's specifications typically form the constraints.

In a project for the construction of a wafer fabrication multistory building, for example, the process engineer laid out their process plans for the various floors. The sub-fab facilities were arranged so precariously on one of the floors that the main fabrication area above this level could not be laid out symmetrically with respect to the building. As customary, this was presented as a constraint to the structural engineers and vibration consultants (of which the author was a member). The objective of the design was a waffle floor system that would ensure that the vibration level in the main fabrication area under ambient conditions would not exceed some extremely low threshold criteria (with velocity limits not exceeding 6.25 μm/s over the frequency range 8 to 100 Hz in the 1/3 octave frequency band). With the original layout, the design would demand some elaborate system of beam girders to take advantage of the shear walls at the perimeter (because no shear walls are allowed in any area within the perimeter) and still would suffer from unnecessary torsional rotation due to the eccentricity of the floor system. It was only after several deliberations that the process engineers finally agreed to modify their layout so that a symmetric design could be accommodated. This resulted in significant savings in terms of construction costs and improved vibration performance. It is common that the initial specifications conflict with basic function of the design, which in this case, is a vibration consideration, leading to poor and expensive solutions, if left unchallenged.

Another consideration stems from the need to generate alternatives — the selection of the value engineering team. Just as the extent of solutions can be curtailed if some poorly defined constraints are left unchallenged, the scope of alternatives can also be severely limited if the value engineering team comprise only the same designers of the system. These designers become so intimate with their designs that they fail to detect areas of unnecessary costs. The approach is to form a multidiscipline team that cuts across the technical areas of the study, comprising one or two members in the major discipline with the others in related fields. In this way, the alternatives tend to be wider ranging and not limited by the experience of a single group. Greater consideration can also be given to the impact of these alternatives on the system as a whole.

As with any program, the VE program has to be well managed with the support of top management in all practical ways. Visible support will entail their presence in many of the review meetings of VE projects, their support with the necessary budget and staff training and participation, and their time to discuss problems associated with the program and implementation of the alternatives. In the construction industry, it is usual to place the VE group with the purchase or design function of the organization.

The success of the VE program also largely depends on the leader of the VE group. Depending on the size of the program and the organization, he could be the Director VE, Value Manager, or simply the Value Engineer. Nevertheless, he must be able to follow organizational culture to gain acceptance of management and colleagues, yet has to have the necessary qualities to bring about changes for the better. His ability to control the dynamics of the group is important if he is to initiate and direct the program successfully.

There are three other important considerations to initiate a successful VE program:

- Bring about an awareness of VE concepts and methodology within the organization.
- Select simple sure winner projects as starters.
- Audit and publish the project after successful implementation with respect to both technical advantages and monetary savings.

7.3 Constructability

Basic Concepts

There are various definitions of the concept of constructability. The definition offered by the Construction Industry Institute has been adopted because of its broad perspective and its emphasis on the importance of construction input to all phases of a project (Jortberg, 1984): "*…the optimum integration of construction knowledge and experience in planning, engineering, procurement, and field operations to achieve overall project objectives*."

Constructability is not merely a construction review of completed drawings to ensure that they do not contain ambiguities or conflicts in specifications and details that will present construction difficulties later during the execution phase. It is also not merely making construction methods more efficient after the project has been mobilized.

Instead, the concept of constructability arises from the recognition that construction is not merely a production function that is separated from engineering design, but their integration can result in significant savings and better project performance. Construction input in design can resolve many design-related difficulties during construction, such as those arising from access restrictions and incompatible design and construction schedules. Construction input includes knowledge of local factors and site conditions that can influence the choice of construction method and, in turn, the design. The benefits of early construction involvement are at least 10 to 20 times the costs (BRT, 1982), and more recently, a study has shown that savings of 30 to 40% in the total installed cost for facilities are readily achievable from constructability implementation (Jergeas and Van der Put, 2001). The effects of an engineering bias to the neglect of construction input are discussed by Kerridge (1993).

The integration of construction knowledge and experience should come on to the project as early as possible when the cost influence of decisions in the early phases is very high (whose trend follows the curve of influencing total value depicted in Fig. 7.3). The highest ability to influence cost comes at the conceptual phase, where the decisions at that time could greatly affect the project plan, site layout and accessibility, and the choice of construction methods. Full integration will require that the contractor or construction representative be brought into the project team at the same time as the designer. Thus, the choice of the contractual approach can be critical in determining early construction involvement in a project.

Another important consideration for meaningful construction input to design is the commitment to preconstruction planning. Preconstruction planning determines three important elements affecting design and plan sequence:

- Selecting construction method and sequence so that designers can incorporate them in their design
- Ensuring that the design is constructible with at least one feasible way to execute the work
- Assuring that all necessary resources will be available when required, including accessibility, construction space, and information

Some of the pertinent concepts applicable to each phase of the project cycle are briefly presented in the following.

Conceptual Planning

The key issues in this phase relate to evaluating construction implications to project objectives, developing a project work plan, site layout, and selecting major construction methods (Tantum, 1987).

Construction-related issues at this stage can have major impacts on budget and schedule. The project objectives must be clearly established so that alternatives in various decisions can be effectively evaluated. The implications from the construction perspective may not be readily apparent to the planning team, unless there is a member experienced in field construction.

An effective work plan requires that work be adequately packaged and programmed so that design information and essential resources and materials required for each package can arrive in a timely fashion. Without construction input, the packaging and availability of design may not allow desirable work packaging or construction sequence. Moreover, the problems or opportunities from local factors and site conditions may be missed. Construction knowledge is also necessary for developing a feasible schedule.

It is usual for the building and site layouts to be determined solely on plant, process, and business objectives. Too often, construction implications are not considered with resulting severe limitations on construction efficiency due to inadequate space for laydown areas, limited access, and restrictions on choice of construction methods.

Construction knowledge is essential in the selection of major construction methods that will influence the design concepts. The possibility of modularization and the degree of prefabrication, for example, are construction issues that must be considered in this early stage.

Engineering and Procurement

The following are some key ideas that are generally applicable for guiding the constructability initiatives during the engineering and procurement phase of the project. With respect to design per se, the general principle is to provide design configurations and concepts that reduce the tasks on site, increase task repeatability, and incorporate accessibility.

- **Construction-driven design and procurement schedules —** Design and procurement activities are scheduled so that detailed designs, shop drawings, and supplies are available when needed according to construction schedule. This will reduce unnecessary delays in the field caused by resource and information unavailability.
- **Simplified designs —** Simplified design configurations generally contribute to efficient construction. Such designs can be achieved using minimal parts or components, simplifying tasks for

execution, and minimizing construction task dependencies. Boyce (1994) presented some interesting principles in this aspect of designing for constructability.

- **Standardization —** The objective in standardization is to reduce the number of variations in the design elements. This will lead to fewer errors in the field, improved productivity through repetitive work, and advantages in managing the supply chain of fewer differing components.
- **Modularization and Preassembly —** These will simplify field operations because the large number of parts have been modularized or preassembled, and are usually under conditions that can provide better control. Focus instead is given to delivery, lifting, and assembly in the field.
- **Accessibility —** Detailed design should consider the accessibility of workmen, material, and equipment. An accessibility checklist may be useful for this. Computerized simulation CAD models are also used in this regard.

A more detailed list including specifications and designing for adverse weather conditions is obtainable from O'Connor, Rusch, and Schulz (1987).

Field Operations

There are constructability issues remaining during field operations. These pertain to task sequencing and improving construction efficiency and effectiveness. Contractors can still reap the benefits of constructability, which can be quite substantial if the decisions are taken collectively. Innovation has been singled as the key concept for enhancing constructability in this phase and is applicable to field tasks sequence, temporary construction systems, use of hand tools, and construction equipment (O'Connor and Davis, 1988).

Many innovations have been made in the use of temporary construction systems, use of hand tools, and construction equipment. The advantages have been obvious: reduced erection and setup times, improved quality in products delivered, and increased construction productivity in related tasks. Many construction problems on site can be resolved quite easily with proper task sequences. Tasks can be better sequenced to minimize work site congestion with its consequent disruptions of work. Unnecessary delays can be avoided if tasks are properly sequenced to ensure that all prerequisites for a task are available before commencement. Effective sequencing can also take advantage of repetitive tasks that follow each other for learning-curve benefits. Sharing of equipment and systems is also an important consideration in tasks sequencing.

Implementation

As in all value methods, to be effective, constructability has to be implemented as a program in the organization and not on an ad-hoc basis. In this program, the construction discipline, represented by constructability members, becomes an integral part of the project team and fully participates in all design planning decisions.

A special publication prepared by the Construction Industry Institute Constructability Implementation Task Force (CII, 1993) presented a clear step-by-step roadmap to provide guidance for implementing the constructability program at the corporate and project levels. There are altogether six milestones envisaged, namely:

- Commitment to implementing the constructability program
- Establishing a corporate constructability program
- Obtaining constructability capabilities
- Planning constructability implementation
- Implementing constructability
- Updating the corporate program

Alternatively, Anderson et al. (2000) employed a process approach based on IDEF0 function modeling to provide the framework for constructability input.

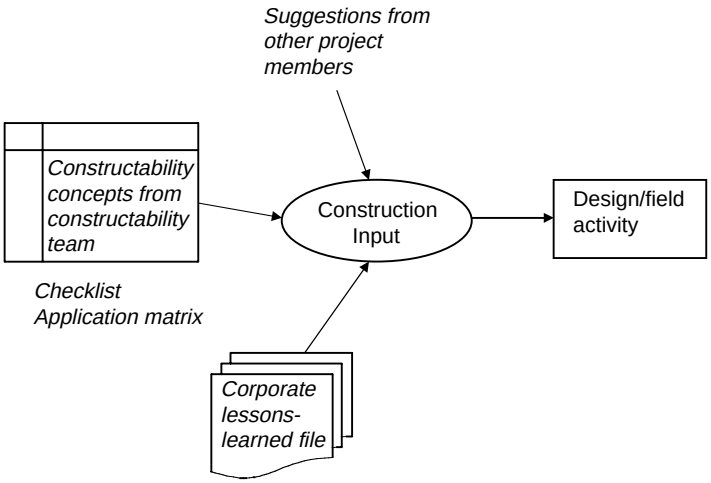

FIGURE 7.4 Constructability integration with activity.

Although there cannot be a single unique constructability program that can suit all companies, invariably, the commitment to a constructability program must come from senior management and be communicated clearly through the organization. Successful and consistent implementation also requires a single point executive sponsor of the program, whose primary role is to promote its awareness and to be accountable for its success.

Another important consideration in the program is to adopt a forward integration planning approach, rather than a backward constructability review of fully or partially completed designs. In the latter approach, the constructability team is excluded from the design planning process, thus preventing early construction input integration. Any changes to be made after the review will usually be taken in an adversarial perspective, in which the designer becomes defensive and takes them to be criticisms. Moreover, the design reworks are unnecessary and make the process inefficient and ineffective. In the forward integration as shown in Fig. 7.4, the constructability concepts are analyzed at each planning phase, and the alternatives from the construction, business, and design perspectives are available up-front and are jointly evaluated before incorporation into the design. The outcome is obvious: improved design quality and reduced design reworks.

As depicted in Fig. 7.4, the constructability activities can be guided from three sources: corporate lessons-learned file, team discussions of constructability concepts, and constructability suggestions. The first contains the feedback on the constructability program documenting specific lessons learned along the way. When the project terminates, each functional design should be evaluated and added to the lessons-learned file. The discussions of constructability concepts can be guided by a checklist of the constructability concepts at each phase or by using a Constructability Applications Matrix (see Fig. 7.5) (Tools 16–19, CII, 1993). More ideas for constructability can also be obtained from suggestions by other personnel involved in the project.

The project constructability team leads the constructability effort at the project level. The constructability team comprises the usual project team members and additional construction experts. If the contractor has not been appointed, an appropriate expertise with field experience has to be provided. The specialists, for example, rigging, HVAC, electrical, and instrumentation, are only referred to on an ad-hoc basis, when their area of expertise is needed for input. A constructability coordinator is also needed, whose role is to coordinate with the corporate constructability structure and program.

Before concluding this section on constructability, it is important to realize that constructability is a complex process, and the constructability process itself is unstructured. Especially, in these days of high-speed computing, technology has provided assistance in conducting this process, and its development

should be closely followed so that it can be incorporated to enhance its effectiveness. Four-dimensional models (McKinny and Fischer, 1997), that is, three-dimensional CAD models with animation, are providing the visualization capabilities to enhance communication between the designers and the constructors. Other models have also been developed for various aspects of constructability, for example, a constructability review of merged schedules checking for construction space, information, and resource availability (Chua and Song, 2001), and a logical scheduler from the workspace perspective (Thabet and Beliveau, 1994).

7.4 Quality Management

Basic Concepts

It cannot be overemphasized that quality is an objective of project management that is equally important to project budget and schedule. Specifications are written into contracts to ensure that the owner gets from the main contractor a product with the type of quality he envisaged. Being able to deliver this is not something that can be left to chance. It will require management. Quality management is the process to use to consistently satisfy the owner's expectations. Quality management has been defined as follows: "*All activities of the overall management function that determine the quality policy, objectives and responsibilities, and implement them by means such as quality planning, quality control, quality assurance, and quality improvement within the quality system*" ISO 8402 (1995).

Quality management has progressed through four stages, beginning with inspection and quality control (QC), and has now arrived at quality assurance (QA) and total quality management (TQM) (Dale et al., 1994). Inspection is the activity that assesses by measurement or testing whether an element has conformed to specifications. Corrective work is then ordered to rectify any nonconformance in the element. QC builds upon the inspection efforts and relies largely on statistical techniques to determine trends and detect problems in the processes. Such techniques are being used routinely in manufacturing. With respect to the construction industry, concrete cube testing is one rare example. Instead of merely detecting the errors for remedial measures, QA and TQM are based on a quality system, with the objective of reducing and ultimately eliminating their occurrences.

Both QA and TQM are focused on meeting customer requirements, and this is at the top of the agenda. Customer in TQM does not necessarily refer only to the owner, as QA tends to imply. The customer perspective in TQM is derived from the process viewpoint. At every stage of a process, there are internal customers. They belong to the group of people who receive some intermediate products from another group. For example, in an on-site precast operation depicted in Fig. 7.6, the crew setting up the mold

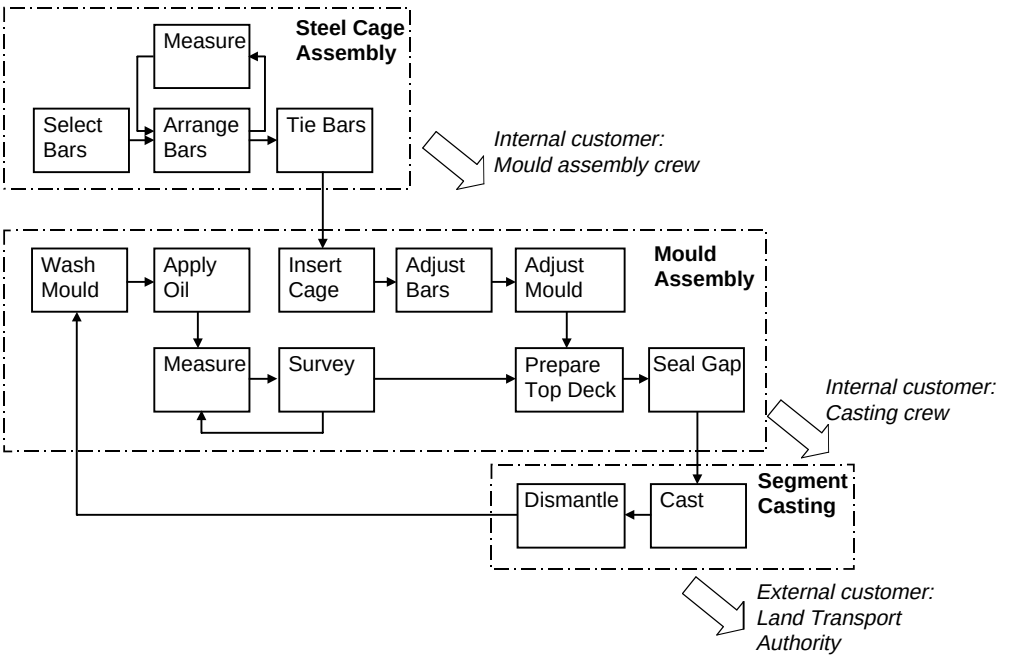

FIGURE 7.6 On-site precast operation.

for casting receives the steel reinforcement assembly from the crew assembling the steel cage. The mold crew is the internal customer of the assembly process. In turn, the casting crew is the internal customer of the mold assembly process, while the Land Transport Authority is the external customer of casting. Each of these crews will require that the intermediate product they receive meets the quality standards to avoid rework. The concept of internal customers ensures that quality permeates through the total operation, and thus by addressing the internal processes in this way, total quality improvement can be achieved.

To ensure that customers get what they want, there is a need to fully understand their requirements and to communicate this throughout the organization. This is at the heart of quality management and is the goal of the quality system. The quality system comprises quality manuals providing the templates to guide the worker in the performance of each particular task. These templates ensure management that proper work has been performed and provide confirmation to the owner that the work has met his requirements. The core of these systems is to present a way of working that either prevents problems arising, or if they do arise, identifies and rectifies them effectively and cheaply. In the next section, an overview of the ISO 9000 quality system will be presented.

Another culture of quality management is the dedication to continual improvement. Such a commitment requires accurate measurement and analysis of the performance of the processes from the viewpoint of the customer. This can take the form of a trend chart showing the trend of the problem. Control charts are also useful to highlight out-of-control conditions. A flowchart or process flow diagram will put the problem in the perspective of the whole operation. Histograms, scatter diagrams, and pareto analysis are other tools that may be used to identify and present the problem. Mears (1995) gave a good account of these and other techniques that have been used for quality improvement. The problem has to be analyzed to identify the root cause. A common and useful technique is the fishbone diagram, also called the cause-and-effect diagram. This and some other improvement techniques will be presented later. The action plan and monitoring of the implementation are the other two steps to complete the improvement process as shown in Fig. 7.7. The action plan describes the action to be taken, assigning responsibility and time lines. Monitoring would confirm that the conditions have improved.

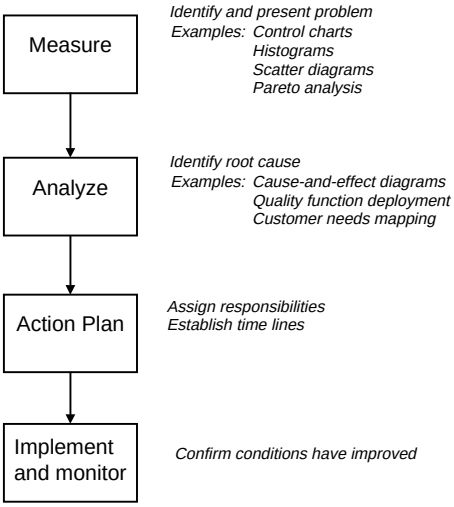

FIGURE 7.7 Quality improvement process.

Quality System

Underlying the concept of quality management is a quality system. It is becoming increasingly common for the ISO 9000 Standards certification to be necessary for tendering in big projects. The Standards provide the framework for developing the quality system. They comprise four main parts:

- **ISO 9001** — Specifications for design/development, production, installation, and servicing
- **ISO 9002** — Specifications for production and installation
- **ISO 9003 —** Specifications for final inspection and test
- **ISO 9004 Parts 1–4** — Quality management and quality systems elements

A company will decide on a suitable form appropriate for its operations and develop its quality system accordingly. ISO 9002 excludes design and is the most appropriate choice for controlling the operations of a contractor. This is also adequate to cover design and build projects, provided that the design is bought-in. ISO 9001 carries an additional clause 4.4 to control design activities and is necessary for a company that carries out design work.

The standards only provide the key elements in a quality system. Evidently, there can be no standardized quality system because the specific choice of quality measures depends on factors such as the main fields of activity, the operational procedures, and the size and structure of the company. Nevertheless, there is a hierarchy of documents making up the quality system (see Fig. 7.8). The quality manual according to Part 1 of ISO 9004 defines an outline structure of the quality system and serves as a permanent reference in the implementation and maintenance of the system. This is supported by the procedures and instructions common to the whole organization at the company level. There are also quality documentation comprising forms and checklists, procedures, and work instructions that are more project specific, in order to operate effectively in the unique circumstances of the project.

There are 20 main clauses in the ISO 9000 Standards (see Table 7.2). A brief synopsis of some of the pertinent clauses follows.

Clause 4.1 Management Responsibility

The implementation of a quality system requires a strong commitment of senior management and clear communication to every member in the organization. This clause relates to quality policy, organization structure defining responsibilities, authority and action to be carried out, management review, and

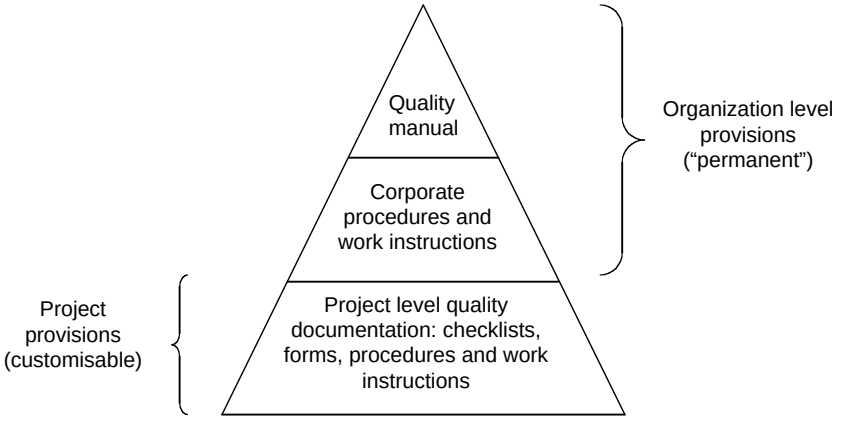

FIGURE 7.8 Hierarchy of documents in quality system.

TABLE 7.2 Main Clauses in ISO 9000 Standards

Clause	Requirement
4.1	Management responsibility
4.2	Quality system
4.3	Contract review
4.4	Design control
4.5	Document and data control
4.6	Purchasing
4.7	Control of customer-supplied product
4.8	Product identification and traceability
4.9	Process control
4.10	Inspection and testing
4.11	Control of inspection, measuring, and test equipment
4.12	Inspection and test status
4.13	Control of nonconforming product
4.14	Corrective and preventive action
4.15	Handling, storage, packaging, preservation, and delivery
4.16	Control of quality records
4.17	Internal quality audits
4.18	Training
4.19	Servicing
4.20	Statistical techniques

management representatives. Review is necessary to ensure the integrity of the system and continual improvement.

Clause 4.2 Quality System

This clause refers to the setup and maintenance of the quality system. It describes the implementation of a quality manual and the documentation necessary to operate the system. Quality planning is also a requirement in the clause, demonstrating how the system will be implemented and consistently applied. It also comprises the quality plans that set out the required good quality practices according to the specific requirements of the contract.

Clause 4.3 Contract Review

Contract review is the process to review the client's requirements. It ensures that they are adequately defined and understood, and any ambiguities or contradictions are resolved. It also looks at the resources

available to ensure that the organization can fulfill the requirements. This clause also includes a documentation of the results of the process.

Clause 4.4 Design Control

This clause has the most elements and deals with the design activity. Design and development planning, and organization and technical interfaces relate to the resources and organizational aspects of the design process. The input and output elements deal with compliance with customer and statutory requirements and mode of output. The remaining elements relate to the management of the design, comprising design review, verification, and validation, to ensure that the design actually meets requirements and original intention, and design changes, ensuring that revisions are adequately communicated and versions are adequately recorded.

Clause 4.5 Document and Data Control

This clause relates to the control of all documents, including external documentation such as codes of practices, health and safety legislation, building regulations and manufacturers' guidelines, and data contained in computer systems. The procedures ensure that the proper documents would be used, that there would be uniform documentation, and that revisions and obsolete documents would be properly handled.

Clause 4.6 Purchasing

The objective is to ensure that all bought-in resources comply with customer's requirements and that those providing them, i.e., subcontractors and suppliers, are competent. The clause covers the evaluation of subcontractors and suppliers, standardization and specification of purchasing data, and verification of the purchased product. Related procedures must also be in place to ensure that customer (client) supplied services or products, including information, also comply with quality standards (Clause 4.7). There are related procedures controlling product identification by marking or by accompanying documentation (Clause 4.8).

The remaining clauses deal with process control, inspection and testing matters, handling and storage issues, quality records, audits, training, servicing, and statistical techniques. The servicing clause deals with after-sales service and may not be appropriate in every construction company.

Quality Improvement Techniques

Mistakes and problems that arise provide opportunities for learning and continual improvement. There are numerous tools that have been used in this context. These range from simple checklists, flowcharts, scatter diagrams, and pareto analysis, to fishbone diagrams and more sophisticated tools such as benchmarking, customer needs mapping, and quality functional deployment (QFD). Essentially, they collect data so that the problem can be identified and aid in finding the cause and developing solutions to improve the situation. In this section, only the fishbone diagram, customer needs mapping, and QFD will be briefly presented. The reader may refer to Mears (1995) and McCabe (1988) for other techniques available.

Fishbone Diagram

The fishbone diagram was first developed by Karou Ishikawa. Essentially, it is a cause and effect analysis used to identify the root causes of a particular problem. The final diagram resembles the skeleton of a fish as shown in Fig. 7.9, where the head is the effect or problem, and the minor spines lead to the main areas or processes that could contribute to the effect. The ribs on the minor spines are the causes within the main areas and can make up a chain of causes. The last rib in the chain is the fundamental root cause that is specific enough to take action on.

Cause and effect analysis is usually used in a brainstorming setting, in which all members of the group should be familiar with the nature of the problem. The analysis begins with a clear definition of the problem, defining its symptom or effect. The effect forms the "fish head" of the diagram. The possible causes are identified, and the main areas for the minor spines are derived by classifying them into natural

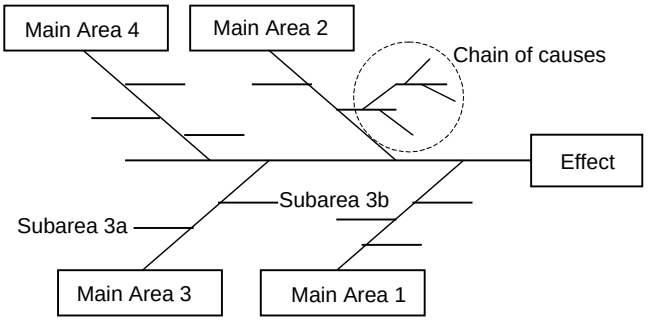

FIGURE 7.9 Fishbone diagram layout.

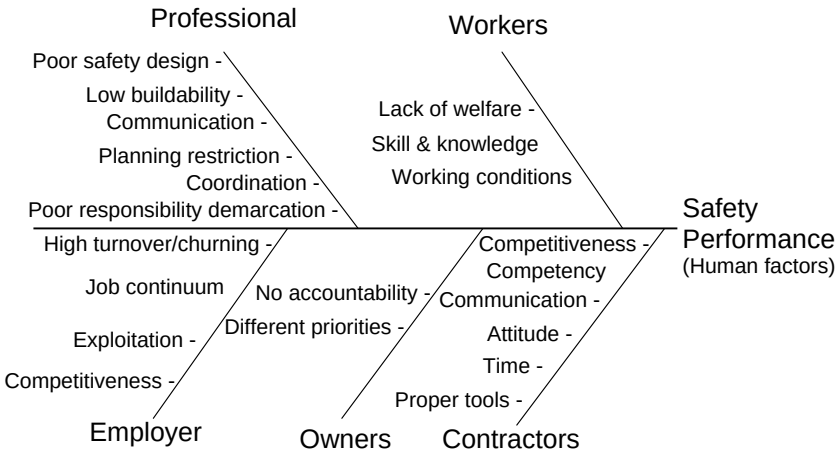

FIGURE 7.10 Fishbone of safety performance (human factors).

groupings or major processes. Figure 7.10 shows the resulting fishbone diagram for improving the human factor element of safety performance in the construction industry obtained in a safety workshop conducted with the participation of leading companies, professional societies, and associations. The major areas have been grouped according to the major project players. In the case of process-related problems, the major groupings can usually be categorized according to resource and methods, such as tools, components, production methods, people, and environment. In larger operations, the groupings could include the major processes making up the whole operation.

The major categories are then refined to determine the root causes. This can be assisted by asking the following questions:

- What causes this?
- Why does this condition exist?

The "why" question may be asked several times, until the causes are specific enough for action to be taken. A plan of action is then formulated based on the root causes that have been uncovered according to a priority ranking system.

Customer Needs Mapping

Customer needs mapping is a technique that analyzes the effectiveness of the internal processes to meet customer requirements (or needs). It is based on a matrix approach, as shown in Fig. 7.11. The customer in the analysis could be an internal customer, especially in the case of support activities such as inventory control and the IT department. After the customers have been identified, their needs may be determined

		Importance Rating	Process 1	Process 2	Process 3	Process 4
Customer needs						
Main group 1	Need 1.1	5	M	L	L	H
	Need 1.2	3	M	M	L	M
	Need 1.3	2	L	H	L	M
	Need 1.4	4	M	L	L	H
Main group 2	Need 2.1	4	L	L	L	L
	Need 2.2	1	H	L	L	M
	Need 2.3	5	L	M	L	H

FIGURE 7.11 Customer needs mapping.

through a combination of customer interviews and brainstorming. The left-hand column of the matrix makes up the customer needs. An importance rating on a scale of 1 (least important) to 5 (most important) is assigned to each item.

The top row of the matrix identifies the internal processes required to meet these needs. Only the major processes are necessary so as not to be bogged down by the details of a complex operation. To complete the matrix, the effectiveness of each process in meeting customer needs is evaluated. The evaluation is obtained through customer interviews and is based on the following scale: high (H), medium (M), and low (L).

With this mapping, the quality improvement team can now identify internal processes that need to be enhanced to improve quality delivery. A customer need with high importance is one point of focus. An internal process that is not effective in meeting any customer needs should also draw attention, for example, internal process 3 of Fig. 7.11. Another benefit of the mapping is the identification of customer requirements that have been neglected, such as customer need 2.1 of Fig. 7.11. A detailed flowchart of the whole operation usually accompanies the mapping so that improvement plans can be developed as a result of the analysis.

Quality Function Deployment

Quality function deployment (QFD) is a structured approach to translating customer requirements into appropriate technical requirements so that customers' needs can be better satisfied. It was first introduced at the Kobe shipyards of Mitsubishi Heavy Industries Ltd. in 1972. Since then, it has gone through several stages of development and has been used in various applications, not only in manufacturing, but also in the AEC industry.

QFD uses a matrix structure in the form of the house of quality (see Fig. 7.12), so called because of its resemblance to a house. The customers' needs are the inputs to the matrix, and the outputs help to set competitive targets and determine the priority action issues for improving customer satisfaction based on their requirements (Day, 1993). The house of quality comprises six main sections, as shown in Table 7.3.

The product characteristics or processes are the technical counterparts that must be deployed to meet customer requirements. These technical counterparts are often related, and their interactions are shown using symbols as shown in Fig. 7.12. The relationship matrix is the main matrix of the house. It shows the relationship between the customer requirements and the technical counterparts. Symbols as shown in the figure are also used to indicate the strength of their relationships. The customer requirements are

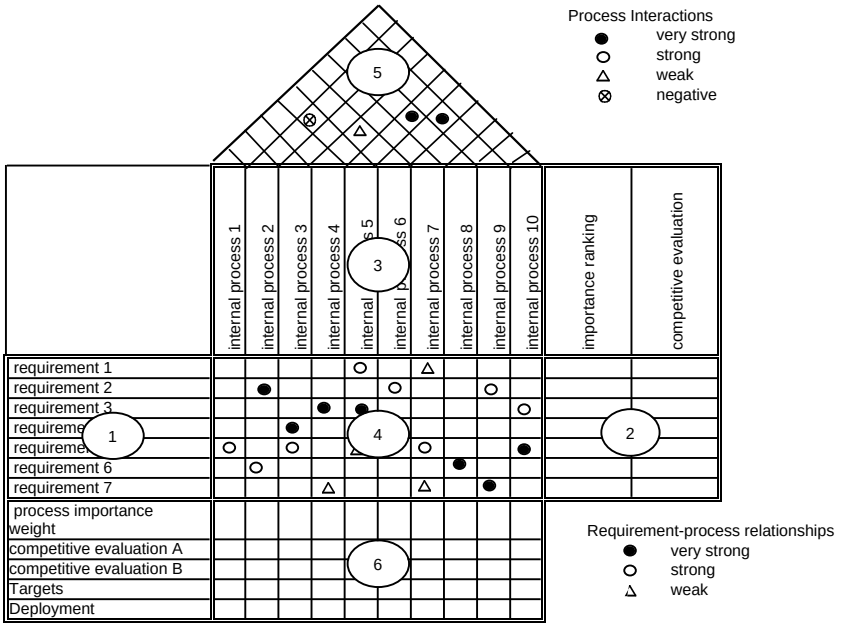

FIGURE 7.12 House of quality.

TABLE 7.3 Main Sections of House of Quality

Section	Description
1	Customer requirements for the product
2	Ranking and rating of customer requirements
3	Product characteristics or processes (technical counterparts)
4	Relationship matrix between customer and technical counterparts
5	Correlation matrix showing technical interactions — this forms the roof of the house
6	Technical rankings and ratings

ranked to give their importance values. It is usual to denote their importance on a 5-point scale (where 5 represents the highest importance). Alternatively, the analytical hierarchical approach (AHP) referred to in the earlier section on value engineering can be used to rank their importance (Akao, 1990). This section of the house of quality also comprises the competitive evaluation of competitors to highlight their strengths and weaknesses to meet their customer needs.

If a numerical score is given to the relationship matrix, the technical rankings (or process importance weights) can be derived as shown in Fig. 7.13 for the case of improving the quality of mold assembly operation in an on-site precast yard. The rankings show the importance of the internal processes in achieving the quality of the finished mold for the casting crew, an internal customer of the whole precast operation. The house of quality can be modified by incorporating an improvement ratio as shown in Fig. 7.14 for the same example, which is the ratio of the planned level and current rating of the customer requirement. The technical rankings obtained in this way would have taken into consideration the current deficiencies in the technical counterparts in meeting the customer requirement.

Implementation

Developing a Quality System

The quality system is an essential aspect of the concept of quality management. The development process is not merely a compilation of forms and documents of procedures and organization, and the amount

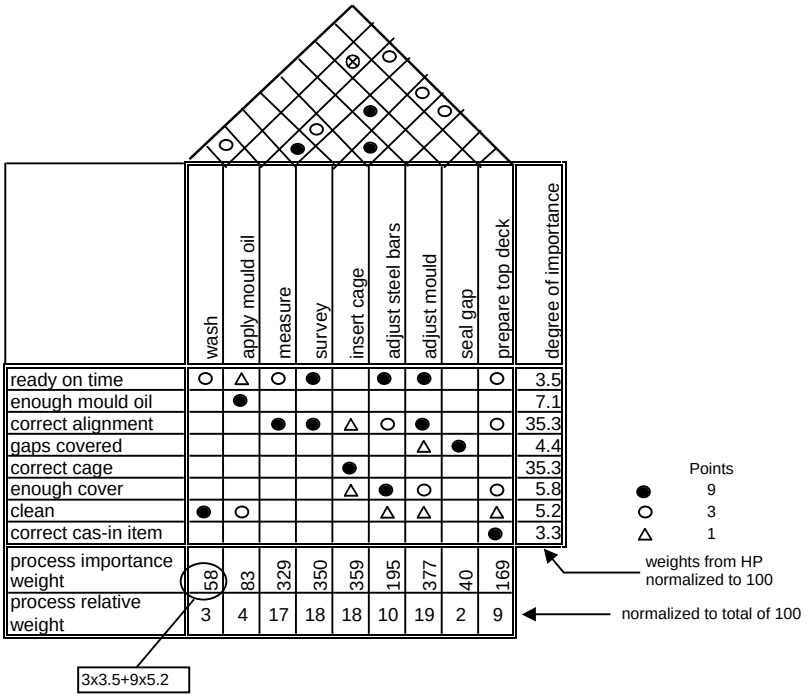

FIGURE 7.13 House of quality for mold assembly.

	degree of importance	current rating	planned level	improvement ratio	attribute importance weight	attribute relative weight
ready on time	3.5	4	3	0.75	2.6	3.2
enough mould oil	7.1	4	4	1	7.1	8.5
correct alignment	35.3	5	4	0.8	28.2	33.9
gaps covered	4.4	3	3	1	4.4	5.3
correct cage	35.3	5	4	0.8	28.2	33.9
enough cover	5.8	4	4	1	5.8	7.0
clean	5.2	5	4	0.8	4.2	5.0
correct cas-in item	3.3	5	4	0.8	2.6	3.2

83.2 sum of importance weights

normalized to total 100 and used to obtain technical rankings

FIGURE 7.14 Modified ratings with improvement ratio.

of effort required cannot be underestimated. It is not the work of an individual appointed from within the organization, in addition to their other duties, as is frequently done. The process can become too long drawn, with the accompanying consequence of loss of impetus or of even having the whole process stalled. Otherwise, there may be a compromise on the depth of coverage, resulting in an ineffective system.

It is insufficient to develop the system. Full implementation, as shown in Fig. 7.15, begins with the analysis phase, which is essentially a critical review of the company in terms of its existing organization

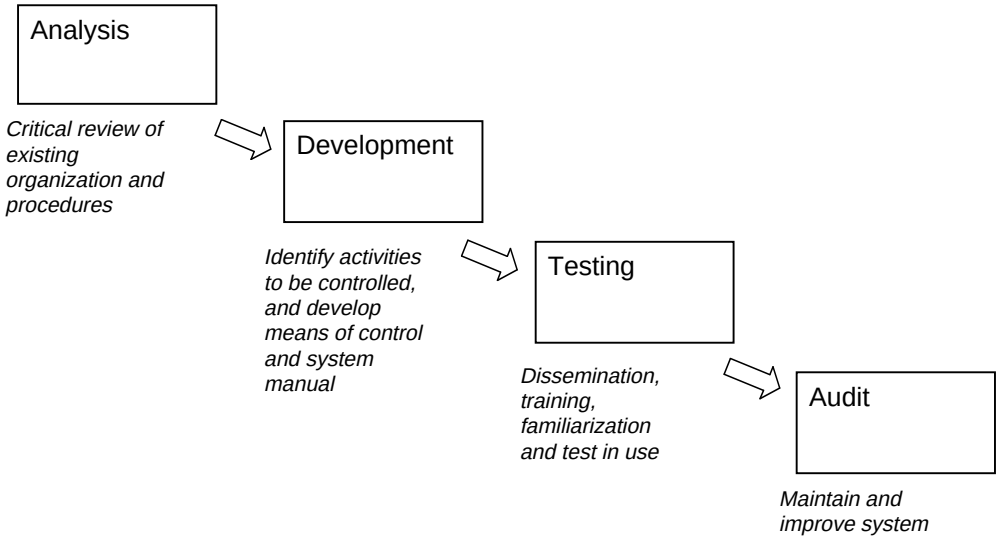

FIGURE 7.15 Implementation cycle of quality system.

and procedures. After development, the system has to be tested before it can be implemented, and auditing is required to maintain the system. Of these phases, the analysis is perhaps most crucial in determining the success of the quality system. Typically, the analysis will reveal deficiencies in the present organization that need to be redressed, such as procedures being ignored or modified for a variety of reasons and contradictory and outdated procedures. Information is gathered through a combination of interviews, questionnaires, review of existing forms and documents, and observation. Effective control can be formulated only if there is sufficient depth in the analysis.

Successful implementation also entails a balance of the need for knowledge of quality management and an understanding of the organization and processes. The use of QA consultants fulfills the first requirement but falls short of the need for company knowledge. A QA manager appointed from within the company's management should lead the implementation, and a combination of self-analysis by departments and by external QA consultants should provide the advantages of expertise and company knowledge to ensure success.

Developing a Quality Culture

The other aspect of successful implementation is developing a quality culture in which everyone is encouraged to be concerned with delivering quality in his or her own work. Instead of merely adopting the quality system as the way things should be done, the quality system will have to become the way things are actually done. Because it requires things to be done differently, a clear and strong commitment from senior management is not an option. Though it starts from the top, this quality culture must be communicated to the worker level.

One way of developing this, is to set up a quality council, which is essentially an executive or steering committee dedicated to maintaining the organization's focus on quality management. It also provides the mechanism for selecting quality improvement projects for developing, forming, and assisting the quality teams, and following up on their implementation. Without such a structure, good improvement ideas suggested by workers, which goes beyond a single department, are usually not followed through because of the lack of authority. Typically, the council is headed by a senior VP of the organization.

Another necessary change is realizing employee participation because such quality initiatives may require the workers to change the way things are done. They must believe that the improvement is good and must also be motivated to put in their best (and thus quality) in their tasks, with the attitude of

doing things right the first time. Along with this is the concept of employee empowerment. Empowerment has been defined as the method by which employees are encouraged to "take personal responsibility for improving the way they do their jobs and contribute to the organisation goals" (Clutterbuck, 1994). Clutterbuck also suggested some techniques for empowerment. They relate to expanding employees' knowledge-base and scope of discretion, involving them in policy making, and providing opportunities to change systems that can affect procedures across functional lines and departments. Employee empowerment is an important key to continuous improvement because they are most involved in line operations and would be most familiar with problems. Quality circles (Lillrank and Kano, 1989) center on the line workers whose day-to-day observation of the process is crucial to continuous improvement.

7.5 Conclusions

Three concepts for value improvement have been presented together with their methodologies and implementation. There are overlaps in their objectives, but their approaches are distinct. Nevertheless, to achieve any significant success, the implementation of any of these concepts must be strongly supported by senior management of the organization and communicated through the organization. Moreover, they cannot be practiced on an ad-hoc basis. A corporate program with clear policies has to be developed, wherein employee activities are integrated into the other activities of the organization. It has been demonstrated that the application of these concepts will lead to great benefits to the organization, such as reduced costs, increased value, better designs, improved performance, and enhanced quality.

Before concluding this chapter, there should be a brief mention of lean construction, which is an emerging concept also focused on value improvement. The concepts of lean construction are applicable to design and field operations and are based on the new production philosophy in manufacturing that has been called by various terms, such as lean production, just-in-time (JIT), and world class manufacturing. It is believed that just as the new production philosophy has made significant impact on production effectiveness and has led to dramatic changes in production management in manufacturing, lean construction can have similar effects in the construction industry.

The new production philosophy originated from plant floor developments initiated by Ohno and Shingo at the Toyota car factories in Japan in the 1950s, but only analyzed and explained in detail in the 1980s. It was only in 1992 that the possibility of applying this new production philosophy in construction was mooted and put into a report (Koskela, 1992). Since then, the application of this philosophy in construction has been termed lean construction. Many of the concepts are still in their germination stages, but they are generally based on adopting a flow production view of construction instead of the traditional activities perspective. By focusing on the flow of production, the nonvalue activities can be identified and minimized, while the value adding activities can be enhanced (Koskela, 1992). One key concept is improving work plan reliability, or conversely reduced variability, through production shielding using the Last Planner system (Ballard and Howell, 1998). The Integrated Production Scheduler (IPS) (Chua and Shen, 2002) is an Internet-enabled system for collaborative scheduling that implements the Last Planner concept and identifies key constraints in the work plan. Some other related principles for flow process design and improvement include reduce cycle times, increase process transparency, and task simplification. The implementation of lean construction will also require a re-look at the relationships to be cultivated between the main contractor and their suppliers and subcontractors.

Introduction • Solid Waste • Landfills

DURING THE EVOLUTION OF THE U.S., the water, air, and land resources available to our forefathers were immeasurably vast. So vast, in fact, that they appeared to be of infinite proportions, and their use and consumption were taken for granted. However, as the population grew, it became clear that these resources, particularly a clean and abundant water supply, were not infinite and, in some cases, not even available. A case in point is the water supply problem that confronted New York almost from its inception. A visitor to New York in 1748 declared, "There is no good water to be met within the town itself" [Koeppel, 1994]. In 1774, the city authorized a water system, but it was not until 1841, when the Croton Aqueduct was completed, that New Yorkers could experience cool, clean water for

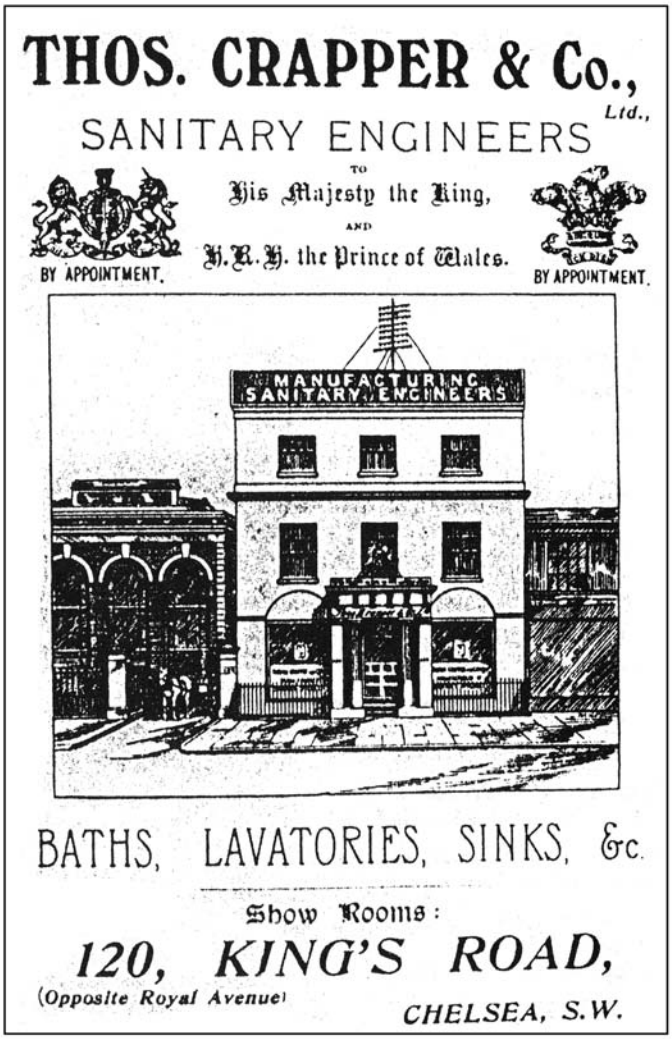

FIGURE II.1 Thomas Crapper invented many improvements to indoor flush toilets.

drinking, bath, and fire fighting. They could even dream about the luxury of indoor plumbing. Four years prior to 1841, a son was born to a humble British family in the Yorkshire town of Thorne, who was to make a major contribution regarding the handling of human waste products. The child's name was Thomas Crapper. Figure II.1 shows an advertisement for Thomas Crapper & Company. Crapper was an entrepreneurial sanitary engineer and the inventor of many improvements to indoor flush toilets [Rayburn, 1989].

By 1840, there were only 83 public water supplies in the U.S., but the demand was growing, and by 1870, there were 243 [Fuhrman, 1984]. With these burgeoning public water supplies came the need to consider the disposal of the "used" water. In Europe during the Middle Ages, people simply threw their excreta out the window, as the woodcut in Fig. II.2 demonstrates [Rayburn, 1989]. Word has it that some sport was involved in this process involving the passersby in the street below [Alleman, 1994].

Recognition at about this time that water supplies, disease, and disposal of human waste were interconnected led to the requirement that used water and excrement be discharged to sewers. In 1850, a member of the Sanitary Commission of Massachusetts, Lemuel Shattuck, reported the relationship between water supply, sewers, and health. He recommended the formation of a State Board of Health, which would include a civil engineer, a chemist or physicist, two physicians, and two others. During this time, a French chemist by the name of Louis Pasteur was initiating research that was to found the field of bacteriology

FIGURE II.2 "Sanitation" in the Middle Ages. (From an old woodcut.)

and connect bacteria with disease. In addition, Pasteur was to demonstrate the benefits of utilizing bacteria in industrial processes. The use of bacteria to stabilize municipal waste was coming to the fore.

In 1887, the Massachusetts State Board of Health established an experiment station at Lawrence for investigating water treatment and water pollution control. This station was similar to others that had been established in England and Germany and was the forerunner of eight others established throughout the U.S. Topics investigated were primary wastewater treatment, secondary treatment via trickling filters, and activated sludge.

As the population of the U.S. continues to grow, greater demand is being placed on our natural resources. What were once adequate treatment and disposal methods now require far greater levels of cleanup before waste is discharged to water courses, the atmosphere, or onto the land. In essence, water, air, and land are no longer free economic goods, as has been assumed for so many years. The cost of using water, air, and land resources is the cleanup cost prior to their return to the environment. This section will deal with those broader topics in water treatment, wastewater treatment, air pollution, landfills, and incineration.

8.1 Standards

Waterworks, water distribution systems, sewerage, and sewage treatment works are an integrated system. The primary purpose of this system is to protect the public health and to prevent nuisances. This is achieved as follows:

- Waterworks produce potable waters that are free of pathogens and poisons.
- Water distribution systems prevent the posttreatment contamination of potable water while storing it and delivering it to users upon demand.
- Sewerage systems efficiently and safely collect contaminated used water, thereby preventing disease transmission and nuisance, and transmit it to sewage treatment works without loss or contamination of the surrounding environment.
- Sewage treatment works remove contaminants from the used water prior to its return to its source, thereby preventing contamination of the source and nuisance.

Overall, this system has been successful in controlling waterborne disease, and such disease is now rare in modern industrial economies.

The secondary purpose of sewage treatment is to preserve wildlife and to maintain an ambient water quality sufficient to permit recreational, industrial, and agricultural uses.

Water Treatment

Potable water quality in the U.S. is regulated by the U.S. EPA under authority of the "Safe Drinking Water Act" of 1974 (PL 93–523) and its amendments. The Act applies to any piped water supply that has at least 15 connections or that regularly serves at least 25 people. The U.S. EPA delegates day-to-day administration of the Act to the states. The fundamental obligations of the U.S. EPA are to establish primary regulations for the protection of the public health; establish secondary regulations relating to

taste, odor, color, and appearance of drinking water; protect underground drinking water supplies; and assist the states via technical assistance, personnel training, and money grants. Regulations include criteria for water composition, treatment technologies, system management, and statistical and chemical analytical techniques.

Maximum Contaminant Limits

The U.S. EPA has established *maximum contaminant limits* (MCL), which are legally enforceable standards of quality, and *maximum contaminant limit goals* (MCLG), which are nonenforceable health-based targets. The MCL are summarized in Table 8.1. For comparative purposes, the earlier standards of the U.S. Public Health Service and the standards of the World Health Organization (WHO) are included.

The standards apply at the consumer's tap, not at the treatment plant or at any point in the distribution system.

It should be noted that the bacterial limits are no longer given as *most probable numbers* (MPN) or as *membrane filter counts* (MFC), but rather as the fraction of 100 mL samples that test positive in any month.

The limits on lead and copper are thresholds that require implementation of specific treatment processes to inhibit corrosion and scale dissolution.

Some substances are not yet subject to regulation, but in the interim, they must be monitored. Some substances must be monitored by all facilities; others must be monitored only if monitoring is warranted in the judgment of the state authority.

Violations of Drinking Water Regulations

Water supply systems must notify the people they serve whenever:

- A violation of a National Primary Drinking Water Regulation or monitoring requirement occurs
- Variances or exemptions are in effect
- Noncompliance with any schedule associated with a variance or exemption occurs

If the violation involves an MCL, a prescribed treatment technique or a variance/exemption schedule, a notice must be published in the local newspapers within 14 days. If there are no local newspapers, the notice must be given by hand delivery or posting. In any case, notification by mail or hand delivery must occur within 45 days, and notification must be repeated quarterly as long as the problem persists.

Notification must be made by television and radio within 72 h if any of the following occur: (1) the violation incurs a severe risk to human health as specified by a state agency, (2) the MCL for nitrate is violated, (3) the MCL for total coliform when fecal coliform or *Escherichia coli* are known to be present is violated, or (4) if there is an outbreak of waterborne disease in an unfiltered supply,.

Wastewater Treatment

Wastewater discharges are regulated under the Federal Water Pollution Control Act of 1972 (PL 92–500), as amended.

Stream Standards

Terms like "pollution" and "contamination" require quantitative definition before abatement programs can be undertaken. Quantification permits engineering and economic analysis of projects. In the U.S., water bodies are first classified as to suitability for "beneficial uses." Possible uses include:

- Wildlife preservation — warm water habitats, exceptional warm water habitats, cold water habitats
- Historic and/or scenic preservation
- Recreation — primary or contact recreation (i.e., swimming) and secondary or noncontact recreation (e.g., boating)
- Fisheries — commercial and sport
- Agricultural usage — crop irrigation and stock watering
- Industrial usage — process water, steam generation, cooling water
- Navigation

- Hydropower
- Public water supply source (which assumes treatment prior to use)

Once a water body has been classified, the water volume and composition needed to sustain that usage can be specified. Such a specification is called a "stream standard." A water body is contaminated if any one of the various volume and composition specifications is violated. Stream standards are revised every 3 years. Standards are issued by state agencies subject to review and approval by the U.S. EPA. Commonly recommended standards for various beneficial uses are given in Tables 8.2 through 8.6.

Rules-of-Thumb for Rivers

The determination of whether a particular discharge will cause a stream standard violation is difficult, particularly when the contaminants undergo physical, chemical, or biological transformations and when competing processes like biochemical oxygen demand (BOD) decay and reaeration occur. There are, however, a few rules-of-thumb that are useful guides to permit specification. The rules-of-thumb restrict BOD_5 and settleable solids, which adversely affect stream dissolved oxygen levels and ammonia, which is toxic to many fish.

Fuller (1912) reviewed several field studies conducted in France, Massachusetts, and Ohio on the effect of sewage discharges on rivers and reached the following conclusions:

- The sewage should be settled and skimmed to remove settleable and floatable material.
- The flow in the receiving stream should be at least 4 to 7 cfs per 1000 cap.

Fuller's recommendations result in an increase of 3 to 5 mg/L in the stream BOD_5. The requirement for sedimentation is especially important, because settleable solids have a disproportionate impact on stream oxygen values. Flotsam should be removed to avoid nuisance.

[d] Absent in 1000 mL.

[e] Human exposure to be minimized.

[f] To be free from substances attributable to wastewaters or other discharges that (1) settle to form objectionable deposits; (2) float as debris, scum, oil, or other matter to form nuisances; (3) produce objectionable color, odor, taste, or turbidity; (4) injure or are toxic or produce adverse physiological response in humans, animals, or plants; and (5) produce undesirable or nuisance aquatic life.

[g] Not objectionable.

[h] Virtually free.

[i] Substances should not be present in concentrations that produce undesirable flavors in the edible portions of aquatic organisms.

In 1913, the Royal Commission on Sewage Disposal published its studies on the development of the biochemical oxygen demand test procedure and its applications. The Commission concluded that the BOD_5 of rivers should be held to less than 4 mg/L. This recommendation is supported by the work of Sladacek and Tucek (1975), who concluded that a BOD_5 of 4 mg/L produced a stream condition called "beta-mesosaprobic" (Kolkwitz and Marrson, 1908, 1909; Fjerdingstad, 1962), in which the stream benthos contains predominately clean water flora and fauna.

The unprotonated ammonia molecule, NH_3, is toxic to fish at concentrations about 0.02 mg NH_3/L (Anon., 1976). Ammonia reacts with water to form the ammonium ion, NH_4^+, which is the predominant form in most natural waters:

$$NH_3 + H_2O = NH_4^+ + OH^- \tag{8.1}$$

The equilibrium constant for this reaction is called the "base ionization constant" and is defined as follows:

$$K_b = \frac{\left[NH_4^+\right]\cdot\left[OH^-\right]}{\left[NH_3\right]} \tag{8.2}$$

[a] Ray, H. C., et al. 1968. Water Quality Criteria, Report of the National Technical Advisory Committee to the Secretary of the Interior. U.S. Department of the Interior, Federal Water Pollution Control Administration.

[b] Council of the European Communities. 1975. Council Directive of 16 June 1975.

[c] All surface waters should be capable of supporting life forms of aesthetic value. Surface waters should be free of substances attributable to discharges or wastes as follows: (1) materials that will settle to form objectionable deposits; (2) floating debris, oil, scum, and other matter; (3) substances producing objectionable color, odor, taste, or turbidity; (4) materials, including radionuclides, in concentrations or in combinations that are toxic or that produce undesirable physiological responses in human, fish, and other animal life and plants; (5)substances and conditions or combinations thereof in concentrations that produce undesirable aquatic life.

[d] Tarry residues and floating materials such as wood, plastic articles, bottles, containers of glass, rubber, or any other substance and waste or splinters shall be absent.

[e] Surface waters, with specific and limited exceptions, should be of such quality as to provide for the enjoyment of recreational activities based on the utilization of fishes, waterfowl, and other forms of life without reference to official designation of use. Species suitable for harvest by recreational users should be fit for human consumption.

[f] No abnormal change.

[g] If the quality of the water has deteriorated or if their presence is suspected, competent authorities shall determine the concentrations of pesticides, heavy metals, cyanides, nitrates, and phosphates. If the water shows a tendency toward eutrophication, competent authorities shall check for ammonia and total Kjeldahl nitrogen.

It is also possible to write what is called an "acid ionization constant":

$$K_a = \frac{\left[H^+\right]\cdot\left[NH_3\right]}{\left[NH_4^+\right]} \tag{8.3}$$

This corresponds to the reaction,

$$NH_4^+ = NH_3 + H^+ \tag{8.4}$$

The ionization product of water relates the two constants:

$$K_a K_b = \left[H^+\right]\cdot\left[OH^-\right] = K_w \tag{8.5}$$

The molar fraction of the total ammonia concentration that is unprotonated ammonia is,

$$f = \frac{\left[NH_3\right]}{\left[NH_3\right]+\left[NH_4^+\right]} = \frac{1}{1+\dfrac{\left[H^+\right]}{K_a}} = \frac{1}{1+\dfrac{K_b}{\left[OH^-\right]}} \tag{8.6}$$

Consequently, a rule-of-thumb estimate of the allowable total ammonia concentration is,

$$\frac{0.02 \text{ mg } NH_3/L}{f} = \left(1+\frac{\left[H^+\right]}{K_a}\right)\times 0.02 \text{ mg } NH_3/L \tag{8.7}$$

Values of the total ammonia concentration that correspond to an unprotonated ammonia concentration of 0.02 mg/L are given in Table 8.7. These differ slightly from the values given by Thurston et al. (1974) because of rounding and differences in values of the acid ionization constants employed.

Rules-of-Thumb for Lakes

The most common problem in lakes is eutrophication (the overfertilization of a lacustrine ecosystem). Extreme cases of eutrophication lead to toxic algal blooms in the epilimnion and anoxia in the hypolimnion, and even mild cases lead to taste and odor problems and nuisance algal scums.

The potential for eutrophication can be judged by use of Vollenweider (1970) diagrams. These are shown in Figs. 8.1 (for phosphorus) and 8.2 (for nitrogen). In each figure, the logarithm of the annual nutrient load per unit area is plotted against the mean depth of the lake, and each lake is judged to be eutrophic or oligotrophic based on the observed epilimnetic algal concentration and the hypolimnetic oxygen concentration. When the plotted points are labeled as to their lakes' trophic status, they form distinct groups as shown. The indicated boundary lines are:

For phosphorus (Fig. 8.1):

oligotrophic: $$J_P \le 0.025 H^{0.6} \tag{8.8}$$

eutrophic: $$J_P \ge 0.05 H^{0.6} \tag{8.9}$$

For nitrogen (Fig. 8.2):

oligotrophic: $$J_N \le 0.4 H^{0.6} \tag{8.10}$$

eutrophic: $$J_N \ge 0.8 H^{0.6} \tag{8.11}$$

TABLE 8.4 Maximum Contaminant Concentrations Allowable in Aquatic Habitats[a]

Parameter	Habitat

TABLE 8.4 (continued) Maximum Contaminant Concentrations Allowable in Aquatic Habitats[a]

[b] Levels of oils or petrochemicals in the sediments that cause deleterious effects to the biota should not be allowed, and surface waters should be virtually free from floating nonpetroleum oils of vegetable or animal origin, as well as petroleum-derived oils.

[c] In cooler months, maximum plume temperatures must be such that important species will not die if the plume temperature falls to the ambient water temperature. In warmer months, the maximum plume temperature may not exceed the optimum temperature of the most sensitive species by more than one-third of the difference between that species' optimum and ultimate upper incipient lethal temperatures. During reproductive seasons, the plume temperature must permit migration, spawning, egg incubation, fry rearing, and other reproductive functions of important species.

[d] The compensation point for photosynthesis may not be reduced by more than 10% of the seasonally adjusted norm.

where H = the mean depth of the lake (m)
J_N = the annual nitrogen load per unit area of lake surface (g N/m^2 yr)
J_P = the annual phosphorus load per unit area of lake surface (g P/m^2 yr)

Total Daily Mass Load

The *total daily mass load* (TDML) is the total amount of a specific contaminant that can be discharged by all point and nonpoint sources to a specified receiving water without violating its water quality standards. It must include an allowance for uncertainty. Once the TDML is established for the whole receiving water, it (less the uncertainty allowance) may be allocated to individual point and nonpoint sources.

Nondegradation

The water quality act of 1972 includes a *nondegradation* provision. This means that there should be no measurable increase in contaminant levels, which as a practical matter, means that no contaminant concentration may be increased by more than 10%.

Effluent Standards

Because of the difficulty in assigning legal responsibility for stream standard violations when more than one discharge occurs, it is administratively easier to impose something called an "effluent standard." Each discharger is required to obtain a "National Pollutant Discharge Elimination System (NPDES)" permit from the competent state authority. The permit specifies the location, times, volume, and composition of the permitted discharge. The permit specifications are set by the state agency so as to prevent any violation of stream standards. However, any violation of a permit condition is prosecutable regardless of the impact on stream conditions.

Permit conditions for conservative contaminants, for poisons, for the traditional rules-of-thumb, and for antidegradation conditons are easily established by calculating a steady-state mass balance on the receiving stream at the point where the outfall meets it:

$$\overline{Q}_R \cdot \overline{C}_{QR} = \overline{Q}_W \cdot \overline{C}_{QW} + \left(\overline{Q}_R + \overline{Q}_W\right) \cdot \overline{C}_o \tag{8.12}$$

where $\overline{C}_o$ = the stream standard for the most stringent beneficial use, generally a 1-day, 4-day, or 7-day average (kg/m^3)
$\overline{C}_{QR}$ = the flow-weighted (flow-composited) contaminant concentration in the river upstream of the outfall (kg/m^3)
$\overline{C}_{QW}$ = the flow-weighted (flow-composited) contaminant concentration in the wastewater (kg/m^3)

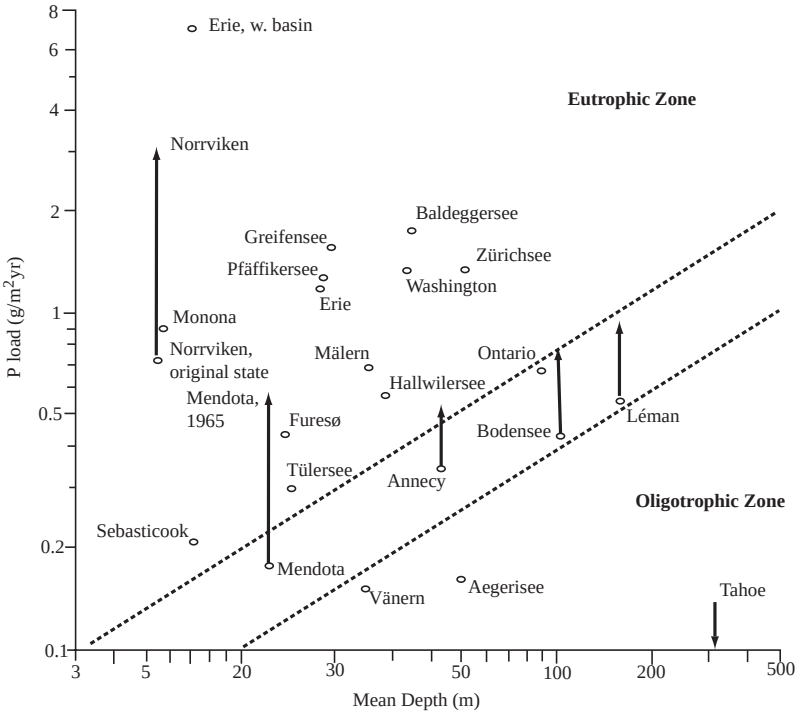

FIGURE 8.1 Classification of European and North American lakes by phosphorus loading and mean depth (International Joint Commission, 1969; Vollenweider, 1970).

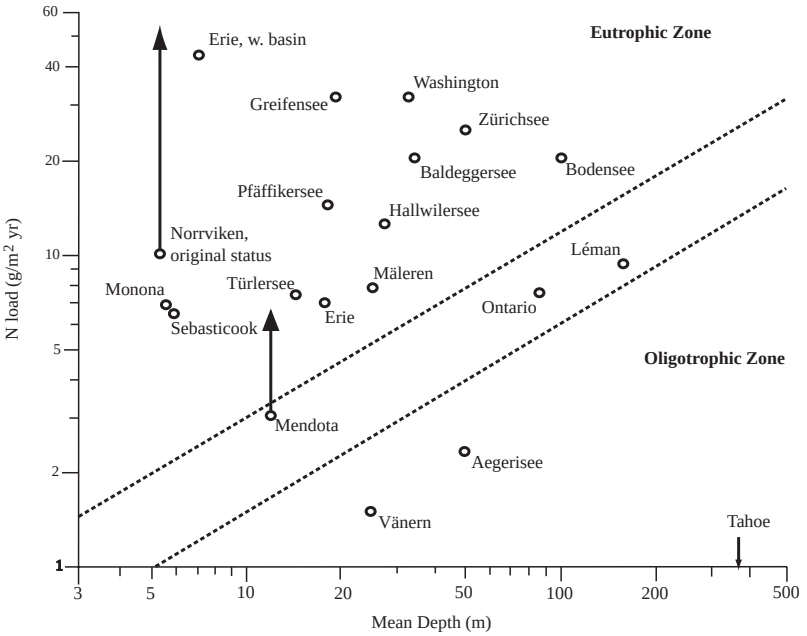

FIGURE 8.2 Classification of European and North American lakes by nitrogen loading and mean depth (International Joint Commission, 1969; Vollenweider, 1970).

The unknown in this case is the contaminant concentration in the treated effluent, $\bar{C}_{QW}$, and it becomes the NPDES permit condition. Sometimes the competent regulatory agency will "reserve" some stream assimilation capacity by using a $\bar{C}_o$ value that is less than the relevant stream standard.

It should be noted that for the purpose of judging compliance with an NPDES permit, the Water Quality Act defines the effluent load to be the product of the arithmetically averaged contaminant concentration and the arithmetically averaged flow. This product will be larger or smaller than the true value depending on whether concentrations and flows are positively or negatively correlated.

For nonconservative contaminants, the permit conditions must be determined via water quality simulations using calibrated, verified models. The verification requires *in situ* field data that were collected and reduced in conformance with the model variables, such as time-averaged and cross-sectionally average concentrations, and during the appropirate drought flow. The process is time consuming and expensive.

Many substances undergo a simple first-order decay process, and the contaminant concentration downstream of a point source may be modeled as,

$$C(x) = C_o e^{-(kx/u)} + \frac{W}{kA}\left[1 - e^{-(kx/u)}\right] \tag{8.13}$$

where A = the cross-sectional area of the receiving stream (m^2)
$C(x)$ = the contaminant concentration downstream of the outfall (kg/m^3)
C_o = the initial contaminant concentration at the outfall (kg/m^3)
k = the contaminant decay rate (per s)
u = the mean stream velocity (m/s)
W = the (uniformly) distributed load along the stream reach below the outfall (kg/m s)
x = the distance below the outfall (m)

In this case, the effluent permit for C_w (which determines C_o), would be set to prevent the maximum downstream concentration from exceeding the water quality standard. For a very long reach, this maximum would be W/kA.

Some substances like oxygen undergo both sink and source processes, and the models become more elaborate. The simple Streeter-Phelps (1925) model for oxygen includes the effects of both carbonaceous BOD oxidation and reaeration:

$$D(x) = D_o e^{-(k_a x/u)} + \frac{k_d L_o}{k_a - k_d}\left[e^{-(k_d x/u)} - e^{-(k_a x/u)}\right] \tag{8.14}$$

where $D(x)$ = the oxygen deficiency downstream of a point source (kg/m^3)
D_o = the initial oxygen deficit at the outfall (kg/m^3)
k_d = the carbonaceous BOD decay rate (per s)
k_a = the oxygen reaeration rate (per s)
L_o = the initial ultimate carbonaceous BOD at the outfall (kg/m^3)

Thomann and Mueller (1987) and Chapra (1997) present and discuss more detailed and realistic models for a wide variety of receiving waters, contaminants, and processes.

The minimum requirements of a NPDES discharge permit are shown in Table 8.8. These requirements define secondary biological treatment. While such requirements might be imposed on a small discharge to a large body of water, most permits are much more stringent in order to meet relevant water quality standards. More comprehensive permits include:

- Separate restrictions for summer and winter conditions
- Limits on ammonia
- Limits on specific substances known to be in the influent wastewater

TABLE 8.8 Default National Pollution Discharge Elimination System Limits[a]

Parameter	Averaging Period	
	7-Days	30-Days
Five-Day Biochemical Oxygen Demand		
Maximum effluent concentration (mg/L)	45	30
Removal efficiency (%)	—	85
Suspended Solids		
Maximum effluent concentration (mg/L)	45	30
Removal Efficiency (%)	—	85
pH (pH Units)		
Minimum	—	6
Maximum	—	9

Note: More stringent limits may be imposed for water quality in limited receiving waters. Other contaminants will be restricted as necessary to maintain water quality standards.

[a] Environmental Protection Agency (1976). "Secondary Treatment Information: Biochemical Oxygen Demand, Suspended Solids and pH," Federal Register, 41(144): 30788.

- More stringent sampling and monitoring requirements, perhaps at various points throughout the treatment facility or tributary sewers instead of only the outfall
- Specification of particular treatment processes

The more important parameters, like $CBOD_5$, are subject to the more stringent sampling programs. Some parameters like flow, oxygen, and chlorine are easily monitored continuously. The discharger may be requested to monitor parameters that have no apparent environmental impact in order to develop databases for future permits.

8.2 Planning

The problem of projecting future demands may be subdivided into two parts, namely, selection of (1) the planning period and (2) the projection technique.

Selection of Planning Period

In order to assess all the impacts of a project, the planning period should be at least as long as the economic life of the facilities. The U.S. Internal Revenue Service publishes estimates of the economic life of equipment, buildings, etc. This is especially important for long-lived facilities, because they tend to attract additional demand beyond that originally planned for.

Buildings have economic lives on the order of 20 years. For large pipelines, the economic life might be 50 years, and dams might have economic lives as long as 100 years. The U.S. Government usually requires a planning period of 20 years for federally subsidized projects. Usefully accurate projections, however, cannot be made for periods much longer than 10 years. The demands projected for the economic life of a project cannot, therefore, be regarded as likely to occur. Rather, the projected demands set the boundaries of the problem. That is, they provide guides to the maximum plant capacity, storage volume, land area, etc., that might be needed. Preliminary facilities designs are made using these guides, but the actual facilities construction is staged to meet shorter-term projected demands. The longer-term projections and plans serve to guarantee that the various construction stages will produce an integrated, efficient facility, and the staging permits reasonably accurate tracking of the actual demand evolution.

Optimum Construction Staging

The basic question is, how much capacity should be constructed at each stage? This is a problem in cost minimization. Consider Fig. 8.3. The smooth curves represent the projected demand over the economic life of some sort of facility, say a treatment plant, and the stepped lines represent the installed capacity. Note that installed capacity always exceeds projected demand. Public utilities usually set their prices to cover their costs. This means that the consumers generally will be paying for capacity they cannot use, and it is desirable to minimize these excess payments on the grounds of equity and efficiency.

The appropriate procedure is to minimize the present worth of the costs for the entire series of construction stages. This is done as follows. The present worth of any future cost is calculated using the prevailing interest rate and the time elapsed between now and the actual expenditure:

$$PW = \sum_{j=0}^{n} C_j \exp\{-it_j\} \tag{8.15}$$

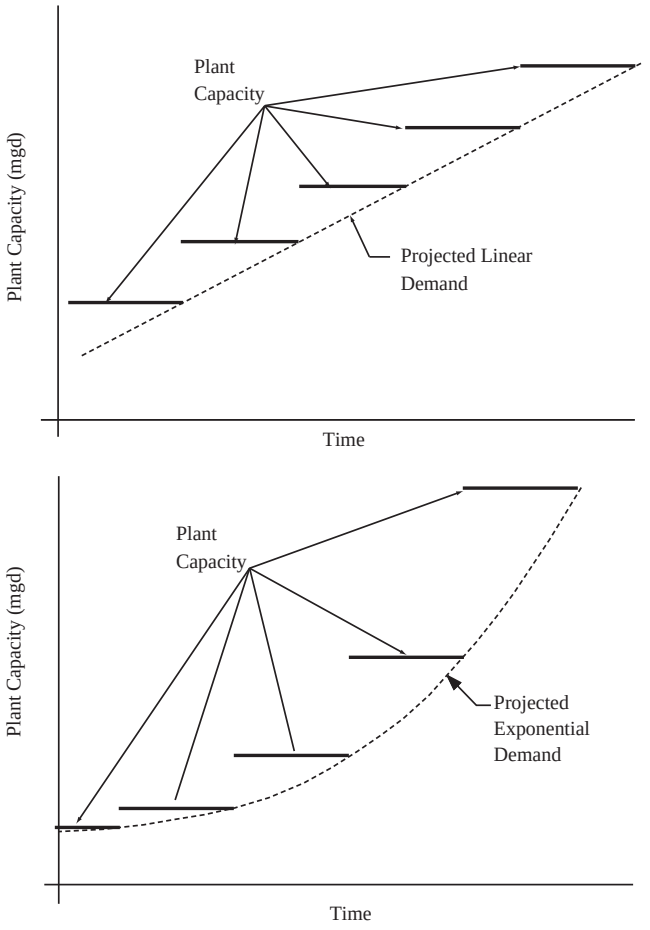

FIGURE 8.3 Capacity construction scheduling for linear and exponential growth.

where PW = the present worth of the jth cost
C_j = the jth cost at the time it is incurred
i = the prevailing interest rate (per year)
t_j = the elapsed time between now and the date of the jth cost

Manne (1967) and Srinivasan (1967) have shown that for either linearly or exponentially increasing demands, the time between capacity additions, Δt, should be constant. The value of Δt is computed by minimizing PW in Eq. (8.15). To do this, it is first necessary to express the cost, C_j, as a function of the added capacity, ΔQ_j. Economies of scale reduce the average cost per unit of capacity as the capacity increases, so the cost-capacity relationship may be approximated functionally as:

$$C = kQ^a \tag{8.16}$$

where a,k = empirical coefficients determined by regression of costs on capacity
C = the cost to construct a facility of capacity Q ($)
Q = the capacity (m^3/s)

For water treatment plants, a is usually between 0.5 and 0.8 (Clark and Dorsey, 1982).

Suppose that the demand is projected to increase linearly over time:

$$Q = Q_o + rt \tag{8.17}$$

where Q_0 = the demand at the beginning of the planning period (m^3/s)
r = the linear rate of increase of demand (m^3/s per year)

The capacity additions are equal to:

$$\Delta Q = r\Delta t \tag{8.18}$$

and the cost of each addition is:

$$C_j = k\left(r\Delta t\right)^a \tag{8.19}$$

Substituting Eq. (8.19) into Eq. (8.15), the present worth of the series of additions becomes:

$$PW = \sum_{j=0}^{n} k\left(r\Delta t\right)^a \exp\left\{-ij\Delta t\right\} \tag{8.20}$$

The problem is somewhat simplified if the number of terms in the summation, n, is allowed to become infinite, because for that case, the series converges to a simpler expression:

$$PW = \frac{k\left(r\Delta t\right)^a}{1-\exp\left\{-i\Delta t\right\}} \tag{8.21}$$

The value of Δt that yields the minimum value of the present worth is determined by taking logarithms of both sides of Eq. (8.21) and differentiating with respect to Δt:

$$a = \frac{i\Delta t}{\exp\left\{i\Delta t\right\}-1} \tag{8.22}$$

It should be noted that for linearly increasing demand, the optimum time between capacity additions, i.e., the time that minimizes the discounted expansion costs, depends only on the interest rate, i, and the economies of scale factor, a. The annual rate of demand increase, r, does not affect the result, and the coefficient k does not affect the result.

It is more usual to project exponentially increasing demands:

$$Q = Q_o \exp\left\{rt\right\} \tag{8.23}$$

In this case, the capacity additions are still spaced equally in time, but the sizes of the additions increase exponentially (Srinivasan, 1967):

$$PW = \frac{k\left(Q_o\left[\exp\left\{r\Delta t\right\}-1\right]\right)^a}{1-\exp\left\{-\left(i-ar\right)\Delta t\right\}} \tag{8.24}$$

$$a = \frac{\left(i-ar\right)\left[1-\exp\left\{-r\Delta t\right\}\right]}{r\left[\exp\left\{\left(i-ar\right)\Delta t\right\}-1\right]} \tag{8.25}$$

In this case, the exponential demand growth rate enters the calculation of Δt.

An exponential growth rate of 2%/year is about twice the national average for the U.S., so Eq. (8.22), which assumes linear growth and is easier to solve, may provide adequate accuracy for most American cities. However, urban areas in some developing countries are growing much faster than 2%/year, and Eq. (8.25) must be used in those cases.

Different components of water supply systems have different cost functions (Rachford, Scarato, and Tchobanoglous, 1969; Clark and Dorsey, 1982), and their capacities should be increased at different time intervals. The analysis just described can also be applied to the system components. In this case, the various component expansions need to be carefully scheduled so that bottlenecks are not created.

Finally, it should be remembered that the future interest rates and growth rates used to estimate the optimum expansion time interval are uncertain. Allowing for these uncertainties by adopting high estimates of these rates in order to calculate "conservative" values for the expansion capacity and costs is not the economically optimum strategy (Berthouex and Polkowski, 1970). Considering first the interest rate, if the range of possible interest rates can be estimated, then the optimum strategy is to adopt the midpoint of the range. The same strategy should be used when selecting growth rates: if the projected growth is exponential, adopt the midrange value of the estimated exponential growth rates. However, for linear growth, a different strategy is indicated: the minimal cost of expansion is achieved by using a linear growth rate somewhat less than the midrange value of the estimated rates. The "under design" capacity increment should be about 5 to 10% less than the capacity increment calculated using the midrange rate.

Population Projections

Because water demand is proportional to population, projections of water demand are reduced to projections of population. Engineers in the U.S. no longer make population projections. Population projection is the responsibility of designated agencies, and any person, company, or agency planning future public works is required to base those plans on the projections provided by the designated agency.

Projection errors of about 10% can be expected for planning periods less than 10 years, but errors in excess of 50% can be expected if the planning period is 20 years or more (McJunkin, 1964). Because nearly all projections are for periods of 20 years or more, all projections are nonsense if one regards them as predictions of future conditions. Their real function is regulatory. They force the engineer to design and build facilities that may be easily modified, either by expansion or decommissioning.

The four most commonly used methods of population projection are as follows:

- Extrapolation of historical census data for the community's total population
- Analysis of components-of-change (alias cohort analysis, projection matrix, and Leslie matrix)
- Correlation with the total population of larger, surrounding regions
- Estimation of ultimate development

The first method was the principal one employed prior to World War II. Nowadays, cohort analysis is nearly the only method used.

Population Extrapolation Methods

Extrapolation procedures consist of fitting some assumed function to historical population data for the community being studied. The procedures differ in the functions fitted, the method of fitting, and the length of the population record employed. The functions usually fitted are the straight line, the exponential, and the logistic:

$$P = P_o + rt \tag{8.26}$$

$$P = P_o \exp\{rt\} \tag{8.27}$$

$$P = \frac{P_{\max}}{1 + \left(\frac{P_{\max}}{P_o} - 1 \right) \exp\{-rt\}} \tag{8.28}$$

where P = the population at time t (capita)
P_{max} = the maximum possible number of people (capita)
P_0 = the population at the beginning of the fitted record (capita)
r = the linear or exponential growth rate (number of people per year or per year, respectively)
t = the elapsed time from the beginning of fitted record (yr)

The preferred method of fitting Eqs. (8.26) through (8.28) to historical population data is least squares regression. Because the exponential and logistic equations are nonlinear, they should be fitted using a nonlinear least squares procedure. Nonlinear least squares procedures are iterative and require a computer. Suitable programs that are available for IBM™-compatible and Macintosh™ personal computers are Minitab™, SAS™, SPSS™, and SYSTAT™.

Components-of-Change

At the present time, the preferred method of population projection is the method of components-of-change. The method is also known as cohort analysis, the projection matrix, and the Leslie (1945) matrix. It is a discretized version of a continuous model originally developed by Lotka (1956).

In this method, the total population is divided into males and females, and the two sexes are subdivided into age groups. For consistency's sake, the time step used in the model must be equal to the age increment. The usual subdivision is a 5-year increment; therefore, the age classes considered are 0/4, 5/9, 10/14, 15/19, etc. This duration is chosen because it is exactly half the interval between censuses, so that every other time step corresponds to a census.

Consider first the female age classes beginning with the second class, i.e., 5/9; the 0/4 class will be considered later. For these higher classes, the only processes affecting the number of females in each age class are survival and migration. The relevant equation is:

$$\begin{aligned}&\left[\text{number of females in age class "i + 1" at time "t + } \Delta t\text{"}\right] = \\ &\quad \left[\text{number of females in age class "i" at time "t" that survive } \Delta t\right] + \\ &\quad\quad \left[\text{number of female migrants during } \Delta t \text{ of age class "i+1"}\right]\end{aligned}$$

$$P_f(i+1, t+\Delta t) = l_f(i,t) \cdot P_f(i,t) + M_f(i+1, t+\Delta t) \tag{8.29}$$

where $l_f(i,t)$ = the fraction of females in the age class "i" (i.e., aged "$5 \cdot i$" through "$5 \cdot i + 4$" years) at time "t" that survive Δt years (here 5)
$M_f(i + 1, t + \Delta t)$ = the net number of female migrants (immigrants positive, emigrants negative) that join the age class "$i + 1$" between times "t" and "$t + \Delta t$"
$P_f(i,t)$ = the number of females in the age class "i" at time "t"
$P_f(i + 1, t + \Delta t)$ = the number of females in age class "$i + 1$" (i.e., aged "$5 \cdot (i + 1)$" through "$5 \cdot (i + 1) + 4$" years) at time "$t + \Delta t$"

The survival fractions, $l_f(i,t)$, can be calculated independently using the community's death records. The migration rates, however, are calculated using Eq. (8.29). This is done by using census data for $P_f(i + 1, t + \Delta t)$ and $P_f(i,t)$ and the independently calculated $l_f(i,t)$. Consequently, any errors in the census data or death records are absorbed into the migration rate.

It is a matter of convenience how the migration is expressed, and it is most convenient to express it as a correction to the calculated number of survivors:

$$M_f(i+1,t+\Delta t) = m_f(i,t)\cdot l_f(i,t)\cdot P_f(i,t) \tag{8.30}$$

where $m_f(i,t)$ = the female migration rate for age class "$i + 1$," in units of number of females joining age class "$i + 1$" during the period "t" to "$t + \Delta t$" per survivor of age class "i."

With this definition, Eq. (8.23) can be written as follows:

$$\begin{aligned} P_f(i+1,t+\Delta t) &= l_f(i,t)\cdot\left[1+m_f(i,t)\right]\cdot P_f(i,t) \\ &= l_{ef}(i,t)\cdot P_f(i,t) \end{aligned} \tag{8.31}$$

where $l_{ef}(i,t)$ = the effective fraction of females in age class "i" that survive from time "t" to "$t + \Delta t$"
$= l_f(i,t)\cdot[1 + m_f(i,t)]$

Now consider the first female age class, which is comprised of individuals aged 0 to 4 years. The processes affecting this class are birth and migration. What is needed is the net result of births and migrations for the 5-year period Δt. However, birth rates are usually given in terms of the number of births per female per year. Therefore, a 1-year rate must be converted into a 5-year rate. Furthermore, over a 5-year period, the number of females in any given age class will change due to death and migration. The birth rate also changes. These changes are handled by averaging the beginning and end of period rates:

$$\begin{aligned} &\left[\text{total births for age class "}i\text{" from "}t\text{" to "}t+\Delta t\text{"}\right] = \\ &\tfrac{5}{2}\cdot\left[b_f(i,t)\cdot P_f(i,t) + b_f(i,t+\Delta t)\cdot P_f(i,t+\Delta t)\right] \end{aligned} \tag{8.32}$$

where $b_f(i,t)$ = the female birth rate for females in age class "i" at time "t" in units of female babies per female per year.

Note that the factor "5" is needed to convert from 1-year to 5-year rates, and the factor "2" is needed to average the two rates.

The total number of births is obtained by summing Eq. (8.32) over all the age classes. If this is done, and if terms containing like age classes are collected, the total number of births is:

$$\begin{aligned} P_f(0,t+\Delta t) &= \tfrac{5}{2}\cdot\sum_{i=0}^{k}\left[b_f(i,t) + b_f(i+1,t+\Delta t)\cdot l_{ef}(i,t)\right]\cdot P_f(i,t) \\ &= \sum_{i=0}^{k}\bar{b}_f(i,t)\cdot P_f(i,t) \end{aligned} \tag{8.33}$$

where $\bar{b}_f(i,t)$ = the average female birth rate for females in the age class "i" for the period "t" to "$t + \Delta t$"
$= 5/2\cdot[b_f(i,t) + b_f(i+1,\, t+\Delta t)\cdot l_{ef}(i,t)]$

Equations 8.31 and 8.33 are most conveniently written in matrix form as follows:

$$\begin{bmatrix} P_f(0,t+\Delta t) \\ P_f(1,t+\Delta t) \\ \vdots \\ P_f(k,t+\Delta t) \end{bmatrix} = \begin{bmatrix} \bar{b}_f(0,t) & \bar{b}_f(1,t) & \cdots & \bar{b}_f(k,t) \\ l_{ef}(0,t) & 0 & \cdots & 0 \\ 0 & l_{ef}(1,t) & \cdots & 0 \\ 0 & 0 & l_{ef}(k-1,t) & 0 \end{bmatrix} \begin{bmatrix} P_f(0,t) \\ P_f(1,t) \\ \vdots \\ P_f(k,t) \end{bmatrix} \tag{8.34}$$

The first row in the coefficient matrix has numerous zeros (because very young and very old women are not fertile), and the main diagonal is entirely zeros.

The model for males is slightly more complicated. First, for all age classes other than the first (i.e., for i = 1,2,3,… k), the number of males depends solely on the fraction of the previous male age class that survives plus any migration that occurs:

$$\begin{aligned} P_m(i+1,t+\Delta t) &= l_m(i,t)\cdot\left[1+m_m(i,t)\right]\cdot P_m(i,t) \\ &= l_{em}(i,t)\cdot P_m(i,t) \end{aligned} \tag{8.35}$$

where $l_{em}(i,t)$ = the effective fraction of males in age class "i" that survive from time "t" to "$t + \Delta t$"
$= l_m(i,t) \cdot [1 + m_m(i,t)]$
$l_m(i,t)$ = the fraction of males in the age class "i" (i.e., aged "$5 \cdot i$" through "$5 \cdot i + 4$" years) at time "t" that survive Δt years (here 5)
$m_m(i,t)$ = the male migration rate for age class "$i + 1$," in units of number of males joining age class "$i + 1$" during the period "t" to "$t + \Delta t$" per survivor of age class "i"
$P_m(i,t)$ = the number of males in the age class "i" at time "t"
$P_m(i + 1,t + \Delta t)$ = the number of males in age class "$i + 1$" [i.e., aged "$5 \cdot (i + 1)$" through "$5 \cdot (i + 1) + 4$" years] at time "$t + \Delta t$"

The male birth rate depends on the number of females, not males, and the number of births must be written in terms of the population vector for women. The number of births for men (aged 0 to 4) is:

$$P_m(0,t+\Delta t) = \sum_{i=0}^{k} \bar{b}_m(i,t)\cdot P_f(i,t) \tag{8.36}$$

where $b_m(i,t)$ = the male birth rate for females in age class "i" at time "t," in units of male babies per female per year
$\bar{b}$ = the average male birth rate for females in age class "i" at time "t," in units of the total number of male babies born during the interval Δt (here 5 years) per female in age class "i"
$= 5/2 \cdot [b_m(i,t) + b_m(i + 1,t + \Delta t) \cdot l_{em}(i,t)]$
$P_m(0,t + \Delta t)$ = the number of males in age class "0" (i.e., aged 0 to 4 years) at time "$t + \Delta t$"

Consequently, the projection for males involves the population vectors for both males and females and coefficient matrices for each and is written:

$$\begin{bmatrix} P_m(0,t+\Delta t) \\ P_m(1,t+\Delta t) \\ \vdots \\ P_m(k,t+\Delta t) \end{bmatrix} = \begin{bmatrix} \bar{b}_m(0,t) & \bar{b}_m(1,t) & \cdots & \bar{b}_m(k,t) \\ 0 & 0 & \cdots & 0 \\ \vdots & \vdots & \vdots & 0 \\ 0 & 0 & \cdots & 0 \end{bmatrix} \begin{bmatrix} P_f(0,t) \\ P_f(1,t) \\ \vdots \\ P_f(k,t) \end{bmatrix} + \cdots$$

$$\cdots + \begin{bmatrix} 0 & 0 & \cdots & 0 \\ l_{em}(0,t) & 0 & \cdots & 0 \\ 0 & l_{em}(1,t) & \vdots & 0 \\ 0 & 0 & l_{em}(k-1,t) & 0 \end{bmatrix} \begin{bmatrix} P_m(0,t) \\ P_m(1,t) \\ \vdots \\ P_m(k,t) \end{bmatrix} \tag{8.37}$$

Correlation Methods

In the correlation method, one attempts to use the projected population of a larger, surrounding area, say a county or state, to estimate the future population of the community being studied. This method is sometimes preferable to a direct projection of the community's population, because there are usually

more accurate and more extensive data available for the larger area. This is especially true for smaller cities. The projected population of the larger, surrounding area is usually obtained by the method of components, which is described above.

The correlation method entails plotting the available population data from the surrounding area and the community against one another. It is assumed that the community is following the pattern of growth exhibited by the surrounding area, or something close to it. The correlation takes the form:

$$P_c(t) = b_1 \cdot P_a(t) + b_o \tag{8.38}$$

where b_0, b_1 = regression coefficients
$P_a(t)$ = the population of the larger, surrounding area at time t
$P_c(t)$ = the population of the community at time t

Ultimate Development

The concept of ultimate or full development is actually somewhat nebulous, but nonetheless useful, at least for short-term projections. Almost all communities have zoning regulations that control the use of developed and undeveloped areas within the communities' jurisdictions. Consequently, mere inspection of the zoning regulations suffices to determine the ultimate population of the undeveloped areas.

There are several problems with this method. First, it cannot assign a date for full development. In fact, because population trends are not considered, the method cannot determine whether full development will ever occur. Second, the method cannot account for the chance that zoning regulations may change, e.g., an area zoned for single family, detached housing may be rezoned for apartments. Zoning changes are quite common in undeveloped areas, because there is no local population to oppose them. Third, the method cannot account for annexations of additional land into the jurisdiction. However, it should be noted that the second and third problems are under the control of the community, so it can force the actual future population to conform to the full development projection.

Siting and Site Plans

Flood Plains

Water and wastewater treatment plants are frequently built in the flood plain. Of course, the intakes of surface water treatment plants and the outfalls of wastewater treatment plants are necessarily in the flood plain. However, the remainder of the facilities are often built in risky areas either to minimize the travel time of maintenance crews or because — in the case of wastewater plants — the site is the low point of a drainage district.

The Wastewater Committee requires that wastewater treatment plants be fully operational during the 25-year flood and that they be protected from the 100-year flood (Wastewater Committee, 1990). The intake pumping stations of water treatment plants should be elevated at least 3 ft above the highest level of either the largest flood of record or the 100-year flood or should be protected to those levels (Water Supply Committee, 1987).

Permits

Water and wastewater treatment plants require a number of permits and must conform to a variety of design, construction, and operating codes.

Federal Permits

The National Environmental Policy Act of 1969 (PL 91–190) requires an Environmental Impact Statement (EIS) for "… major federal actions significantly affecting the quality of the human environment." The EIS should consider alternatives to the proposed action, both long-term and short-term effects, irreversible and irretrievable commitments of resources, and unavoidable adverse impacts. An EIS may be required even if the only federal action is the issuance of a permit. An EIS is not required if the relevant federal agency (here, the U.S. Army Corps of Engineers or U.S. EPA) certifies that there is no significant environmental impact.

The fundamental federal permit is the National Pollution Discharge Elimination System (NPDES) permit, which the Federal Water Pollution Control Act of 1972 requires for each discharge to a navigable waterway. Authority to grant permits is vested in the U.S. EPA, however, it has delegated that authority to the various states, and as a practical matter, dischargers apply to the relevant state agency.

Treatment plants may also be required to obtain a 404 permit from the U.S. Army Corps of Engineers if the proposed facility creates an obstruction in or over a navigable waterway.

A broadcasting license may be required by the Federal Communications Commission if radio signals are used for telemetry and remote control.

Besides these permits and licenses, treatment plants must be designed in conformance with a number of federal regulations, including:

- Clean Air Act requirements governing emissions from storage tanks for chemicals and fuels (Title 40, Parts 50 to 99 and 280 to 281)
- Americans with Disabilities Act of 1990 (PL 101–336) requirements regarding access for handicapped persons
- Occupational Health and Safety Act requirements regarding workplace safety

State and Local Permits

The design of water and wastewater treatment plants is subject to review and regulation by state agencies. Such reviews are normally conducted upon receipt of an application for a NPDES permit. The states are generally required to make use of U.S. EPA guidance documents regarding the suitability of various treatment processes and recommended design criteria. Some states also explicitly require adherence to the so-called "Ten States Standards," which are more correctly referred to as Great Lakes-Upper Mississippi River Board of State Public Health and Environmental Managers' "Recommended Standards for Water Works" and "Recommended Standards for Wastewater Facilities."

States also require permits for construction in floodplains, because large facilities will alter flood heights and durations.

Highway departments require permits for pipelines that cross state roads. Generally, such crossings must be bored or jacked so that traffic is not disrupted.

Facilities must also conform to local codes, including:

- State building codes [usually based on the Building Official and Code Administrators (BOCA) Building Code]
- State electrical codes [usually based on the National Electrical Code as specified by the National Fire Protection Association (NFPA-70)]
- State plumbing code

These are usually administered locally by county, municipal, or township agencies. Most commonly, the agencies require a permit to build (which must be obtained before construction and which requires submission of plans and specifications to the appropriate agencies) and a permit to occupy (which requires a postconstruction inspection).

In many cases, design engineers voluntarily adhere to or local regulations require adherence to other specifications, e.g.:

- General materials specifications, sampling procedures, and analytical methods — American Society for Testing and Materials (1916 Race Street, Philadelphia, PA 19103–1187)
- Specifications for water treatment chemicals and equipment — American Water Works Association (6666 West Quincy Avenue, Denver, CO 80235)
- Specifications for fire control systems and chemical storage facilities — National Fire Protection Association (1 Batterymarch Park, PO Box 9101, Quincy, MA 02269–9191)
- Specifications for chemical analytical methods — Water Environment Federation (601 Wythe Street, Alexandria, VA 22314–1994) and American Water Works Association (6666 West Quincy Avenue, Denver, CO 80235)

Other Permits

Railroad crossings require the permission of the railroad. As with highways, pipelines must be bored or jacked under the roadbed so that traffic is not disrupted.

Excavation almost always occurs near other utilities, and this should be coordinated with them.

8.3 Design Flows and Loads

Flow and Load Averaging

Designers must account for the inherent variability in flows and loads. This is done by defining various duration averages, maxima, and minima. The average flow for some specified time period, T, is for continuous and discrete data, respectively,

$$\overline{Q} = \frac{1}{T}\int_0^T Q(t)\cdot dt \tag{8.39}$$

$$\overline{Q} = \frac{\sum_i Q_i}{n} \tag{8.40}$$

where n = the number of discrete flow measurements during the specified period (dimensionless)
$Q(t)$ = the flow at time instant t (m^3/s)
$\overline{Q}$ = the arithmetic mean volumetric flow for the specified period (m^3/s)

Q_i = the "ith" flow measurement during the specified period (m^3/s)
T = the duration of the specified period (s)
t = the time elapsed since the beginning of the period (s)

The usual averaging periods (T) are:

- The annual average, alias average day
- The maximum (or minimum) 1-h average
- The maximum (or minimum) 24-h average
- The maximum (or minimum) 3-day average
- The maximum (or minimum) 7-day average
- The maximum (or minimum) 30-day average

In each case, the database consists of 12 consecutive months of flow and load records. A maximum average flow or load for some specified period is computed by identifying the continuous time interval in the annual record that is equal in duration to the specified period and that produces the maximum total volume of flow or mass of contaminant load. The minimum averages are determined similarly. If the NPDES permit is written with seasonal limits, the maxima and minima should be determined using seasonal rather annual data.

The *instantaneous* contaminant load is the product of the instantaneous contaminant concentration and the instantaneous wastewater volumetric flow rate:

$$W(t) = Q(t) \cdot C(t) \tag{8.41}$$

$$W_i = Q_i \cdot C_i \tag{8.42}$$

where $C(t)$ = the contaminant concentration at time instant t (kg/m^3)
C_i = the "ith" measurement of the contaminant concentration (kg/m^3)
$W(t)$ = the load at time instant t, (kg/s)
W_i = the "ith" load measurement (kg/s)

The *average* contaminant load during some interval T is calculated as,

$$\overline{W} = \frac{1}{T}\int_0^T W(t) \cdot dt \tag{8.43}$$

$$\overline{W} = \frac{\sum_i W_i}{n} \tag{8.44}$$

where $\overline{W}$ = the average contaminant load for the specified period (kg/s).

The Average Concentration

The most natural and useful definition of an average concentration is the *flow-weighted* (*flow-composited*) concentration:

$$\overline{C}_Q = \frac{\int_0^T Q(t) \cdot C(t) \cdot dt}{\int_0^T Q(t) \cdot dt} = \frac{\overline{W}}{\overline{Q}} \tag{8.45}$$

$$\overline{C}_Q = \frac{\sum_i Q_i \cdot C_i}{\sum_i Q_i} = \frac{\overline{W}}{\overline{Q}} \tag{8.46}$$

where $\overline{C}_Q$ = the flow-weighted (flow-composited) average concentration (kg/m^3).

Note that the (arithmetic) average load is the product of the (arithmetic) average flow and the flow-weighted average concentration.

The simple arithmetic average concentration is frequently encountered,

$$\overline{C} = \frac{1}{T}\int_0^T C(t) \cdot dt \tag{8.47}$$

$$\overline{C} = \frac{\sum_i C_i}{n} \tag{8.48}$$

where $\overline{C}$ = the arithmetic average contaminant concentration (kg/m^3).

The general relationship between the average load and the arithmetic average concentration is,

$$\overline{W} = \overline{Q} \cdot \overline{C} + \mathrm{CoVar}(Q,C) = \overline{Q} \cdot \overline{C} + \rho_{QC} \cdot \sigma_Q \cdot \sigma_C \tag{8.49}$$

where CoVar(Q,C) = the covariance of Q and C (kg/s)

$$= \frac{\sum_i (Q_i - \overline{Q})(C_i - \overline{C})}{n}$$

ρ_{QC} = the Pearson product-moment correlation coefficient (dimensionless)

$$= \frac{\sum_i (Q_i - \overline{Q})(C_i - \overline{C})}{\sqrt{\sum_i (Q_i - \overline{Q})^2} \cdot \sqrt{\sum_i (C_i - \overline{C})^2}}$$

σ_C = the standard deviation of the contaminant concentration measurements (kg/m^3)

$$= \sqrt{\frac{\sum_i (C_i - \overline{C})^2}{n}}$$

σ_Q = the standard deviation of the flow measurements (m^3/s)

$$= \sqrt{\frac{\sum_i (Q_i - \overline{Q})^2}{n}}$$

Note that the average load is equal to the product of the average flow and arithmetic average concentration only if the flows and concentrations are uncorrelated ($\rho_{QC} = 0$). This is generally false for raw wastewaters, but it may be true for biologically treated effluents. In most raw wastewaters, the flows and concentrations are positively correlated. Therefore, the product $\overline{Q} \cdot \overline{C}$ underestimates the mean load. The underestimate can be substantial.

For NPDES permits, the U.S. EPA defines the average load to be the product of the arithmetic average flow and the arithmetic average concentration, $\bar{Q} \cdot \bar{C}$. The great majority of discharges are biologically treated effluents, so there is no significant error in the EPA's definition.

Annual Average per Caput Flows and Loads

The annual average per capita water demand is the total volume of water supplied during a complete year divided by the mid-year population. The usual units are either gallons per caput per day (gpcd) or liters per caput per day (Lpcd). Sometimes the volumes are expressed as cubic feet or cubic meters. The calculation proceeds as follows:

$$\bar{Q}_{pc} = \frac{1}{T}\int_0^T \frac{Q(t)\cdot dt}{P(t)} = \frac{1}{n}\sum_{i=1}^{n}\frac{Q_i}{P_i} \tag{8.50}$$

$$\bar{W}_{pc} = \frac{1}{T}\int_0^T \frac{Q(t)\cdot C(t)\cdot dt}{P(t)} = \frac{1}{n}\sum_{i=1}^{n}\frac{Q_i\cdot C_i}{P_i} \tag{8.51}$$

where $\bar{Q}_{pc}$ = the annual average per caput water demand (m^3/cap·s)
$\bar{W}_{pc}$ = the annual average per caput load (kg/cap·s)

Because the rate of population increase is usually only a few percent per year, or less, the integral and sum are evaluated by assuming P is constant and equal to the mid-year population. P is then factored out, and the integral and sum become the total volume of water supplied in gallons or liters during the year.

Automatic Samplers

Some automatic samplers capture a constant sample volume at uniformly spaced time increments: the data from these samplers are arithmetically averaged concentrations. Other samplers capture sample volumes at uniformly spaced time increments, but the sample volumes are proportional to the simultaneous flow rate: the data from these samplers are flow-weighted average concentrations. Flow-weighted concentrations are also produced by samplers that collect constant sample volumes but adjust the sampling time increments so that each sample represents the same total flow volume.

Water Treatment

The flow through water treatment plants is controlled by the operator, and this simplifies the design process. The designer must still allow for variations in consumption, but these can be satisfied by system storage of finished water.

Annual Average per Caput Flows and Loads

In public water supplies, the water demand is the sum of the volumes supplied to households, commercial and industrial enterprises, and public agencies. An approximate breakdown by use of the water withdrawn for public supplies in 1980 is given in Table 8.9. The estimates were compiled from several independent sources, and they may each be in error by several gpcd. The data are national averages, and particular cities will exhibit substantial divergences from them. In 1980, public water supplies in the U.S. served 186 million people (81% of the total population), and their total withdrawal from surface and ground waters amounted to 183 gpcd (Solley, Chase, and Mann, 1983). Of the total withdrawal, 66% was obtained from surface waters, and 34% came from ground waters. And, 21% of the withdrawal went to consumptive uses, most of which was lawn sprinkling.

These national averages mask a wide range of local variations (Solley, Chase, and Mann, 1983). For example, the amount of water withdrawn in 1980 varied from 63 gpcd in the Virgin Islands to 575 gpcd in Utah, and the consumptive use varied from none in Delaware to 71% in Wyoming. In general, per caput water withdrawals are greatest in the hot, arid Colorado River valley and the Great Basin (341 gpcd, 45% consumptive) and least in the wetter, cooler New England states (148 gpcd, 10% consumptive).

TABLE 8.9 Estimate of Uses of the Annual Average Withdrawal by Public Supplies in 1980

Use	Rate (gpcd)	Percent of Total Withdrawal

About one-eighth of the withdrawal is lost either as treatment byproducts (i.e., sludges and brines) or as unaccounted for water. The latter category includes such things as unmetered (i.e., free) water, leakage, fire control, and metering errors.

One-third of the withdrawal is supplied to commercial and industrial enterprises, although many industrial plants have independent supplies.

Somewhat less than half the withdrawal is supplied to households. The principal uses there are lawn sprinkling, toilet flushing, and bathing. The particular estimates of aggregate household use cited in Table 8.9 are the weighted average of the demands reported by Linaweaver, Geyer, and Wolff (1966) for detached, single-family houses and apartments that had metered water and sewerage. It was assumed that detached, single-family homes comprised 67% of the total number of housing units, and that the

remainder were apartments. For detached, single-family homes with metered water and septic tanks, a better estimate of usage exclusive of lawn sprinkling is 44 gpcd (Schmidt et al., 1980), and lawn sprinkling might be reduced by two-thirds (Linaweaver, Geyer, and Wolff, 1966). For high-income areas, the lawn sprinkling usage might be doubled, but in-house usage would only increase by about 10%.

The per caput annual average withdrawal rate for public supplies rose steadily at about 1%/year for over 100 years. Some statistics are given in Table 8.10. The rate of increase from 1870 is 1.09%/year, and the rate since 1950 is 0.78%/year. The annual increase in withdrawals may have declined or even ceased since the mid-1980s because of conservation efforts.

Because it is probable that no city in the U.S. has a usage breakdown like that shown in Table 8.9, local usage projections should always be based on local data. This is not a very severe requirement, because all American cities already have water supply systems, and the records maintained by these systems can be used as the basis of design. National average data is more useful for making adjustments to local usage projections to account for factors like income levels, water prices, and climate.

Peak Demand

Some reported peaking factors for entire cities are given in Table 8.11. The 1882 data given by Fanning are for large cities in the Northeast, and the 1913 data given by Metcalf et al. are for cities and towns in Massachusetts. The data for 1932 and 1936 were obtained from numerous cities of all sizes throughout the country. The peak data for 1936 were obtained during a severe drought, and the peak-to-average ratio was calculated using the average demand for June of 1935. Wolff's data were obtained from cities in the Northeast.

The detailed data reported in the cited papers indicate that the peak demands for the 4-h averaging period are only slightly smaller than those for the 1-h averaging period. The 3-day averages are also nearly equal to the 1-day averages. However, the ratio of peak-to-average demands generally declines as the peak averaging period increases, as it must.

The detailed data also show a weak tendency for the peak-to-average ratio to decline as the population rises. This tendency is not apparent in the data for 1932 and 1936, which represent about 400 cities nationwide. However, for 70 cities in the Northeast, Wolff (1957) reported the following ratios of peak 1-day to average day demands:

TABLE 8.11 Reported Ratios of Peak to Average per Capita Demands for American Cities

For purely residential areas:

$$\frac{\text{maximum 1-day average demand}}{\text{annual average demand}} = 2.51P^{-0.0855} \tag{8.52}$$

For combined residential and industrial areas:

$$\frac{\text{maximum 1-day average demand}}{\text{annual average demand}} = 2.09P^{-0.0574} \tag{8.53}$$

where P = the service population in thousands.

In view of the insensitivity of peaking factors to population, the peaking factors in Table 8.12 are recommended for American communities. These ratios are somewhat higher than those recommended a generation ago (e.g., Fair, Geyer, and Morris, 1954), but the amount of lawn sprinkling has increased substantially since then, and lawn sprinkling is a major component of the peak demands. The same ratios may be used for residential neighborhoods, with two exceptions (Linaweaver, Geyer, and Wolff, 1966).

TABLE 8.12 Recommended Peaking Factors for Water Demand

	Averaging Period

[b] Critchlow, H. T. 1951. "Discussion: S.K. Keller (1951), 'Seasonal Water Demands in Vacation Areas'," *Journal of the American Water Works Association,* 43(9): 701.

The exceptions are newly developed lots where new lawns are being established and very large lots in high-income areas. In these areas, the ratio of peak hour to average day demands reaches 15 to 20.

In the late 19th Century, peak demands in northern cities usually occurred in the winter. This was a result of the need to discharge water through hydrants and household taps to prevent freezing, the water mains often being shallow and the houses poorly heated. By the early 20th Century, lawn sprinkling had shifted the peak demand to summer. By 1930, 55% of American cities reported that peak demand occurred in July, and 25% reported that it occurred in August (Folwell, 1932). Only 15% of the cities experienced peak demands in the winter.

The peaking factors cited above are weighted toward Eastern cities, which receive significant rainfall throughout the summer. This somewhat mitigates lawn sprinkling. Many Western cities, however, receive little or no rain in the summer, and residents often water their lawns several times a week. The practical result of this practice is that the so-called maximum daily average demand occurs nearly every day during the Western summer (Linaweaver, Geyer, and Wolff, 1966).

Finally, there is the issue of fire demands. The amount of water used for fire control over an entire year is small, and it might not affect the peak demand statistics for a whole city. However, in the neighborhood of an ongoing fire, the fire demand dominates the local water requirements and controls the design of the local storage and distribution systems. In the U.S., water supply systems are usually designed in accordance with the recommendations of the Insurance Services Office (ISO). These recommendations are used to set fire insurance premiums for new cities and for small cities for which there is little data on fire insurance claims. For old, large cities that have ample statistics on claims, premiums are usually set on an actuarial basis.

The ISO calculates a "Needed Fire Flow" (NFF_i) at each of several representative locations in the city. It is assumed that only one building is on fire at any time. The formula for the NFF_i is (Anonymous, 1980):

$$NFF_i = C_i \cdot O_i \cdot \left(X + P\right)_i \tag{8.54}$$

where NFF_i = the needed fire flow (gpm)

C_i = the fire flow based on the size of the building and its construction (ranging from 500 to 8000 gpm)

O_i = a correction factor for the kinds of materials stored in the building (ranging from 0.75 to 1.25)

$(X + P)_i$ = a correction factor for the proximity of other buildings (ranging from 0.0 to 1.75)

Criteria for assigning values to the various factors in Eq. (8.54) are given in the ISO recommendations. In any case, the NFF_i must be not be greater than 12,000 gpm or less than 500 gpm. For one- and two-family dwellings, the NFF_i ranges from 500 to 1500 gpm; for larger dwellings, NFF_i is increased up to a maximum of 3500 gpm. The water supply system should be able to deliver to the fire location the total of the NFF_i and the maximum 24-h average demand, while maintaining a system pressure of at least 20 psig everywhere. For an NFF_i of 2500 gpm or less, the total flow must be sustainable for 2 h; for an NFF_i between 3000 and 3500 gpm, it must be sustainable for 3 h; and for an NFF_i greater than 3500 gpm, it must be sustainable for 4 h.

These recommendations refer to the water distribution system. The treatment plant design flow need not be the total of the NFF_i and the maximum 24-h average demand, so long as there is sufficient storage capacity to make up the difference between plant capacity and the total flow.

Factors Affecting Household Demand

The principal factors affecting household water demand are household income, water price, climate, and conservation regulations. They primarily affect lawn sprinkling, and there is a strong climatic effect that distinguishes the humid East from the arid West.

In general, lawn sprinkling demand amounts to about 60% of the net evapotranspiration rate (Linaweaver, Geyer, and Wolff, 1966):

$$Q_{ls} = 0.60 \cdot A_l \cdot \left(E_{pot} - P_{eff}\right) \tag{8.55}$$

where Q_{ls} = the lawn sprinkling demand (annual, monthly, or daily average, as appropriate, in m^3/s)
A_l = the lawn area (hectares)
E_{pot} = the potential evapotranspiration rate (annual, monthly, or daily average to conform to Q_{ls} in $m^3/ha{\cdot}s$)
P_{eff} = the effective precipitation rate (annual, monthly, or daily average to conform to Q_{ls} in $m^3/ha \cdot s$)

Lawn sprinkling demand is modified by household income and water price. Lawn sprinkling demand elasticities for income and price are calculated as:

$$\eta_I = \frac{dQ_{ls}/Q_{ls}}{dI/I} \tag{8.56}$$

$$\eta_C = \frac{dQ_{ls}/Q_{ls}}{dC/C} \tag{8.57}$$

where C = water cost ($/m^3$)
I = household income ($/yr)
Q_{ls} = lawn sprinkling demand (m^3/s)
η_C = the elasticity of lawn sprinking demand with respect to water cost (dimensionless)
η_I = the elasticity of lawn sprinkling demand with respect to household income (dimensionless)

In metered, sewered Eastern communities, the income and price elasticities for the summer average lawn sprinkling demand are about 1.5 and -1.6, respectively (Howe and Linaweaver, 1967). This means that if household income were increased by 10%, lawn sprinkling demand would be increased by 15%; if water prices were increased by 10%, lawn sprinkling demand would be reduced by 16%. In metered, sewered Western communities, however, the income and price elasticities are only 0.4 and -0.7, respectively.

These differences in response are due to climate. In the humid East, there are frequent summer rains, and reductions in lawn sprinkling will not result in loss of lawns. In the arid West, however, summer rains are infrequent or nonexistent, and lawns will die without regular irrigation.

Prices and incomes have less effect on peak daily lawn sprinkling demands than on the summer average. This is an artifact of utility billing practices (Howe and Linaweaver, 1967). Because consumers are billed only monthly or quarterly for the total amount of water used, the cost of a single afternoon's watering is not a major portion of the bill and does not deter water use. If necessary, peak daily demands can be curtailed by use prohibitions (Heggie, 1957).

Wastewater Treatment

It has been the custom in the U.S. to use the annual average flows and loads as the basis of process design, exceptions being made for process components that are especially sensitive to maximum and/or minimum flows and loads. However, nowadays, NPDES permits generally are written in terms of 30-day and 7-day average limits, and this suggests that the design basis should be a maximum 30-day average or maximum 7-day average load or flow (Joint Task Force, 1992). If other averages are written into the permit, they should become the design basis. If the permit conditions are seasonal, then the averages should be calculated on a seasonal basis, e.g., a maximum 30-day average load for the winter, a maximum 30-day average load for the summer, etc. Consequently, the design of each component in a treatment plant must consider several different loading and flow conditions, and the most severe condition will control its design.

Table 8.13 is a compilation of recommended design flows and loads for various treatment plant components. The basic design period is assumed to be either the maximum 7-day or 30-day average flow or load, depending on which is most severe given the associated temperature and composition. Most regulatory authorities still use the annual average load or flow in their regulations.

TABLE 8.13 Recommended Design Flows and Loads for Wastewater Treatment Plant Components[a]

Process or Material	Design Period	Peaking Factor Peak Value/Annual Average
Operating costs		
Chemicals	Annual average	1
Electricity	Annual average	1
Ultimate hydraulic capacity of tanks, conduits, pumps, weirs, screens, etc.	Transmit the instantaneous annual maximum flow with one of each parallel units out of service; check solids deposition at minimum flows	Maximum and minimum rated capacities of influent sewer or pumping station

Wastewater Committee of the Great Lakes-Upper Mississippi River Board of State Public Health and Environment Managers. 1990. Recommended Standards for Wastewater Facilities, 1990 Edition. Health Education Services, Albany, NY.

Typical peaking factors are included in Table 8.13. There is substantial variation in peaking factors between communities, especially between large and small communities, and designs should be based on local data.

Flow and Load Equalization

The design flows and load recommendations in Table 8.13 generally do not account for hourly flow variations within a 24-h period. Normal daily peak flows and loads do not affect average activated sludge process performance unless the daily 3-h average maximum flow exceeds 160% of the 24-h average flow (140% of the average for the 6-h average maximum flow). If higher peak flows occur, they can be accounted for by increasing the size of the aeration tank. An approximate rule for the volume increase is (Joint Committee, 1977):

$$\Delta V = 60\left(PF_{3h} - 1.6\right) \tag{8.58}$$

where ΔV = the additional aeration tank volume needed to account for excessive peak flows (%)
PF_{3h} = the peaking factor for the daily 3-h average maximum flow (decimal fraction)

For the daily 6-h average maximum flow, the rule is,

$$\Delta V = 60\left(PF_{6h} - 1.4\right) \tag{8.59}$$

where PF_{6h} = the peaking factor for the daily 6-h average maximum flow (decimal fraction).

Flow equalization is generally not recommended at municipal wastewater treatment plants unless the daily 3-h average maximum flow exceeds 210% of the average (180% of the average for the daily 6-h average maximum flow). The principal cause of performance degradation during peak hydraulic loads is secondary clarifier failure. In activated sludge plants, this seems to become a problem at overflow rates of about 1000 gpd/ft^2 (Ongerth, 1979).

Population Equivalents

The concentrations of various substances in raw sewage varies widely, because (1) water consumption rates vary widely, yielding differing degrees of dilution, and (2) potable waters start out with different amounts of minerals depending on local geology. However, the rates of contaminant mass generation per capita are fairly uniform, even across cultures. Table 8.14 presents a summary of American and some European data.

The organic fraction is reported variously as 5-day biochemical oxygen demand (BOD), (dichromate) chemical oxygen demand (COD), volatile solids (VS), and total organic carbon (TOC). Approximate ratios among some of these parameters are given in Table 8.15. The tabulated ratios are weighted toward the results of the U.S. EPA study (Burns and Roe, Inc., 1977), because of the large number of plants included.

TABLE 8.14 Population Equivalents for Municipal Sewage

8.4 Intakes and Wells

Natural waters are almost never homogeneous, either in space or in time. Even aquifers often show some vertical and/or seasonal variation in water composition. There are, however, patterns to the variations, and a judicious selection of the exact point and timing of water withdrawals can simplify and improve treatment plant design, operation, and performance.

The factors requiring consideration by the designer of an intake or well field are as follows (Babbitt, Doland, and Cleasby, 1967; Burdick, 1930):

- Source of supply — e.g., river, lake, impounding reservoir, spring, or well
- Nature of the withdrawal site — e.g., depth of water, character of bottom (silt, gravel, cobbles, etc.), wind fetch and wave protection, flow stratification and seasonal turnover, salt fronts and intrusion, consolidated or unconsolidated aquifer materials, artesian or nonartesian aquifer
- Relationship of site to possible or actual sources of contamination
- Permanence of existing conditions — e.g., to what extent floods, droughts, other development, etc., might change the quantity and quality of the water, the site topography, or access to the water source
- Special requirements of the site — e.g., the need to provide special facilities to cope with moving sand bars, fish and wildlife, seasonal debris, ice, navigation, violent storms, high flood stages and low drought stages, accessibility of site, availability and reliability of electrical power, and distance to pumping station
- Site properties that affect the stability of the proposed structures — e.g., the character of the foundation soils

The source of supply, nature of the withdrawal site, special requirements of the site, and the relationship of the site to sources of contamination have direct impacts on the quality of the raw water and the treatment it requires. Each of these is discussed below.

River Intakes

Hazards

River intakes are exposed to a variety of hazards, including floating and suspended debris, fish and wildlife, ice, variable water stages due to floods and droughts, shipping, and pleasure boating. Although these hazards primarily affect the longevity and reliability of the structures involved, there are some indirect affects on water quality.

Debris and Wildlife

The principal concern raised by debris and wildlife is that they might enter the plant piping and damage mechanical equipment, such as pumps and valves. Small and fragile debris like fish, leaves, floating oils, cloth, and paper may pass through pumps and valves without damaging them. Nevertheless, such materials are objectionable, because they are macerated by the mechanical equipment and increase the amount of organic matter dissolved in the raw water. High concentrations of dissolved organic matter produce tastes, odors, colors, and turbidity; reduce the efficiency of disinfection; and promote the regrowth of microbes in the distribution system. This regrowth increases the threat of disease transmission and system corrosion.

The defense against debris and wildlife is screens. For intakes, these come in two general classes: bar racks and traveling screens. Screen design is discussed in Chapter 9.

The screenings collected by manual and/or mechanical cleaning undergo some compaction and decay during collection and storage, and they should not be returned to the raw water source. The debris has been concentrated from a large volume of water, and its physical, chemical, and biological properties may have been changed. The mere fact of concentration means that if the debris is returned to the raw

water source, a high local debris concentration will be created, which may be a nuisance. The changes in properties may cause the debris to settle in the water source, forming sludge deposits, or the dissolved organic matter concentration in the source may be increased. The preferred route of disposal is incineration or landfill.

Fish require special considerations, which are listed in Chapter 9.

Ice

A major hazard to all surface water intakes in the temperate zone is ice. The principal ice forms are surface, anchor, frazil, and slush (Baylis and Gerstein, 1948; Gisiger, 1947).

Frazil ice consists of fine needle-like ice crystals that form suspended in the water and later deposit on various surfaces. It sometimes accumulates in the water as slushy masses. Because the crystals are small and the slush is fragile, they can penetrate deeply into the intake piping system, and large amounts of ice may coat intake screens, the inside of conduits, and even pump impellors. This generally results in serious clogging of the intake system. Frazil ice occurs under turbulent conditions in a narrow temperature range, maybe only -0.05 to +0.10°C. The condition is usually temporary, starting in the late evening to early morning and lasting until noon. Its formation is prevented by restricting the velocity through intake screens and conduits to less than 30 fpm and by mild heating of the flow to about 2°F above the ambient water temperature (Pankratz, 1988).

Anchor ice forms on submerged objects. This is especially troublesome in the guideways for slidegates. The usual preventive measure includes some sort of heating device, which may be as simple as an air bubble curtain or as involved as hot steam lines.

Surface ice damages structures by impact, static horizontal pressure, and static lifting. The last occurs when ice forms on the structure during low water stages, and the water levels subsequently rise. Drifting surface ice and ice floes may also enter the intakes, clogging them. In large lakes and rivers, ice floes may pile up against structures or be stranded in shallow water. At the Chicago intakes in Lake Michigan, stranded ice has been observed reaching from the Lake bottom some 37 ft below the water surface to 25 ft above the water surface (Burdick, 1946). Consequently, even bottom intakes are threatened. Because of these possibilites, intakes are usually designed to incorporate barriers and deflectors to keep ice away from the exposed structures.

Floods and Droughts

Floods threaten intakes by simple submergence, which may damage electric equipment and furnishings, and by structural damage due to hydraulic forces and the impacts of entrained debris, like logs and large rocks. Floods also move sand bars and may bury intakes or isolate them from the water flow. Droughts can lower water stages to the point that the intakes no longer contact the water. Very low water stages, if they happen fast enough, may destabilize river banks, causing the banks to slump and threaten intake foundations and screens.

Flood protection consists of barriers and deflectors like pilings, river training to stabilize the banks, and levees to protect buildings and equipment. Regulatory authorities may require that pumps, controls, and electrical switching equipment be installed above the expected maximum flood stage for some rare design flood. Drought protection generally involves the capability to withdraw water from several different elevations. This may be done by constructing multiple intakes or by constructing floating or moving intakes. The former are built on moored barges; the latter are built on rails that permit the pump suction bell to be moved up and down the bank as the river stage changes.

Floods and droughts exacerbate the problem of suspended debris, especially silts and sands. Floods resuspend stream bottoms and carry increased land erosion, and droughts often force water intakes to be placed so close to the bottom that the intake suction resuspends some sediments.

All of these problems require estimates of flood and drought stages. First, each time series (not the ranked values) is analyzed for trends and serial correlation. If none are found, the series may be fitted to some extreme value distribution, usually either Gumbel's distribution or the log Pearson Type III distribution.

Next, the maximum annual flood and minimum annual drought water surface elevations are ranked according to severity. For floods, this means highest ($m = 1$) to lowest ($m = n$), but for droughts, it means lowest ($m = 1$) to highest ($m = n$). Each elevation is then assigned an "exceedance" probability and a return period based on its rank:

$$P = \frac{m}{n+1} = \frac{1}{T} \tag{8.60}$$

where m = the rank of a flood or a drought beginning with most severe (highest stage for flood, lowest for drought) and ending with least severe (lowest stage for flood, highest for drought) (dimensionless)
n = the number of records of maximum annual flood or minimum annual drought (dimensionless)
P = the "exceedance" probability of either (1) the probability of a flood stage greater than or equal to the given elevation or (2) the probability of a drought stage less than or equal to the given elevation (per year)
T = the return period of either (1) a flood stage equal to or larger than the given elevation or (2) a drought stage less than or equal to the given elevation (year)

For small data sets, the probabilities are sometimes assigned according to Eq. (8.61) (Taylor, 1990):

$$P = \frac{m-0.5}{n} = \frac{1}{T} \tag{8.61}$$

The exceedance probability is the probability that a flood or drought equal to or worse than the given event will occur in any randomly chosen year. The return period is the average length of time between such occurrences.

Each elevation can also be assigned a nonexceedance probability and an associated return period:

$$P + P_o = 1 \tag{8.62}$$

$$\frac{1}{T} + \frac{1}{T_o} = 1 \tag{8.63}$$

where P_0 = the "nonexceedance" probability — either (1) the probability of a flood stage elevation less than the given elevation or (2) the probability of a drought stage greater than the given elevation (per year)
T_0 = the return period of either (1) a flood stage less than the given elevation or (2) a drought stage greater than the given elevation (year)

If the Gumbel equation gives an adequate fit (a plot of the flows vs. the equivalent flood return period on Gumbel probability paper should be linear), the design flood and drought stages for some design return period, T, may be calculated from Eqs. (8.58) and (8.59), respectively:

$$z_F(T) = \bar{z}_F - s_F \frac{\sqrt{6}}{\pi}\left[\gamma + \ln\left(\ln T_o\right)\right] \tag{8.64}$$

$$z_D(T) = \bar{z}_D - s_D \frac{\sqrt{6}}{\pi}\left[\gamma + \ln\left(\ln T\right)\right] \tag{8.65}$$

where s_D = the standard deviation of the observed minimum annual drought stages (m)
s_F = the standard deviation of the observed maximum annual flood stages (m)
$\bar{z}_D$ = the arithmetic average of the observed minimum annual drought stages (m)

$z_D(T)$ = the estimated drought stage elevation with a return period of T years (m)
$\bar{z}_F$ = the arithmetic average of the observed maximum annual flood stages (m)
$z_F(T)$ = the estimated flood stage elevation with a return period of T years (m)
$\gamma = 0.57722\ldots$, Euler's constant

Although the Gumbel distribution often provides a satisfactory fit, other distributions may be needed in other cases. A collection of these may be found in Chow (1964). The U.S. Water Resources Council adopted the log Pearson Type III distribution for flood analyses on federally funded projects (Hydrology Committee, 1977).

Navigation

The principal hazards due to navigation are collisions between boats and the intake structure, anchors snagging parts of the intake, and contaminants discharged accidentally or deliberately. The recommended defense against these hazards is avoidance of navigation channels. However, this conflicts with the need for access to deep water during droughts and cannot always be achieved. Once again, various kinds of barriers and deflectors are constructed, and intake depths are selected to avoid water contaminated by waste discharges from boats. This normally means selection of deeper waters.

In the U.S., all navigable waters are under the jurisdiction of the U.S. Army Corps of Engineers, and construction within navigable waters requires a Corps-issued permit.

Contaminant Distribution

Rivers are frequently stratified horizontally and vertically. This is important for two reasons:

- First, water quality in rivers can be expected to vary significantly with the distance from the bank. Most importantly, contaminants will tend to cling to the bank from which they are discharged, so that water intakes are best placed on the opposite bank.
- Second, contaminant dilution does not always or even usually occur. What is needed is a method to predict when and where contaminants will occur. It is especially desirable to locate zones of low contamination and to predict when known spills will arrive at the intake.

In order to predict where contaminants are at any time, it is necessary to consider how they are transported by the water source. There are four mechanisms that need to be accounted for: advection (convection), shear flow dispersion, turbulent diffusion, and molecular (Fickian) diffusion. Advection is the transport achieved by the average motion of the whole body of water. In the case of rivers, this is the transport due to the mean velocity. Shear flow dispersion is caused by the vertical and horizontal variations in velocity over the cross section. If velocity measurements are taken at small time intervals at a fixed point in the cross section, it will be discovered that the velocity there fluctuates. These short period fluctuations about the predicted velocity distribution give rise to another transport mode — turbulent diffusion. Finally, there is molecular diffusion, which arises because of the random thermal motions of contaminant molecules.

These four transport mechanisms are additive. However, one or more of them may sometimes be ignored. For example, by definition, there is no advection or shear flow dispersion vertically or laterally in a river; transport in these directions is due entirely to turbulent diffusion and molecular diffusion. In river mouths and in estuaries and lakes, the mean velocity is often small, and advection is negligible, even in the "downstream" direction. In these cases, only shear flow dispersion, turbulent diffusion, and molecular diffusion are active. But, in the main stem of most rivers, only advection need be considered.

Longitudinal Transport

Longitudinal transport in rivers is dominated by advection. Shear flow dispersion is a minor component, but it becomes important during unsteady phenomena like spills. Turbulent diffusion and molecular diffusion are negligible contributors to longitudinal transport.

Consider a spill of a conservation contaminant some distance upstream of an intake. If the flow is uniform and steady, the predicted arealy-weighted cross-sectional average contaminant concentration at the intake is (Crank, 1975; Fischer et al., 1979),

$$\overline{C}_A(x,t) = \frac{M/A}{\sqrt{4\pi Kt}} \cdot \exp\left[-\frac{(x-Ut)^2}{4Kt}\right] \tag{8.66}$$

where A = the cross-sectional area of the stream (m^2)
$\overline{C}_A(x,t)$ = the cross-sectional average contaminant concentration at x downstream from the apparent origin at time t after the spill (kg/m^3)
K = the longitudinal shear flow diffusivity (m^2/s)
M = the mass of the contaminant spilled (kg)
t = the time elapsed since the spill (s)
U = the (uniform flow) arealy-weighted, cross-sectional average stream velocity between the spill and the intake (m/s)
x = the effective distance the spill has traveled from its apparent origin (m)

A commonly used semiempirical formula for K is (Fischer et al., 1979),

$$K = \frac{0.011U^2W^2}{Hv_*} \tag{8.67}$$

where g = the acceleration due to gravity (9.806650 m/s^2)
H = the mean depth (m)
R = the hydraulic radius (m)
S = the energy gradient (m/m)
v_* = the shear velocity (m/s)
$= \sqrt{gRS}$
W = the stream (top) width (m)

The minimum distance downstream of a spill or an outfall that the water must travel before the contaminant has spread sufficiently for Eq. (8.66) to apply is called the "initial period" and is given approximately by (Fischer et al., 1979),

$$L_{ip} = \frac{0.67UW^2}{Hv_*} \tag{8.68}$$

where L_{ip} = the initial period (m).

The error in Eq. (8.62) is on the order of 50%. At L_{ip} from the spill, the contaminant cloud looks as if it had traveled a shorter distance.

The apparent origin of the spill is L_{ao} downstream from its actual location (Fischer et al., 1979):

$$L_{ao} = \frac{0.12UW^2}{Hv_*} \tag{8.69}$$

where L_{ao} = the distance from the actual spill to its apparent origin (m). This equation also has an error of about 50%.

Lateral Distribution

If a spill occurs within L_{ip} of an intake, the effect of lateral spreading of the contaminant will be important. The transport problem is now two-dimensional, and the important processes are advection and turbulent diffusion. Vertical mixing can be ignored, because streams are very much wider than they are deep, and the vertical velocity gradients are steeper than the horizontal velocity gradients, so they become vertically mixed long before they are laterally mixed. For steady, uniform flow with a uniform velocity profile and

isotropic turbulence, the longitudinal and lateral contaminant concentrations due to a spill can be estimated from,

$$\overline{C}_z(x,y,t) = \frac{M/H}{4\pi t\sqrt{KE}} \cdot \exp\left[-\frac{(x-Ut)^2}{4Kt}\right] \times \ldots$$
$$\ldots \times \sum_{j=-\infty}^{\infty} \left\{ \exp\left[-\frac{(y-2jW-y_o)^2}{4Et}\right] + \exp\left[-\frac{(y-2jW+y_o)^2}{4Et}\right] \right\} \tag{8.70}$$

where $\overline{C}$ = the depth-averaged contaminant concentration at x downstream from the apparent origin, y from the right bank, and t after the spill (kg/m^3)
E = the turbulent diffusivity (m^2/s)
H = the mean depth (m)
M = the mass of the contaminant spilled (kg)
t = the time elapsed since the spill (s)
U = the (uniform flow) arealy-weighted, cross-sectional average stream velocity between the spill and the intake (m/s)
x = the effective distance the spill has traveled from its apparent origin (m)
y = the distance across a stream measured from the right bank (m)
y_0 = the location of a spill measured from the right bank (m)

The error in this equation is approximately 50%. As a practical matter, we are interested in peak concentrations, which occur when $x = Ut$; the first exponential term is unity. As for the summation, only the few terms centered on $j = 0$ need to be computed.

A commonly used estimate of E is (Fischer et al., 1979),

$$E = 0.6Hv_* \tag{8.71}$$

If the source of the contaminant is a steady discharge rather than a spill, then the steady state, depth-averaged prediction is (Fischer et al., 1979),

$$\overline{C}_{z,t}(x,y) = \frac{W\overline{Q}_W\overline{C}_{QW}/(\overline{Q}_R+\overline{Q}_W)}{\sqrt{4\pi E\tau}} \times \ldots$$
$$\ldots \times \sum_{j=-\infty}^{\infty} \left\{ \exp\left[-\frac{(y-2jW-y_o)^2}{4E\tau}\right] + \exp\left[-\frac{(y-2jW+y_o)^2}{4E\tau}\right] \right\} \tag{8.72}$$

where $\overline{C}_{QR}$ = the flow-weighted (flow-composited) contaminant concentration in the river upstream of the outfall (kg/m^3)
$\overline{C}_{QW}$ = the flow-weighted (flow-composited) contaminant concentration in the wastewater (kg/m^3)
$\overline{C}_{z,t}(x, y)$ = the depth- and time-averaged concentration at distance x from the apparent origin and y from the right bank (kg/m^3)
$\overline{Q}_R$ = the time-averaged (steady state) river flow for the critical period, generally the 7-day-average low flow with a 10-year return period (m^3/s)
$\overline{Q}_W$ = the time-averaged (steady state) wastewater flow for the critical period, generally the maximum 7-day or 30-day average wastewater flow rate (m^3/s)
τ = the time-of-travel from the apparent origin (s)

Note that the time-of-travel from the source, τ, replaces the elapsed time, t.

Adsorbed Contaminants

Because streams mix vertically more quickly than they mix laterally, it is usually assumed that contaminant concentrations are uniform with respect to depth. There are, however, important exceptions to this rule: settleable solids — especially sand, silt, and clay — and floatable solids like grease.

Sands, silts, and clays, are important for two reasons. First, they are contaminants, causing turbidity. However, this is not a major issue. Sands, silts, and clays are quite reactive, and they adsorb a large number of other contaminants, particularly pesticides, volatile organic substances, and heavy metals. Consequently, the presence of sand, silt, and clay in a finished water raises the possibility that other, more serious contaminants are present. There is one advantage in all this: they are easily removed and so, consequently, are the poisons adsorbed to them.

The amount of contaminant sorbed onto silt and clay particles can be expressed in terms of a partition coefficient (Thomann and Mueller, 1987):

$$\Pi = \frac{C_p}{C_d} \tag{8.73}$$

where C_d = the dissolved contaminant concentration based on total volume of liquid and solids (kg/m^3)
C_p = the concentration of contaminant adsorbed to suspended solids (kg contaminant/kg clay)
Π = the partition coefficient (m^3/kg)

The partition coefficient may be used to calculate the fraction of the contaminant that is dissolved or adsorbed (Thomann and Mueller, 1987):

$$\frac{C_d}{C_t} = \frac{1}{1+\Pi C_c} \tag{8.74}$$

$$\frac{C_p}{C_t} = \frac{\Pi C_c}{1+\Pi C_c} \tag{8.75}$$

where C_t = the total concentration of contaminant based on the total volume of liquid and solids (kg/m^3)
$= C_d + C_p C_c$

If there is no resuspension of sediment, then a simple steady, uniform flow model for contaminant loss due to sedimentation of silts and clays is,

$$C_t(x) = C_{to}\frac{1+\Pi C_{co}\exp\left(-\frac{v_s x}{HU}\right)}{1+\Pi C_{co}} \tag{8.76}$$

where C_{C0} = the initial silt and clay concentration at a point source of sorbable contaminants (kg/m^3)
C_{t0} = the initial total concentration of contaminant at a point source (kg/m^3)
$C_t(x)$ = the total concentration of contaminant at distance x from a point source (kg/m^3)
v_s = the settling velocity of the sediment (m/s)
x = the distance from the point source (m)

Lake and Reservoir Intakes

Hazards

All of the hazards that threaten river intakes also threaten lake intakes: namely, debris and wildlife, ice, floods and droughts, and shipping. There are, of course, differences. Ice and debris in rivers are often

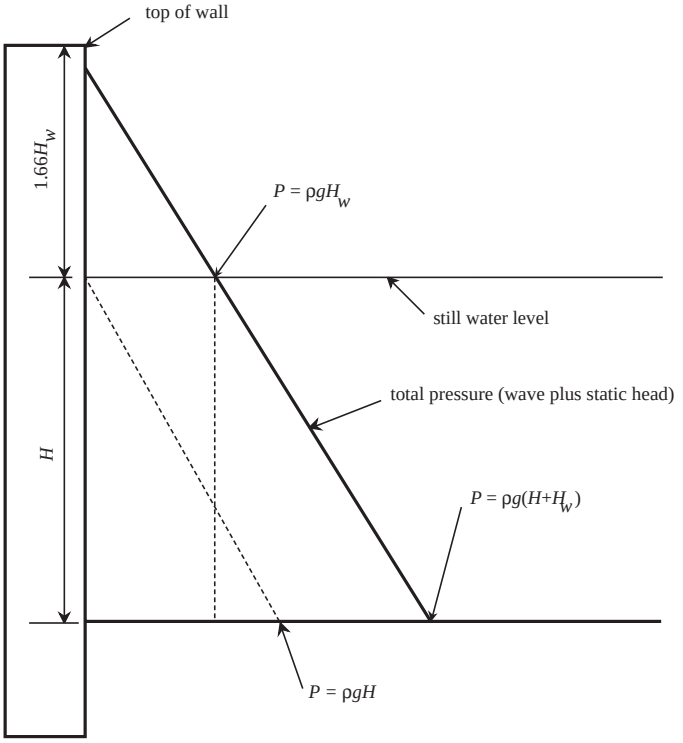

FIGURE 8.4 Reflected wave pressure on vertical wall (Minikin, 1950).

carried by strong currents that may produce strong impacts. In lakes, the currents and impacts are less severe. Rivers in flood can move sizeable boulders, but the debris in lakes is limited to floatable objects. Floods and droughts in rivers are generally short-term phenomena, driven by recent weather and lasting a few days to a season or two, whereas floods and droughts in lakes often last for years and are driven by long-cycle weather patterns. There are, however, two hazards that are peculiar to lakes: surface waves and seiches. Both are wind-driven phenomena.

Surface Waves

Waves are formed initially by fluctuations in the wind stress on the water surface, but once formed, they interact with each other and the wind to form a large variety of wave sizes. Wave power is transmitted to structures when the waves (1) are reflected by the structure, (2) break on the structure, or (3), if it is submerged, pass over the structure.

For reflected, nonbreaking waves, the simplest analysis is Minikin's (1950). If a wave is reflected by a vertical wall, it is supposed to rise up the wall above the still water level a distance equal to 1.66 times the wave height. This produces a momentary pressure gradient like that shown in Fig. 8.4, with a wave pressure at the still water elevation of $\rho g H_w$. The total horizontal force due to the wave of,

$$F = \underbrace{\rho g W H H_w}_{\text{wave force below still water depth}} + \underbrace{\rho g W \frac{H_w^2}{2}}_{\text{wave force above still water depth}} \tag{8.77}$$

where F = the total wave force (N)
g = the acceleration due to gravity (9.80665 m/s^2)
H = the still water depth (m)
H_w = the wave height measured crest to trough (m)

W = the width of the wall (m)
ρ = the density of water (kg/m^3)

and a wave moment of

$$M = \rho g W\left[\frac{1.66H_w^2}{2}\left(H + \frac{1.66H_w}{3}\right) + \frac{H^2 H_w}{2}\right] \tag{8.78}$$

where M = the turning moment (Nm).

These estimates should be doubled for ratios of water depth to wave length less than about 0.20 (King and Brater, 1963). The forces and moments due to the still water level should be added to the wave forces and moments.

Breaking waves would develop horizontal forces on the order of (King and Brater, 1963),

$$F = 87.8WH_w^2 \tag{8.79}$$

where F = the horizontal wave force (lbf)
H_w = the wave height (ft)
W = the width of the structure (ft)

Note that this is an empirical equation written in customary American units. The force would be centered at the still water level and be distributed approximately ½ H_w above and below the still water level.

Forces on submerged structures depend upon the depth of submergence and the dimensions of the structure relative to the wave length of the waves. Horizontal and vertical forces can be developed.

In many locales, wave heights are routinely recorded, and the needed information can be obtained from the records. Designs will generally be based on some rare, large wave, and it will be necessary to interpolate within or extrapolate from the recorded waves to get the design wave height, H_{wd}. Interpolation/extrapolation is normally done using the Rayleigh distribution (Coastal Engineering Research Center, 1984):

$$P = \text{Prob}\left(H_w \geq H_{wd}\right) = \exp\left(-\frac{H_{wd}^2}{H_{rms}^2}\right) \tag{8.80}$$

$$H_{rms} = \sqrt{\frac{\sum_1^n H_w^2}{n}} \tag{8.81}$$

where H_{wd} = the design wave height (m) and H_{rms} = the root-mean-square wave height (m).

A semilog plot of the exceedance vs. the square of the wave heights is a straight line, so linear regression techniques may be used to make the interpolation/extrapolation unbiased and objective. The wave heights are rank ordered from largest to smallest, and the exceedance probability is calculated for each recorded height using $m/(n + 1)$, where m is the rank of the recorded height.

If wave records are unavailable, then wave heights are estimated using the dimensions of the lake and wind speed records. The simplest procedure uses an empirical equation for the highest waves given by Stevenson (Hutchinson, 1975):

$$H_w = 0.105\sqrt{L_f} \tag{8.82}$$

where H_w = the highest wave height (cm)
L_f = the fetch, i.e., the distance across the lake measured from the point of interest upwind (cm)

The wind is supposed to be steady over the fetch length, and it is supposed to last long enough to fully develop the waves. In large lakes, this may not be the case. Methods for handling these cases and others are described in the *Shore Protection Manual* (Coastal Engineering Research Center, 1984).

Seiches

If the wind blows long enough, water will tend to pile up on the lee side of the lake, and the entire lake surface will be tilted upwards downwind. This phenomenon is called a "seiche," and the difference in water surface elevations from one end of the lake to the other is called the "set-up."

An estimate for the set-up can be derived from a simple, steady state momentum balance on an arbitrary control volume (Hutchinson, 1975):

$$H_{su} = \frac{\tau_w L}{\rho g H} \tag{8.83}$$

As a first-order approximation, the distance L may be identified as the length of the lake, H as its mean depth, and H_{su} its setup. This implies that the sloping lake surface is planar; it is usually curved. The effects of varying lake depth and thermal stratification have also been ignored, but their incorporation requires a complete two- or three-dimensional hydrodynamic model, and what is wanted here is an order of magnitude estimate of the setup.

The wind shear stress may be estimated by a variety of semiempirical formulas, but a common estimate is (Hutchinson, 1975):

$$\tau_w = 3.5 \times 10^{-6} v_{10}^2 \tag{8.84}$$

where v_{10} = the wind velocity 10 m above the surface (cm/s)
τ_w = the wind shear stress (dynes/cm^2)

Note that Eq. (8.84) gives the stress in cgs units, so if it is used in Eq. (8.83), cgs units must be used there, too.

Another empirical equation for the set-up is (King and Brater, 1963):

$$\frac{H_{su}}{H} = 4.88 \times 10^{-5} \left(\frac{L_f}{H} \right)^{1.66} \left(\frac{v_{10}^2}{g L_f} \right)^{2.20 \left(L_f / H \right)^{-0.0768}} \tag{8.85}$$

Note that this equation is written in dimensionless ratios.

Lake Stratification

During the summer, temperate zone lakes tend to be stratified vertically. The stratified lake may be divided into three zones: an epilimnion, a mesolimnion (alias thermocline and metalimnion), and a hypolimnion. The epilimnion is the top portion of the lake. It is generally well mixed and somewhat turbulent, because of the wind. It is also warm. The bottom part of the lake is the hypolimnion. It, too, is homogeneous, but it is poorly mixed and nonturbulent or even laminar. It is cool. The mesolimnion is the transition zone between the other layers. It is normally defined as the region in which the temperature changes.

The stratification is due to the density differences between the warm, light surface water and the cold, heavy bottom water. It develops as follows: In the early spring, the lake is still cold from the previous winter, and it is well mixed from top to bottom, because of the seasonally strong winds. As the spring and early summer progress, solar heating increases, and the winds die down. The heating tends to produce a warm surface layer that is lighter than the cold, deep waters. If the winds are strong enough, they will mix the warm and cold waters, and the whole lake will warm uniformly. However, at some point, the increasing heating rate will overcome the decreasing wind shear, and the warm surface waters will not be mixed down into the whole lake. The lake is then stratified. The epilimnion will continue to warm during the summer, but the hypolimnion will remain cool.

The stratification breaks down in the fall as solar heating declines and the winds pick up. This generally results in complete mixing of the lake. If the lake surface does not freeze during the winter, the mixing will continue until the next spring, when the lake again stratifies. Such lakes are called "monomictic," meaning one mixing per year. If the lake surface freezes, wind mixing is impossible, and the lake becomes stagnant. It may exhibit an inverse stratification with near 0°C water just under the ice and denser 4°C water below. Such lakes are called "dimictic," meaning two mixings per year.

Many variations are possible. First, lakes might not stratify. High-latitude and high-altitude lakes may cycle between frozen, stagnant periods and well-mixed periods, and equatorial lakes may be mixed continuously throughout the year. Second, in temperate lakes, local conditions may result in weak stratification that comes and goes during the summer, or the lake may stratify into more than three zones. Third, deep bottom waters may remain permanently segregated from the rest of the lake, not participating in the general mixing. Such lakes are called "meromictic." The bottom waters of these lakes are always significantly denser than the remainder of the lake, especially the hypolimnion, because they contain elevated concentrations of dissolved solids.

Intake Location

Because lakes and reservoirs stratify, the depth of intakes requires special consideration. The temperature difference between the epilimnion and hypolimnion is usually large enough to affect the kinetics and hydraulics of the various treatment processes, and tank volumes, chemical dosages, and power consumption will depend on whether upper or lower waters are withdrawn. Particularly in the cases of tastes and odors and turbidity, there may be major differences between the epilimnion and hypolimnion, and these differences may dictate the kinds of treatment processes used, not merely their sizing. Many of the characteristics of the epilimnion and hypolimnion change during the year, and a single depth of withdrawal will not always be preferred. Consequently, the intakes should be designed with multiple inlet ports at various depths.

The effects of seiches also deserve consideration. When strong winds set-up a lake, it is the epilimnion waters that pile up on the lee end. This means that at the lee end, the epilimnion becomes deeper, and the hypolimnion is compressed and becomes shallower. In fact, the epilimnion may become deep enough that the hypolimnion is completely displaced. The opposite occurs at the windward end of the lake: the epilimnion may be completely blown away, and the hypolimnion may surface. The result of these effects is that the plant operator may not be able to control the kinds of water withdrawn from the lake, and the plant must be designed to accommodate any raw water.

Stratification also affects the fate of contaminant discharges and spills. These inputs will tend to seek water of their own density rather than simply disperse any that may be found at any elevation in the lake. The elevation may vary seasonally as the input's density varies and the lake temperatures change.

Algal Growth in the Epilimnion

The principal water quality problems associated with stratification are (1) the presence of algae and their metabolic products in the epilimnion and (2) reduced oxygen concentrations and algal decay products in the hypolimnion. These problems are connected.

Algae grow by absorbing nutrients and water and using light energy to convert them to more algae. Except for diatoms, the synthesis stoichiometry for algae growing on nitrate and phosphorus is approximately as follows (Jewell, 1968):

$$106\ CO_2 + 16\ HNO_3 + H_3PO_4 + \frac{162}{2}\ H_2O = C_{106}H_{180}O_{45}N_{16}P + \frac{599}{4}\ O_2 \qquad (8.86)$$

The algae have a formula weight of 2428, and they are, on a dry weight basis, 52% carbon, 30% oxygen, 9.2% nitrogen, 7.4% hydrogen, and 1.3% phosphorus. Diatoms have an exterior shell of silica, which comprises about one-fourth of the dry weight. However, the material inside the shell has the composition given above. If the synthesis begins from ammonia rather than nitrate, the stoichiometry is:

$$106\ CO_2 + 16\ NH_3 + H_3PO_4 + \frac{129}{2}\ H_2O = C_{106}H_{180}O_{45}N_{16}P + \frac{471}{4}\ O_2 \tag{8.87}$$

Note that the formation of 1 g of algae results in the release of either 1.97 g of oxygen or 1.55 g, depending on whether the synthesis starts with nitrate or ammonia, respectively. Conversely, when the algae decay, the same amount of oxygen is consumed. Algae grow in the warm, illuminated epilimnion and settle into the cool, dark hypolimnion. This leads to the fundamental problem of lakes: oxygen release occurs in the epilimnion, whereas oxygen consumption occurs in the hypolimnion, and because the two do not mix, the hypolimnion can become anoxic.

The effects of algae may be estimated by a somewhat simplified analysis of the spring bloom. The algae growing in the epilimnion may be either nutrient-limited or light-limited. They are most likely nutrient limited, if the epilimnion is clear and shallow. In this case, the algae grow until some nutrient is exhausted. Supposing that nutrient is phosphorus, the maximum possible algal concentration is:

$$X_{\max} = Y_P P_o \tag{8.88}$$

where P_0 = the initial available orthophosphate concentration (kg/m^3)
X_{max} = the maximum possible algal concentration in the epiliminion due to nutrient limitation (kg/m^3)
Y_p = the algal true growth yield coefficient on phosphorus (kg algae/kg P)

Other nutrients can be limiting. Diatoms are often limited by silica.

Limnologists prefer to work in terms of the areal concentration rather than the volumetric concentration. This can be calculated by multiplying X_{max} by the volume of the epilimnion and dividing it by the surface area of the lake:

$$\frac{X_{\max} V_e}{A} = Y_P P_o H_e \tag{8.89}$$

where A = the epilimnion plan area (m^2)
H_e = the epilimnion depth (m)
V_e = the epilimnion volume (m^3)

Note that the areal concentration is simply proportional to the epilimnion depth and the initial phosphorus concentration. Of course, if nitrogen was the limiting nutrient, the slope would depend on nitrogen rather than phosphorus.

The light-limited case is more complicated, because the maximum algal concentration is the result of a balancing of rates rather than simple nutrient exhaustion. The simplest mass balance for the algae in the epilimnion is:

$$\underbrace{V_e \frac{dX}{dt}}_{\text{rate of algal accumulation}} = \underbrace{\mu X V_e}_{\text{rate of algal growth}} - \underbrace{k_d X V_e}_{\text{rate of algal loss}} \tag{8.90}$$

where k_d = the algal decay rate (per sec)
t = elapsed time (sec)
X = the algal concentation (kg/m^3)
μ = the algal specific growth rate (per sec)

In this simplified model, the specific growth rate is supposed to depend only on light intensity and temperature, and the decay rate is supposed to depend only on temperature.

The dependency of the specific growth rate on light can be represented by Steele's (1965) equation:

$$\mu(z) = \mu_{\max} \frac{I(z)}{I_{sat}} \exp\left(1 - \frac{I(z)}{I_{sat}}\right) \tag{8.91}$$

where I_{sat} = the saturation light intensity for the algae (W/m^2)
$I(z)$ = the light intensity at depth z from the surface (W/m^2)
μ_{max} = the maximum algal specific growth rate (per sec)
$\mu(z)$ = the algal specific growth rate at depth z (per sec)
z = the depth from the surface (m or ft)

The light intensity declines exponentially with depth according to the Beer-Lambert Law:

$$I(z) = I_o \exp\left[-(a + bX)z\right] \tag{8.92}$$

where a = the water extinction coefficient (per m)
b = the algal extinction coefficient (m^2/kg)
I_o = the surface light intensity (W/m^2)

Substituting Eq. (8.92) into Eq. (8.95) and averaging over depth and time yields (Thomann and Mueller, 1987):

$$\bar{\mu}_{zt} = \frac{ef\mu_{\max}}{(a + bX)H_e} \left\{ \exp\left[-\frac{\bar{I}_o}{I_{sat}} \exp\left(-\left[a + bX\right]H_e\right)\right] - \exp\left(-\frac{\bar{I}_o}{I_{sat}}\right)\right\} \tag{8.93}$$

where e = 2.7183…, the base of the natural logarithms
f = the fraction of the 24-h day that is sunlit (dimensionless)
$\bar{I}_o$ = the average sunlight intensity during daylight (W/m^2)
$\bar{\mu}_{zt}$ = the depth- and time-averaged algal specific growth rate (per sec)

During the summer, the average surface light intensity is usually much larger than the saturation light intensity, and the exponential of their ratio is nearly zero. Also, the light intensity at the bottom of the epilimnion will be close to zero, because the algal population will increase until nearly all the light has been absorbed. The exponential of zero is one, so Eq. (8.93) reduces to (Lorenzen and Mitchell, 1973; 1975):

$$\bar{\mu}_{zt} \cong \frac{2.718 f\mu_{\max}}{(a + bX)H_e} \tag{8.94}$$

The algal growth rate declines as its population increases (which is called *self-shading*), and at some point, it just equals the decay rate. No further population increase is possible, so this becomes the maximum algal concentration. Substituting Eq. (8.94) into (8.90) and solving for the steady state algal concentration yields:

$$X_{\max} H_e = \frac{2.718 f\mu_{\max}}{bk_d} - \frac{a}{b} H_e \tag{8.95}$$

Diehl (2002) and Diehl et al. (2002) have recently published the theory and supporting field data for a more detailed model that adds algal sinking and nutrient concentration gradients to the Lorenzen-Mitchell analysis.

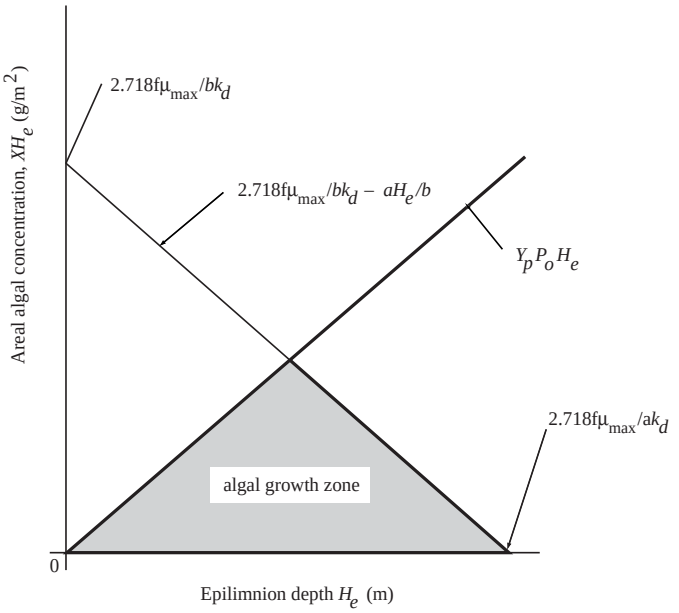

FIGURE 8.5 Algal epilimnetic growth zone.

Equation (8.95) predicts that the maximum areal algal concentration under light-limited conditions will be a linear function of epilimnion depth with a negative slope. Under nutrient-limited conditions, the maximum areal concentration is also linear, but it has a positive slope. These two lines form the boundaries to a triangular region, shown in Fig. 8.5, that contains all possible areal algal concentrations. Any given lake will have some specific epilimnetic depth. The maximum algal concentration that can occur in that lake can be determined by projecting a vertical line from the depth axis to the first line intersected. That line will give the concentration. If the epilimnetic depth is so deep that it lies outside the triangular region, no algae will be found in the lake. In fact, it is the reduction in mixed depth in the spring due to stratification that permits algal blooms to occur.

Algal Death in the Hypolimnion

As a first-order approximation, it may be assumed that the quantity of algae that settles into the hypolimnion is equal to the amount of algae that can be formed from the limiting nutrient in the epilimnion. This will be true even in light-limited lakes, because the algal concentration given by Eq. (8.89) is a dynamic equilibrium, and algae will be continuously formed and removed at that concentration until the limiting nutrient is exhausted. Algal decay results in oxygen consumption, so the oxygen balance in the hypolimnion is:

$$\beta_X X_{max} V_e = (C_o - C) V_h \tag{8.96}$$

where C = the final oxygen concentration in the hypolimnion (kg/m^3)
C_0 = the initial oxygen concentration in the hypolimnion (kg/m^3)
V_h = the volume of the hypolimnion (m^3)
β_X = the algal oxygen demand (kg O_2/kg algae)

When algae decay, their nitrogen content is first released as ammonia, and the ammonia is subsequently converted to nitrate. This means that the algal "carbonaceous" oxygen demand of 1.55 g O_2/g algae is satisfied first, and it proceeds as long as C is greater than zero. The ammonia released during this process is oxidized only if oxygen is left over from the first step.

Algal Control

Figure 8.5 and Eq. (8.96) provide the means of estimating the impacts of algae on lakes and reservoirs and clues to the control of excessive algal blooms:

- The initial nutrient concentration may be reduced by changes in land use and by restrictions on used water discharges.
- The algal decay rate could be increased by adding some sort of poison.
- The lake may be artificially mixed to increase the epilimnetic depth, thereby shifting the algal concentration rightwards and downwards along the light-limited line.

Restriction of nutrient input is the method of choice, but the underlying assumption is that the algae are nutrient-limited to begin with or that inputs can be reduced to the point that they become nutrient-limited. If the algae are or remain light-limited, control of nutrient inputs will not affect the concentration of algae in the epilimnion. The effect of nutrient restrictions is to reduce the slope of the nutrient line in Fig. 8.5, so if the algae are nutrient-limited, the reduction in algae is proportional to the reduction in nutrient input. Nutrient reductions will always reduce the amount of oxygen consumption in the hypolimnion and the amount of algal excretion product in the epilimnion. Nutrient input reductions are relatively easily attained when the inputs come from point sources like sewage treatment plants, but reductions are difficult to come by when the sources are diffuse like agriculture, forests, or lawns.

Poisons like copper sulfate [$CuSO_4 \cdot 5H_2O$], calcium hypochlorite [$Ca(OCl)_2$], and various organic algicides act by increasing the algal death rate. This has the effect of reducing the verical intercept of Eq. (8.95) and lowering the whole light-limited line. Normal dosages are a few tenths of a mg/L of either copper sulfate or calcium hypochlorite, but the dosages are species-specific and vary substantially depending on the kinds of algae present (Hale, 1957). For reasons of economy, the epilimnion should be small. The poison dosages needed to kill algae are often fatal to other wildlife, and this may prevent their use.

The reduction of epilimnetic algal concentrations by artificial mixing of lakes and reservoirs to control algae has been achieved many times (Cooley and Harris, 1954; Fast, 1971; Hogan et al., 1970; Hooper et al., 1952; Leach and Harlin, 1970; Lomax and Orsborn, 1970; Lorenzen and Fast, 1977; Lorenzen and Mitchell, 1975; Riddick, 1958; Symons, 1969; Torrest and Wen, 1976; Zieminski and Whittemore, 1970). Furthermore, cyanobacteria (formerly *blue-green algae*), which are especially objectionable, are more susceptible to control by mixing than are other kinds of algae. To be effective, the lake must be deep enough that the algae either are or will become light-limited. Referring to Fig. 8.5, it can be seen that increasing the depth of shallow, nutrient-rich systems will only increase the number of algae present, and this effect also has been observed (Hooper, Ball, and Tanner, 1952; Symons, 1969).

The usual method of mixing is air diffusion. This is preferred because many hypolimnetic waters are oxygen depleted, and mixing low-oxygen water into the epilimnion may kill or injure wildlife and may contribute to taste and odor problems. The amount of air required for satisfactory mixing is dependent on the total work required to mix the lake, the mixing work supplied by the wind, and the offsetting heat input from the sun. The resulting air requirement is strongly dependent on local conditions, but a rough and ready rule of thumb is 20 scfm per million square feet of lake surface (Lorenzen and Fast, 1977).

Littoral vs. Pelagic Zones

Lakes also stratify horizontally and may be divided into a "littoral" or near-shore zone and a "pelagic" or central zone. Contaminant levels are generally higher in the littoral than in the pelagic zone. The kinds of contaminants present depend largely on lake size and the intensity of currents and waves that develop in the lake as a consequence of its size.

Small lakes have weak currents and little or no waves, except during storms. The littoral zone in these lakes is usually defined to be the zone of rooted aquatic plants, and it is subdivided into zones of (a) emergent plants, (b) floating plants, and (c) submerged plants (Wetzel, 1975). The emergent plants are generally limited to water depths less than about 1.5 m, the floating plants can exist in depths between 0.5 and 3.0 m, and the submerged plants can maintain themselves at virtually any depth that has sufficient sunlight.

Conditions in the small lake littoral zone are good for plant growth. Land drainage, with its generally high nutrient load, must first pass through the littoral zone, and the weak currents there insure that much of the nutrient load is retained. The littoral zone is shallow and well illuminated, and the rooted plants provide a large surface area for the attachment and growth of microscopic algae. The net result is that plant productivity in the littoral zone is very high and may, in some cases, comprise the bulk of the net photosynthesis in the whole lake (Wetzel, 1975). The net result of all of this activity is a water that is high in turbidity, color, taste, and odor.

The littoral zone of large lakes is defined to be the region between the shoreline and the breakers (Coastal Engineering Research Center, 1984). Within this zone, there are few aquatic plants, the bottom is coarse grained, and the water has a high turbidity because of suspended silt and sand. There is almost always a *littoral drift,* i.e., a current parallel to the shore and tending in the same direction as the mean wind. Somewhat farther offshore, there may be a *coastal jet,* i.e., a fairly strong current parallel to the coast (Csanady, 1975).

Water quality in littoral zones is generally not suitable for water supplies, and better quality water may be had farther offshore. The likelihood of contamination from spills on land is also greatly reduced, because they are intercepted by the drift and coastal jet. Placement of the intake in the open water will also provide the opportunity to choose between epilimnetic and hypolimnetic waters, although there are more hazards due to boating and shipping.

Wells

Aquifer Choice

Groundwaters occur in a variety of geological strata, including unconsolidated materials, porous rocks, fractured rocks, and limestones with solution channels. Any of these formations can be developed into an acceptable source, as long as:

- The water can be brought up to acceptable quality standards by treatment.
- The permeability of the formation permits adequate flows into the wells.
- The volume and recharge rate of the aquifer permit useful long-term withdrawal rates.

Except where igneous or other impermeable rocks lie close to the surface, usable groundwater supplies are found everywhere that has a net runoff of precipitation. They are even found in deserts, but these supplies are usually fossil deposits from an earlier climatological epoch (and nonrenewable) or fed from distance precipitation and subject to low renewal rates.

It is commonly believed that well waters are pure, because they have been filtered through great thicknesses of fine-pored material. This, of course, is false. First, some common contaminants are derived from the weathering of the formations that produce the well waters. Second, there are a variety of ways by which wells become contaminated. And third, it is not true that all wells draw on naturally filtered water: in heavily weathered limestone regions, the wells may tap actual underground pools or streams.

The composition of groundwater supplies frequently exhibits strong vertical stratification. In part, this is because the waters in different strata may be separated by impermeable materials, which prevent vertical mixing of the supplies. The separated aquifers may be in formations with different mineralogies. In this case, the weathering products would be different, both in amount and kind.

Shallow aquifers near the surface are replenished by local precipitation and are vulnerable to contamination by spills on the surface and drainage from local agriculture and lawns, transportation modes, and even land treatment of used water. Most contaminants enter the aquifer with water percolating from the surface, and they tend to form a layer on top of the supply. Vertical mixing deeper into the supply well proceeds slowly unless the groundwater table undergoes seasonal variations in elevation. These variations move the surface contaminant layer up and down through the soil and so distribute the contaminant in depth.

Deep aquifers may be fed from afar and are subject to similar contamination, depending on their origin.

Common contaminants due to surface spills and land use practices are gasoline and other fuels (from leaking storage tanks), tetraethyl lead (in the gasoline), road salts (NaCl and $CaCl_2$), ammonia, and nitrate. The occurrence of these contaminants is predictable, and well fields can be sited to avoid them. Where this is not possible, suitable regulations can sometimes mitigate the contamination.

Common contaminants due to formation weathering are total dissolved solids, calcium, magnesium, sulfate, sodium, chloride, ferrous iron, manganous manganese, and sulfide. Occasionally, one finds arsenic, copper, lead, or mercury, which are derived from local ore deposits. Reliable treatment processes exist for the removal of all of these contaminants. However, they can frequently be avoided by switching to a different aquifer, and this is often a matter of simply changing the well depth.

Groundwaters can also be contaminated by wells. The most common problem is the well casing. The placement of the casing frequently leaves small channels between the casing wall and the surrounding formation, and these channels serve as routes by which surface drainage may enter the aquifer. These channels may be closed by grouting operations and by paving the ground near the well to deflect surface drainage. The inside of the well casing is an even better route of contamination, and the tops of the casings must be sealed to prevent the entry of surface drainage, soil, and dust.

The same problems exist with other kinds of wells that may penetrate the aquifer, even if they do not draw from it. These other wells include gas and oil wells and deep well injection facilities. In these cases, contamination from below the aquifer is also possible, because these systems are usually pressurized. The kinds of contaminants associated with gas and oil wells include various hydrocarbons, hydrogen sulfide, and brines associated with the deposits. Virtually anything can be found in deep well injection systems, and because such systems are often used to dispose of especially hazardous materials, the contamination from them may pose severe public health problems.

Well Construction and Operation

The construction and operation of wells also can contribute to water supply contamination. This occurs three ways:

- Failure to properly develop the well
- Corrosion of the well materials
- Precipitate formation during pumping

When wells are constructed, the formation next to the casing normally becomes plugged with fines (Johnson Division, 1975). This occurs in two general ways. First, if the formation consists of unconsolidated materials, the well-drilling operation will compact the materials near the casing, reducing their porosity and permeability. Second, if the well is drilled in rock, the drilling muds used to lubricate the bits and remove the cuttings will deposit clays in the pores of the rock. The compactions and deposits are eliminated by *developing* the well. This generally consists of rapidly changing the direction of flow through the well screen or flushing the screens with high-velocity water jets. Well development will also remove fine material from the formation itself, at least near the casing, and this will increase well yields. Failure to develop wells generally results in reduced water flow rates and continuing problems with sands, silts, and clays in the water supply.

Well casings and screens are subject to corrosion at varying rates and ultimately must be replaced. However, corrosion rates can be greatly accelerated if unsuitable materials are used in certain waters. Groundwater conditions leading to excessive rates of corrosion include (Johnson Division, 1975):

- pH less than 7
- Dissolved oxygen concentration greater than 2.0 mg/L
- Almost any hydrogen sulfide concentration, even below 1 mg/L
- Total dissolved solids in excess of 1000 mg/L
- Carbon dioxide concentration above 50 mg/L
- Chloride concentration greater than 500 mg/L

The well screen is more vulnerable to corrosion than the casing, because its function is to screen out the sands and gravels surrounding the well and prevent their entry into the pump. Any small failure of the screen will allow large amounts of material into the casing.

The corrosion products are also of interest. Most of the product will be ferrous or ferric iron. However, many older wells also have a lead packer that closes the opening between the casing and the well screen. This packer is also subject to corrosion, and this will introduce lead into the supply. Many submersible pumps have brass or bronze fittings, which leach lead.

Finally, there is precipitate formation. This occurs in the screen openings and the pores of the formation near the well. It is a problem associated with hard, alkaline waters. The flow through the formation pores and screen can be rapid, and this results in a low-pressure zone. Any dissolved gases in the formation are at equilibrium with the static formation pressure, so they tend to come out of solution in the low-pressure zone. In the case of carbon dioxide, its loss from solution causes bicarbonate to decompose, forming new carbon dioxide to replace that lost and carbonate:

$$2\,HCO_3^- = CO_2 + H_2O + CO_3^{2-} \tag{8.97}$$

The increased carbonate will precipitate calcium and ferrous iron as carbonates:

$$Ca^{2+} + CO_3^{2-} = CaCO_3 \tag{8.98}$$

$$Fe^{2+} + CO_3^{2+} = FeCO_3 \tag{8.99}$$

Both of these materials can enter the water distribution system, causing nuisances, and in large quantities, both can clog the screen and the surrounding formation. They are generally removed with acids, but acids can corrode the screen and casing and should be used cautiously.

9.1 Screens

The important kinds of screening devices are bar screens, coarse screens, comminutors and in-line grinders, fine screens, and microscreens (Pankratz, 1988).

Bar Screens

Bar screens may be subdivided into (1) trash racks, (2) mechanically cleaned bar screens, and (3) manually cleaned bar screens.

Trash Racks

Trash racks are frequently installed in surface water treatment plant intakes to protect course screens from impacts by large debris and to prevent large debris from entering combined/storm water sewerage systems. Typical openings are 1 to 4 in. The bars are made of steel, and their shape and size depend on the expected structural loads, which are both static (due to the headloss through the rack) and dynamic (due to the impacts of moving debris). The racks are cleaned intermittently by mechanically driven rakes that are drawn across the outside of the bars. The raking mechanism should be able to lift and move that largest expected object.

Mechanically Cleaned Bar Screens

Mechanically cleaned bar screens are usually installed in the headworks of sewage treatment plants to intercept large debris. They may be followed by coarse screens and comminutors and in-line grinders. The clear openings between the bars are usually ½ to 1¾ in. wide (Hardenbergh and Rodie, 1960; Pankratz, 1988; Wastewater Committee, 1990). In sewage treatment plants, the approach channel should be perpendicular to the plane of the bar screen and straight. Approach velocities should lie between 1.25 ft/sec (to avoid grit deposition) and 3 ft/sec (to avoid forcing material through the openings) (Wastewater Committee, 1990). Velocities through the openings should be limited to 2 to 4 ft/sec (Joint Task Force, 1992).

Several different designs are offered (Pankratz, 1988).

Inclined and Vertical Multirake Bar Screens

Multirake bar screens are used wherever intermittent or continuous heavy debris loads are expected. The spaces between the bars are kept clear by several rows of rakes mounted on continuous belts. The rake speed and spacing is adjusted so that any particular place on the screen is cleaned at intervals of less than 1 min. The bars may be either vertical or inclined, although the latter facilitates debris lifting.

The raking mechanism may be placed in front of the bars, behind them, or may loop around them. In the most common arrangement, the continuous belt and rakes are installed in front of the screen, and the ascending side of the belt is the cleaning side. At the top of the motion, a high-pressure water spray dislodges debris from the rake and deposits it into a collection device.

If the belt and rakes are installed so that the descending side is behind the screen (and the ascending side is either in front of or behind the screen), there will be some debris carryover.

Catenary, Multirake Bar Screens

Standard multirake bar screens support and drive the rake belt with chain guides, shafts, and sprockets at the top and the bottom of the screen. The catenary bar screen dispenses with the bottom chain guide, shaft, and sprocket. This avoids the problem of interference by deposited debris in front of the screen. The rakes are weighted so that they drag over debris deposits, and the bar screen is inclined so that the weighted rakes lie on it.

Reciprocating Rake Bar Screens

Reciprocating rake bar screens have a single rake that is intermittently drawn up the face of the screen. Because of their lower solids handling capacity, they are used only in low debris loading situations. The reciprocating mechanism also requires more head room than multirake designs. However, they are intrinsically simpler in construction, have fewer submerged moving parts, and are less likely to jam.

Arc, Single-Rake Bar Screens

In these devices, the bars are bent into circular arcs, and the cleaning rake describes a circular arc. The rake is normally cleaned at the top of the arc by a wiper. The flow is into the concave face of the screen, and the rakes are upstream of it.

Manually Cleaned Bar Screens

Manually cleaned bar screens are sometimes installed in temporary bypass channels for use when the mechanically cleaned bar screen is down for servicing. The bars should slope at 30 to 45° from the

TABLE 9.1 Kirschmer's Shape Factors for Bars

Bar Cross Section	Shape Factor (Dimensionless)
Sharp-edged, rectangular	2.42
Rectangular with semicircular upstream face	1.83
Circular	1.79
Rectangular with semicircular faces upstream and downstream	1.67
Teardrop with wide face upstream	0.76

horizontal, and the total length of bars from the invert to the top must be reachable by the rake. The opening between the bars should not be less than 1 in, and the velocity through it should be between 1 and 2 ft/sec. The screenings will usually be dragged up over the top of the bars and deposited into some sort of container. The floor supporting this container should be drained or grated.

Bar Screen Head Losses

The maximum headloss allowed for dirty bar racks is normally about 2.5 ft (Fair and Geyer, 1954). For clean bar racks, the minimum headloss can be calculated from Kirschmer's formula, Eq. (9.1) (Fair and Geyer, 1954):

$$h_L = \beta\left(\frac{w}{b}\right)^{4/3} h_v \sin\theta \tag{9.1}$$

where b = the minimum opening between the bars (m)
h_L = the headloss through the bar rack (m)
h_v = the velocity head of the approaching flow (m)
w = the maximum width of the bars facing the flow (m)
β = a dimensionless shape factor for the bars
θ = the angle between the facial plane of the bar rack and the horizontal

Some typical values of the shape factor β are given in Table 9.1.

The angle θ is an important design consideration, because a sloping bar rack increases the open area exposed to the flow and helps to keep the velocity through the openings to less than the desired maximum. Slopes as flat as 30° from the horizontal make manual cleaning of the racks easier, although nowadays, racks are always mechanically cleaned.

Coarse Screens

Coarse screens may be constructed as traveling screens, rotating drum screens, rotating disc screens, or fish screens (Pankratz, 1988).

Traveling Screens

Traveling screens are the most common type of coarse screen. They are used in water intakes to protect treatment plant equipment from debris and at wastewater treatment plants to remove debris from the raw sewage. They consist of flat panels of woven wire mesh supported on steel frames. The panels are hinged together to form continuous belt loops that are mounted on motor-driven shafts and sprockets. Traveling screens are used to remove debris smaller than 2 in., and the mesh openings are generally about 1/8 in. to 3/4 in., typically 1/4 to 3/8 in. Traveling screens are often preceded by bar racks to prevent damage by large objects. When used in water intakes in cold or temperate climates, the approach velocity to traveling screens is normally kept below 0.5 ft/sec in order to prevent the formation of frazil ice, to prevent resuspension of sediment near the intake, and to permit fish to swim away.

Traveling screens are cleaned intermittently by advancing the continuous belt so that dirty panels are lifted out of the water. The panels are cleaned by high-pressure water sprays, and the removed debris is deposited into a drainage channel for removal.

Traveling screens may be installed so that their face is either perpendicular to the flow or parallel to it, and either one or both sides of the continuous belt loop may be used for screening. The alternatives are as follows (Pankratz, 1988):

- Direct, through, or single flow — The screen is installed perpendicular to the flow, and only the outer face of the upstream side of the belt screens the flow. The chief advantage to this design is the simplicity of the inlet channel.
- Dual flow — The screen is installed so that both the ascending and descending sides of the belt screen the flow. This is accomplished either by arranging the inlet and outlet channels so that (1) the flow enters through the outside face of the loop and discharges along the center axis of the loop (dual entrance, single exit) or (2) the flow enters along the central axis of the loop and discharges through the inner face of the loop (single entrance, dual exit). The chief advantage to this design is that both sides of the belt loop screen the water, and the required screen area is half that of a direct flow design.

Rotating Drum Screens

In drum screens, the wire mesh is wrapped around a cylindrical framework, and the cylinder is partially submerged in the flow, typically to about two-thirds to three-fourths of the drum diameter. As the mesh becomes clogged, the drum is rotated, and high-pressure water sprays mounted above the drum remove the debris.

The flow may enter the drum along its central axis and exit through the inner face of the drum or enter the drum through the outer face of the mesh and exit along its central axis. The flow along the central axis may be one way, in which case one end of the drum is blocked, or two way.

Rotating Disc Screens

In disc screens, the wire mesh is supported on a circular disc framework, and the disc is partially submerged in the flow, typically to about two-thirds to three-fourths of the disc diameter. As the mesh becomes clogged, the disc is rotated, and the mesh is cleaned by a high-pressure water spray above it. The discs may be mounted so that the disc plane is either vertical or inclined.

For reasons of economy, disc screens are normally limited to flows less than 20,000 gpm (Pankratz, 1988).

Fish Screens

Surface water intakes must be designed to minimize injury to fish by the intake screens. This generally entails several design and operating features and may require consultation with fisheries biologists (Pankratz, 1988):

- Small mesh sizes — Mesh sizes should be small enough to prevent fish from becoming lodged in the openings.
- Low intake velocities — The clean screen should have an approach velocity of less than 0.5 fps to permit fish to swim away.
- Continuous operation — This minimizes the amount of debris on the screen and the local water velocities near the screen surface, which enables fish to swim away.
- Escape routes — The intake structure should be designed so that the screen is not at the downstream end of a channel. This generally means that the intake channel should direct flow parallel or at an angle to the screens with an outlet passage downstream of the screens.
- Barriers — The inlet end of the intake channel should have some kind of fish barrier, such as a curtain of air bubbles.

- Fish pans and two-stage cleaning — The screen panels should have a tray on their bottom edge that will hold fish in a few inches of water as the panels are lifted out of the flow. As the screen rotates over the top sprocket, the fish tray should dump its contents into a special discharge channel, and the screen and tray should be subjected to a low-pressure water spray to move the fish through the channel back to the water source. A second, high-pressure water spray is used to clean the screen once the fish are out of the way.

Wire Mesh Head Losses

Traveling screens are usually cleaned intermittently when the headloss reaches 3 to 6 in. The maximum design headloss for structural design is about 5 ft (Pankratz, 1988).

The headloss through a screen made of vertical, round, parallel wires or rods is (Blevins, 1984)

$$h_L = 0.52 \cdot \frac{1-\varepsilon^2}{\varepsilon^2} \cdot \frac{U^2}{2g} \tag{9.2}$$

if

$$\boldsymbol{Re} = \frac{\rho U d}{\varepsilon \mu} > 500 \tag{9.3}$$

and

$$0.10 < \varepsilon < 0.85 \tag{9.4}$$

where d = the diameter of the wires or rods in a screen (m)
g = the acceleration due to gravity (9.806 65 m/s^2)
s = the distance between wire or rod centers in a screen (m)
U = the approach velocity (m/sec or ft/sec)
ε = the screen porosity, i.e., the ratio of the open area measured at the closest approach of the wires to the total area occupied by the screen (dimensionless)
$= \frac{s-d}{s}$
μ = the dynamic viscosity of water (N·sec/m^2)
ρ = the water density (kg/m^3)

Blevins (1984) gives headloss data for a wide variety of other screen designs.

Comminutors and In-Line Grinders

Comminutors and in-line grinders are used to reduce the size of objects in raw wastewater. They are supposed to eliminate the need for coarse screens and screenings handling and disposal. They require upstream bar screens for protection from impacts from large debris.

Comminutors consist of a rotating, slotted drum that acts as a screen, and peripheral cutting teeth and shear bars that cut down objects too large to pass through the slots and that are trapped on the drum surface. The flow is from outside the drum to its inside. Typical slot openings are 1/4 to 3/8 in. Typical headlosses are 2 to 12 in.

In-line grinders consist of pairs of counterrotating, intermeshing cutters that shear objects in the wastewater. The product sizes also are typically 1/4 to 3/8 in., and the headlosses are typically 12 to 18 in.

Both in-line grinders and comminutors tend to produce “ropes” and “balls” from cloth, which can jam downstream equipment. If the wastewater contains large amounts of rags and solids, in-line grinders and comminutors may require protection by upstream coarse screens, which defeats their function. Comminutors and in-line grinders also chop up plastics and other nonbiodegradable materials, which

end up in wastewater sludges and may prevent disposal of the sludges on land because of aesthetics. Comminutors and in-line grinders are also subject to wear from grit and require relatively frequent replacement. Comminutors and, to a lesser extent, in-line grinders, are nowadays not recommended (Joint Task Force, 1992).

Fine Screens

Fine screens are sometimes used in place of clarifiers, in scum dewatering and in concentrate and sludge screening. In wastewater treatment, they are preceded by bar screens for protection from impact by large debris, but not by comminutors, because screen performance depends on the development of a "precoat" of solids. Fine screens generally remove fewer solids from raw sewage than do primary settling tanks, say 15 to 30% of suspended solids for openings of 1 to 6 mm (Joint Task Force, 1992). There are four kinds of fine screens (Hazen and Sawyer, Engineers, 1975; Metcalf & Eddy, Inc., 1991; Pankratz, 1988).

Continuous-Belt Fine Screens

Continous-belt fine screens consist of stainless steel wedgewire elements mounted on horizontal supporting rods and forming a continuous belt loop. As the loop moves, the clogged region of the screen is lifted out of the water. The supporting rods or the upper head sprocket mount blades fit between the wires and dislodge accumulated debris as the wires are carried over the head sprocket. A supplementary brush or doctor blade may be used to remove sticky material.

The openings between the wires are generally between 3/16 to 1/2 in. The openings in continuous-belt fine screens are usually too coarse for use as primary sewage treatment devices, although they may be satisfactory for some industrial wastewaters containing fibrous or coarse solids.

Rotary Drum Fine Screens

In rotary drum fine screens, stainless steel wedgewire is wrapped around a horizontal cylindrical framework that is partially submerged. Generally, about 75% of the drum diameter and 66% of its mesh surface area are submerged. As the drum rotates, dirty wire is brought to the top, where it is cleaned by high-pressure water sprays and doctor blades.

The flow direction may be in along the drum axis and out through the inner surface of the wedgewire or in through the outer surface of the wedgewire and out along the axis.

Common openings are 0.01 to 0.06 in. (0.06 in. is preferred for raw wastewater), and the usual wire diameter is 0.06 in. Typical hydraulic loadings are 16 to 112 gpm/ft^2, and typical suspended solids removals for raw municipal sewage are 5 to 25%.

Inclined, Self-Cleaning Static Screens

Inclined, self-cleaning, static screens consist of inclined panes of stainless steel wedgewire. The wire runs horizontally. The flow is introduced at the top of the screen, and it travels downwards along the screen surface. Solids are retained on the surface, and screened water passes through it and is collected underneath the screen. As solids accumulate on the screen surface, they impede the water flow, which causes the water to move the solids downwards to the screen bottom.

Common openings are 0.01 to 0.06 in. (determined by *in situ* tests), and the usual wire diameter is 0.06 in. Typical hydraulic loadings are 4 to 16 gpm/in. of screen width, and typical suspended solids removals for raw municipal sewage are 5 to 25%.

Disc Fine Screens

Disc fine screens consist of flat discs of woven stainless steel wire supported on steel frameworks and partially submerged in the flow. As the disc rotates, the dirty area is lifted out of the flow and cleaned by high-pressure water sprays.

The mesh openings are generally about 1/32 in.

Disc fine screens are limited to small flows, generally less than 20,000 gpm for reasons of economy (Pankratz, 1988).

Microscreens

Microscreens are used as tertiary suspended solids removal devices following biological wastewater treatment and secondary clarification (Hazen and Sawyer, Engineers, 1975). Typical mesh openings are 20 to 25 μm and range from about 15 to 60 μm. The hydraulic loading is typically 5 to 10 gpm/ft^2 of submerged area. The suspended solids removal from secondary clarifier effluents is about 40 to 60%. Effluent suspended solids concentrations are typically 5 to 10 mg/L.

Most microscreens are rotary drums, but there are some disc microscreens. These are similar to rotary drum and disc fine screens, except for the mesh size and material, which is usually a woven polyester fiber.

Microscreen fabrics gradually become clogged despite the high-pressure water sprays, and the fabric must be removed from the drum or disc for special cleaning every few weeks.

Orifice Walls

Orifice walls are sometimes installed in the inlet zones of sedimentation tanks to improve the lateral and vertical distribution of the flow. Orifice walls will not disperse longitudinal jets, and if jet formation cannot be prevented, it may be desirable to install adjustable vertical vanes to redirect the flow over the inlet cross section.

The relationship between head across an orifice and the flow through it is (King and Brater, 1963):

$$Q = C_D A \sqrt{2gh_L} \tag{9.5}$$

Empirical discharge coefficients for sharp-edged orifices of any shape lie between about 0.59 and 0.66, as long as the orifice Reynolds number is larger than about 10^5, which is usually the case (Lea, 1938; Smith and Walker, 1923). Most of the results are close to 0.60.

Orifice Reynolds number:

$$\left(\boldsymbol{Re} = d\sqrt{gh_L}/\upsilon\right)$$

In Hudson's (1981) design examples, the individual orifices are typically 15 to 30 cm in diameter, and they are spaced 0.5 to 1.0 m apart. The jets from these orifices will merge about six orifice diameters downstream from the orifice wall — which would be about 1 to 2 m in Hudson's examples — and that imaginary plane should be taken as the boundary between the inlet zone and settling zone.

9.2 Chemical Reactors

Hydraulic Retention Time

Regardless of tank configuration, mixing condition, or the number or volume of recycle flows, the average residence for water molecules in a tank is as follows (Wen and Fan, 1975),

$$\tau = \frac{V}{Q} \tag{9.6}$$

where τ = the hydraulic retention time (s)
V = the active liquid volume in the tank (m^3)
Q = the volumetric flow rate through the tank not counting any recycle flows (m^3/s)

Note that Q does not include any recycle flows. The *hydraulic retention time* is also called the *hydraulic detention time* and, by chemical engineers, the *space time*. It is often abbreviated HRT.

Reaction Order

The reaction order is the apparent number of reactant molecules participating in the reaction. Mathematically, it is the exponent on the reactant concentration in the rate expression:

$$r_{1,2} = kC_1^p C_2^q \tag{9.7}$$

where C_1 = the concentration of substance 1 (mol/L)
C_2 = the concentration of substance 2 (mol/L)
k = the reaction rate coefficient (units vary)
p = the reaction order of substance 1 (dimensionless)
q = the reaction order of substance 2 (dimensionless)
$r_{1,2}$ = the rate of reaction of components 1 and 2 (units vary)

In this case, the reaction rate is pth order with respect to substance 1 and qth order with respect to substance 2.

Many biological reactions are represented by the Monod equation (Monod, 1942):

$$r = \frac{r_{max} \cdot C}{K_C + C} \tag{9.8}$$

where r_{max} = the maximum reaction rate (units vary, same as r)
K_C = the affinity constant (same units as C)

The Monod function is an example of a "mixed" order rate expression, because the rate varies from first order to zero order as the concentration increases.

The units of the reaction rate vary depending on the mass balance involved. In general, one identifies a control volume (usually one compartment or differential volume element in a tank) and constructs a

mass balance on some substance of interest. The units of the reaction rate will then be the mass of the substance per unit volume per time. The units of the rate constant will be determined by the need for dimensional consistency.

It is important to note that masses in chemical reaction rates have identities, and they do not cancel. Consequently, the ratio kg COD/kg VSS·s does not reduce to 1/s. This becomes obvious if it is remembered that the mass of a particular organic substance can be reported in a variety of ways: kg, mol, BOD, COD, TOC, etc. The ratios of these various units are not unity, and the actual numerical value of a rate will depend on the method of expression of the mass.

Many reactions in environmental engineering are represented satisfactorily as first order. This is a consequence of the fact that the substances are contaminants, and the goal of the treatment process is to reduce their concentrations to very low levels. In this case, the Maclaurin series representation of the rate expression may be truncated to the first-order terms:

$$r(C_1) = \underbrace{r(0)}_{=0} + \underbrace{(C_1 - 0)\left.\frac{\partial r}{\partial C_1}\right|_{C_1=0}}_{\text{first order in } C_1} + \underbrace{\text{higher order terms}}_{\text{truncated}} \tag{9.9}$$

Many precipitation and oxidation reactions are first order in the reactants. Disinfection is frequently first order in the microbial concentration, but the order of the disinfectant may vary. Flocculation is second order. Substrate removal reactions in biological processes generally are first order at low concentration and zero order at high concentration.

Effect of Tank Configuration on Removal Efficiency

The general steady state removal efficiency is,

$$E = \frac{C_o - C}{C_o} \tag{9.10}$$

This is affected by the reaction kinetics and the hydraulic regime in the reactor.

Completely Mixed Reactors

The completely mixed reactor (CMR) is also known as the continuous flow, stirred tank reactor (CFSTR or, more commonly, CSTR). Because of mixing, the contents of the tank are homogeneous, and a mass balance yields:

$$\frac{dVC}{dt} = QC_o - QC - kC^nV \tag{9.11}$$

where C = the concentration in the homogeneous tank and its effluent flow (kg/m^3 or slug/ft^3)
C_0 = the concentration in the influent liquid (kg/m^3 or slug/ft^3)
k = the reaction rate constant (here, m^{3n}/kg^n·sec or ft^{3n}/slug^n·sec)
n = the reaction order (dimensionless)
Q = the volumetric flow rate (m^3/s or ft^3/sec)
V = the tank volume (m^3 or ft^3)
t = elapsed time (s)

The steady state solution is,

$$\frac{C}{C_o} = \frac{1}{1 + kC^{n-1}\tau} \tag{9.12}$$

For first-order reactions, this becomes,

$$\frac{C}{C_o} = \frac{1}{1+k\tau} \tag{9.13}$$

In the case of zero-order reactions, the steady state solution is,

$$C_o - C = k\tau \tag{9.14}$$

If the mixing intensity is low, CSTRs may develop "dead zones" that do not exchange water with the inflow.

If the inlets and outlets are poorly arranged, some of the inflow may pass directly to the outlet without mixing with the tank contents. This latter phenomenon is called "short-circuiting." In the older literature, short-circuiting and complete mixing were often confused. They are opposites. Short-circuiting cannot occur in a tank that is truly completely mixed.

Short-circuiting in clarifiers is discussed separately, below.

The analysis of short-circuiting and dead zones in mixed tanks is due to Cholette and Cloutier (1959) and Cholette et al. (1960). For a "completely mixed" reactor with both short-circuiting and dead volume, the mass balance of an inert tracer on the mixed volume is:

$$\underbrace{f_m V \frac{dC_m}{dt}}_{\text{accumulation in mixed volume}} = \underbrace{\left(1-f_s\right)QC_o}_{\text{fraction of influent entering mixed volume}} \underbrace{-\left(1-f_s\right)QC_m}_{\text{flow leaving mixed volume}} \tag{9.15}$$

where C_m = the concentration of tracer in the mixed zone (kg/m^3)
C_0 = the concentration of tracer in the feed (kg/m^3)
f_m = the fraction of the reactor volume that is mixed (dimensionless)
f_s = the fraction of the influent that is short-circuited directly to the outlet (dimensionless)

The observed effluent is a mixture of the short-circuited flow and the flow leaving the mixed zone:

$$QC = f_s QC_o + \left(1-f_s\right)QC_m \tag{9.16}$$

Consequently, for a slug application of tracer (in which the influent momentarily contains some tracer and is thereafter free of it), the observed washout curve is,

$$\frac{C}{C_i} = \left(1-f_s\right)\exp\left\{-\frac{\left(1-f_s\right)Qt}{f_m V}\right\} \tag{9.17}$$

where C_i =the apparent initial concentration (kg/m^3).

Equation (9.17) provides a convenient way to determine the mixing and flow conditions in "completely mixed" tanks. All that is required is a slug tracer study. The natural logarithms of the measured effluent concentrations are then plotted against time, and the slope and intercept yield the values of the fraction short-circuited and the fraction mixed.

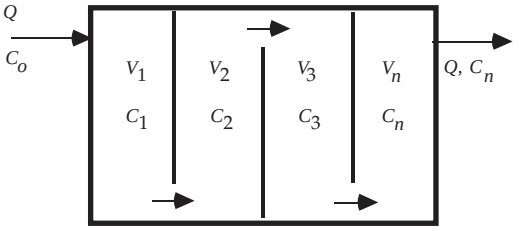

FIGURE 9.1 Mixed-cells-in-series flow pattern.

Mixed-Cells-in-Series

Consider the rapid mixing tank shown in Fig. 9.1. This particular configuration is called "mixed-cells-in-series" or "tanks-in-series," because the liquid flows sequentially from one cell to the next. Each cell has a mixer, and each cell is completely mixed. Mixed-cells-in-series is the usual configuration for flocculation tanks and activated sludge aeration tanks.

The flow is assumed to be continuous and steady, and each compartment has the same volume, i.e., $V_1 = V_2 = V_3 = \ldots = V_n$. The substance concentrations in the first through last compartments are C_1, C_2, C_3,…C_n, respectively. The substance mass balance for each compartment has the same mathematical form as Eq. (9.11), above, and the steady state concentration in each compartment is given by Eq. (9.12) (Hazen, 1904; MacMullin and Weber, 1935; Kehr, 1936; Ham and Coe, 1918; Langelier, 1921).

Because of the mixing, the concentration in the last compartment is also the effluent concentration. Consequently, the ratio of effluent to influent concentrations is:

$$\frac{C_n}{C_o} = \frac{C_1}{C_o} \cdot \frac{C_2}{C_1} \cdot \frac{C_3}{C_2} \cdot \ldots \cdot \frac{C_n}{C_{n-1}} \tag{9.18}$$

Because all compartments have the same volume and process the same flow, all their HRTs are equal. Therefore, for a first-order reaction, Eq. (9.18) becomes,

$$\frac{C_n}{C_o} = \left(\frac{1}{1 + k\tau_1} \right)^n \tag{9.19}$$

where τ_1 = the HRT of a single compartment (s)
$= V/nQ$
n = the number of mixed-cells-in-series

Equation (9.19) has significant implications for the design of all processing tanks used in natural and used water treatment. Suppose that all the internal partitions in Fig. 9.1 are removed, so that the whole tank is one completely mixed, homogenous compartment. Because there is only one compartment, its HRT is n times the HRT of a single compartment in the partitioned tank. Now, divide Eq. (9.12) by Eq. (9.19) and expand the bracketed term in Eq. (9.19) by the binomial theorem:

$$\frac{C(\text{one cell})}{C_n(\text{n cells})} = \frac{1 + nk\tau_1 + \dfrac{n(n-1)}{2!}(k\tau_1)^2 + \ldots + (k\tau_1)^n}{1 + nk\tau_1} > 1 \tag{9.20}$$

Therefore, the effect of partitioning the tank is to reduce the concentration of reactants in its effluent, i.e., to increase the removal efficiency.

The effect of partitioning on second- and higher-order reactions is even more pronounced. Partitioning has no effect in the case of zero-order reactions (Levenspiel, 1972).

The efficiency increases with the number of cells. It also increases with the hydraulic retention time. This means that total tank volume can be traded against the number of cells. A tank can be made smaller — more economical — and still achieve the same degree of particle destabilization, if the number of compartments in it is raised.

Ideal Plug Flow

As n becomes very large, the compartments approach differential volume elements, and, if the partitions are eliminated, the concentration gradient along the tank becomes continuous. The result is an "ideal plug flow" tank. The only transport mechanism along the tank is advection: there is no dispersion. This means that water molecules that enter the tank together stay together and exit together. Consequently, ideal plug flow is hydraulically the same as batch processing. The distance traveled along the plug flow tank is simply proportional to the processing time in a batch reactor, and the coefficient of proportionality is the average longitudinal velocity.

Referring to Fig. 9.2, the mass balance on a differential volume element is:

$$\frac{\partial C}{\partial t} = -U\frac{\partial C}{\partial x} - kC^{p} \tag{9.21}$$

where U = the plug flow velocity (m/sec or ft/sec).

For steady state conditions, this becomes for reaction orders greater than one:

$$C^{1-p} = C_o^{1-p} - (1-p)k\tau \tag{9.22}$$

For first-order reactions, one gets,

$$C = C_o \exp\{-k\tau\} \tag{9.23}$$

The relative efficiencies of ideal plug flow tanks and tanks that are mixed-cells-in-series is easily established. In the case of first-order reactions, the power series expansion of the exponential is,

$$\exp\{-k\tau\} = 1 - k\tau + \frac{(k\tau)^2}{2!} - \frac{(k\tau)^3}{3!} + \ldots < \lim_{n\to\infty}\left(\frac{1}{1+k\tau_1}\right)^n \tag{9.24}$$

Consequently, ideal plug flow tanks are the most efficient; completely mixed tanks are the least efficient; and tanks consisting of mixed-cells-in-seres are intermediate.

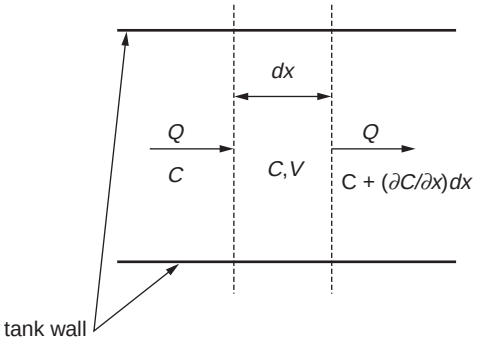

FIGURE 9.2 Control volume for ideal plug-flow mass balance.

Plug Flow with Axial Dispersion

Of course, no real plug flow tank is ideal. If it contains mixers, they will break down the concentration gradients and tend to produce a completely mixed tank. Furthermore, the cross-sectional velocity variations induced by the wall boundary layer will produce a longitudinal mixing called shear-flow dispersion. Shear-flow dispersion shows up in the mass balance equation as a "diffusion" term, so Eq. (9.21) should be revised as follows:

$$\frac{\partial C}{\partial t} = K\frac{\partial^2 C}{\partial x^2} - U\frac{\partial C}{\partial x} - kC^p \tag{9.25}$$

where K = the (axial) shear flow dispersion coefficient (m^2/s or ft^2/sec).

Langmuir's (1908) boundary conditions for a tank are:

Inlet:

$$x = 0; \qquad QC_o = QC - KA\frac{dC}{dx} \tag{9.26}$$

Outlet:

$$x = L; \qquad \frac{dC}{dx} = 0 \tag{9.27}$$

where A = the cross-sectional area of the reactor (m^2 or ft^2)
L = the length of the reactor (m or ft).

The first condition is a mass balance around the tank inlet. The rate of mass flow (kg/sec) approaching the tank inlet in the influent pipe must equal the mass flow leaving the inlet in the tank itself. Transport within the tank is due to advection and dispersion, but dispersion in the pipe is assumed to be negligible, because the pipe velocity is high. The outlet condition assumes that the reaction is nearly complete — which is, of course, the goal of tank design — so the concentration gradient is nearly zero, and there is no dispersive flux. The Langmuir boundary conditions produce a formula that reduces the limit to ideal plug flow as K approaches zero and to ideal complete mixing as K approaches infinity. A correct formula must do this. No other set of boundary conditions produces this result (Wehner and Wilhem, 1956; Pearson, 1959; Bishoff, 1961; Fan and Ahn, 1963). The general solution is (Danckwerts, 1953):

$$\frac{C}{C_o} = \frac{4a\cdot\exp\left\{\frac{1}{2}(1+a)\boldsymbol{Pe}\right\}}{(1+a)^2\cdot\exp\{a\boldsymbol{Pe}\} - (1-a)^2} \tag{9.28}$$

where a = part of the solution to the characteristic equation of the differential equation (1/m or 1/ft)

$$= \sqrt{1+\frac{4kK}{U^2}}$$

Pe = the turbulent Peclet number (dimensionless)
$= UL/K$

A tank with axial dispersion has an efficiency somewhere between ideal plug flow and ideal complete mixing. Consequently, a real plug flow tank with axial dispersion behaves as if it were compartmentalized. The equivalence of the number of compartments and the shear flow diffusivity can be represented by (Levenspiel and Bischoff, 1963):

$$\frac{1}{n} = 2\cdot\boldsymbol{Pe}^{-1} - 2\cdot\boldsymbol{Pe}^{-2}\cdot\left[1-\exp\left\{-\boldsymbol{Pe}^{-1}\right\}\right] \tag{9.29}$$

The axial dispersion — and, consequently, the Peclet number — in pipes and ducts has been extensively studied, and the experimental results can be summarized as follows (Wen and Fan, 1975):

Reynolds numbers less than 2000:

$$\frac{1}{\boldsymbol{Pe}} = \frac{1}{\boldsymbol{Pe}\cdot\boldsymbol{Sc}} + \frac{\boldsymbol{Re}\cdot\boldsymbol{Sc}}{192} \tag{9.30}$$

Reynolds numbers greater than 2000:

$$\frac{1}{\boldsymbol{Pe}} = \frac{30.\times 10^{6}}{\boldsymbol{Re}^{2.1}} + \frac{1.35}{\boldsymbol{Re}^{1/8}} \tag{9.31}$$

where D = the molecular diffusivity of the substance (m^2/s or ft^2/sec)
d = the pipe or duct diameter (m or ft)
Pe = the duct Peclet number (dimensionless)
$= Ud/K$
Re = the duct Reynolds number (dimensionless)
$= Ud/\nu$
ν = the kinematic viscosity (m^2/s or ft^2/sec)
Sc = the Schmidt number (dimensionless)
$= \nu/D$

These formulae assume that the dispersion is generated entirely by the shear flow of the fluid in the pipe or duct. When mixers are installed in tanks, Eqs. (9.30) and (9.31) no longer apply, and the axial dispersion coefficient must be determined experimentally.

More importantly, the use of mixers generally results in very small Peclet numbers, and the reactors tend to approach completely mixed behavior, which is undesirable, because the efficiency is reduced. Thus, there is an inherent contradiction between high turbulence and ideal plug flow, both of which are wanted in order to maximize tank efficiency. The usual solution to this problem is to construct the reactor as a series of completely mixed cells. This allows the use of any desired mixing power and preserves the reactor efficiency.

9.3 Mixers And Mixing

The principal objects of mixing are (1) blending different liquid streams, (2) suspending particles, and (3) mass transfer. The main mass transfer operations are treated in separate sections below. This section focuses on blending and particle suspension.

Mixing Devices

Mixing devices are specialized to either laminar or turbulent flow conditions.

Laminar/High Viscosity

Low-speed mixing in high-viscosity liquids is done in the laminar region with impeller Reynolds numbers below about 10. (See below.) The mechanical mixers most commonly used are:

- Gated anchors and horseshoes (large U-shaped mixers that fit against or near the tank wall and bottom, usually with cross members running between the upright limbs of the U called gates)
- Helical ribbons
- Helical screws
- Paddles
- Perforated plates (usually in stacks of several separated plates having an oscillatory motion, with the flat portion of the plate normal to the direction of movement)

Turbulent/Low to Medium Viscosity

High-speed mixing in low- to moderate-viscosity fluids is done in the turbulent region with impeller Reynolds numbers above 10,000. The commonly used agitators are:

- Anchors and horseshoes
- Disk (either with or without serrated or sawtooth edge for high shear)
- Jets
- Propellers
- Static in-line mixers (tubing with internal vanes fixed to the inner tubing wall that are set at an angle to the flow to induce cross currents in the flow)
- Radial flow turbines [blades are mounted either to a hub on the drive shaft or to a flat disc (Rushton turbines) attached to the drive shaft; blades are oriented radially and may be flat with the flat side

oriented perpendicular to the direction of rotation or curved with the convex side oriented perpendicular to the direction of rotation]

- Axial flow turbines [blades are mounted either to a hub on the drive shaft or to a flat disc (Rushton turbines) attached to the drive shaft; blades flat and pitched with the flat side oriented at an angle (usually 45°) to the direction of rotation]
- Smith turbines (turbines specialized for gas transfer with straight blades having a C-shaped cross section and oriented with the open part of the C facing the direction of rotation)
- Fluidfoil (having hub-mounted blades with wing-like cross sections to induce axial flow)

Power Dissipation

Fluid Deformation Power

Energy is dissipated in turbulent flow by the internal work due to volume element compression, stretching, and twisting (Lamb, 1932):

$$\frac{\Phi}{\mu} = 2\left(\frac{\partial u}{\partial x}\right)^2 + 2\left(\frac{\partial v}{\partial y}\right)^2 + 2\left(\frac{\partial w}{\partial z}\right)^2 + \left(\frac{\partial u}{\partial y} + \frac{\partial v}{\partial x}\right)^2 + \left(\frac{\partial u}{\partial z} + \frac{\partial w}{\partial x}\right)^2 + \left(\frac{\partial v}{\partial z} + \frac{\partial w}{\partial y}\right)^2 \tag{9.32}$$

where u,v,w = the local velocities in the x,y,z directions, respectively (m/s or ft/sec)
Φ = Stokes' (1845) energy dissipation function (W/m^3 or ft lbf/ft^3·sec)
μ = the absolute or dynamic viscosity (N s/m^2 or lbf sec/ft^2)

The first three terms on the right-hand-side of Eq. (9.32) are compression and stretching terms, and the last three are twisting terms. The left-hand-side of Eq. (9.32) can also be written as:

$$\frac{\Phi}{\mu} = \frac{\varepsilon}{\nu} = \Gamma^2 \tag{9.33}$$

where ε = the local power dissipation per unit mass (watts/kg or ft·lbf/sec·slug)
ν = the kinematic viscosity (m^2/s or ft^2/sec)
Γ = the characteristic strain rate (per sec)

Equation (9.33) applies only at a point. If the total energy dissipated in a mixed tank is needed, it must be averaged over the tank volume. If the temperature and composition are uniform everywhere in the tank, the kinematic viscosity is a constant, and one gets,

$$\overline{\Gamma}^2 = \frac{1}{\nu V}\iiint \varepsilon \cdot dxdydz \tag{9.34}$$

where V = the tank volume (m^3 or ft^3)
$\overline{\Gamma}$ = the spatially averaged (root-mean-square) characteristic strain rate (per sec).

With this definition, the total power dissipated by mixing is,

$$P = \Phi V = \mu \overline{\Gamma}^2 V \tag{9.35}$$

where P = the mixing power (W or ft·lbf/sec).

Camp–Stein Theory

Camp and Stein (1943) assumed that the axial compression/stretching terms can always be eliminated by a suitable rotation of axes so that a differential volume element is in pure shear. This may not be true

for all three-dimensional flow fields, but there is numerical evidence that it is true for some (Clark, 1985). Consequently, the power expenditure per unit volume is,

$$\frac{dP}{dV} = \Phi = \mu\left[\left(\frac{\partial u}{\partial y}+\frac{\partial v}{\partial x}\right)^2+\left(\frac{\partial u}{\partial z}+\frac{\partial w}{\partial x}\right)^2+\left(\frac{\partial v}{\partial z}+\frac{\partial w}{\partial y}\right)^2\right] = \mu G^2 \tag{9.36}$$

where dP = the total power dissipated deforming the differential volume element (N·m/sec, ft·lbf/sec)
dV = the volume of the element (m^3 or ft^3)
G = the absolute velocity gradient (per sec)
Φ = Stoke's (1845) dissipation function (watts/m^3 or lbf/ft^2·sec)

If the velocity gradient is volume-averaged over the whole tank, one gets,

$$P = \mu \bar{G}^2 V \tag{9.37}$$

where $\bar{G}$ = the root-mean-square (r.m.s.) velocity gradient (per sec).

The Camp–Stein r.m.s. velocity gradient is numerically identical to the r.m.s. characteristic strain rate, but (because of the unproved assumption of pure shear embedded in $\bar{G}$) $\bar{\Gamma}$ is the preferred concept. Camp and Stein used the assumption of pure shear to derive a formula for the flow around a particle and the resulting particle collision rate, thereby connecting the flocculation rate to $\bar{G}$ and P. However, it is also possible to derive collision rate based on $\bar{\Gamma}$ (Saffman and Turner, 1956), which yields a better physical representation of the flocculation process and is nowadays preferred.

Energy Spectrum and Eddy Size

Mixing devices are pumps, and they create macroscopic, directed currents. As the currents flow away from the mixer, they rub against and collide with the rest of the water in the tank. These collisions and rubbings break off large eddies from the current. The large eddies repeat the process of collision/shear, producing smaller eddies, and these do the same until there is a spectrum of eddy sizes. The largest eddies in the spectrum are of the same order of size as the mixer. The large eddies move quickly, they contain most of the kinetic energy of the turbulence, and their motion is controlled by inertia rather than viscosity. The small eddies move slowly, and they are affected by viscosity.

The size of the smallest eddies is called the "Kolmogorov length scale" (Landahl and Mollo-Christensen, 1986):

$$\eta = \left(\frac{\nu^3}{\varepsilon}\right)^{1/4} \tag{9.38}$$

where ε = the power input per unit mass (watts/kg or ft·lbf/sec·slug)
η = the Kolmogorov length (m or ft).

The Kolmogorov wave number is defined by custom as (Landahl and Mollo-Christensen, 1986):

$$k_K = \frac{1}{\eta} \tag{9.39}$$

where k_K = the Kolmogorov wave number (per m or per ft).

The general formula for the wave number is,

$$k = \frac{2\pi}{L} \tag{9.40}$$

where L = the wave length (m or ft).

The kinetic energy contained by an eddy is one-half the square of its velocity times its mass. It is easier to calculate the energy per unit mass, because this is merely one-half the square of the velocity. The mean water velocity in mixed tanks is small, so nearly all the kinetic energy of the turbulence is in the velocity fluctuations, and the kinetic energy density function can be defined in terms of these fluctuations:

$$E(k)dk = \tfrac{1}{2}\left(u_k^2 + v_k^2 + w_k^2\right)n(k)dk \tag{9.41}$$

where $E(k)dk$ = the total kinetic energy contained in the eddies between wave numbers k and $k + dk$ (m^2/s^2 or ft^2/sec^2)

$n(k)dk$ = the number of eddies between the wave numbers k and $k + dk$ (dimensionless)

u_k, v_k, w_k = the components of the velocity fluctuation in the x, y, and z directions for eddies in the wave length interval k to $k + dk$ (m/s or ft/sec)

A plot of $E(k)dk$ vs. k is called the energy spectrum. An energy spectrum plot can have a wide variety of shapes, depending on the power input and the system geometry (Brodkey, 1967). However, if the power input is large enough, all spectra contain a range of small-sized eddies that are a few orders of magnitude larger than the Kolmogorov length scale η. The turbulence in this range of eddy sizes is isotropic and independent of the geometry of the mixing device, although it depends on the power input. Consequently, it is called the "universal equilibrium range." At very high power inputs, the universal equilibrium range subdivides into a class of larger eddies that are influenced only by inertial forces and a class of smaller eddies that are influenced by molecular viscous forces. These subranges are called the "inertial convective subrange" and the "viscous dissipation subrange," respectively.

When the energy density, $E(k)$, is measured, the inertial convection subrange is found to occur at wave numbers less than about one-tenth the Kolmogorov wave length, and the viscous dissipation subrange lies entirely between about 0.1 k_K and k_K (Grant, Stewart, and Moillet, 1962; Stewart and Grant, 1962). Similar results have been obtained theoretically (Matsuo and Unno, 1981). Therefore, η is the diameter of the smallest eddy in the viscous dissipative subrange, and the largest eddy in the viscous dissipation subrange has a diameter of about $20\pi\eta$.

The relative sizes of floc particles and eddies is important in understanding how they interact. If the eddies are larger than the floc particles, they entrain the flocs and transport them. If the eddies are smaller than the flocs, the only interaction is shearing of the floc by the eddies. It is also important whether the flocs interact with the inertial convective subrange eddies or the viscous dissipative subrange eddies, because the formulae connecting eddy diameter and velocity with mixing power are different for the two subranges. In particular, a collision rate formula based on $\bar{\Gamma}$ would be correct only in the viscous dissipative subrange (Cleasby, 1984).

Typical recommended $\bar{\Gamma}$ values are on the order of 900/sec for rapid mixing tanks and 75/sec for flocculation tanks (Joint Committee, 1969). At 20°C, the implied power inputs per unit volume are about 0.81 m^2/sec^3 for rapid mixing and 0.0056 m^2/sec^3 for flocculation. The diameter of the smallest eddy in the viscous dissipative subrange in rapid mixing tanks is 0.030 mm, and the diameter of the largest eddy is 1.9 mm. The sizes of flocculated particles generally range from a few hundredths of a millimeter to a few millimeters, and the sizes tend to decline as the mixing power input rises (Boadway, 1978; Lagvankar and Gemmell, 1968; Parker, Kaufman, and Jenkins, 1972; Tambo and Watanabe, 1979; Tambo and Hozumi, 1979). Therefore, they are usually contained within the viscous dissipative subrange, or they are smaller than any possible eddy and lie outside the universal equilibrium range. In water treatment, only the viscous dissipative subrange processes need to be considered.

Turbines

An example of a typical rapid mixing tank is shown in Fig. 9.3. Such tanks approximate cubes or right cylinders; the liquid depth approximates the tank diameter. The impeller is usually a flat disc with several short blades mounted near the disc's circumference. The blades may be flat and perpendicular to the

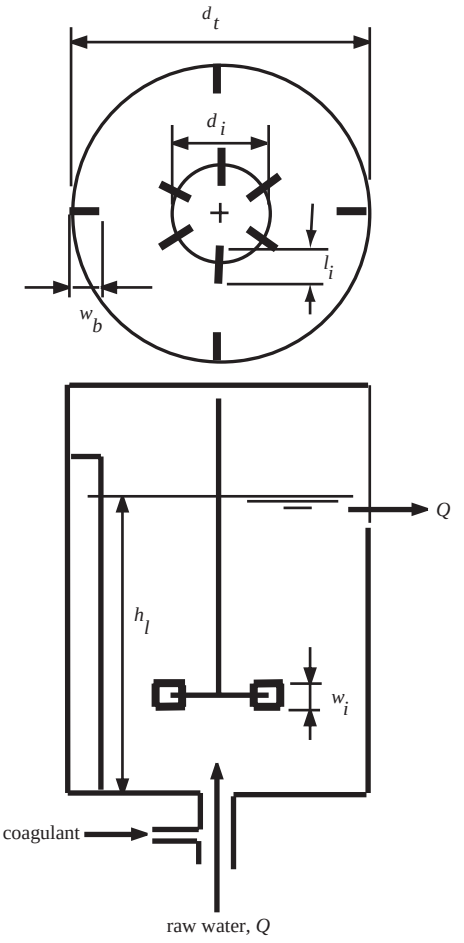

FIGURE 9.3 Turbine definition sketch.

disc, as shown, or they may be curved or pitched at an angle to the disc. The number of blades varies, but a common choice is six. Almost always, there are several baffles mounted along the tank wall to prevent vortexing of the liquid. The number of baffles and their width are design choices, but most commonly, there are four baffles.

The power dissipated by the turbulence in a tank is related to the geometry of the tank and mixer and the rotational speed of the mixer. Dimensional analysis suggests an equation of the following form (Rushton, Costich, and Everett, 1950):

$$\boldsymbol{Ru} = f\left(\boldsymbol{Re}, \boldsymbol{Fr}, d_i, d_t, h_i, h_l, l_i, N_b, N_i, n_b, n_i, p_i, w_b, w_i\right) \tag{9.42}$$

where d_i = the impeller diameter (m or ft)
d_t = the tank diameter (m or ft)
Fr = the Froude number of the impeller (dimensionless)
$= \omega^2 d_i / g$
g = the acceleration due to gravity (m/s^2 or ft/sec^2)
h_l = the depth of liquid in the tank (m or ft)
h_i = the height of the impeller above the tank bottom (m or ft)
l_i = the impeller blade length (m or ft)

N_b = the baffle reference number, i.e., the number of baffles in some arbitrarily chosen "standard" tank (dimensionless)
n_b = the number of baffles in the tank (dimensionless)
N_i = the impeller reference number, i.e., the number of impeller blades on some arbitrarily chosen "standard" impeller (dimensionless)
n_i = the number of impeller blades (dimensionless)
P = the power dissipated by the turbulence (watts or ft·lbf/sec)
p_i = the impeller blade pitch (m or ft)
Re = the impeller Reynolds number (dimensionless)
$= \omega d_i^2/\nu$
Ru = the Rushton power number (dimensionless)
$= P/\rho\omega^3 d_i^5$
w_b = the width of the baffles (m or ft)
w_i = the impeller blade width (m or ft)
ν = the kinematic viscosity of the liquid (m^2/sec or ft^2/sec)
ρ = the mass density of the liquid (kg/m^3 or slugs/ft^3)
ω = the rotational speed of the impeller (Hz, revolutions per sec)

The geometry of turbine/tank systems has been more or less standardized against the tank diameter (Holland and Chapman, 1966; Tatterson, 1994):

$$\frac{h_l}{d_t} = 1 \tag{9.43}$$

$$\tfrac{1}{6} \le \frac{h_i}{d_t} \le \tfrac{1}{2};\ \text{usually } d_i \tag{9.44}$$

$$\tfrac{1}{4} \le \frac{d_i}{d_t} \le \tfrac{1}{2};\ \text{usually } 1/3 \tag{9.45}$$

$$\tfrac{1}{6} \le \frac{w_i}{d_i} \le \tfrac{1}{4};\ \text{usually } 1/5 \tag{9.46}$$

$$\frac{l_i}{d_i} = \tfrac{1}{4};\ \text{for hub-mounted blades} \tag{9.47}$$

$$\frac{l_i}{d_i} = \tfrac{1}{8};\ \text{for disk-mounted blades} \tag{9.48}$$

$$\tfrac{1}{12} \le \frac{w_b}{d_t} \le \tfrac{1}{10};\ \text{usually } 1/10 \tag{9.49}$$

Turbines usually have six blades, and tanks usually have four baffles extending from the tank bottom to somewhat above the highest liquid operating level.

For any given tank, all the geometric ratios are constants, so the power number is a function of only the Reynolds number and the Froude number. Numerous examples of such relationships are given by Holland and Chapman (1966).

For impeller Reynolds numbers below 10, the hydraulic regime is laminar, and Eq. (9.42) is found experimentally to be,

$$\boldsymbol{Re} \cdot \boldsymbol{Ru} = \text{a constant} \tag{9.50}$$

The value of the constant is typically about 300, but it varies between 20 and 4000 (Tatterson, 1994).

Equation (9.50) indicates that the power dissipation is proportional to the viscosity, the square of the impeller rotational speed and the cube of the impeller diameter:

$$P \propto \mu\omega^2 d_i^3 \tag{9.51}$$

For impeller Reynolds numbers above 10,000, the hydraulic regime is turbulent, and the experimental relationship for baffled tanks is,

$$\boldsymbol{Ru} = \text{a constant} \tag{9.52}$$

Typical values of the constant are (Tatterson, 1994):

- Hub-mounted flat blades, 4
- Disk-mounted flat blades, 5
- Pitched blades, 1.27
- Propellers, 0.6

The power number for any class of impeller varies significantly with the details of the design. Impeller design and performance are discussed by Oldshue and Trussell (1991).

Equation (9.52) indicates that the power dissipation is proportional to the liquid density, the cube of the impeller rotational speed, and the fifth power of the impeller diameter:

$$P \propto \rho\omega^3 d_i^5 \tag{9.53}$$

The typical turbine installation operates in the turbulent region. Operation in the transition region between the laminar and turbulent zones is not recommended, because mass transfer rates in the transition region tend to be lower and less predictable than in the other regions (Tatterson, 1994).

Paddle Wheel Flocculators

A typical flocculation tank compartment is depicted in Fig. 9.4. Paddle flocculators similar to this design, but without the stators and baffles and with the axles transverse to the flow, were first introduced by Smith (1932). A set of flocculation paddles is mounted on a drive axle, which runs along the length of the compartment parallel to the flow. The axle may be continuous throughout the whole tank, or it may serve only one or two compartments. Alternatively, the axle may be mounted vertically in the compartment or horizontally but transverse to the flow. In these cases, each compartment has its own axle. The paddles are mounted parallel to the drive axle. The number of paddles may be the same in each compartment or may vary. The compartments in the flocculator are separated from each other by cross walls called "baffles." The baffles are not continuous across the tank; there are openings between the baffles and tank walls so that water can flow from one compartment to the next. In Fig. 9.4, an opening is shown at one end of each baffle, and the openings alternate from one side of the tank to the other, so they do not line up. This arrangement minimizes short-circuiting. The spaces are sometimes put at the top or bottom of the baffles so as to force an over-and-under flow pattern. The compartments also contain stators. These are boards fixed to the baffle walls. They are intended to prevent the setup of a vortex in the compartment.

Although flocculator performance is usually correlated with tank-average parameters like $\bar{\Gamma}$ and HRT, it should be remembered that the actual flocculation process occurs in the immediate vicinity of the paddles and their structural supports. The flow around the paddles and supports is sensitive to their exact geometry and their rotational speed. This means that precise prediction of flocculator performance

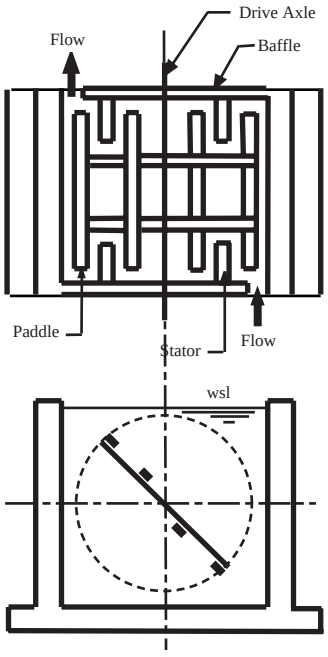

FIGURE 9.4 Flocculation tank plan and cross section.

requires the testing of full-scale units. Facilities may require redesign and reconstruction of the paddle system in the light of operating experience. Some engineers will prefer to specify commercially available paddle systems, which have demonstrated satisfactory performance on similar waters. Contracts with vendors should include performance specifications and guarantees.

Paddle geometry can be connected to power input by Camp's (1955) method. The drag force on the paddle is given by:

$$F_D = \tfrac{1}{2} C_D \rho A \left(v_p - v\right)^2 \tag{9.54}$$

where F_D = the drag force on the paddle (N or lbf)
C_D = the drag coefficient (dimensionless)
A = the area of the paddle normal to the direction of movement (m^2 or ft^2)
v_p = the velocity of the paddle relative to the tank (m/s or ft/sec)
v = the velocity of the water relative to the tank (m/s or ft/sec)
ρ = the density of the water (kg/m^3 or $slug/ft^3$)

The power dissipated by the paddle is simply the drag force multiplied by the velocity of the paddle relative to the tank (not relative to the water, as is often incorrectly stated):

$$P_p = \tfrac{1}{2} C_D \rho A v_p \left(v_p - v\right)^2 \tag{9.55}$$

where P_p = the power dissipated by the paddle (W or ft·lb/sec).

Once steady state mixing is established, the water velocity will be some constant fraction of the paddle velocity, i.e., $v = kv_p$. The paddle speed is taken to be the speed of its centroid around the axle, which is related to its radial distance from the axle. Making these substitutions yields:

$$P_p = 4\pi^3 C_D \rho \left(1-k\right)^2 A r^3 \omega^3 \tag{9.56}$$

where k = the ratio of the water velocity to the paddle velocity (dimensionless)
r = the radial distance of the centroid of the paddle to the axle (m or ft)
ω = the rotational velocity of the paddle (revolutions/sec)

If the paddle is wide, the area should be weighted by the cube of its distance from the axle (Fair, Geyer, and Okun, 1968).

$$r^3 A = \int_{r_o}^{r_1} r^3 L dB = \tfrac{1}{4}\left(r_1 - r_o\right)^4 L \tag{9.57}$$

where B = the width of the paddle (m or ft)
L = the length of the paddle (m or ft)
r_1 = the distance of the outer edge of the paddle from the axle (m or ft)
r_0 = the distance of the inner edge of the paddle from the axle (m or ft)

This refinement changes Eq. (9.56) to:

$$P_p = \pi^3 C_D \rho \left(1-k\right)^2 \left(r_1 - r_o\right)^4 L\omega^3 \tag{9.58}$$

Equation (9.56) or Eq. (9.58) should be applied to each paddle and support in the tank, and the results should be summed to obtain the total power dissipation:

$$P = 4\pi^3 C_D \rho \left(1-k\right)^2 \omega^3 \sum_{i=1}^{n} A_i r_i^3 \tag{9.59}$$

$$P = \pi^3 C_D \rho \left(1-k\right)^2 \omega^3 \sum_{i=1}^{n} \left(r_{1,i} - r_{o,i}\right)^4 L_i \tag{9.60}$$

Equations (9.59) and (9.60) provide the needed connection to the volume-averaged characteristic strain rate:

$$\bar{\Gamma}^2 = \frac{\varepsilon}{\nu} = \frac{P}{\mu V} \tag{9.61}$$

It is generally recommended that the strain rate be tapering downwards from the inlet chamber to the outlet chamber, say from 100/sec to 50/sec. The tapering of $\bar{\Gamma}$ that is required can be achieved by reducing, from inlet to outlet, either the rotational speed of the paddle assemblies or the paddle area.

Another criterion sometimes encountered is the "Bean Number" (Bean, 1953). This is defined as the volume swept out by the elements of the paddle assembly per unit time — called the "displacement" — divided by the flow through the flocculation tank:

$$\boldsymbol{Be} = \frac{2\pi\omega \sum_{i=1}^{n} r_i A_i}{Q} \tag{9.62}$$

where **Be** = the Bean number (dimensionless).

Bean's recommendation, based on a survey of actual plants, is that **Be** should be kept between 30 and 40, if it is calculated using all the paddle assemblies in the flocculation tank (Bean, 1953). For a given facility, the Bean number is proportional to the spatially averaged characteristic strain rate and the total water power. However, the ratio varies as the square of the rotational speed.

The mixing conditions inside a tank compartment are usually turbulent, so the drag coefficient is a constant.

Camp reports that the value of k for paddle flocculators *with stators* varies between 0.32 and 0.24 as the rotational speed increases (Camp, 1955).

The peripheral speed of the paddle assembly is usually kept below 2 ft/sec, and speeds of less than 1 ft/sec are recommended for the final compartment (Bean, 1953; Hopkins and Bean, 1966). In older plants, peripheral speeds were generally below 1.8 ft/sec (Bean, 1953). This practice appears to have been based on laboratory data that was developed using 1 gal jars without stators. The laboratory data indicated impaired flocculation at peripheral speeds above 1.8 ft/sec, but the results may have been caused by vortexing, which would actually reduce the velocity gradients in the liquid (Leipold, 1934).

Paddles are usually between 4 and 8 in. wide, and the spacing between paddles should be greater than this (Bean, 1953). The total paddle area should be less than 25% of the plan area of the compartment.

Jets

The power expended by a jet is simply the kinetic energy of the mass of liquid injected into the tank:

$$P = \frac{1}{2}\dot{m}v^2 \tag{9.63}$$

where $\dot{m}$ is the mass flow rate in the jet at its inlet (kg/s or slug/sec). The mass flow rate is determined by the mixing requirements.

Static In-Line Mixers

The energy dissipated by static mixers is determined by the pressure drop through the unit:

$$P = Q \cdot \Delta p \tag{9.64}$$

where Δp = the pressure drop (N/m^2 or lbf/ft^2)
Q = the volumetric flow rate (m^3/s or ft^3/sec).

The pressure drop depends on the details of the mixer design.

Gas Sparging

The power dissipated by gas bubbles is,

$$P = \rho g Q H \tag{9.65}$$

where g = the acceleration due to gravity (9.80665 m/s^2 or 32.174 ft/sec^2)
H = the depth of bubble injection (m or ft)
Q = the gas flow rate (m^3/s or ft^3/sec)
ρ = the liquid density (kg/m^3 or slug/ft^3)

Blending

The principal purpose of all mixing is blending two or more different liquid streams.

Batch Mixing Times

The time required to blend two or more liquids to some acceptable level of macroscopic homogeneity is determined by batch blending tests. The test results are usually reported in terms of a homogenization number that is defined to be the number of impeller revolutions required to achieve homogenization (Tatterson, 1994):

$$\boldsymbol{Ho} = \omega\tau_m \tag{9.66}$$

where **Ho** = the homogenization number (dimensionless)
τ_m = the blending time (sec)
ω = the rotational speed of the impeller (Hz, revolutions per sec)

The degree of mixing is often determined from tracer data by calculating the "fractional unmixedness," which is defined in terms of measured concentration fluctuations (Godfrey and Amirtharajah, 1991; Tatterson, 1994):

$$X_t = \left| \frac{C_t - C_\infty}{C_\infty - C_o} \right| \tag{9.67}$$

where C_0 = the initial tracer concentration the tank, if any, prior to tracer addition and mixing (kg/m^3 or lb/ft^3)
C_t = the maximum tracer concentration at any point in the tank at time t (kg/m^3 or lb/ft^3)
C_∞ = the calculated tracer concentration for perfect mixing (kg/m^3 or lb/ft^3)
X_t = the fractional unmixedness (dimensionless)

Blending is considered to be complete when X_t falls to 0.05, meaning that the observed concentration fluctuations are within 5% of the perfectly mixed condition.

Turbines

The Prochazka-Landau correlation (Tatterson, 1994) for a turbine with six flat, disk-mounted blades in a baffled tank is,

$$\omega\tau_m = 0.905\left(\frac{d_t}{d_i}\right)^{2.57} \log\left(\frac{X_o}{X_f}\right) \tag{9.68}$$

For a turbine with four pitched blades, their correlation is,

$$\omega\tau_m = 2.02\left(\frac{d_t}{d_i}\right)^{2.20} \log\left(\frac{X_o}{X_f}\right) \tag{9.69}$$

And for a three-bladed marine propeller, it is,

$$\omega\tau_m = 3.48\left(\frac{d_t}{d_i}\right)^{2.05} \log\left(\frac{X_o}{X_f}\right) \tag{9.70}$$

where d_i = the impeller diameter (m or ft)
d_t = the tank diameter (m or ft)
X_0 = the initial fractional unmixedness, typically between 2 and 3 in the cited report (dimensionless)
X_f = the final fractional unmixedness, typically 0.05
τ_m = the required batch mixing time (sec)
ω = the impeller rotational speed (Hz, revolutions per sec)

Note that impeller diameter is more important than impeller speed, because the mixing time is inversely proportional to the impeller diameter raised to a power greater than 2, whereas it is inversely proportional to the speed to the first power.

Equations (9.68) through (9.70) demonstrate that for any particular design, the homogenization number is a constant. The equations are best used to convert data from one impeller size to another.

The homogenization number is also a constant in the laminar region, but the constant is independent of impeller size. Turbines are seldom used in laminar conditions, but propellers mounted in draft tubes are. Reported homogenization numbers for propeller/tube mixers range from 16 to 130 (Tatterson, 1994).

Static In-Line Mixers

A wide variety of proprietary static in-line mixers is available. Some designs are specialized to laminar or turbulent flow conditions, and other designs are general purpose mixers. Static mixers are liable to clog with large suspended solids and require filtered or screened feed streams.

The usual specification is that the coefficient of variation of concentration measurements in the mixer outlet be equal to less than 0.05 (Godfrey and Amirtharajah, 1991; Tatterson, 1994). Mixer unit lengths are typically 5 to 50 times the pipe diameter, depending on the design.

The standard deviation of concentration measurements over any mixer cross section declines exponentially with mixer length and may be correlated by (Godfrey and Amirtharajah, 1991),

$$\frac{s}{s_o} = 2\exp\left(-\frac{1.54 f^{0.5} L}{D}\right) \tag{9.71}$$

where D = the mixer's diameter
f = the mixer's Darcy-Weisbach friction factor (dimensionless)
L = the mixer's length (m or ft)
s = the standard deviation of the concentration measurements over the outlet cross section (kg/m^3 or lb/ft^3)
s_0 = the standard deviation of the concentration measurements over the inlet cross section (kg/m^3 or lb/ft^3)

Jets

Jet mixers have relatively high power requirements, but they are low-maintenance devices. They are restricted to turbulent, medium- to low-viscosity liquid mixing, and the jet Reynolds number at the inlet should be above 2100 (Tatterson, 1994). The required pump may be inside or outside the tank, depending on equipment design.

Jets may enter the tank axially on the tank bottom or radially along the tank side. Axial entry can be used for deep tanks in which the liquid depth to tank diameter ratio is between 0.75 and 3, and radial entry can be used for shallow tanks in which the depth–diameter ratio is between 0.25 and 1.25 (Godfrey and Amirtharajah, 1991). If the depth–diameter ratio exceeds 3, multiple jets are required at different levels. Radial inlets are frequently angled upwards.

Mixing of the jet and surrounding fluid does not begin until the jet has traveled at least 10 inlet diameters, and effective mixing occurs out to about 100 inlet diameters. Oldshue and Trussell (1991) recommend that the tank diameter to jet inlet diameter ratio be between 50 and 500.

If the initial jet Reynolds number is 5000 or more, the batch mixing time is given by (Godfrey and Amirtharajah, 1991),

$$\frac{\tau_m v_j}{d_j} = 6\left(\frac{d_t}{d_j}\right)^{3/2}\left(\frac{d_l}{d_j}\right)^{1/2} \tag{9.72}$$

For initial jet Reynold's numbers below 5000, the mixing time is given by,

$$\frac{\tau_m v_j}{d_j} = \frac{30\,000}{\boldsymbol{Re}}\left(\frac{d_t}{d_j}\right)^{3/2}\left(\frac{d_l}{d_j}\right)^{1/2} \tag{9.73}$$

where d_j = the jet's inlet diameter (m or ft)
d_l = the liquid depth (m or ft)
d_t = the tank diameter (m or ft)
Re = the jet's inlet Reynold's number (dimensionless)
$= \nu_j d_j / \nu$
ν_j = the jet's inlet velocity (m/s of ft/sec)
τ_m = the required mixing time (sec)

Other correlations are given by Tatterson (1994).

Continuous Flow

In order to account for their exponential residence time distributions, the required hydraulic retention time in continuous flow tanks ranges from 50 to 200 times the batch mixing time, and is typically about 100 times τ_m (Tatterson, 1994):

$$\tau_h \approx 100\tau_m \tag{9.74}$$

Particle Suspension

Settleable Solids

Settleable solids are usually put into suspension using downwards-directed axial flow turbines, sometimes with draft tubes. Tank bottoms should be dished, and the turbine should be placed relatively close to the bottom, say between 1/6 and 1/4 of the tank diameter (Godfrey and Amirtharajah, 1991). Antivortex baffles are required. Sloping side walls, bottom baffles, flat bottoms, radial flow turbines, and large tank diameter to impeller diameter ratios should be avoided, as they permit solids accumulation on the tank floor (Godfrey and Amirtharajah, 1991; Tatterson, 1994).

The impeller speed required for the suspension of settleable solids is given by the Zweitering (1958) correlation:

$$\omega_{js} = \frac{S\nu^{0.1} d_p^{0.2} \left[\dfrac{g(\rho_p - \rho)}{\rho} \right]^{0.45} X_p^{0.13}}{d_i^{0.85}} \tag{9.75}$$

where d_p = the particle diameter (m or ft)
d_i = the turbine diameter (m or ft)
g = the acceleration due to gravity (9.80665 m/s^2 or 32.174 ft/sec^2)
S = the impeller/tank geometry factor (dimensionless)
X_p = the weight fraction of solids in the suspension (dimensionless)
ω_{js} = the impeller rotational speed required to just suspend the particles (Hz, revolutions per sec)
ρ = the liquid density (kg/m^3 or slug/ft^3)
ρ_p = the particle density (kg/m^3 or slug/ft^3)

Equation (9.75) is the "just suspended" criterion. Lower impeller speeds will allow solids to deposit on the tank floor. The impeller/tank geometry factor varies significantly. Typical values for many different configurations are given by Zweitering (1958).

The Zweitering correlation leads to a prediction for power scale-up that may not be correct. In the standard geometry, the liquid depth, tank diameter, and impeller diameter are proportional. Combining this geometry with the power correlation for the turbulent regime [Eq. (9.57)], one gets,

$$\frac{P}{V} \propto \frac{\omega^3 d_i^5}{d_l d_t^2} \propto \frac{d_i^{-2.55} d_i^5}{d_l d_t^2} \propto d_t^{-0.55} \tag{9.76}$$

Some manufactures prefer to scale power per unit volume as $d_t^{-0.28}$ and others prefer to keep the power per unit volume constant.

If solids are to be distributed throughout the whole depth of the liquid, then the modified Froude number must be greater than 20 (Tatterson, 1994):

$$\boldsymbol{Fr} = \frac{\rho\omega^2 d_i^2}{g\left(\rho_p - \rho\right)d_p}\left(\frac{d_p}{d_i}\right)^{0.45} > 20 \tag{9.77}$$

The concentration profile can be estimated from (Tatterson, 1994):

$$\frac{X_p(z)}{\bar{X}_p} = \frac{\boldsymbol{Pe}\cdot\exp\left(-\dfrac{\boldsymbol{Pe}\cdot z}{d_l}\right)}{1-\exp\left(-\boldsymbol{Pe}\right)} \tag{9.78}$$

$$\boldsymbol{Pe} = 330\left(\frac{\omega d_i}{\nu_p}\right)^{-1.17}\left(\frac{\varepsilon d_p^4}{\nu^3}\right)^{-0.095} \tag{9.79}$$

where d_i = the impeller's diameter (m or ft)
d_l = the total liquid depth (m or ft)
d_p = the particle's diameter (m or ft)
Pe = the solid's Peclet number (dimensionless)
$= \nu_{ps} d_l / d_p$
ν_p = the particle's free settling velocity in still liquid (m/s or ft/sec)
ν_{ps} = the particle's free settling velocity in stirred liquid (m/s or ft/sec)
$\bar{X}_p$ = the mean particle mass fraction in the tank (dimensionless)
$X_p(z)$ = the particle mass fraction at elevation z above the tank bottom (dimensionless)
z = the elevation above the tank bottom (m or ft)
ε = the power per unit mass (W/kg or ft·lbf/slug·sec)
ρ = the density of the liquid (kg/m^3 or slug/ft^3)
ρ_p = the density of the particle (kg/m^3 or slug/ft^3)
ν = the kinematic viscosity (m^2/s or ft^2/sec)
ω = the rotational speed of the impeller (Hz, revolutions per sec)

Floatable Solids

The submergence of low-density, floating solids requires the development of a vortex, so only one antivortex baffle or narrow baffles ($w_b = d_t/50$) should be installed (Godfrey and Amirtharajah, 1991). The axial flow turbine should be installed close to the tank bottom and perhaps off-center. The tank bottom should be dished. The minimum Froude number for uniform mixing is given by,

$$\boldsymbol{Fr}_{\min} = 0.036\left(\frac{d_i}{d_t}\right)^{-3.65}\left(\frac{\rho_p - \rho}{\rho}\right)^{0.42} \tag{9.80}$$

where $\mathbf{Fr}_{\min}$ = the required minimum value of the Froude number (dimensionless)
Fr = the impeller Froude number (dimensionless)
$= \omega^2 d_i / g$

9.4 Rapid Mixing and Flocculation

Rapid Mixing

Rapid or flash mixers are required to blend treatment chemicals with the water being processed. Chemical reactions also occur in the rapid mixer, and the process of colloid destabilization and flocculation begins there.

Particle Collision Rate

Within the viscous dissipation subrange, the relative velocity between two points along the line connecting them is (Saffman and Turner, 1956; Spielman, 1978):

$$\overline{|u|} = \sqrt{\frac{2\varepsilon}{15\pi\nu}} \cdot r \tag{9.81}$$

where r = the radial distance between the two points (m or ft)
$\bar{u}$ = the average of the absolute value of the relative velocity of two points in the liquid along the line connecting them (m/s or ft/sec)
ε = the power input per unit mass (W/kg or ft·lbf/slug·sec)
ν = the kinematic viscosity (m^2/s or ft^2/sec)

One selects a target particle of radius r_1 and number concentration C_1 and a moving particle of radius r_2 and number concentration C_2. The moving particle is carried by the local eddies, which may move toward or away from the target particle at velocities given by Eq. (9.81). A collision will occur whenever the center of a moving particle crosses a sphere of radius $r_1 + r_2$ centered on the target particle. The volume of liquid crossing this sphere is:

$$Q = \tfrac{1}{2}\overline{|u|}4\pi\left(r_1 + r_2\right)^2 = \sqrt{\frac{8\pi}{15}}\sqrt{\frac{\varepsilon}{\nu}}\left(r_1 + r_2\right)^3 \tag{9.82}$$

where Q = the volumetric rate of flow of liquid into the collision sphere(m^3/sec or ft^3/sec).

The Saffman–Turner collision rate is, therefore:

$$R_{1,2} = \sqrt{\frac{8\pi}{15}}\sqrt{\frac{\varepsilon}{\nu}}C_1C_2\left(r_1 + r_2\right)^3 \tag{9.83}$$

A similar formula has been derived by Delichatsios and Probstein (1975).

Particle Destabilization

The destabilization process may be visualized as the collision of colloidal particles with eddies containing the coagulants. If the diameter of the eddies is estimated to be η, then Eq. (9.83) can be written as,

$$\sqrt{\frac{\pi}{120}}\sqrt{\frac{\varepsilon}{\nu}}C_1C_\eta\left(d_1 + \eta\right)^3 \tag{9.84}$$

where $C\eta$ = the "concentration" of eddies containing the coagulant (dimensionless)
d_1 = the diameter of the colloidal particles (m or ft)
$R_{1,}\eta$ = the rate of particle destabilization (no./m$^3\cdot$s or no./ft$^3\cdot$sec)
η = the diameter of the eddies containing the coagulant (m or ft)

Equation (9.84) is the Amirtharajah–Trusler (1986) destabilization rate formula. The "concentration" $C\eta$ may be regarded as an unknown constant that is proportional to the coagulant dosage.

The effect of a collision between a stable particle and an eddy containing coagulant is a reduction in the net surface charge of the particle. The particle's surface charge is proportional to its zeta potential, which in turn, is proportional to its electrophoretic mobility. Consequently, $R_{1,}\eta$ is the rate of reduction of the average electrophoretic mobility of the suspension.

Equation (9.84) has unexpected implications. First, the specific mixing power may be eliminated from Eq. (9.84) by means of the definition of the Kolmogorov length scale, yielding (Amirtharajah and Trusler, 1986):

$$R_{1,\eta} = \sqrt{\frac{\pi}{120}}C_\eta\frac{\left(d_1 + \eta\right)^3}{\eta^2}C_1 \tag{9.85}$$

The predicted rate has a minimum value when the Kolmogorov length scale is twice the particle diameter, i.e., $\eta = 2d_1$ and the mixing power per unit mass required to produce this ratio is:

$$\varepsilon = \frac{\nu^3}{16d_1} \tag{9.86}$$

In strongly mixed tanks, the power dissipation rate varies greatly from one part of the tank to another. It is highest near the mixer, and ε should be interpreted as the power dissipation at the mixer.

The predicted minimum is supported by experiment, and it occurs at about $\eta = 2d_1$, if η is calculated for the conditions next to the mixer (Amirtharajah and Trusler, 1986). For a given tank and mixer geometry, the energy dissipation rate near the mixer is related to the average dissipation rate for the whole tank. In the case of completely mixed tanks stirred by turbines, the minimum destabilization rate will occur at values of $\bar{\Gamma}$ between about 1500 and 3500 per sec, which is substantially above the usual practice. (See below.)

Second, the destabilization rate is directly proportional to the stable particle concentration:

$$R_{1,\eta} = kC_1 \tag{9.87}$$

where k = the first-order destabilization rate coefficient (per sec).

The rate coefficient, k, applies to the conditions near the mixer. However, what is needed for design is the rate R_1,η volume averaged over the whole tank. If the tank is completely mixed, C_1 is the same everywhere and can be factored out of the volume average. Thus, the volume average of the rate, R_1,η becomes a volume average of the rate coefficient, k. Throughout most of the volume, the power dissipation rate is much smaller than the rate near the mixer, and in general, $\eta \gg d_1$. Therefore, the particle diameter can be neglected, and to a first-order approximation one has:

$$\bar{k} = \sqrt{\frac{\pi}{120}} \sqrt{\frac{\nu^3}{\bar{\Gamma}}} C_\eta \tag{9.88}$$

Equation (9.88) is limited to power dissipation rates less than 1500 per sec.

Inspection of Eq. (9.88) shows that the rate of destabilization should *decrease* if the temperature or the mixing power *increases*. This is counterintuitive. Experience with simple chemical reactions and flocculation indicates that reaction rates always rise whenever the temperature or mixing power is increased. However, in chemical reactions and particle flocculation, the driving forces are the velocity of the particles and their concentrations. In destabilization, the driving forces are these plus the size of the eddies, and eddy size dominates.

The prediction that the destabilization rate decreases as the mixing power increases has indirect experimental support, although it may be true only for completely mixed tanks (Amirtharajah and Trusler, 1986; Camp, 1968; Vrale and Jorden, 1971). The prediction regarding temperature has not been tested.

Optimum Rapid Mixing Time

It is known that there is a well-defined optimum rapid mixing time (Letterman, Quon, and Gemmell, 1973; Camp, 1968). This optimum is not predicted by the Amirtharajah–Trusler formula. If rapid mixing is continued beyond this optimum, the flocculation of the destabilized particles and their settling will be impaired, or at least there will be no further improvement. For the flocculation of activated carbon with filter alum, the relationship between the r.m.s. strain rate, batch processing time, and alum dose is (Letterman, Quon, and Gemmell, 1973):

$$\bar{\Gamma} t C^{1.46} = 5.9 \times 10^6 \left(\text{mg/L}\right)^{1.46} \tag{9.89}$$

where C = the dosage of filter alum, $Al_2(SO_4)_3(H_2O)_{18}$ (mg/L)
t = the duration of the batch mixing period (sec).

Equation (9.89) does not apply to alum dosages above 50 mg/L, because optimum rapid mixing times were not always observed at higher alum dosages. The experiments considered powdered activated carbon concentrations between 50 and 1000 mg/L, alum dosages between 10 and 50 mg/L, and values of $\bar{\Gamma}$ between 100 and 1000 per sec. At the highest mixing intensities, the optimum value of t ranged from 14 sec to 2.5 min. These results have not been tested for other coagulants or particles. Consequently, it is not certain that they are generally applicable. Also, the underlying cause of the optimum is not known.

It is also clear that very high mixing powers in the rapid mixing tank impair subsequent flocculation in the flocculation tank. For example, Camp (1968) reports that rapid mixing for 2 min at a $\bar{\Gamma}$ of 12,500/sec prevents flocculation for at least 45 min. If $\bar{\Gamma}$ is reduced to 10,800/sec, flocculation is prevented for 30 min. The period of inhibition was reduced to 10 min when $\bar{\Gamma}$ was reduced to 4400/sec. Strangely enough, if the particles were first destabilized at a $\bar{\Gamma}$ of 1000/sec, subsequent exposure to 12,500/sec had no effect. Again, the cause of the phenomenon is not known.

Design Criteria for Rapid Mixers

Typical engineering practice calls for a r.m.s. characteristic strain rate in the rapid mixing tank of about 600 to 1000/sec (Joint Task Force, 1990). Recommendations for hydraulic retention time vary from 1 to 3 sec for particle destabilization (Joint Task Force, 1990) to 20 to >40 sec for precipitate enmeshment (AWWA, 1969). Impeller tip speeds should be limited to less than 5 m/s to avoid polymer shear.

Flocs begin to form within 2 sec, and conduits downstream of the rapid mixing chamber should be designed to minimize turbulence. Typical conduit velocities are 1.5 to 3 ft/sec.

Flocculation

Quiescent and Laminar Flow Conditions

In quiescent water, the Brownian motion of the destabilized colloids will cause them to collide and agglomerate. Eventually, particles large enough to settle will form, and the water will be clarified. The rate of agglomeration is increased substantially by mixing. This is due to the fact that mixing creates velocity differences between neighboring colloidal particles, which increases their collision frequency.

Perikinetic Flocculation

Coagulation due to the Brownian motion is called "perikinetic" flocculation. The rate of perikinetic coagulation was first derived by v. Smoluchowski in 1916/17 as follows (Levich, 1962). Consider a reference particle having a radius r_1. A collision will occur with another particle having a radius r_2 whenever the distance between the centers of the two particles is reduced to $r_1 + r_2$. (Actually, because of the van der Waals attraction, the collision will occur even if the particles are somewhat farther apart.) The collision rate will be the rate at which particles with radius r_2 diffuse across a sphere of radius $r_1 + r_2$ centered on the reference particle. For a spherically symmetrical case like this, the mass conservation equation becomes (Crank, 1975):

$$\frac{\partial C_2(r,t)}{\partial t} = \frac{D_{1,2}}{r^2}\frac{\partial}{\partial r}\left[r^2\frac{\partial C_2(r,t)}{\partial t}\right] \tag{9.90}$$

where $C_2(r,t)$ = the number concentration of the particle with radius r_2 at a point a distance r from the reference particle at time t (no./m^3 or no./ft^3)
$D_{1,2}$ = the mutual diffusion coefficient of the two particles (m^2/sec or ft^2/sec)
$= D_1 + D_2$
D_1 = the diffusion coefficient of the reference particle (m^2/s or ft^2/sec)
D_2 = the diffusion coefficient of the particle with radius r_2 (m^2/sec or ft^2/sec)
r = the radial distance from the center of the reference particle (m or ft)
t = elapsed time (sec)

Only the steady state solution is needed, so the left-hand-side of Eq. (9.90) is zero. The boundary conditions are:

$$r \to \infty; \qquad C_2(r) = C_2 \tag{9.91}$$

$$r = r_1 + r_2; \quad C_2(r) = 0 \tag{9.92}$$

Therefore, the particular solution is:

$$C_2(r) = C_2\left(1 - \frac{r_1 + r_2}{r}\right) \tag{9.93}$$

The rate at which particles with radius r_2 diffuse across the spherical surface is:

$$4\pi(r_1 + r_2)^2 D_{1,2}\left.\frac{dC_2(r)}{dr}\right|_{r=r_1+r_2} = 4\pi D_{1,2}C_2(r_1 + r_2) \tag{9.94}$$

If the concentration of reference particles is C_1, the collision rate will be:

$$R_{1,2} = 4\pi D_{1,2} C_1 C_2 \left(r_1 + r_2\right) \tag{9.95}$$

where $R_{1,2}$ = the rate of collisions between particles of radius r_1 and radius r_2 due to Brownian motion (collisions/m^3·sec or collisions/ft^3·sec).

Orthokinetic Flocculation

If the suspension is gently stirred, so as to produce a laminar flow field, the collision rate is greatly increased. The mixing is supposed to produce a velocity gradient near the reference particle, $G = du/dy$. The velocity, u, is perpendicular to the axis of the derivative y. The collisions now are due to the velocity gradient, and the process is called "gradient" or "orthokinetic" flocculation. As before, a collision is possible if the distance between the centers of two particles is less than the sum of their radii, $r_1 + r_2$. v. Smoluchowski selects a reference particle with a radius of r_1, and, using the local velocity gradient, one calculates the total fluid flow through a circle centered on the reference particle with radius $r_1 + r_2$ (Freundlich, 1922):

$$Q = 4\int_0^{r_1+r_2} Gy\left(r^2 - y^2\right)^{1/2} dy = \tfrac{4}{3} G\left(r_1 + r_2\right)^3 \tag{9.96}$$

where G = the velocity gradient (per sec)
Q = the total flow through the collision circle (m^3/s or ft^3/sec)
ν = the distance from the center of the reference particle normal to the local velocity field (m or ft)

The total collision rate between the two particle classes will be:

$$R_{1,2} = \tfrac{4}{3} G C_1 C_2 \left(r_1 + r_3\right)^3 \tag{9.97}$$

The ratio of the orthokinetic to perikinetic collision rates for equal size particles is:

$$\frac{R_{1,2}(\text{ortho})}{R_{1,2}(\text{peri})} = \frac{4\mu G N_A r^3}{RT} \tag{9.98}$$

where N_A = Avogadro's constant (6.022 137∞10^{23} particles per mol)
R = the gas constant (8.3243 J/mol·K or 1.987 Btu/lb·°R)
T = the absolute temperature (K or °R)

Einstein's (1956) formula for the diffusivity of colloidal particles has been used to eliminate the joint diffusion constant. Note that the effect of mixing is very sensitive to the particle size, varying as the cube of the radius. In fact, until the particles have grown by diffusion to some minimal size, mixing appears to have little or no effect. Once the minimal size is reached, however, flocculation is very rapid (Freundlich, 1922).

Corrections to v. Smoluchowski's analysis to account for van der Waals forces and hydrodynamic effects are reviewed by Spielman (1978).

Turbulent Flocculation and Deflocculation

The purposes of the flocculation tank are to complete the particle destabilization begun in the rapid mixing tank and to agglomerate the destabilized particles. Flocculation tanks are operated at relatively low power dissipation rates, and destabilization proceeds quite rapidly; it is probably completed less than 1 min after the water enters the tank. Floc agglomeration is a much slower process, and its kinetics are

different. Furthermore, the kinds of mixing devices used in flocculation are different from those used in rapid mixing. The effects of tank partitioning upon the degree of agglomeration achieved are quite striking, and flocculation tanks are always partitioned into at least four mixed-cells-in-series.

Flocculation Rate

First, consider the kinetics of flocculation. Floc particles form when smaller particles collide and stick together. The basic collision rate is given by the Saffman–Turner equation (Harris, Kaufman, and Krone, 1966; Argaman and Kaufman, 1970; Parker, Kaufman, and Jenkins, 1972):

$$R_{1,2} = \sqrt{\frac{8\pi}{15}}\sqrt{\frac{\varepsilon}{\nu}}C_1C_2\left(r_1 + r_2\right)^3 \tag{9.99}$$

This needs to be adapted to the situation in which there is a wide variety of particle sizes, not just two. This may be done as follows (Harris, Kaufman, and Krone, 1966). It is first supposed that the destabilized colloids, also called the "primary particles," may be represented as spheres, each having the same radius r. The volume of such a sphere is:

$$V_1 = \tfrac{4}{3}\pi r^3 \tag{9.100}$$

Floc particles are aggregations of these primary particles, and the volume of the aggregate is equal to the sum of the volumes of the primary particle it contains. An aggregate consisting of i primary particles is called an "i-fold" particle and has a volume equal to:

$$V_i = \tfrac{4}{3}\pi i r^3 \tag{9.101}$$

From this, it is seen that the i-fold particle has an effective radius given by:

$$r_i = \sqrt[3]{ir^3} \tag{9.102}$$

The total floc volume concentration is:

$$\Phi = \tfrac{4}{3}\pi r^3 \sum_{i=1}^{p} iC_i \tag{9.103}$$

where C_i = the number concentration of aggregates containing i primary particles (no./m^3 or no./ft^3)
p = the number of primary particles in the largest floc in the suspension (dimensionless)
Φ = the floc volume concentration (m^3 floc/m^3 water or ft^3 floc/ft^3 water)

A k-fold particle can arise in several ways. All that is required is that the colliding flocs contain a total of k particles, so the colliding pairs may be:

- A floc having $k - 1$ primary particles and a floc having one primary particle
- A floc having $k - 2$ primary particles and a floc having two primary particles
- A floc having $k - 3$ primary particles and a floc having three primary particles, etc.

The k-fold particle will disappear, and form a larger particle, if it collides with anything except a p-fold particle. Collisions with p-fold particles cannot result in adhesion, because the p-fold particle is supposed to be the largest possible. In both kinds of collisions, it is assumed that the effective radius of a particle is somewhat larger than its actual radius because of the attraction of van der Waals forces. Each kind of collision can be represented by a summation of terms, like Eq. (9.99), and the net rate of formation of k-fold particles is the difference between the summations (Harris, Kaufman, and Krone, 1966):

$$R_k = \bar{\Gamma}\sqrt{\frac{8\pi}{15}} \cdot \left[\frac{1}{2} \sum_{\substack{i=1,\\ j=k-1}}^{k} \left(ar_i + ar_j\right)^3 C_i C_j - \sum_{i=1}^{p-1} \left(ar_k + ar_i\right)^3 C_k C_i \right] \tag{9.104}$$

where R_k = the net rate of formation of k-fold particles (no./sec·m^3 or no./sec·ft^3)
a = the ratio of the effective particle radius to its actual radius (dimensionless).

Note that the factor 1/2 in the first summation is required to avoid double counting of collisions.

If there is no formation process for primary particles, Eq. (9.104) reduces to:

$$R_1 = -\bar{\Gamma}\sqrt{\frac{8\pi}{15}} \cdot \left[\sum_{i=1}^{p-1} \left(ar + ar_i\right)^3 C_i \right] \cdot C_1 \tag{9.105}$$

where R_1 = the rate of loss of primary particles due to flocculation (no./sec·m^3 or no./sec·ft^3).

The summation may be rearranged by factoring out r, which requires use of Eq. (9.102) to eliminate r_i, and by using Eq. (9.103) to replace the resulting r^3:

$$R_1 = -\sqrt{\frac{3}{10\pi}}\bar{\Gamma} a^3 \Phi \sigma C_1 \tag{9.106}$$

where σ = the particle size distribution factor (dimensionless)

$$= \frac{\sum_{i=1}^{p-1} C_i \left(1 + i^{1/3}\right)^3}{\sum_{i=1}^{p-1} i C_i}$$

Except for a factor reflecting particle attachment efficiciency (which is not included above) and substitution of the Saffman–Turner collision rate for the Camp–Stein collision rate, Eq. (9.106) is the Harris–Kaufman–Krone flocculation rate formula for primary particles.

In any given situation, the resulting rate expression involves only two variables: the number concentration of primary particles, C_i, and the particle size distribution factor, σ. The power dissipation rate, kinematic viscosity, and floc volume concentration will be constants. Initially, all the particles are primary, and the size distribution factor has a value of 8. As flocculation progresses, primary particles are incorporated into ever larger aggregates, and σ declines in value, approaching a lower limit of 1.

If the flocculation tank consists of mixed-cells-in-series, σ will approach a constant but different value in each compartment. If the mixing power in each compartment is the same, the average particle size distribution factor will be (Harris, Kaufman, and Krone, 1966):

$$\bar{\sigma} = \frac{\left(\frac{C_{1,o}}{C_{1,e}}\right)^{1/n} - 1}{\sqrt{\frac{3}{10\pi}}\bar{\Gamma} a^3 \Phi} \tag{9.107}$$

where $\bar{\sigma}$ = the average particle size distribution factor for a flocculation tank consisting of n mixed-cells-in-series (dimensionless)
$C_{1,0}$ = the number concentration of primary particles in the raw water (no./m^3 or no./ft^3)
$C_{1,e}$ = the number concentration of primary particles in the flocculated water (no./m^3 or no./ft^3)

An equation of the same form as Eq. (9.105) has been derived by Argaman and Kaufman (1970) by substituting a formula for a turbulent eddy diffusivity into Smoluchowski's quiescent rate formula [Eq. (9.95)]. They make two simplifications. First, they observe that the radius of a typical floc is much larger than that of a primary particle, so r can be eliminated from Eq. (9.95). Second, ignoring the primary particles and the largest flocs, the total floc volume concentration, which is a constant everywhere in the flocculation tank, would be:

$$\Phi \approx \tfrac{4}{3}\sum_{i=2}^{p-1} C_i r_i^3 \tag{9.108}$$

Therefore:

$$R_1 \approx -\sqrt{\frac{3}{10\pi}}\bar{\Gamma}\Phi a^3 C_1 \tag{9.109}$$

These two substitutions eliminate any explicit use of the particle size distribution function. However, early in the flocculation process, the primary particles comprise most of the particle volume, so Eq. (9.109) is at some points of the process grossly in error.

Equations (9.106) and (9.109) are devices for understanding the flocculation process. The essential prediction of the models is that flocculation of primary particles can be represented as a first-order reaction with an apparent rate coefficient that depends only on the total floc volume concentration, the mixing power, and the water viscosity.

Experiments in which a kaolin/alum mixture was flocculated in a tank configured as one to four mixed-cells-in-series were well described by the model, as long as the value of $\bar{\Gamma}$ as kept below about 60/sec (Harris, Kaufman, and Krone, 1966). The average particle size distribution factor, $\bar{\sigma}$, was observed to vary between about 1 and 4, and it appeared to decrease as the mixing power increased.

Deflocculation Rate

If the mixing power is high enough, the collisions between the flocs and the surrounding liquid eddies will scour off some of the floc's primary particles, and this scouring will limit the maximum floc size that can be attained.

The maximum size can be estimated from the Basset–Tchen equation for the sedimentation of a sphere in a turbulent liquid (Basset, 1888; Hinze, 1959):

$$\begin{aligned}\rho_p V\frac{du_p}{dt} &= \rho_p Vg - \rho Vg - 3\pi\rho\nu d_p\left(u-u_p\right) + \rho V\frac{du}{dt} - \tfrac{1}{2}\rho\nu\frac{d\left(u-u_p\right)}{dt} \\ &\quad - \frac{9\rho V\sqrt{\nu/\pi}}{d_p}\int_0^t \frac{d\left[u\left(t-\tau\right)-u_p\left(t-\tau\right)\right]}{\sqrt{t-\tau}}\end{aligned} \tag{9.110}$$

where d_p = the floc diameter (m or ft)
g = the acceleration due to gravity (9.80665 m/s^2 or 32.174 ft/sec^2)
t = the elapsed time from the beginning of the floc's motion(s)
u = the velocity of the liquid near the floc (m/sec or ft/sec)
u_p = the velocity of the floc (m/s or ft/s)
V = the floc volume (m^3 or ft^3)
ν = the kinematic viscosity (m^2/sec or ft^2/sec)
ρ = the density of the liquid (kg/m^3 or slug/ft^3)
ρ_p = the density of the floc (kg/m^3 or slug/ft^3)
τ = the variable of integration(s)

The terms in this equation may be explained as follows. The term on the left-hand-side is merely the rate of change of the floc's downward momentum. According to Newton's second law, this is equal to the resultant force on the floc, which is given by the terms on the right-hand-side. The first term is the floc's weight. The second term is the buoyant force due to the displaced water. The density of the floc is assumed to be nearly equal to the density of the liquid, so the gravitational and buoyant forces nearly cancel. The third term is Stoke's drag force, which is written in terms of the difference in velocity between the floc and the liquid. Stoke's drag force would be the only drag force experienced by the particle, if the particle were moving at a constant velocity with a Reynold's number much less than one and the liquid was stationary. However, the moving floc displaces liquid, and when the floc is accelerated, some liquid must be accelerated also, and this gives rise to the remaining terms. The fourth term is an acceleration due to the local pressure gradients set up by the acceleration of the liquid. The fifth and sixth terms represent the additional drag forces resulting from the acceleration of the displaced liquid. The fifth term is the "virtual inertia" of the floc. It represents the additional drag due to the acceleration of displaced liquid in the absence of viscosity. The sixth term is the so-called "Basset term." It is a further correction to the virtual inertia for the viscosity of the liquid.

Parker, Kaufman, and Jenkins (1972) used the Basset–Tchen equation to estimate the largest possible floc diameter in a turbulent flow. They first absorb the last term into the Stoke's drag force. Then, they subtract from both sides the following quantity:

$$\rho_p V \frac{du}{dt} + \tfrac{1}{2}\rho V \frac{du}{dt}$$

getting

$$\left(\rho_p + \tfrac{1}{2}\rho\right)V \frac{d\left(u-u_p\right)}{dt} = \left(\rho_p - \rho\right)V \frac{du}{dt} - 3b\pi\rho\nu d_p\left(u-u_p\right) \tag{9.111}$$

where b = a coefficient greater than one that reflects the contribution of the Basset term to the drag force (dimensionless).

They argue that the relative acceleration of the liquid and floc, which is the term on the left-hand-side, is small relative to the acceleration of the liquid:

$$3b\pi\rho\nu d_p\left(u-u_p\right) \approx \left(\rho_p - \rho\right)V \frac{du}{dt} \tag{9.112}$$

The time required by an eddy to move a distance equal to its own diameter is approximately:

$$t \approx \frac{d}{u} \tag{9.113}$$

This is also approximately the time required to accelerate the eddy from zero to u, so the derivative in the right-hand-side of Eq. (9.112) is:

$$\frac{du}{dt} \approx \frac{u^2}{d} \tag{9.114}$$

Therefore:

$$3b\pi\rho\nu d_p\left(u-u_p\right) \approx \left(\rho_p - \rho\right)V \frac{u^2}{d} \tag{9.115}$$

Finally, it is assumed that the effective eddy is the same size as the floc; this also means the distance between them is the floc diameter. The eddy velocity is estimated as its fluctuation, which is given by the Saffman–Turner formula, yielding:

$$3b\pi\nu d_p\left(u-u_p\right)\approx\left(\rho_p-\rho\right)V\frac{2\varepsilon d_p^2}{15\pi\nu d_p} \tag{9.116}$$

Now, the left-hand-side is the total drag force acting on the floc. Ignoring the contribution of the liquid pressure, an upper bound on the shearing stress on the floc surface can be calculated as:

$$\tau_s 4\pi d_p^2\approx 3b\pi\rho\nu d_p\left(u-u_p\right)=\left(\rho_p-\rho\right)\frac{\pi d_p^3}{6}\frac{2\varepsilon d_p^2}{15\pi\nu d_p} \tag{9.117}$$

Note that the shearing stress τ_S increases as the square of the floc diameter. If τ_S is set equal to the maximum shearing strength that the floc surface can sustain, without loss of primary particles, then the largest possible floc diameter is (Parker, Kaufman, and Jenkins, 1972):

$$d_{p\max}\approx\left[\frac{180\pi\tau_{s\max}}{\left(\rho_p-\rho\right)\left(\frac{\varepsilon}{\nu}\right)}\right]^{1/2} \tag{9.118}$$

The rate at which primary particles are eroded from flocs by shear may now be estimated; it is assumed that only the largest flocs are eroded. The largest flocs are supposed to comprise a constant fraction of the total floc volume:

$$\tfrac{4}{3}\pi r_p^3 C_p = f\,\tfrac{4}{3}\pi r^3\sum_{i=1}^{p} iC_i \tag{9.119}$$

$$C_p=\frac{f}{p}\sum_{i=1}^{p} iC_i \tag{9.120}$$

where f = the fraction of the total floc volume contained in the largest flocs (dimensionless)
r_p = the effective radius of the largest floc (m or ft)
$= p^{1/3} r$

Each erosion event is supposed to remove a volume ΔV_p from the largest flocs:

$$\Delta V_p = f_e 4\pi r_p^2\cdot\Delta r_p \tag{9.121}$$

where ΔV_p = the volume eroded from the largest floc surface in one erosion event (m^3 or ft^3)
f_e = the fraction of the surface that is eroded per erosion event (dimensionless).

If the surface layer is only one primary particle thick, Δr_p is equal to the diameter of a primary particle, i.e., $2r$. The number of primary particles contained in the eroded layer is equal to the fraction of its volume that is occupied by primary particles divided by the volume of one primary particle (Parker, Kaufman, and Jenkins, 1972):

$$n=\frac{f_p f_e 4\pi r_p^2 2r}{\frac{4}{3}\pi r^3} \tag{9.122}$$

$$n=6 f_p f_e p^{2/3} \tag{9.123}$$

where n = the number of primary particles eroded per erosion event (no. primary particles/floc·erosion)
f_p = the fraction of the eroded layer occupied by primary particles (dimensionless)
p = the number of primary particles in the largest floc (dimensionless)

The frequency of erosion events is approximated by dividing the velocity of the effective eddy by its diameter. This represents the reciprocal of the time required for an eddy to travel its own diameter and the reciprocal of the time interval between successive arrivals. If it is assumed that the effective eddy is about the same size as the largest floc, then the Saffman–Turner formula gives:

$$f = \left(\frac{2\varepsilon}{15\pi\nu}\right)^{1/2} \tag{9.124}$$

Combining these results, one obtains the primary particle erosion rate (Parker, Kaufman, and Jenkins, 1972):

$$R_{1e} = \overline{\Gamma}\sqrt{\frac{24}{5\pi}} \cdot \left(\frac{f \cdot f_p \cdot f_e}{p^{1/3}}\right) \cdot \sum_{i=1}^{p} iC_i \tag{9.125}$$

The radius of the largest floc may be eliminated from Eq. (9.125) by using Eq. (9.118), producing:

$$R_{1e} = \overline{\Gamma}^2 \sqrt{\frac{3}{200}} \cdot \frac{f \cdot f_p \cdot f_e \Phi \sqrt{\rho_p - \rho}}{\pi\sqrt{\tau_s r}} \tag{9.126}$$

$$R_{1e} = k_e \Phi \overline{\Gamma}^2 \tag{9.127}$$

where k_e = the erosion rate coefficient (no. primary particles·sec/m^3 floc).

The rate of primary particle removal by flocculation, given by Eq. (9.106), can be written as follows:

$$R_{1f} = k_f \Phi \overline{\Gamma} C_1 \tag{9.128}$$

where k_f = the flocculation rate coefficient (m^3 water/m^3 floc).

The derivation makes it obvious that k_f depends on the floc size distribution. It should be remembered, however, that the coefficient k_e contains f, which is the fraction of the floc volume contained in the largest flocs. Consequently, k_e is also a function of the floc size distribution. Also, note that the rate of primary particle loss due to flocculation varies as the square root of the mixing power, while the rate of primary particle production due to erosion varies directly as the mixing power. This implies that there is a maximum permissible mixing power.

If the products $k_e\Phi$ and $k_f\Phi$ are constants, then a steady state particle balance on a flocculator consisting of equivolume mixed-cells-in-series yields (Argaman and Kaufman, 1970):

$$\frac{C_{1,e}}{C_{1,o}} = \frac{1 + \dfrac{k_e \Phi \overline{\Gamma}^2 V_1}{C_{1,o} Q} \displaystyle\sum_{i=1}^{n-1} \left(1 + \frac{k_f \Phi \overline{\Gamma} V_1}{Q}\right)^i}{\left(1 + \dfrac{k_f \Phi \overline{\Gamma} V_1}{Q}\right)^n} \tag{9.129}$$

where n = the number of mixed-cells-in-series (dimensionless)
V_1 = the volume of one cell (m^3 or ft^3).

Equation (9.129) was tested in laboratory flocculators consisting of four mixed-cells-in-series with turbines or paddle mixers (Argaman and Kaufman, 1970). The raw water fed to the flocculators contained 25 mg/L kaolin that had been destabilized with 25 mg/L of filter alum. The total hydraulic retention times varied from 8 to 24 min, and the r.m.s. characteristic strain rate varied from 15 to 240/sec. The concentration of primary particles was estimated by allowing the flocculated water to settle quiescently for 30 min and measuring the residual turbidity. The experimental data for single compartment flocculators was represented accurately by the model. With both kinds of mixers, the optimum value of $\bar{\Gamma}$ varied from about 100/sec down to about 60/sec as the hydraulic retention time was increased from 8 to 24 min. The observed minimum in the primary particle concentration is about 10 to 15% lower than the prediction, regardless of the number of compartments in the flocculator.

Flocculation Design Criteria

The degree of flocculation is determined by the dimensionless number $\bar{\sigma}\Phi\bar{\Gamma}\tau_h$. The floc volume concentration is fixed by the amount and character of the suspended solids in the raw water, and the particle size distribution factor is determined by the mixing power, flocculator configuration, and raw water suspended solids. For a given plant, then, the dimensionless number can be reduced to $\bar{\Gamma}\tau_h$, which is sometimes called the "Camp Number" in honor of Thomas R. Camp, who promoted its use in flocculator design.

The Camp number is proportional to the total number of collisions that occur in the suspension as it passes through a compartment. Because flocculation is a result of particle collisions, the Camp number is a performance indicator and a basic design consideration. In fact, specification of the Camp number and either the spatially averaged characteristic strain rate or hydraulic detention time suffices to determine the total tankage and mixing power required. It is commonly recommended that flocculator design be based on the product $\bar{\Gamma}\tau_h$ and some upper limit on $\bar{\Gamma}$ to avoid floc breakup (Camp, 1955; James M. Montgomery, Inc., 1985; Joint Task Force, 1990). Many regulatory authorities require a minimum HRT in the flocculation tank of at least 30 min (Water Supply Committee, 1987). In this case, the design problem is reduced to selection of $\bar{\Gamma}$.

Another recommendation is that flocculator design requires only the specification of the product $\bar{\Gamma}\Phi\tau_h$; sometimes Φ is replaced by something related to it, like raw water turbidity of coagulant dosage (O'Melia, 1972; Ives, 1968; Culp/Wesner/Culp, Inc., 1986). This recommendation really applies to upflow contact clarifiers in which the floc volume concentration can be manipulated.

The average absolute velocity gradient employed in the flocculation tanks studied by Camp ranged from 20 to 74/sec, and the median value was about 40/sec; hydraulic retention times ranged from 10 to 100 min, and the median value was 25 min (Camp, 1955). Both the $\bar{\Gamma}$ values and HRTs are somewhat smaller than current practice. Following the practice of Langelier (1921), who introduced mechanical flocculators, most existing flocculators are designed with tapered power inputs. This practice is supposed to increase the settling velocity of the flocs produced. In a study of the coagulation of colloidal silica with alum, TeKippe and Ham (1971) showed that tapered flocculation produced the fastest settling floc. Their best results were obtained with a flocculator divided into four equal compartments, each having a hydraulic retention time of 5 min, and $\bar{\Gamma}$ values of 140, 90, 70 and 50/sec respectively. The $\bar{\Gamma}\tau_h$ product was 105,000. A commonly recommended design for flocculators that precede settlers calls for a Camp number between 30,000 to 60,000, an HRT of at least 1000 to 1500 sec (at 20°C and maximum plant flow), and a tapered r.m.s. characteristic strain rate ranging from about 60/sec in the first compartment to 10/sec in the last compartment (Joint Task Force, 1990). For direct filtration, smaller flocs are desired, and the Camp number is increased from 40,000 to 75,000, the detention time is between 900 and 1500 sec, and the r.m.s. characteristic strain rate is tapered from 75 to 20/sec.

None of these recommendations is fully in accord with the kinetic model or the empirical data. They ignore the effect of the size distribution factor, which causes the flocculation rate for primary particles to vary by a factor of at least four, and which is itself affected by mixing power and configuration. The consequence of this omission is that different flocculators designed for the same $\bar{\Gamma}\tau_h$ or $\bar{\Gamma}\Phi\tau_h$ will produce different results if the mixing power distributions or tank configurations are different. Also, pilot

data obtained at one set of mixing powers or tank configurations cannot be extrapolated to others. The recommendations quoted above merely indicate in a general way the things that require attention. In every case, flocculator design requires a special pilot plant study to determine the best combination of coagulant dosage, tank configuration, and power distribution.

Finally, the data of Argaman and Kaufman suggest that at any given average characteristic strain rate, there is an optimum flocculator hydraulic retention time, and the converse is also true. The existence of an optimum HRT has also been reported by Hudson (1973) and by Griffith and Williams (1972). This optimum HRT is not predicted by the Argaman–Kaufman model; Eq. (9.129) predicts the degree of flocculation will increase uniformly as τ_h increases. Using an alum/kaolin suspension and a completely mixed flocculator, Andreu-Villegas and Letterman (1976) showed that the conditions for optimum flocculation were approximately:

$$\bar{\Gamma}^{2.8} C\tau_h = 44 \times 10^5 \left(\text{mg min/L s}^{2.8}\right) \tag{9.130}$$

The Andreu-Villegas–Letterman equation gives optimum $\bar{\Gamma}$ and HRT values that are low compared to most other reports. In one study, when the $\bar{\Gamma}$ values were tapered from 182 to 16/sec in flocculators with both paddles and stators, the optimum mixing times were 30 to 40 min (Wagner, 1974).

9.5 Sedimentation

Kinds of Sedimentation

Four distinct kinds of sedimentation processes are recognized:

- Free settling — When discrete particles settle independently of each other and the tank walls, the process is called "free," "unhindered," "discrete," "Type I," or "Class I" settling. This is a limiting case for dilute suspensions of noninteracting particles. It is unlikely that free settling ever occurs in purification plants, but its theory is simple and serves as a starting point for more realistic analyses.
- Flocculent settling — In "flocculent," "Class II," or "Type II" settling, the particle agglomeration process continues in the clarifier. Because the velocity gradients in clarifiers are small, the particle collisions are due primarily to the differences in the particle settling velocities. Aside from the collisions, and the resulting flocculation, there are no interactions between particles or between particles and the tank wall. This is probably the most common settling process in treatment plants designed for turbidity removal.

- Hindered settling — "Hindered" settling — also known as "Type III," "Class III," and "Zone" settling — occurs whenever the particle concentration is high enough that particles are influenced either by the hydrodynamic wakes of their neighbors or by the counterflow of the displaced water. When observed, the process looks like a slowly shrinking lattice, with the particles representing the lattice points. The rate of sedimentation is dependent on the local particle concentration. Hindered settling is the usual phenomenon in lime/soda softening plants, upflow contact clarifiers, secondary clarifiers in sewage treatment plants, and sludge thickeners.
- Compressive settling — "Compressive settling" is the final stage of sludge thickening. It occurs in sludge storage lagoons. It also occurs in batch thickeners, if the sludge is left in them long enough. In this process, the bottom particles are in contact with the tank or lagoon floor, and the others are supported by mutual contact. A slow compaction process takes place as water is exuded from between and within the particles, and the particle lattice collapses.

Kinds of Settling Tanks

There are several kinds of settlement tanks in use:

- Conventional — The most common are the "conventional rectangular" and "conventional circular" tanks. "Rectangular" and "circular" refer to the tank's shape in plan sections. In each of the designs, the water flow is horizontal, and the particles settle vertically relative to the water flow (but at an angle relative to the horizontal). The settling process is either free settling or flocculent settling.
- Tube, tray, or high-rate — Sometimes, sedimentation tanks are built with an internal system of baffles, which are intended to regulate the hydraulic regime and impose ideal flow conditions on the tank. Such tanks are called "tube," "tray," or "high-rate" settling tanks. The water flow is parallel to the plane of the baffles, and the particle paths form some angle with the flow. The settling process is either free settling or flocculent settling.
- Upflow — In "upflow contact clarifiers," the water flow is upwards, and the particles settle downwards. The rise velocity of the water is adjusted so that it is equal to the settling velocity of the particles, and a "sludge blanket" is trapped within the clarifier. The settling process in an upflow clarifier is hindered settling, and the design methodology is more akin to that of thickeners.
- Thickeners — "Thickeners" are tanks designed to further concentrate the sludges collected from settling tanks. They are employed when sludges require some moderate degree of dewatering prior to final disposal, transport, or further treatment. They look like conventional rectangular or circular settling tanks, except they contain mixing devices. An example is shown in Fig. 9.8. The settling process is hindered settling.
- Flotation — Finally, there are "flotation tanks." In these tanks, the particles rise upwards through the water, and they may be thought of as upside down settling tanks. Obviously, the particle density must be less than the density of water, so the particles can float. Oils and greases are good candidates for flotation. However, it is possible to attach air bubbles to almost any particle, so almost any particle can be removed in a flotation tank. The process of attaching air bubbles to particles is called "dissolved air flotation." Flotation tanks can be designed for mere particle removal or for sludge thickening

Floc Properties

The most important property of the floc is its settling velocity. Actually, coagulation/flocculation produces flocs with a wide range of settling velocities, and plant performance is best judged by the velocity distribution curve. It is the slowest flocs that control settling tank design. In good plants, one can expect the slowest 5% by wt of the flocs to have settling velocities less than about 2 to 10 cm/min. The higher velocity is found in plants with high raw water turbidities, because the degree of flocculation increases

with floc volume concentration. The slowest 2% by wt. will have velocities less than roughly 0.5 to 3 cm/min. Poor plants will produce flocs that are much slower.

Alum/clay floc sizes range from a few hundredths of a mm to a few mm (Boadway, 1978; Dick, 1970; Lagvankar and Gemmell, 1968; Parker, Kaufman, and Jenkins, 1972; Tambo and Hozumi, 1979; Tambo and Watanabe, 1979). A typical median floc diameter for alum coagulation might be a few tenths of a mm; the largest diameter might be 10 times as large. Ferric iron/clay flocs are generally larger than alum flocs (Ham and Christman, 1969; Parker, Kaufman, and Jenkins, 1972). Floc size is correlated with the mixing power and the suspended solids concentration. Relationships of the following form have been reported (Boadway, 1978; François, 1987):

$$d_p \propto \frac{X^b}{\bar{\Gamma}^a} \tag{9.131}$$

where a = a constant ranging from 0.2 to 1.5 (dimensionless)
b = a constant (dimensionless)
d_p = the minimum, median, mean, or maximum floc size (m or ft)
X = the suspended solids concentration (kg/m^3 or lb/ft^3)
$\bar{\Gamma}$ = the r.m.s. characteristic strain rate (per sec)

Equation (9.131) applies to all parts of the floc size distribution curve, including the largest observed floc diameter, the median floc diameter, etc. The floc size distribution is controlled by the forces in the immediate vicinity of the mixer, and these forces are dependent on the geometry of the mixing device (François, 1987). This makes the reported values of the coefficients highly variable, and, although good correlations may be developed for a particular facility or laboratory apparatus, the correlations cannot be transferred to other plants or devices unless the conditions are identical.

When flocs grown at one root mean square velocity gradient are transferred to a higher one, they become smaller. The breakdown process takes less than a minute (Boadway, 1978). If the gradient is subsequently reduced to its former values, the flocs will regrow, but the regrown flocs are weaker and smaller than the originals (François, 1987).

Flocs consist of a combination of silt/clay particles, the crystalline products of the coagulant, and entrained water. The specific gravities of aluminum hydroxide and ferric hydroxide crystals are about 2.4 and 3.4, respectively, and the specific gravities of most silts and clays are about 2.65 (Hudson, 1972). However, the lattice of solid particles is loose, and nearly all of the floc mass is due to entrained water. Consequently, the mass density of alum/clay flocs ranges from 1.002 to 1.010 g/cm^3, and the density of iron/clay flocs ranges from 1.004 to 1.040 g/cm^3 (Lagvankar and Gemmell, 1968; Tambo and Watanabe, 1979). With both coagulants, density decreases with floc diameter and mixing power. Typically,

$$\rho_p - \rho \propto \frac{1}{d_p^a} \tag{9.132}$$

Free Settling

Free settling includes nonflocculent and flocculent settling.

Calculation of the Free, Nonflocculent Settling Velocity

Under quiescent conditions in settling tanks, particles quickly reach a constant, so-called "terminal" settling velocity, Bassett's (1888) equation for the force balance on a particle becomes:

$$\underbrace{0}_{\text{change in momentum}} = \underbrace{\rho_p V_p g}_{\text{particle weight}} - \underbrace{\rho V_p g}_{\text{buoyant force}} \underbrace{- C_D \rho A_p \frac{v_s^2}{2g}}_{\text{drag force}} \tag{9.133}$$

$$v_s = \sqrt{\frac{2gV_p(\rho_p - \rho)}{C_D \rho A_p}} \tag{9.134}$$

where A_p = the cross-sectional area of the particle normal to the direction of fall (m^2 or ft^2)
C_D = the drag coefficient (dimensionless)
g = the acceleration due to gravity (9.80665 m/s^2 or 32.174 ft/sec^2)
V_p = the volume of the particle (m^3 or ft^3)
ν_s = the terminal settling velocity of the particle (m/s or ft/sec)
ρ = the density of the liquid (kg/m^3 or $slug/ft^3$)
ρ_p = the density of the particle (kg/m^3 or $slug/ft^3$)

For a sphere, Eq. (9.134) becomes:

$$v_s = \sqrt{\frac{4gd_p(\rho_p - \rho)}{3C_D \rho}} \tag{9.135}$$

where d_p = the particle's diameter (m or ft).

Newton assumed that the drag coefficient was a constant, and indeed, if the particle is moving very quickly it is a constant, with a value of about 0.44 for spheres. However, in general, the drag coefficient depends upon the size, shape, and velocity of the particle. It is usually expressed as a function of the particle Reynolds number. For spheres, the definition is as follows:

$$\boldsymbol{Re} = \frac{\rho v_s d_p}{\mu} \tag{9.136}$$

The empirical correlations for C_D and **Re** for spheres are shown in Fig. 9.5 (Rouse, 1937). Different portions of the empirical curve may be represented by the following theoretical and empirical formulae:

Theoretical Formulas

*Stokes (1856) (for **Re** < 0.1)*

$$C_D = \frac{24}{\boldsymbol{Re}} \tag{9.137}$$

For spheres, the Stokes terminal settling velocity is

$$v_s = \frac{g(\rho_p - \rho)d_p^2}{18\mu} \tag{9.138}$$

*Oseen (1913)–Burgess (1916) (for **Re** < 1)*

$$C_D = \frac{24}{\boldsymbol{Re}} \cdot \left(1 + \frac{3\boldsymbol{Re}}{16}\right) \tag{9.139}$$

*Goldstein (1929) (for **Re** < 2)*

$$C_D = \frac{24}{\boldsymbol{Re}} \cdot \left[1 + \frac{3\boldsymbol{Re}}{16} - \frac{19\boldsymbol{Re}^2}{1,280} + \frac{71\boldsymbol{Re}^3}{20,480} - \frac{30,179\boldsymbol{Re}^4}{34,406,400} + \frac{122,519\boldsymbol{Re}^5}{560,742,400} - \ldots\right] \tag{9.140}$$

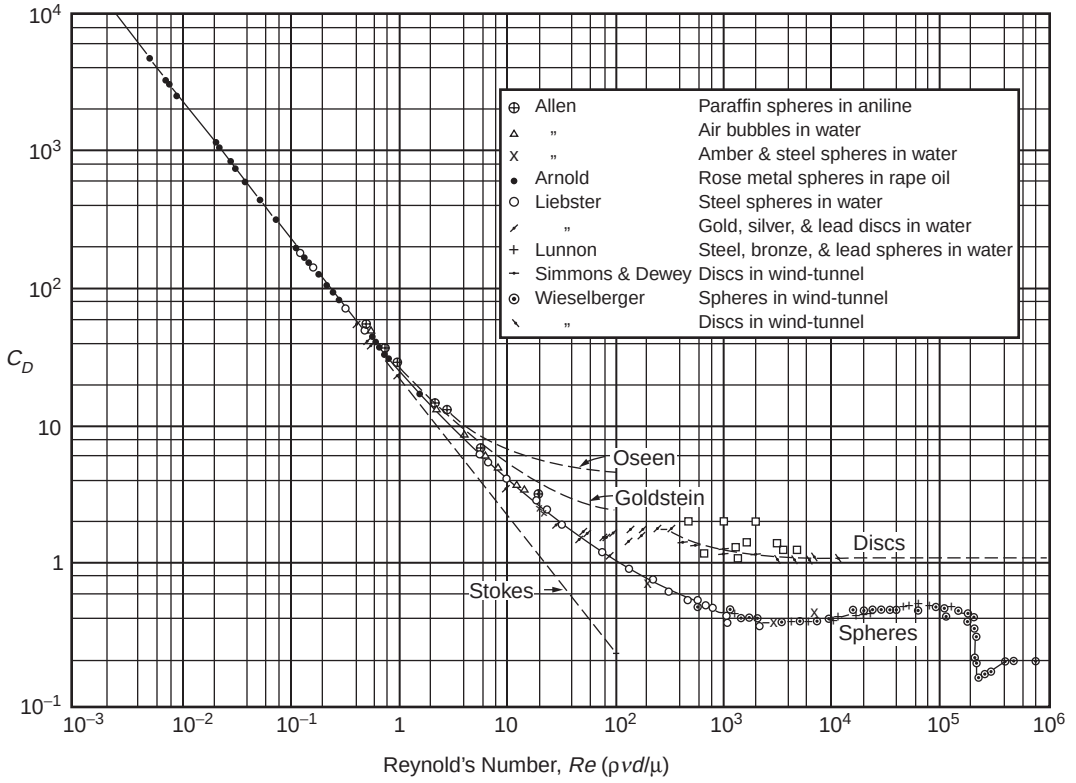

FIGURE 9.5 Drag coefficients for sedimentation (Rouse, H. 1937. Nomogram for the Settling Velocity of Spheres. *Report of the Committee on Sedimentation*, p. 57, P.D. Trask, chm., National Research Council, Div. Geol. and Geog.)

Empirical Formulas

Allen (1900) (for $10 < \mathbf{Re}_{eff} < 200$)

$$C_D = \frac{10.7}{\sqrt{\mathbf{Re}_{eff}}} \tag{9.141}$$

The Reynolds number in Eq. (9.141) is based on an "effective" particle diameter:

$$\mathbf{Re}_{eff} = \frac{\rho v_s d_{eff}}{\mu} \tag{9.142}$$

where d_p = the actual particle diameter (m or ft)
d_2 = the diameter of a sphere that settles at a Reynolds number of 2 (m or ft)
d_{eff} = the effective particle diameter (m or ft)
$= d_p - 0.40\ d_2$

The effective diameter was introduced by Allen to improve the curve fit. The definition of d_2 was arbitrary: Stokes' Law does not apply at a Reynolds number of 2. For spheres, the Allen terminal settling velocity is,

$$v_s = 0.25 d_{eff} \left[\frac{g\left(\rho_p - \rho\right)}{\sqrt{\rho\mu}} \right]^{2/3} \tag{9.143}$$

*Shepherd (Anderson, 1941) (for 1.9 < **Re** < 500)*

$$C_D = \frac{18.5}{\boldsymbol{Re}^{0.60}} \tag{9.144}$$

For spheres, the Shepherd terminal settling velocity is (McGaughey, 1956),

$$v_s = 0.153 d_p^{1.143} \left[\frac{g(\rho_p - \rho)}{\rho^{0.40} \mu^{0.60}} \right]^{0.714} \tag{9.145}$$

Examination of Fig. 9.5 shows that the slope of the curve varies from –1 to 0 as the Reynolds number increases from about 0.5 to about 4000. This is the transition region between the laminar Stokes' Law and the fully turbulent Newton's Law. For this region, the drag coefficient may be generalized as follows:

$$C_D = k\boldsymbol{Re}^{n-2} \tag{9.146}$$

$$v_s^n = \frac{4g}{3k} d_p^{3-n} \left(\frac{\rho_p - \rho}{\rho^{n-1} \cdot \mu^{2-n}} \right) \tag{9.147}$$

where k = a dimensionless curve-fitting constant ranging in value from 24 to 0.44
n = a dimensionless curve-fitting constant ranging in value from 1 to 2.

Equation (9.146) represents the transition region as a series of straight line segments. Each segment will be accurate for only a limited range of Reynolds numbers.

*Fair–Geyer (1954) (for **Re** < 10^4)*

$$C_D = \frac{24}{\boldsymbol{Re}} + \frac{3}{\sqrt{\boldsymbol{Re}}} + 0.34 \tag{9.148}$$

*Newton (Anderson, 1941) (for 500 < **Re** < 200,000)*

$$C_D = 0.44 \tag{9.149}$$

For spheres, the Newton terminal settling velocity is

$$v_s = 1.74 \sqrt{\frac{g d_p (\rho_p - \rho)}{\rho}} \tag{9.150}$$

Referring to Fig. 9.5, it can be seen that there is a sharp discontinuity in the drag coefficient for spheres at a Reynolds number of about 200,000. The discontinuity is caused by the surface roughness of the particles and turbulence in the surrounding liquid. It is not important, because Reynolds' numbers this large are never encountered in water treatment.

A sphere with the properties of a median alum floc (d_p = 0.50 mm and S_p = 1.005) would have a settling velocity of about 0.5 mm/sec and a Reynolds number of about 0.2 (at 10°C). Most floc particles are smaller than 0.5 mm, so they will be slower and have smaller Reynolds numbers. This means that Stokes' Law is an acceptable approximation in most cases of alum/clay floc sedimentation.

For sand grains, the Reynolds number is well into the transition region, and the Fair–Geyer formula is preferred. If reduced accuracy is acceptable, one of the Allen/Shepherd formulae may be used.

Except for the Stokes, Newton, Allen, and Shepherd laws, the calculation of the terminal settling velocity is iterative, because the drag coefficient is a polynomial function of the velocity. Graphical solutions are presented by Camp (1936a), Fair, Geyer, and Morris (1954), and Anderson (1941).

Nonspherical particles can be characterized by the ratios of their diameters measured along their principal axes of rotation. Spherical and nonspherical particles are said to be "equivalent," if they have the same volume and weight. If **Re** is less than 100 and the ratios are 1:1:1 (as in a cube), the nonspherical particles settle at 90 to 100% of the velocity of the equivalent sphere (Task Committee, 1975). For ratios of 4:1:1, 4:2:1, or 4:4:1, the velocity of the nonspherical particle is about two-thirds the velocity of the equivalent sphere. If the ratios are increased to 8:1:1, 8:2:1, or 8:4:1, the settling velocity of the nonspherical particles falls to a little more than half that of the equivalent sphere. The shape problem is lessened by the fact that floc particles are formed by the drag force into roughly spherical or teardrop shapes.

In practice, Eqs. (9.138) through (9.150) are almost never used to calculate settling velocities. The reason for this is the onerous experimental and computational work load their use requires. Floc particles come in a wide range of sizes, and the determination of the size distribution would require an extensive experimental program. Moreover, the specific gravity of each size class would be needed. In the face of this projected effort, it is easier to measure settling velocities directly using a method like Seddon's, which is described below.

The settling velocity equations are useful when experimental data obtained under one set of conditions must be extrapolated to another. For example, terminal settling velocities depend on water temperature, because temperature strongly affects viscosity. The ratio of water viscosities for 0 to 30°C, which is the typical range of raw water temperatures in the temperature zone, is about 2.24. This means that a settling tank designed for winter conditions will be between 1.50 and 2.24 times as big as a tank designed for summer conditions, depending on the Reynolds number.

The terminal velocity also varies with particle diameter and specific gravity. Because particle size and density are inversely correlated, increases in diameter tend to be offset by decreases in specific gravity, and some intermediate particle size will have the fastest settling velocity. This is the reason for the traditional advice that "pinhead" flocs are best.

Settling Velocity Measurement

The distribution of particle settling velocities can be determined by the method first described by Seddon (1889) and further developed by Camp (1945). Tests for the measurement of settling velocities must be continued for at least as long as the intended settling zone detention time. Furthermore, samples must be collected at several time intervals in order to determine whether the concentration trajectories are linear or concave downwards.

A vertical tube is filled from the bottom with a representative sample of the water leaving the flocculation tank, or any other suspension of interest. The depth of water in the tube should be at least equal to the expected depth of the settling zone, and there should be several sampling ports at different depths. The tube and the sample in it should be kept at a constant, uniform temperature to avoid the development of convection currents. A tube diameter at least 100 times the diameter of the largest particle is needed to avoid measurable "wall effects" (Dryden, Murnaghan, and Bateman, 1956). The effect of smaller tube/particle diameter ratios can be estimated using McNown's (Task Committee, 1975) formula:

$$\frac{v_s}{v_t} = 1 + \frac{9d_p}{4d_t} + \left(\frac{9d_p}{4d_t}\right)^2 \tag{9.151}$$

where d_p = the particle's diameter (m or ft)
d_t = the tube's diameter (m or ft)
v_s = the particle's free terminal settling velocity (m/s or ft/sec)
v_t = the particle's settling velocity in the tube (m/s or ft/sec)

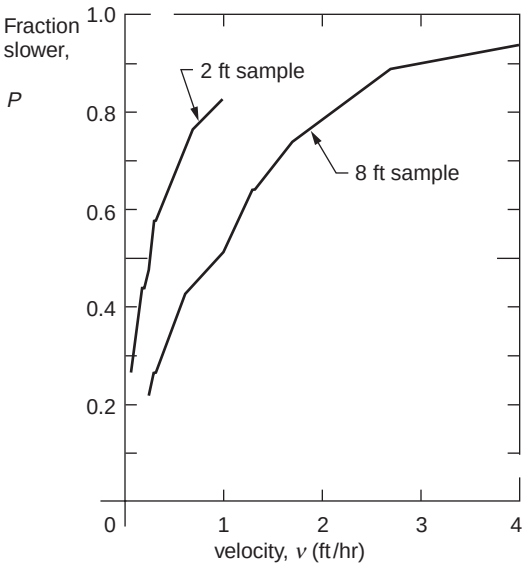

FIGURE 9.6 Settling velocity distributions for Mississippi River sediments. [Seddon, J.A. 1889. Clearing Water by Settlement, *J. Assoc. Eng'g Soc.*, 8(10): 477.]

The largest expected flocs are on the order of a few mm in diameter, so the minimum tube diameter will be tens of cm.

Initially, all the various particle velocity classes are distributed uniformly throughout the depth of the tube. Therefore, at any particular sampling time after the settling begins, say t_i the particles sampled at a distance h below the water surface must be settling at a velocity less than,

$$v_i = \frac{h_i}{t_i} \tag{9.152}$$

where h_i = the depth below the water's surface of the sampling port for the i-th sample (m or ft)
t_i = the i-th sampling time (sec)
ν_i = the limiting velocity for the particles sampled at t_i (m/s or ft/sec)

The weight fraction of particles that are slower than this is simply the concentration of particles in the sample divided by the initial particle concentration:

$$P_i = \frac{X_i}{X_o} \tag{9.153}$$

where P_i = the weight fraction of the suspended solids that settle more slowly than ν_i (dimensionless)
X_i = the suspended solids concentration in the sample collected at t_i (kg/m^3 or lb/ft^3)
X_0 = the initial, homogeneous suspended solids concentration in the tube (kg/m^3 or lb/ft^3)

The results of a settling column test would look something like the data in Fig. 9.6, which are taken from Seddon's paper. The data represent the velocities of river muds, which are slower than alum or iron flocs.

Flocculent versus Nonflocculent Settling

In nonflocculent settling, the sizes and velocities of the particles do not change. Consequently, if the trajectory of a particular concentration is plotted on depth-time axes, a straight line is obtained. In flocculent settling, the particles grow and accelerate as the settling test progresses, and the concentration

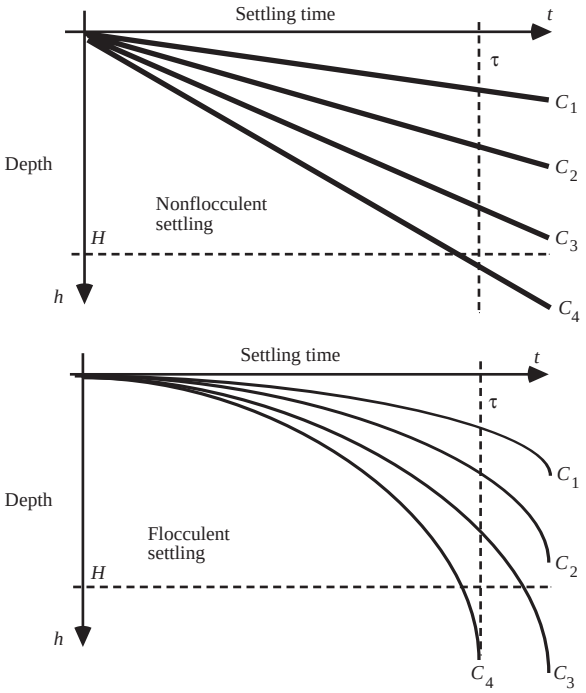

FIGURE 9.7 Particle depth-time trajectories for nonflocculent and flocculent settling.

trajectories are concave downwards. These two possibilities are shown in Fig. 9.7. The same effect is seen in Fig. 9.6, where the samples from 8 ft, which represent longer sampling times, yield higher settling velocities than the 2 ft samples.

Design of Rectangular Clarifiers

What follows is the Hazen (1904)–Camp (1936a, 1936b) theory of free settling in rectangular tanks. Refer to Fig. 9.8. The liquid volume of the tank is divided into four zones: (1) an inlet or dispersion zone, (2) a settling zone, (3) a sludge zone, and (4) an outlet or collection zone (Camp, 1936b).

The inlet zone is supposed to be constructed so that each velocity class of the incoming suspended particles is uniformly distributed over the tank's transverse vertical cross section. A homogeneous distribution is achieved in many water treatment plants as a consequence of the way flocculation tanks and rectangular settling tanks must be connected. It is not achieved in circular tanks or in rectangular tanks in sewage treatment plants, unless special designs are adopted.

The sludge zone contains accumulated sludge and sludge removal equipment. Particles that enter the sludge zone are assumed to remain there until removed by the sludge removal equipment. Scour of the sludge must be prevented. Sludge thickening and compression also occur in the sludge zone, but this is not normally considered in clarifier design.

The water flow through the settling zone is supposed to be laminar and horizontal, and the water velocity is supposed to be the same at each depth. Laminar flow is readily achievable by baffling, but the resulting water velocities are not uniform, and often they are not horizontal. The corrections needed for these conditions are discussed below.

The outlet zone contains the mechanisms for removing the clarified water from the tank. Almost always, water is removed from near the water surface, so the water velocity in the outlet zone has a net upwards component. This upwards component may exceed the settling velocities of the slowest particles, so it is assumed that any particle that enters the outlet zone escapes in the tank effluent.

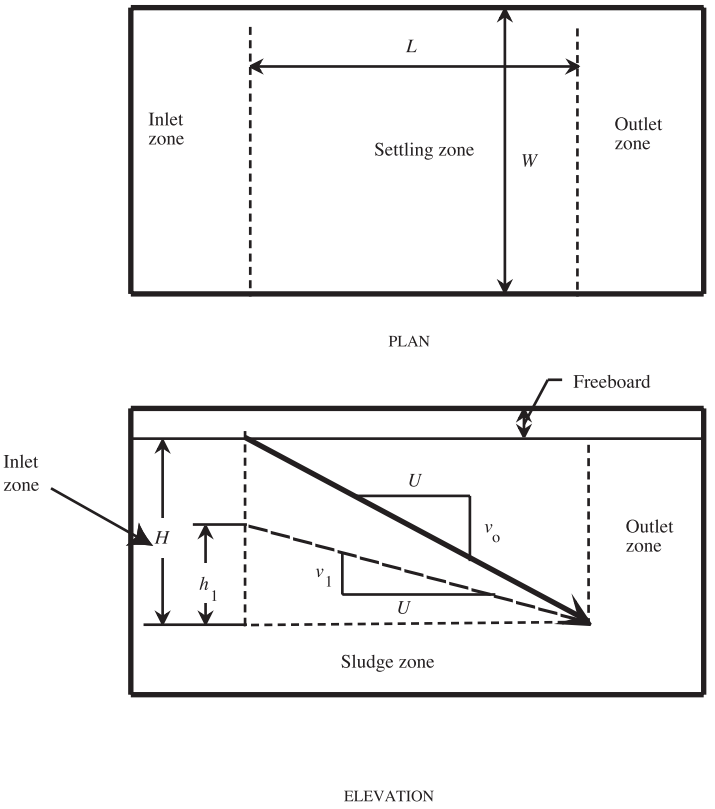

FIGURE 9.8 Settling tank definition sketch [after Camp, T.R. 1936. A Study of the Rational Design of Settling Tanks, *Sewage Works J.*, 8 (5): 742].

There are five problems that need to be considered in rectangular clarifier design: (1) sedimentation of the floc particles out of the settling zone and into the sludge zone, (2) the settling velocity distribution of the floc particles, (3) scour and resuspension of settled particles from the sludge zone, (4) turbulence *in the settling zone*, and (5) short-circuiting of the flow.

Sedimentation

Suppose that the settling occurs in Camp's ideal rectangular clarifier, and the horizontal water velocity is steady and uniform. In this case, column test sampling time may be equated with time-of-travel through the settling zone, and the depth–time plot of concentration trajectories in a settling column is also a plot of the trajectories in the settling zone. The settling zone can be represented in Fig. 9.7 by drawing a horizontal line at the settling zone depth, H, and a vertical line at its hydraulic retention time, τ. Trajectories that cross the horizontal line before τ represent those particles that are captured and enter the sludge zone. Trajectories that cross the vertical line above H represent those particles that escape capture and appear in the tank effluent.

The flow-weighted average concentration in the effluent can be estimated by a simple depth average over the outlet plane:

$$\overline{C}_H = \frac{1}{Q}\int_0^H C \cdot dQ = \frac{1}{UWH}\int_0^H CUW \cdot dh = \frac{1}{H}\int_0^H C \cdot dh \tag{9.154}$$

where C = the suspended solids' concentration at depth h (kg/m^3 or lb/ft^3)
$\overline{C}_H$ = the depth-averaged suspended solids' concentration over the settling zone outlet's outlet plane (kg/m^3 or lb/ft^3)
H = the settling zone's depth (m or ft)
L = the settling zone's length (m or ft)
Q = the flow through the settling zone (m^3/s or ft^3/sec)
U = the horizontal water velocity through the settling zone (m/s or ft/sec)
W = the settling zone's width (m or ft)

The settling zone particle removal efficiency is (San, 1989),

$$E = \frac{C_i - \overline{C}_H}{C_i} = \frac{1}{H}\int_0^H f \cdot dh \tag{9.155}$$

where C_i = the suspended solids' concentration in the influent flow to the settling zone (kg/m^3 or lb/ft^3)
E = the removal efficiency (dimensionless)
f = the fraction removed at each depth at the outlet plane of the settling zone (dimensionless)

The removal efficiency can also be calculated from the settling velocity distribution, such as in Fig. 9.6 (Sykes, 1993):

$$E = 1 - P_o + \frac{1}{v_o}\int_0^{P_o} v \cdot dP \tag{9.156}$$

where P = the weight fraction of the suspended solids that settles more slowly than ν (dimensionless)
P_0 = the weight fraction of the suspended solids that settles more slowly than ν_0 (dimensionless)
ν = any settling velocity between zero and ν_0 (m/s of ft/sec)
ν_0 = the tank overflow rate (m/s or ft/sec) (See below.)

Note that the integration is performed along the vertical axis, and the integral represents the area between the velocity distribution curve and the vertical axis. The limiting velocities are calculated using Eq. (9.152) by holding the sampling time t_i constant at τ and using concentration data from different depths. Equation (9.156) reduces to the formulas used by Zanoni and Blomquist (1975) to calculate removal efficiencies for flocculating suspensions.

Nonflocculent Settling

Certain simplifications occur if the settling process is nonflocculent. However, nonflocculent settling is probably limited to grit chambers (Camp, 1953). Referring to Fig. 9.8, the critical particle trajectory goes from the top of the settling zone on the inlet end to the bottom of the settling zone on the outlet end. The settling velocity that produces this trajectory is ν_0. Any particle that settles at ν_0 or faster is removed from the flow. A particle that settles more slowly than ν_0, say ν_1, is removed only if it begins its trajectory within h_1 of the settling zone's bottom. Similar triangles show that this critical settling velocity is also the tank overflow rate, and to the ratio of the settling zone depth to hydraulic retention time:

$$v_o = \frac{Q}{WL} = \frac{H}{\tau} \tag{9.157}$$

where ν_0 = the critical particles' settling velocity (m/s or ft/sec).

In nonflocculent free settling, the settling velocity distribution does not change with settling time, and the efficiency predicted by Eq. (9.156) depends only on overflow rate, regardless of the combination of depth and detention time that produces it. Increasing the overflow rate always reduces the efficiency, and reducing the overflow rate always increases it.

Flocculent Settling

This is not the case in flocculent settling. Consider a point on one of the curvilinear contours shown in Fig. 9.7. Equation (9.152) now represents the average velocity of the selected concentration up to the selected instant. In the case of the contour that exits the settling zone at its bottom, the slope of the chord is v_o. The average velocity of any given contour increases as the sampling time increases. This has several consequences:

- Fixing $\mathbf{v}_0$ and increasing both H and $\boldsymbol{\tau}$ increases the efficiency.
- Fixing $\mathbf{v}_0$ and reducing both H and $\boldsymbol{\tau}$ reduces the efficiency.
- Increasing $\mathbf{v}_0$ by increasing both H and $\boldsymbol{\tau}$ may increase, decrease, or not change the efficiency depending on the trajectories of the contours; if the curvature of the contours is large, efficiency increases will occur for new overflow rates that are close to the original $\mathbf{v}_0$.
- Reducing $\mathbf{v}_0$ by reducing both H and $\boldsymbol{\tau}$ may increase, decrease, or not change the efficiency, depending on the trajectories of the contours; if the curvature of the contours is large, efficiency reductions will occur for new overflow rates that are close to the original $\mathbf{v}_0$.

Any other method of increasing or decreasing v_0 yields the same results as those obtained in nonflocculent settling.

Scour

Settling zone depth is important. The meaning of Eq. (9.157) is that if a particle's settling velocity is equal to the overflow rate, it will reach the top of the sludge zone. However, once there, it still may be scoured from the sludge zone and resuspended in the flow. Repeated depositions and scourings would gradually transport the particle through the tank and into the effluent flow, resulting in clarifier failure. Whether or not this happens depends on the depth-to-length ratio of the settling zone.

Camp (1942) assumes that the important variable is the average shearing stress in the settling zone/sludge zone interface. In the case of steady, uniform flow, the accelerating force due to the weight of the water is balanced by retarding forces due to the shearing stresses on the channel walls and floor (Yalin, 1977):

$$\tau_o = \gamma HS \tag{9.158}$$

The shearing stress depends on the water velocity and the settling zone depth. The critical shearing stress is that which initiates mass movement in the settled particles. Dimensional analysis suggests a correlation of the following form (Task Committee, 1975):

$$\frac{\tau_c}{(\gamma_p - \gamma)d_p} = \mathrm{f}(\mathbf{Re}_*) \tag{9.159}$$

where d_p = the particle's diameter (m or ft)
$\mathbf{Re}_*$ = the boundary Reynolds number (dimensionless)
$= v_* d_p / \nu$
v_* = the shear velocity (m/s or ft/sec)
$= \sqrt{\frac{\tau_c}{\rho}}$
γ = the specific weight of the liquid (N/m^3 or lbf/ft^3)
γ_p = the specific weight of the particle (N/m^3 or lbf/ft^3)
ν = the kinematic viscosity of the liquid (m^2/s or ft^2/sec)
ρ = the density of the liquid (kg/m^3 or slug/ft^3)
τ_c = the critical shearing stress that initiates particle movement (N/m^2 or lbf/ft^2)

Equation (9.159) applies to granular, noncohesive materials like sand. Alum and iron flocs are cohesive. The cohesion is especially well-developed on aging, and individual floc particles tend to merge together. However, a conservative assumption is that the top layer of the deposited floc, which is fresh, coheres weakly.

For the conditions in clarifiers, Eq. (9.159) becomes (Mantz, 1977),

$$\frac{\tau_c}{\left(\gamma_p - \gamma\right)d_p} = \frac{0.1}{\boldsymbol{Re}_*^{0.30}} \tag{9.160}$$

This leads to relationships among the settling zone's depth and length. For example, the horizontal velocity is related to the critical shearing stress by the following (Chow, 1959):

$$U_c = \sqrt{8/f}\sqrt{\tau_c/\rho} \tag{9.161}$$

where f = the Darcy-Weisbach friction factor (dimensionless)
U_C = the critical horizontal velocity that initiates particle movement (m/s or ft/sec).

Consequently,

$$\frac{H}{L} \geq \frac{v_o}{\sqrt{8/f}\sqrt{\tau_c/\rho}} = \text{a constant} \tag{9.162}$$

Equation (9.162) is a lower limit on the depth-to-length ratio.

Ingersoll, McKee, and Brooks (1956) assume that the turbulent fluctuations in the water velocity at the interface cause scour. They hypothesize that the deposited flocs will be resuspended if the vertical fluctuations in the water velocity at the sludge interface are larger than the particle settling velocity. Using the data of Laufer (1950), they concluded that the vertical component of the root-mean-square velocity fluctuation of these eddies is approximately equal to the shear velocity, and they suggested that scour and resuspension will be prevented if,

$$\frac{v_o}{\sqrt{\tau_o/\rho}} > 1.2 \text{ to } 2.0 \tag{9.163}$$

This leads to the following:

$$\frac{H}{L} > \left(1.2 \text{ to } 2.0\right)\sqrt{f/8} \tag{9.164}$$

The Darcy–Weisbach friction factor for a clarifier is about 0.02, so the right-hand-side of Eq. (9.164) is between 0.06 and 0.1, which means that the length must be *less than* 10 to 16 times the depth. Camp's criterion would permit a horizontal velocity that is 2 to 4 times as large as the velocity permitted by the Ingersoll–McKee–Brooks analysis.

Short-Circuiting

A tank is said to "short-circuit" if a large portion of the influent flow traverses a small portion of the tank's volume. In extreme cases, some of the tank's volume is a "dead zone" that neither receives nor discharges liquid. Two kinds of short-circuiting occur: "density currents" and "streaming."

Density Currents

Density currents develop when the density of the influent liquid is significantly different from the density of the tank's contents. The result is that the influent flow either floats over the surface of the tank or

sinks to its bottom. The two common causes of density differences are differences in (1) temperature and (2) suspended solids concentrations.

Temperature differences arise because the histories of the water bodies differ. For example, the influent flow may have been drawn from the lower portions of a reservoir, while the water in the tank may have been exposed to surface weather conditions for several hours. Small temperature differences can be significant.

Suspended solids have a similar effect. The specific gravity of a suspension can be calculated as follows (Fair, Geyer, and Morris, 1954):

$$S_s = \frac{S_p S_w}{f_w S_p + (1 - f_w) S_w} \tag{9.165}$$

where f_w = the weight fraction of water in the suspension (dimensionless)
S_p = the specific gravity of the particles (dimensionless)
S_S = the specific gravity of the suspension (dimensionless)
S_w = the specific gravity of the water (dimensionless)

By convention, all specific gravities are referenced to the density of pure water at 3.98°C, where it attains its maximum value. Equation (9.165) can be written in terms of the usual concentration units of mass/volume as follows:

$$S_s = S_w + \frac{X}{\rho} \cdot \left(1 - \frac{S_w}{S_p}\right) \tag{9.166}$$

where X = the concentration of suspended solids (kg/m^3 or slug/ft^3)
ρ = the density of water (kg/m^3 or slug/ft^3)

Whether or not the density current has important effects depends on its location and its speed (Eliassen, 1946; Fitch, 1957). If the influent liquid is lighter than the tank contents and spreads over the tank surface, any particle that settles out of the influent flow enters the stagnant water lying beneath the flow and settles vertically all the way to the tank bottom. During their transit of the stagnant zone, the particles are protected from scour, so once they leave the flow, they are permanently removed from it. If the influent liquid spreads across the entire width of the settling zone, then the density current may be regarded as an ideal clarifier. In this case, the depth of the settling zone is irrelevant. Clearly, this kind of short-circuiting is desirable.

If the influent liquid is heavier than the tank contents, it will settle to the bottom of the tank. As long as the flow uniformly covers the entire bottom of the tank, the density current may be treated as an ideal clarifier. Now, however, the short-circuiting flow may scour sludge from the tank bottom. The likelihood of scour depends on the velocity of the density current. According to von Karman (1940), the density current velocity is:

$$U_{dc} = \left[\frac{2gQ(\rho_{dc} - \rho)}{\rho W}\right]^{1/3} \tag{9.167}$$

where g = the acceleration due to gravity (9.80665 m/s^2 or 32.174 ft/sec^2)
Q = the flow rate of the density current (m^3/s or ft^3/sec)
U_{dc} = the velocity of the density current (m/s or ft/sec)
W = the width of the clarifier (m or ft)
ρ = the density of the liquid in the clarifier (kg/m^3 or slug/ft^3)
ρ_{dc} = the density of the density current (kg/m^3 or slug/ft^3)

Streaming

Density currents divide the tank into horizontal layers stacked one above the other. An alternative arrangement would be for the tank to be divided into vertical sections placed side-by-side. The sections would be oriented to run the length of the tank from inlet to outlet. Fitch (1956) calls this flow arrangement "streaming."

Suppose that the flow consists of two parallel streams, each occupying one-half of the tank width. A fraction f of the flow traverses the left section, and a fraction $1 - f$ traverses the right section. Within each section, the flow is distributed uniformly over the depth. The effective overflow rate for the left-hand section is v_1, and a weight fraction P_1 settles slower than this. For the right-hand section, the overflow rate is v_2, and the slower fraction is P_2. The flow-weighted average removal efficiency would be:

$$\bar{E} = f \cdot \left(1 - P_1 + \frac{1}{v_1} \int_0^{P_1} v \cdot dP \right) + (1 - f) \cdot \left(1 - P_2 + \frac{1}{v_2} \int_0^{P_2} v \cdot dP \right) \tag{9.168}$$

This can also be written as:

$$\begin{aligned} \bar{E} = {} & 1 - P_o + \frac{1}{v_o} \int_0^{P_o} v \cdot dP \\ & + f(P_o - P_1) - \frac{1}{2v_o} \int_{P_1}^{P_o} v \cdot dP \\ & - (1 - f)(P_2 - P_o) + \frac{1}{2v_o} \int_{P_o}^{P_2} v \cdot dP \end{aligned} \tag{9.169}$$

The first line on the right-hand side is the removal efficiency without streaming. The second and third lines represent corrections to the ideal removal efficiency due to streaming. Fitch shows that both corrections are always negative, and the effect of streaming is to reduce tank efficiency. The degree of reduction depends on the shape of the velocity distribution curve and the design surface loading rate.

The fact that tanks have walls means that some streaming is inevitable: the drag exerted by the walls causes a lateral velocity distribution. However, more importantly, inlet and outlet conditions must be designed to achieve and maintain uniform lateral distribution of the flow. One design criterion used to achieve uniform lateral distribution is a length-to-width ratio. The traditional recommendation was that the length-to-width ratio should lie between 3:1 and 5:1 (Joint Task Force, 1969). However, length-to-width ratio restrictions are no longer recommended (Joint Committee, 1990). It is more important to prevent the formation of longitudinal jets. This can be done by properly designing inlet details.

The specification of a surface loading rate, a length-to-depth ratio, and a length-to-width ratio uniquely determine the dimensions of a rectangular clarifier and account for the chief hydraulic problems encountered in clarification.

Traditional Rules of Thumb

Some regulatory authorities specify a minimum hydraulic retention time, a maximum horizontal velocity, or both: e.g., for water treatment (Water Supply Committee, 1987),

$$\tau = \frac{WHL}{Q} \geq 4 \text{ hr} \tag{9.170}$$

$$U = \frac{Q}{WH} \leq 0.5 \text{ fpm} \tag{9.171}$$

Hydraulic detention times for primary clarifiers in wastewater treatment tend to be 2 h at peak flow (Joint Task Force, 1992).

Some current recommendations for the overflow rate for rectangular and circular clarifiers for water treatment are (Joint Committee, 1990):

Lime/soda softening —
low magnesium, v_o = 1700 gpd/ft^2
high magnesium, v_o = 1400 gpd/ft^2
Alum or iron coagulation —
turbidity removal, v_o = 1000 gpd/ft^2
color removal, v_o = 700 gpd/ft^2
algae removal, v_o = 500 gpd/ft^2

The recommendations for wastewater treatment are (Wastewater Committee, 1990):

Primary clarifiers —
average flow, v_o = 1000 gpd/ft^2
peak hourly flow, v_o = 1500 to 3000 gpd/ft^2
Activated sludge clarifiers, at peak hourly flow, not counting recycles —
conventional, v_o = 1200 gpd/ft^2
extended aeration, v_o = 1000 gpd/ft^2
second stage nitrification, v_o = 800 gpd/ft^2
Trickling filter humus tanks, at peak hourly flow —
v_o = 1200 gpd/ft^2

The traditional rule-of-thumb overflow rates for conventional rectangular clarifiers in alum coagulation plants are 0.25 gal/min·ft^2 (360 gpd/ft^2) in regions with cold winters and 0.38 gal/min·ft^2 (550 gpd/ft^2) in regions with mild winters. The Joint Task Force (1992) summarizes an extensive survey of the criteria used by numerous engineering companies for the design of wastewater clarifiers. The typical practice appears to be about 800 gpd/ft^2 at average flow for primary clarifiers and 600 gpd/ft^2 for secondary clarifiers. The latter rate is doubled for peak flow conditions.

Typical side water depths for all clarifiers is 10 to 16 ft. Secondary wastewater clarifiers should be designed at the high end of the range.

Hudson (1981) reported that in manually cleaned, conventional clarifiers, the sludge deposits often reach to within 30 cm of the water surface near the tank inlets, and scour velocities range from 3.5 to 40 cm/sec. The sludge deposits in manually cleaned tanks are often quite old, at least beneath the surface layer, and the particles in the deposits are highly flocculated and "sticky." Also, the deposits are well-compacted, because there is no mechanical collection device to stir them up. Consequently, Hudson's data represent the upper limits of scour resistance.

The limit on horizontal velocity, Camp's shearing stress criterion, and the Ingersoll–McKee–Brook's velocity fluctutation criterion are different ways of representing the same phenomenon. In principle, all three criteria should be consistent and produce the same length-to-depth ratio limit. However, different workers have access to different data sets and draw somewhat different conclusions. Because scour is a major problem, a conservative criterion should be adopted. This means a relatively short length-to-depth ratio, which means a relatively deep tank.

The limits on tank overflow rate, horizontal velocity, length-to-depth ratio, and hydraulic retention time overdetermine the design; only three of them are needed to specify the dimensions of the settling zone. They may also be incompatible.

Design of Circular Tanks

In most designs, the suspension enters the tank at the center and flows radially to the circumference. Other designs reverse the flow direction, and in one proprietary design, the flow enters along the circumference and follows a spiral path to the center.

The collection mechanisms in circular tanks have no bearings under water and are less subject to corrosion, reducing maintenance. However, center-feed tanks tend to exhibit streaming, especially in tank diameters larger than about 125 ft. Streaming is reduced in peripheral feed tanks and in center feed tanks with baffles (Joint Committee, 1990).

The design principles used for rectangular tanks also apply, with a few exceptions, to circular tanks.

Free, Nonflocculent Settling

The analysis of particle trajectories for circular tanks is given by Fair, Geyer, and Morris (1954) for center-feed, circular clarifiers. The trajectory of a freely settling, nonflocculent particle curves downwards, because as the distance from the center-feed increases, the horizontal water velocity decreases. At any point along the trajectory, the slope of the trajectory is given by the ratio of the settling velocity to the water velocity:

$$\frac{dz}{dr} = -\frac{v_s}{U_r} = -\frac{2\pi H v_s}{Q} \tag{9.172}$$

where H = the water depth in the settling zone (m or ft)
Q = the flow through the settling zone (m^3/s or ft^3/sec)
r = the distance from the center of the tank (m or feet)
U_r = the horizontal water velocity at r (m/s or ft/sec)
v_s = the particle's settling velocity (m/s or ft/sec)
z = the elevation of the particle about the tank's bottom (m or ft)

The minus sign on the right-hand-side is needed, because the depth variable is positive upwards, and the particle is moving down.

Equation (9.172) can be solved for the critical case of a particle that enters the settling zone at the water surface and reaches the bottom of the settling zone at its outlet cylinder:

$$v_o = \frac{Q}{\pi\left(r_o^2 - r_i^2\right)} \tag{9.173}$$

where r_i = the radius of the inlet baffle (m or ft)
r_o = the radius of the outlet weir (m or ft).

The denominator in Eq. (9.173) is the plan area of the settling zone. Consequently, the critical settling velocity is equal to the settling zone overflow rate.

The analysis leading to Eq. (9.173) also applies to tanks with peripheral feed and central takeoff. The only change required is the deletion of the minus sign in the right-hand side of Eq. (9.172), because the direction of the flow is reversed, and the slope of the trajectory is positive in the given coordinate system. Furthermore, the analysis applies to spiral flow tanks, if the integration is performed along the spiral stream lines. Consequently, all horizontal flow tanks are governed by the same principle.

Free, Flocculent Settling

The trajectories of nonflocculating particles in a circular clarifier are curved in space. However, if the horizontal coordinate were the time-of-travel along the settling zone, the trajectories would be linear. This can be shown by a simple change of variable:

$$\frac{dz}{dt} = \frac{dz}{dr} \cdot \frac{dr}{dt} = -\frac{v_s}{U_r} \cdot U_r = -v_s \tag{9.174}$$

This means that Fig. 9.7 also applies to circular tanks, if the horizontal coordinate is the time-of-travel. Furthermore, it applies to flocculent and nonflocculent settling in circular tanks.

Equation (9.156) applies to circular tanks with uniform feed over the inlet depth, whether they are center-feed, peripheral-feed, or spiral-flow tanks.

Unfortunately, the inlet designs of most circular clarifiers do not produce a vertically uniform feeding pattern. Usually, all of the flow is injected over a small portion of the settling zone depth. As long as the flow is injected at the top of the settling zone, this does not change matters, but other arrangements may.

One case where Camp's formula for clarifier efficiency does not apply is the upflow clarifier. However, this is also a case of hindered settling, and it will be discussed later.

The plan area of the circular settling zone is determined by the overflow rate, and this rate will be equal to the one used for a rectangular tank having the same efficiency. The design is completed by choosing a settling zone depth or a detention time. No general analysis for the selection of these parameters has been published, and designers are usually guided by traditional rules of thumb. The traditional rule of thumb in the United States is a detention time of 2 to 4 hr (Joint Task Force, 1969). Many regulatory agencies insist on a 4 hr detention time (Water Supply Committee, 1987).

Design of High-Rate, Tube, or Tray Clarifiers

"High-rate" settlers, also known as "tray" or "tube" settlers, are laminar flow devices. They eliminate turbulence, density currents, and streaming, and the problems associated with them. Their behavior is nearly ideal and predictable. Consequently, allowances for nonideal and uncertain behavior can be eliminated, and high-rate settlers can be made much smaller than conventional rectangular and circular clarifiers; hence, their name.

Hayden (1914) published the first experimental study of the efficiency of high-rate clarifiers. His unit consisted of a more-or-less conventional rectangular settler containing a system of corrugated steel sheets. This is a form of Camp's tray clarifier. The sheets were installed 45° from the horizontal, so that particles that deposited on them would slide down the sheets into the collection hoppers below. The sheets were corrugated for structural stiffness. The high-rate clarifier had removal efficiencies that were between 40 and 100% higher than simple rectangular clarifiers having the same geometry and dimensions and treating the same flow.

Nowadays, Hayden's corrugated sheets and the Hazen–Camp trays are replaced by modules made out of arrays of plastic tubes. The usual tube cross section is an area-filling polygon, such as the isoceles triangle, the hexagon, the square, and the chevron. Triangles, squares, and chevrons are preferred, because alternate rows of tubes can be sloped in different directions, which stiffens the module and makes it self-supporting. When area-filling hexagons are used, the alternate rows interdigitate and must be strictly parallel. Alternate rows of hexagons can be sloped at different angles, if the space-filling property is sacrificed.

Sedimentation

Consider a particle being transported along a tube that is inclined at an angle θ from the horizontal. Yao (1970, 1973) analyzes the situation as follows. Refer to Fig. 9.9. The coordinate axes are parallel and perpendicular to the tube axis. The trajectory of the particle along the tube will be resultant of the particle's settling velocity and the velocity of the water in the tube:

$$\frac{dx}{dt} = v_x = u - v_s \sin\theta \tag{9.175}$$

$$\frac{dy}{dt} = v_y = -v_s \cos\theta \tag{9.176}$$

where t = time (sec)
u = the water velocity at a point in the tube (m/s or ft/sec)
v_s = the particle's settling velocity (m/s or ft/sec)
v_x = the particle's resultant velocity in the x direction (m/s or ft/sec)

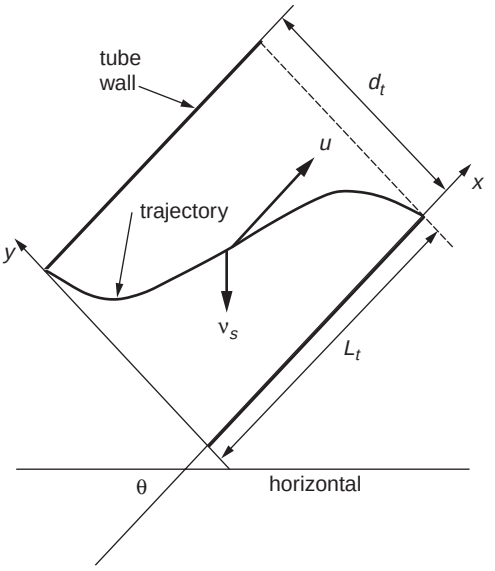

FIGURE 9.9 Trajectory of the critical particle in a tube. [Yao, K.M. 1970. Theoretical Study of High-Rate Sedimentation, *J. Water Pollut. Control Fed.*, 42 (no. 2, part 1): 218.]

v_y = the particle's resultant velocity in the y direction (m/s or ft/sec)
θ = the angle of the tube with the horizontal (rad)

Equations (9.175) and (9.176) may be combined to yield the differential equation of the trajectory of a particle transitting the tube:

$$\frac{dy}{dx} = -\frac{v_s \cos\theta}{u - v_s \sin\theta} \tag{9.177}$$

The water velocity u varies from point to point across the tube cross section. For fully developed laminar flow in a circular tube, the distribution is a parabola (Rouse, 1978):

$$\frac{u}{U_t} = 8\left(\frac{y}{d_t} - \frac{y^2}{d_t^2}\right) \tag{9.178}$$

where d_t = the tube diameter (m or ft)
U_t = the mean water velocity in the tube (m/s or ft/sec)
y = the distance from the tube invert (m or ft)

The critical trajectory begins at the crown of the tube and ends at its invert. Substituting for u and integrating between these two points yields the following relationship between the settling velocity of a particle that is just captured and the mean water velocity in a circular tube (Yao, 1970):

Laminar flow in circular tubes:

$$\frac{v_s}{U_t} = \frac{\frac{4}{3}}{\sin\theta + \frac{L_t}{d_t}\cdot\cos\theta} \tag{9.179}$$

where L_t = the effective length of the tube (m or ft).

Yao (1970) has performed the same analysis for other cross-sectional shapes, and the equations differ only in the numerical value of the numerator on the right-hand side.

Laminar flow in square tubes:

$$\frac{v_s}{U_t} = \frac{11/8}{\sin\theta + \frac{L_t}{a_t}\cdot\cos\theta} \tag{9.180}$$

where a = the length of one side of the square cross section (m or ft).

Laminar flow between parallel plates, or for laminar flow over a plane, or for an idealized flow that has a uniform velocity everywhere:

$$\frac{v_s}{U_t} = \frac{1}{\sin\theta + \frac{L_t}{h_p}\cdot\cos\theta} \tag{9.181}$$

where h_p = the thickness of the flow (m or ft).

This critical velocity may be related to the tube overflow rate. The definition of the overflow rate for a square tube is:

$$\text{tube overflow rate} = \frac{\text{flow through tube}}{\text{horizontally projected area}}$$

$$v_{ot} = \frac{U_t a_t^2}{L_t a_t \cos\theta} = \frac{U_t}{\frac{L_t}{a_t}\cos\theta} \tag{9.182}$$

where v_{ot} = the tube overflow rate (m/s or ft/sec).

Therefore,

$$v_s = \frac{\frac{11}{8} v_{ot}}{1 + \frac{L_t}{a_t}\cdot\tan\theta} \tag{9.183}$$

In the ideal Hazen–Camp clarifier, the critical settling velocity is equal to the tank overflow rate. This is not true for tubes. Tubes are always installed as arrays, and the critical velocity for the array is much less than the tank overflow rate. The number of tubes in such an array can be calculated as follows. First, the fraction of the settling zone surface occupied by the tube ends is less than the plan area of the zone, because the inclination of the tubes prevents full coverage. The area occupied by open tube ends that can accept flow is:

$$A_o = W\left(L - L_t\cdot\cos\theta\right) \tag{9.184}$$

where A_0 = the area of the settling zone occupied by tube ends (m^2 or ft^2)
L = the length of the settling zone (m or ft)
L_t = the length of the tubes (m or ft)
W = the width of the settling zone (m or ft)
θ = the angle of the tubes with the horizontal plane (rad)

The number of square tubes in this area is:

$$n_t = \frac{W\left(L - L_t \cos\theta\right)}{a_t^2 / \sin\theta} \tag{9.185}$$

The effective plan area of the array of square tubes is simply the number of tubes times the plan area of a single tube:

$$A_{eff} = n_t L_t a_t \cos\theta = W\left(L - L_t \cos\theta\right)\frac{L_t}{a_t}\sin\theta\cos\theta \tag{9.186}$$

The overflow rate of the array of square tubes is:

$$v_o = \frac{Q}{W\left(L - L_t \cdot \cos\theta\right)\cdot \dfrac{L_t}{a_t}\cdot \sin\theta \cdot \cos\theta} \tag{9.187}$$

This is also the overflow rate of each tube in the array, if the flow is divided equally among them.

Assuming equal distribution of flow, the critical settling velocity may be related to the overflow rate of the array of square tubes by substituting Eq. (9.187) into (9.183):

$$v_s = \frac{\frac{11}{8}Q}{\left(1 + \dfrac{L_t}{a_t}\tan\theta\right)W\left(L - L_t\cos\theta\right)\dfrac{L_t}{a_t}\sin\theta\cos\theta} \tag{9.188}$$

For parallel plates, the equivalent formula is:

$$v_s = \frac{Q}{\left(1 + \dfrac{L_t}{h_p}\tan\theta\right)W\left(L - L_t\cos\theta\right)\dfrac{L_t}{h_p}\sin\theta\cos\theta} \tag{9.189}$$

Tube Inlets

Near the tube inlet, the velocity distribution is uniform, not parabolic:

$$u = U_t \tag{9.190}$$

The relationships just derived do not apply in the inlet region, and the effective length of the tubes should be diminished by the inlet length.

The distance required for the transition from a uniform to a parabolic distribution in a circular tube is given by the Schiller–Goldstein equation (Goldstein, 1965):

$$L_{en} = 0.0575 r_t \boldsymbol{Re}_t \tag{9.191}$$

where L_{en} = the length of the inlet region (m or ft)
Ret = the tube's Reynolds number (dimensionless)
$= U_t\, d_t/\nu$
r_t = the tube's radius (m or ft)

Tube diameters are typically 2 in., and tube lengths are typically 2 ft (Culp/Wesner/Culp, 1986). The transition zone length near the inlet of a circular tube will be about 0.15 to 0.75 ft. Tubes are normally 2 ft long, depending on water temperature and velocity.

If the velocity remained uniform everywhere for the whole length of the tube, the formula for the critical velocity in a circular tube would be,

$$\frac{v_s}{U_t} = \frac{1}{\sin\theta + \frac{L_t}{d_t}\cdot\cos\theta} \tag{9.192}$$

Comparison with Eq. (9.179) shows that this is actually one-fourth less than the critical velocity for a fully developed parabolic velocity profile, so the effect of a nonuniform velocity field is to reduce the efficiency of the tube.

Performance Data

Long, narrow tubes with low water velocities perform best (Hansen and Culp, 1967). However, water velocity is more important than tube diameter, and tube diameter is more important than tube length. For tubes that were 2 in. in diameter and 2 ft long, turbidity removal was seriously degraded when the water velocity exceeded 0.0045 ft/sec.

Recommended tank overflow rates for tube settlers range from 2.5 to 4.0 gpm/ft^2 (Culp/Wesner/Culp, Inc., 1986). It is assumed that the tubes are 2 in. in diameter, 2 ft long, and inclined at 60°. For conventional rapid sand filters, a settled water turbidity of less than 3 TU is preferred, and the overflow rate should not exceed 2.5 gpm/ft^2 at temperatures above 50°F. A settled water turbidity of up to 5 TU is acceptable to dual media filters, and the overflow rate should not exceed 2.5 gpm/ft^2 at temperatures below 40°F and 3.0 gpm/ft^2 at temperatures above 50°F.

Clarifier Inlets

Conventional Clarifiers

The inlet zone should distribute the influent flow uniformly over the depth and the width of the settling zone. If both goals cannot be met, then uniform distribution across the width has priority, because streaming degrades tank performance more than do density currents. Several design principles should be followed:

- In order to prevent floc breakage, the r.m.s. characteristic strain rates in the influent channel, piping, and appurtenances must not exceed the velocity gradient in the final compartment of the flocculation tank. Alum/clay flocs and sludges should not be pumped or allowed to free-fall over weirs at any stage of their handling. This rule does not apply to the transfer of settled water to the filters (Hudson and Wolfner, 1967; Hudson, 1981).
- The influent flow should approach the inlet zone parallel to the longitudinal axis of the clarifier. Avoid side-overflow weirs. The flow in channels feeding such weirs is normal to the axis of the clarifier, and its momentum across the tank will cause a nonuniform lateral distribution. At low flows, most of the water will enter the clarifier from the upstream end of the influent channel, and at high flows, most of it will enter the clarifier from the downstream end of the channel. These maldistributions occur even if baffles and orifice walls are installed in the inlet zone (Yee and Babb, 1985).
- A simple inlet pipe is unsatisfactory, even if it is centered on the tank axis and even if there is an orifice wall downstream of it, because the orifice wall will not dissipate the inlet jet. The inlet pipe must end in a tee that discharges horizontally, and an orifice wall should be installed downstream of the tee (Kleinschmidt, 1961). A wall consisting of adjustable vertical vanes may be preferable to an orifice wall.

The orifice wall should have about 30 to 40% open area (Hudson, 1981). The orifice diameters should be between 1/64 and 1/32 of the smallest dimension of the wall, and the distance between the wall and

the inlet tee should be approximately equal to the water depth. The headloss through the orifice wall should be about four times the approaching velocity head.

High-Rate Clarifiers

In a high-rate clarifier, the settling zone is the tube modules. The inlet zone consists of the following regions and appurtenances:

- A region near the tank inlet that contains the inlet pipe and tee, a solid baffle wall extending from above the water surface to below the tube modules, and, perhaps, an orifice wall below the solid baffle
- The water layer under the settling modules and above the sludge zone

The inlet pipe and tee are required for uniform lateral distribution of the flow. The solid baffle wall must deflect the flow under the tube modules. Horizontally, it extends completely across the tank. Vertically, it extends from a few inches above maximum water level to the bottom of the tube modules. If the raw water contains significant amounts of floatables, the baffle wall should extend sufficiently above the maximum water surface to accommodate some sort of skimming device. The orifice wall extends across the tank and from the bottom of the baffle wall to the tank floor. The extension of the orifice wall to the tank bottom requires that special consideration be given to the sludge removal mechanism.

Most tube modules are installed in existing conventional clarifiers to increase their hydraulic capacity. The usual depth of submergence of tube modules in retrofitted tanks is 2 to 4 ft, in order to provide room for the outlet launders, and the modules are generally about 2 to 3 ft thick.

The water layer under the tube modules needs to be thick enough to prevent scour of the sludge deposited on the tank floor. Conley and Hansen (1978) recommend a minimum depth under the modules of 4 ft.

Outlets

Outlet structures regulate the depth of flow in the settling tank and help to maintain a uniform lateral flow distribution. In high-rate clarifiers, they also control the flow distribution among the tubes, which must be uniform.

Launders

The device that collects the clarified water usually is called a "launder." There are three arrangements:

- Troughs with side-overflow weirs (the most common design)
- Troughs with submerged perforations along the sides
- Submerged pipes with side perforations

Launders may be constructed of any convenient, stable material; concrete and steel are the common choices. A supporting structure is needed to hold them up when the tank is empty and down when the tank is full. Launders are usually provided with invert drains and crown vents to minimize the loads on the supports induced by tank filling and draining. The complete outlet structure consists of the launder plus any ancillary baffles and the supporting beams and columns.

Clarified water flows into the launders either by passing over weirs set along the upper edges of troughs or by passing through perforations in the sides of troughs or pipes. The launders merge downstream until only a single channel pierces the tank's end wall.

The outlet structures in some old plants consist of simple overflow weirs set in the top of the downstream end wall. This design is unacceptable.

If troughs-with-weirs are built, the weir settings will control the water surface elevation in the tank. "V-notch" weirs are preferred over horizontal sharp-crested weirs, because they are more easily adjusted. V-notch weirs tend to break up large, fragile alum flocs. This may not be important.

Perforated launders are built with the perforations set 1 to 2 ft below the operating water surface (Hudson, 1981; Culp/Wesner/Culp, Inc., 1986). This design is preferred when the settled water contains significant amounts of scum or floating debris, when surface freezing is likely, and when floc breakage must be minimized (Hudson, 1981; Culp/Wesner/Culp, Inc., 1986). Perforated launders permit significant variations in the water surface elevation, which may help to break up surface ice.

"Finger launders" (James M. Montgomery, Consulting Engineers, Inc., 1985) consist of long troughs or pipes run the length of the settling zone and discharged into a common channel or manifold at the downstream end of the tank. Finger launders are preferred for all rectangular clarifiers, with or without settling tube modules, because they maximize floc removal efficiency. There are several reasons for the superiority of finger launders (James M. Montgomery, Consulting Engineers, Inc., 1985):

- By drawing off water continuously along the tank, they reduce tank turbulence, especially near the outlet end.
- They dampen wind-induced waves. This is especially true of troughs with weirs, because the weirs protrude above the water surface.
- If a diving density current raises sludge from the tank bottom, the sludge plume is concentrated at the downstream end of the tank. Therefore, most of the launder continues to draw off clear water near the center and upstream end of the tank.
- Finger launders impose a nearly uniform vertical velocity component everywhere in the settling zone, which produces a predictable, uniform velocity field. This uniform velocity field eliminates many of the causes of settler inefficiency, including bottom scour, streaming, and gradients in the horizontal velocity field.
- Finger launders eliminate the need for a separate outlet zone. Settled water is collected from the top of the settling zone, so the outlet and settling zones are effectively merged.

The last two advantages are consequences of Fisherström's (1955) analysis of the velocity field under finger launders. The presence or absence of settling tube modules does not affect the analysis, or change the conclusions. The modules merely permit the capture of particles that would otherwise escape.

The outlet design should include so-called "hanging" or "cross" baffles between the launders. Hanging baffles run across the width of the clarifier, and they extend from a few inches above the maximum water surface elevation to a few feet below it. If settling tube modules are installed in the clarifier, the hanging baffle should extend all the way to the top of the modules. In this case, it is better called a cross baffle. The baffles are pierced by the launders. The purpose of the baffles is to promote a uniform vertical velocity component everywhere in the settling/outlet zone. They do this by suppressing the longitudinal surface currents in the settling/outlet zone that are induced by diving density currents and wind.

The number of finger launders is determined by the need to achieve a uniform vertical velocity field everywhere in the tank. There is no firm rule for this. Hudson (1981) recommends that the center-to-center distance between launders be 1 to 2 tank depths. The number of hanging baffles is likewise indeterminate. Slechta and Conley (1971) successfully suppressed surface currents by placing the baffles at the quarter points of the settling/outlet zone. However, this spacing may be too long. The clarifier in question also had tube modules, which helped to regulate the velocity field below the launders.

Other launder layouts have serious defects and should be avoided. The worst choice for the outlet of a conventional rectangular clarifier consists of a weir running across the top of the downstream end wall, which was a common design 50 years ago. The flow over the weir will induce an upward component in the water velocity near the end wall. This causes strong vertical currents, which carry all but the fastest particles over the outlet weir.

Regulatory authorities often attempt to control the upward velocity components in the outlet zone by limiting the so-called "weir loading" or "weir overflow rate." This number is defined to be the ratio of the volumetric flow rate of settled water to the total length of weir crest or perforated wall. If water enters both sides of the launder, the lengths of both sides may be counted in calculating the rate.

A commonly used upper limit on the weir rate is the "Ten States" specification of 20,000 gal/ft·day for peak hourly flows ≤1 mgd and 30,000 gal/ft·day for peak hourly flows >1 mgd (Wastewater Committee, 1990). Babbitt, Dolan, and Cleasby (1967) recommend an upper limit of 5000 gal/ft·day. Walker Process Equipment, Inc., recommends the following limits, which are based on coagulant type:

- Low raw water turbidity/alum — 8 to 10 gpm/ft (11,520 to 14,400 gal/day ft)
- High raw water turbidity/alum — 10 to 15 gpm/ft (14,400 to 21,600 gal/day ft)
- Lime/soda softening — 15 to 18 gpm/ft (21,600 to 25,920 gal/ft day)

The "Ten States" weir loading yields relatively short launders and high upward velocity components. Launders designed according to the "Ten States" regulation require a separate outlet zone, which would be defined to be all the water under the horizontal projection of the launders. A commonly followed recommendation (Joint Task Force, 1969) is to make the outlet zone one-third of the total tank length and to cover the entire outlet zone with a network of launders. More recently, it is recommended that the weirs cover enough of the settling zone surface so that the average rise rate under them not exceed 1 to 1.5 gpm/ft^2 (Joint Committee, 1990).

Weir/Trough Design

The usual effluent launder weir consists of a series of "v-notch" or "triangular" weirs. The angle of the notch is normally 90°, because this is the easiest angle to fabricate, it is less likely to collect trash than narrower angles, and the flow through it is more predictable than wider angles. Individual weir plates are typically 10 cm wide, and the depth of the notch is generally around 5 cm. The spacing between notches is about 15 cm, measured bottom point to bottom point. The flat surface between notches is for worker safety. If the sides of the notches merged in a point, the point would be hazardous to people working around the launders. The sides of the "V" are beveled at 45° to produce a sharp edge, the edge being located on the weir inlet side. The stock from which the weirs are cut is usually hot-dipped galvanized steel or aluminum sheet 5 to 13 mm thick. Fiberglass also has been used. Note the bolt slots, which permit vertical adjustment of the weir plates.

The usual head-flow correlation for 90° v-notch weirs is King's (1963) equation:

$$Q = 2.52H^{2.47} \tag{9.193}$$

where Q = the flow over the weir in ft^3/sec
H = the head over the weir notch in ft

Adjacent weirs behave nearly independently of one another as long as the distance between the notches is at least 3.5 times the head (Barr, 1910a, 1910b; Rowell, 1913). Weir discharge is independent of temperature between 39 and 165°F (Switzer, 1915).

Because finger launders are supposed to produce a uniform vertical velocity field in the settling zone, each weir must have the same discharge. This means that the depth of flow over each notch must be the same. The hydraulic gradient along the tank is also small, and the water surface may be regarded as flat, at least for design purposes. Wind setup may influence the water surface more than clarifier wall friction.

The water profile in the effluent trough may be derived by writing a momentum balance for a differential cross-sectional volume element. The result is the so-called Hinds (1926)–Favre (1933) equation (Camp, 1940; Chow, 1959):

$$\frac{dy}{dx} = \frac{S_o - S_f - \dfrac{2nq_wQ_x}{gA_x^2}}{1 - \dfrac{Q_x^2}{gA_x^2H_x}} \tag{9.194}$$

where A_x = the cross-sectional area of the flow at x (m^2 or ft^2)
B_x = the top-width of the flow at x (m or ft)
g = the acceleration due to gravity (9.80665 m/s^2 or 32.174 ft/sec^2)
H_x = the mean depth of flow at x (m or ft)
$= A_x/B_x$
n = the number of weir plates attached to the trough (dimensionless)
= 1, if flow enters over one edge only
= 2, if flow enters over both edges
Q_x = the flow at x (m^3/s or ft^3/sec)
q_w = the weir loading rate ($m^3/m \cdot s$ or $ft^3/ft \cdot sec$)
S_f = the energy gradient (dimensionless)
S_0 = the invert slope (dimensionless)
x = the distance along the channel (m or ft)
y = the depth above the channel invert at x (m or ft)

For a rectangular cross section, which is the usual trough shape, the mean depth is equal to the depth.

If it is assumed that the energy gradient is caused only by wall friction, then it may be replaced by the Darcy–Weisbach formula (or any other wall friction formula):

$$S_f = \frac{fU^2}{8gR} \tag{9.195}$$

where f = the Darcy–Weisbach friction factor (dimensionless)
R = the hydraulic radius (m or ft)
U = the mean velocity (m/s or ft/sec)

An approximate solution to Eq. (9.194) may be had by substituting the average values of the depth and the hydraulic radius into the integral. The information desired is the depth of water at the upstream end of the trough, because this will be the point of highest water surface elevation (even if not the greatest depth in the trough). Camp's (1940) solution for the upstream depth is as follows:

$$H_o = \sqrt{H_x^2 + \frac{2Q_x^2}{gb^2H_x} - 2x\overline{H}\left(S_o - \overline{S}_f\right)} \tag{9.196}$$

where $\overline{H}$ = the mean depth along the channel (m or ft)
H_0 = the depth of flow at the upstream end of the channel (m or ft)
$\overline{S}_f$ = the average energy gradient along the channel (dimensionless)

H_o can be calculated if the depth of flow is known at any point along the trough. The most obvious and convenient choice is the depth at the free overflow end of the channel, where the flow is critical. The critical depth for a rectangular channel is given by (King and Brater, 1963):

$$H_c = \sqrt[3]{\frac{Q_c^2}{gb^2}} \tag{9.197}$$

In smooth channels, the critical depth section is located at a distance of about $4H_C$ from the end of the channel (Rouse, 1936; O'Brien, 1932). In a long channel, the total discharge can be used with little error.

The actual location of the critical depth section is not important, because the overflow depth is simply proportional to the critical depth (Rouse, 1936, 1943; Moore, 1943):

$$H_e = 0.715H_c \tag{9.198}$$

Estimation of the mean values of the depth, hydraulic radius, and energy gradient for use in Eq. (9.196) requires knowledge of H_o, so an iterative calculation is required. An initial estimate for H_o can be obtained by assuming that the trough is flat and frictionless and that the critical depth occurs at the overflow. This yields:

$$H_o \cong \sqrt{3} \cdot \sqrt[3]{\frac{Q^2}{gb^2}} \tag{9.199}$$

A first estimate for the average value of the depth of flow may now be calculated. Because the water surface in the trough is nearly parabolic, the best estimators for the averages are as follows (Camp, 1940):

$$\overline{H} = \frac{2H_o + H_e}{3} \tag{9.200}$$

$$\overline{R} = \frac{b\overline{H}}{b + 2\overline{H}} \tag{9.201}$$

The average energy gradient can be approximated using any of the standard friction formulae, e.g., the Manning equation. The side inflow has the effect of slowing the velocity in the trough, because the inflow must be accelerated, and a somewhat higher than normal friction factor is needed.

Combining-Flow Manifold Design

A perforated trough may be treated as a trough with weirs, if the orifices discharge freely to the air. In this case, all the orifices have the same diameter, and the orifice equation may be used to calculate the required diameters. If the orifices are submerged, then the launder is a combining flow manifold, and a different design procedure is required.

Consider a conduit with several perpendicular laterals. The hydraulic analysis of each junction involves eight variables (McNown, 1945, 1954):

- The velocity in the conduit upstream of the junction
- Velocity in the lateral
- Velocity of the combined flow in the conduit downstream of the junction
- Pressure difference in the conduit upstream and downstream of the junction
- Pressure difference between the lateral exit and the conduit downstream of the junction
- Conduit diameter (assumed to be the same upstream and downstream of the junction)
- Lateral diameter
- Density of the fluid

There are three equations connecting these variables, namely:

- Continuity
- Headloss for the lateral flow
- Headloss for the conduit flow

Besides these equations, there is the requirement that all laterals deliver the same flow. The conduit diameter is usually kept constant.

The continuity equation for the junction is simply:

$$Q_d = Q_u + Q_l \tag{9.202}$$

where Q_d = the flow downstream from the lateral (m^3/s or ft^3/sec)
Q_l = the flow entering from the lateral (m^3/s or ft^3/sec)
Q_u = the flow upstream from the lateral (m^3/s or ft^3/sec)

If the conduit has the same diameter above and below the junction with the lateral, the headloss for the conduit flow may be represented as a sudden contraction (McNown, 1945; Naiz, 1954):

$$h_{Lc} = K_c\left(\frac{U_d^2}{2g} - \frac{U_u^2}{2g}\right) \tag{9.203}$$

where h_{Lc} = the headloss in the conduit at the lateral (m or ft)
K_c = the headloss coefficient (dimensionless)
U_d = the velocity downstream of the lateral (m/s or ft/sec)
U_u = the velocity upstream of the lateral (m/s or ft/sec)

The headloss coefficient, K_c, depends upon the ratio of the lateral and conduit diameters (Soucek and Zelnick, 1945; McNown, 1954; Naiz, 1954; Powell, 1954). Niaz's (1954) analysis of McNown's data yields the following approximate relationships:

$$\begin{aligned} \frac{d_l}{d_c} &= \tfrac{1}{4} \rightarrow K_c = 1.4 \\ \frac{d_l}{d_c} &= \tfrac{1}{2} \rightarrow K_c = 1.0 \\ \frac{d_l}{d_c} &= 1 \rightarrow K_c = 0.5 \end{aligned} \tag{9.204}$$

where d_c = the diameter of the conduit (m or ft)
d_l = the diameter of the lateral (m or ft).

The situation with respect to the lateral headloss is more complicated. The headloss may be expressed in terms of the lateral velocity or in terms of the downstream conduit velocity (McNown, 1954):

$$h_{Ll} = K_{ll} \cdot \frac{U_l^2}{2g} \tag{9.205}$$

$$h_{Ll} = K_{lc} \cdot \frac{U_d^2}{2g} \tag{9.206}$$

where h_{Ll} = the headloss in the lateral (m or ft)
K_{lc} = the lateral's headloss coefficient based on the conduit's velocity (dimensionless)
K_{ll} = the lateral's headloss coefficient based on the lateral's velocity (dimensionless)
U_d = the conduit's velocity downstream of the lateral (m/s or ft/sec)
U_l = the lateral's velocity (m/s or ft/sec)

The headloss coefficients depend upon the ratio of the lateral and conduit diameters and the ratio of the lateral and conduit flows (or velocities). If the lateral velocity is much larger than the conduit velocity, all of the lateral velocity head is lost, and K_{ll} is equal to 1. The situation here is similar to that of a jet entering a reservoir. If the lateral velocity is much smaller than the conduit velocity, the lateral flow loses no energy. In fact, the headloss calculated from the Bernoulli equation will be negative, and its magnitude will approach the velocity head in the conduit downstream of the junction. For this case, K_{lc} will approach –1. The negative headloss is an artifact caused by the use of cross-sectional average velocities in the Bernoulli equation. If the lateral discharge is small relative to the conduit flow, it enters the conduit boundary layer, which has a small velocity. Some empirical data on the variation of the headloss coefficients are given by McNown (1954) and Powell (1954).

The energy equation is written for an arbitrary element of water along its path from the clarifier to the outlet of the launder. To simplify matters, it is assumed that the launder discharges freely to the atmosphere. The water element enters the launder through the "*j*th" lateral, counting from the downstream end of the launder:

$$\frac{U_o^2}{2g} + \frac{p_o}{\gamma} + z_o = \frac{U_e^2}{2g} + \frac{p_e}{\gamma} + z_e + h_{Li}(j) + h_{Ll}(j) + \sum_{i=1}^{j-1} h_{Lc}(i) \tag{9.207}$$

where p_e = the pressure at the conduit's exit (N/m^2 or lbf/ft^2)
p_0 = the pressure in the clarifier (N/m^2 or lbf/ft^2)
U_e = the velocity at the conduit's exit (m/s or ft/sec)
U_0 = the velocity in the clarifier (m/s or ft/sec)
z_e = the elevation at the conduit's exit (m or ft)
z_0 = the elevation in the clarifier (m or ft)

Wall friction losses in the launder and its laterals are ignored, because they are usually small compared to the other terms. The velocity of the water element at the beginning of its path in the clarifier will be small and can be deleted. The sum of the pressure and elevation terms at the beginning is simply the water surface elevation. The pressure of a free discharge is zero (gauge pressure). Consequently, Eq. (9.207) becomes:

$$h_{Li}(j) + h_{Ll}(j) + \sum_{i=1}^{j-1} h_{Lc}(i) = z_{cws} - z_{ews} - \frac{U_e^2}{2g} \tag{9.208}$$

where z_{cws} = the clarifier's water surface (m or ft)
z_{ews} = the conduit exit's water surface (m or ft).

Equation (9.208) assumes that the laterals do not interact. This will be true as long as the lateral spacing is at least six lateral diameters (Soucek and Zelnick, 1945).

The right-hand side of Eq. (9.208) is a constant and is the same for each lateral. All the water elements begin with the same total energy, and they all end up with the same total energy, so the total energy loss for each element must be the same.

The flows into laterals far from the outlet of the launder experience more junction losses than those close to the outlet. This means that the head available for lateral entrance and exit is reduced for the distant laterals. Consequently, if all the lateral diameters are equal, the lateral discharge will decrease from the launder outlet to its beginning (Soucek and Zelnick, 1945). The result will be a nonuniform vertical velocity distribution in the settling zone of the clarifier. This can be overcome by increasing the lateral diameters from the launder outlet to its beginning.

Most perforated launders are built without lateral tubes. The headloss data quoted above do not apply to this situation, because the velocity vectors for simple orifice inlets are different from the velocity vectors for lateral tube inlets. Despite this difference, some engineers use the lateral headloss data for orifice design (Hudson, 1981).

Data are also lacking for launders with laterals or orifices on each side. These data deficiencies make perforated launder design uncertain. It is usually recommended that the design be confirmed by full-scale tests.

The usual reason given for perforated launders is their relative immunity to clogging by surface ice. However, the need for a uniform velocity everywhere in the settling zone controls the design. If freezing is likely, it would be better to cover the clarifiers. The launders could then be designed for v-notch weirs or freely discharging orifices, which are well understood.

Sludge Zone

Sludge Collection

The sludge collection zone lies under the settling zone. It provides space for the sludge removal equipment and, if necessary, for temporary sludge storage.

The most common design consists of a bottom scraper and a single hopper. Periodically, the solids deposited on the clarifier floor are scraped to the hopper set into the tank floor. The solids are collected as a sludge that is so dilute it behaves hydraulically, like pure water. Periodically, the solids are removed from the hopper via a discharge line connected to the hopper bottom.

An alternative scheme is sometimes found in the chemical and mining industries and in dust collection facilities. In these cases, the entire tank floor is covered with hoppers. No scraper mechanisms are required. However, the piping system needed to drain the hoppers is more complex.

A third system consists of perforated pipes suspended near the tank floor and lying parallel to it. A slight suction head is put on the pipes, and they are drawn over the entire tank floor, sucking up the deposited solids. This system eliminates the need for hoppers, but it produces a very dilute sludge.

Sludge Composition

The composition of the sludges produced by the coagulation and sedimentation of natural waters is summarized in Table 9.2, and by wastewater treatment, in Table 9.3. Alum coagulation is applied to surface waters containing significant amounts of clays and organic particles, so the sludges produced also contain significant amounts of these materials. Lime softening is often applied to groundwaters, which are generally clear. Consequently, lime sludges consist mostly of calcium and magnesium precipitates.

TABLE 9.2 Range of Composition of Water Treatment Sludges

Sludge Component	Alum Sludges	Iron Sludges	Lime Sludges
Total Suspended Solids:			
(% by wt)	0.2–4.0	0.25–3.5	2.0–15.0
Aluminum:			
(% by wt of TSS, as Al)	4.0–11.0	—	—
(mg/L, as Al)	295–3750	—	—
Iron:			
(% by wt of TSS, as Fe)	—	4.6–20.6	—
(mg/L, as Fe, for 2% TSS)	—	930–4120	—
Calcium:			
(% by wt of TSS, as Ca)	—	—	30–40
Silica/Ash:			
(% by wt of TSS)	35–70	—	3–12
Volatile Suspended Solids:			
(% by wt of TSS)	15–25	5.1–14.1	7 (as carbon)
BOD_5 (mg/L)	30–300	—	Little or none
COD (mg/L)	30–5000	—	Little or none
pH (standard units)	6–8	7.4–8.5	9–11
Color (sensory)	Gray-brown	Red-brown	White
Odor (sensory)	None	—	None to musty
Absolute viscosity:			
(g/cm·sec)	0.03 (non-Newtonian)	—	—
Dewaterability	Concentrates to 10% solids in 2 days on sand beds, producing a spongy semisolid	—	Compacts to 50% solids in lagoons, producing a sticky semisolid; dewatering impaired if Ca/Mg ratio is 2 or less
Settleability	50% in 8 hr	—	50% in 1 week
Specific resistance:			
(sec^2/g)	1.0×10^9–5.4×10^{11}	4.1×10^8–2×10^{12}	0.20×10^7–26×10^7
Filterability	Poor	—	Poor

Sludge Collectors/Conveyors

There are a variety of patented sludge collection systems offered for sale by several manufacturers. The two general kinds of sludge removal devices are "flights" or "squeegees" and "suction manifolds."

The first consists of a series of boards, called "flights" or "squeegees," that extend across the width of the tank. The boards may be constructed of water-resistant woods, corrosion-resistant metals, or engineering plastics. In traditional designs, the flights are attached to continuous chain loops, which are mounted on sprockets and moved by a drive mechanism. The flights, chains, and sprockets are submerged. The drive mechanism is placed at ground level and connected to the sprocket/chain system by some sort of transmission. In addition to the primary flight system, which moves sludge to one end of the tank, there may be a secondary flight system, which moves the sludge collected at the tank end to one or more hoppers.

In some newer designs, the flights are suspended from a traveling bridge, which moves along tracks set at ground level along either side of the clarifier. Bridge-driven flights cannot be used with high-rate settlers, because the flight suspension system interferes with the tube modules. Bridge systems also require careful design to assure compatibility with effluent launders. If finger launders extending the whole length of the settling zone are used, bridge systems may not be feasible.

In either system, the bottom of the tank is normally finished with a smooth layer of grout, and two or more longitudinal rails are placed along the length of the tank to provide a relatively smooth bearing surface for the flights. The tops of the rails are set slightly above the smooth grout layer. The grout surface is normally pitched toward the sludge hopper to permit tank drainage for maintenance. The recommended minimum pitch is 1/16 in./ft (0.5%) (Joint Task Force, 1969).

The flights are periodically dragged along the bottom of the tank to scrape the deposited sludge into the sludge hoppers. The scraping may be continuous or intermittent depending on the rate of sludge deposition. Flight speeds are generally limited to less than 1 ft/min to avoid solids resuspension (Joint Task Force, 1969).

In some traveling bridge designs, the flights are replaced by perforated pipes, which are subjected to a slight suction head. The pipes suck deposited solids off the tank floor and transfer them directly to the sludge processing and disposal systems. Suction manifolds dispense with the need for sludge hoppers, which simplifies and economizes tank construction, but they tend to produce dilute sludges, and they may not be able to collect large, dense flocs.

The sludge zone should be deep enough to contain whatever collection device is used and to provide storage for sludge solids accumulated between removal operations. Generally, 12 to 18 in. of additional tank depth is provided.

Sludge Hoppers

Sludge hoppers serve several purposes. First, they store the sludge until it is removed for processing and storage. For this reason, the hoppers should have sufficient volume to contain all the solids deposited on the tank floor between sludge removals. Second, they channel the flow of the sludge to the inlet of the drainpipe. To facilitate this, the bottom of the hoppers should be square and only somewhat larger than the inlet pipe bell. Third, the hoppers provide sufficient depth of sludge over the pipe inlet to prevent short-circuiting of clear water. There is no general rule regarding the minimum hopper depth. Fourth, hoppers prevent resuspension of solids by diving density currents near the inlet and by the upflow at the outlet end of the tank. Fourth, hoppers provide some sludge thickening.

The number of hoppers and their dimensions are determined by the width of the tank and the need, if any, for cross collectors. For example, the length of a hopper side at the top of the hopper will be the minimum width of the cross collector. At the bottom of the hopper, the minimum side length will be somewhat larger than the diameter of the pipe inlet bell. The minimum side wall slopes are generally set at 45° to prevent sludge adhesion.

Freeboard

The tops of the sedimentation tank walls must be higher than the maximum water level that can occur in the tank. Under steady flow, the water level in the tank is set by the backwater from the effluent launder. In the case of effluent troughs with v-notch weirs, the maximum steady flow water level is the depth over the notch for the maximum expected flow, which is the design flow. From time to time, waves caused by hydraulic surges and the wind will raise the water above the expected backwater. In order to provide for these transients, some "freeboard" is provided. The freeboard is defined to be the distance between the top of the tank walls and the predicted water surface level for the (steady) design flow. The actual amount of freeboard is somewhat arbitrary, but a common choice in the U.S. is 18 in. (Joint Task Force, 1969).

The freeboard may also be set by safety considerations. In order to minimize pumping, the operating water level in most tanks is usually near the local ground surface elevation. Consequently, the tops of the tank walls will be near the ground level. In this situation, the tanks require some sort of guardrail and curb in order to prevent pedestrians, vehicles, and debris from falling in. The top of the curb becomes the effective top of the tank wall. Curbs are usually at least 6 in. above the local ground level.

Hindered Settling

In hindered settling, particles are close enough to be affected by the hydrodynamic wakes of their neighbors, and the settling velocity becomes a property of the suspension. The particles move as a group, maintaining their relative positions like a slowly collapsing lattice: large particles do not pass small particles. The process is similar to low Reynolds number bed expansion during filter backwashing, and the Richardson–Zaki (1954) correlation would apply, if the particles were of uniform size and density and their settling velocity were known. Instead, the velocity must be measured.

Hindered settling is characteristic of activated sludge clarifiers, many lime-soda sludge clarifiers, and gravity sludge thickeners.

Settling Column Tests

If the particle concentration is large enough, a well-defined interface forms between the clear supernatant and the slowly settling particles. Formation of the interface is characteristic of hindered settling; if a sharp interface does not form, the settling is free.

Hindered settling velocities are frequently determined in laboratory-scale settling columns. Vesilind (1974) identifies several deficiencies in laboratory-scale units, which do not occur in field units:

- The initial settling velocity depends on the liquid depth (Dick and Ewing, 1967).
- "Channeling" takes place in narrow diameter cylinders, where the water tends to flow along the cylinder wall, which is the path of least resistance, and the measured settling velocity is increased.
- "Volcanoing" takes place in the latter part of the settling process, during compression, when small columns of clear liquid erupt at various places across the sludge/water interface, which increases the measured interface velocity. (This is a form of channeling that occurs in wide, unmixed columns.)
- At high solids concentrations, narrow cylinders also permit sludge solids bridging across the cylinder, which inhibits settling.
- Narrow cylinders dampen liquid turbulence, which prevents flocculation and reduces measured settling velocities.

Vesilind (1974) recommends the following procedure for laboratory settling column tests:

- The minimum column diameter should be 8 in., but larger diameters are preferred.
- The depth should be that of the proposed thickener, but at least 3 ft.
- The column should be filled from the bottom from an aerated, mixed tank.
- The columns less than about 12 in. in diameter should be gently stirred at about 0.5 rpm.

In any settling test, the object is to produce a plot of the batch flux (the rate of solids transport to settling across a unit area) versus the solids concentration. There are two procedures in general use.

Kynch's Method

Kynch's (1952) batch settling analysis is frequently employed. The movement of the interface is monitored and plotted as in Fig. 9.10. The settling velocity of the interface is obviously the velocity of the particles in it, and it can be calculated as the slope of the interface height-time plot:

$$v_X = \frac{z' - z}{t} \tag{9.209}$$

where t = the sampling time (sec)
v_X = the settling velocity of the particles (which are at concentration X) in the interface (m/s or ft/sec)
z = the height of the interface at time t (m or ft)
z' = the height of the vertical intercept of the tangent line to the interface height-time plot (m or ft)

Initially the slope is linear, and the calculated velocity is the velocity of the suspension's initial concentration. As settling proceeds, the interface particle concentration increases, and its settling velocity decreases, which is indicated by the gradual flattening of the interface/time plot. The interface concentration at any time can be calculated from Kynch's (1952) formula:

$$X = \frac{X_o z_o}{z'} \tag{9.210}$$

where X = the interface suspended solids concentration (kg/m^3 or lb/ft^3)
X_0 = the initial, homogeneous suspended solids' concentration (kg/m^3 or lb/ft^3)
z_0 = the initial interface height and the liquid depth (m or ft)

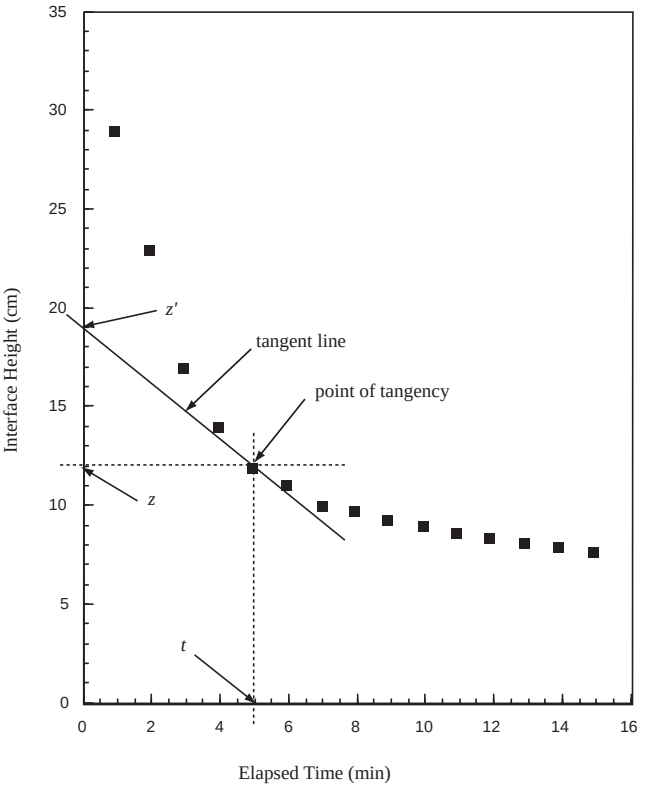

FIGURE 9.10 Typical interface height-time plot for hindered settling.

Note that the elevation in the denominator is the intercept of the extrapolated tangent to the interface height/time curve; it is not the elevation of the interface.

The batch flux for any specified solids concentration is as follows:

$$F = v_X X \tag{9.211}$$

where F = the flux of solids settling through a horizontal plane in a batch container (kg/m^2·s or lb/ft^2·sec).

In the derivation of Eq. (9.210), Kynch shows that if the water is stationary, a concentration layer that appears on the bottom of the settling column travels at a constant velocity upwards until it intersects the interface. The concentration exists momentarily at the interface and then is replaced by another higher concentration. Dick and Ewing (1967) reviewed earlier studies and concluded that there were several deficiencies with the Kynch analysis, namely:

- Concentration layers do not travel at constant velocities, at least in clay suspensions.
- Stirring the bottom of a suspension increases the rate of subsidence of the interface.
- The Talmadge–Fitch (1955) procedure, which is an application of Kynch's method for estimating interface concentrations, underestimates the settling velocities at high sludge concentrations (Fitch, 1962; Alderton, 1963).

Vesilind (1974) recommends that this method not be used for designing thickeners for wastewater sludges or for other highly compressible sludges.

Initial Settling Velocity Method

Most engineers prefer to prepare a series of dilutions of the sludge to be tested and to determine only the initial settling velocity that occurs during the linear portion of the interface height/time curve. The

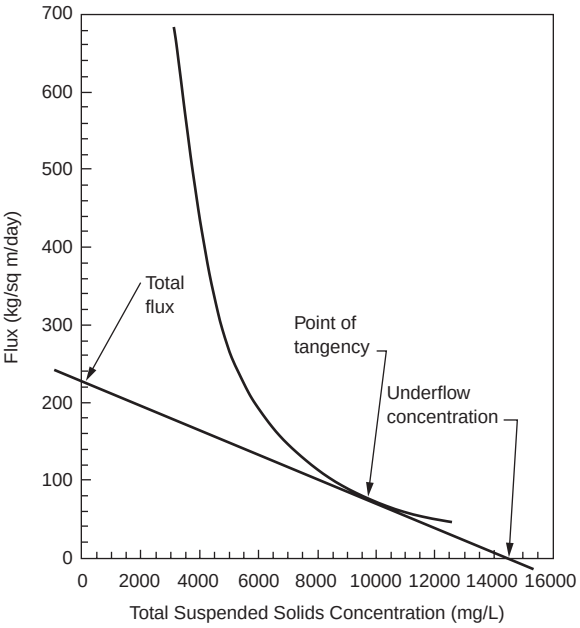

FIGURE 9.11 Yoshioka construction for the total flux.

resulting correlation between the initial settling velocities and the initial solids concentration can usually be represented by the simple decaying exponential proposed by Duncan and Kawata (1968):

$$v_{X_o} = aX_o^{-b} \tag{9.212}$$

where a = a positive constant (units vary)
b = a positive constant (dimensionless)
X_0 = the initial suspended solids concentration in the column (kg/m^3 lb/ft^3)
v_{X0} = the settling velocity for a suspended solids' concentration of X_0 (m/s or ft/sec)

The batch flux for each intial concentration is calculated using Eq. (9.211), and it is plotted versus the suspended solids concentration. An example is shown in Fig. 9.11. This method assumes that the concentration in the interface is not changing as long as the height–time plot is linear, and by doing so, it necessarily entails Kynch's theory.

Thickener Design

Thickeners can conceptually be divided into three layers. On the top is a clear water zone in which free, flocculent settling occurs. Below this is a sludge blanket. The upper portion of the sludge blanket is a zone of hindered settling. The lower portion is a zone of compression. Many engineers believe that the particles in the compression zone form a self-supporting lattice, which must be broken down by gentle mixing. The compression zone may not exist in continuous flow thickeners.

Hindered Settling Zone

In free settling, the critical loading parameter is the hydraulic flow per unit plan area (e.g., m^3/m^2·s or ft^3/ft^2·sec). In hindered settling, the critical loading parameter is the total solids flux, which is the solids mass loading rate per unit area (e.g., kg/m^2·s or lbm/ft^2·sec). The result of a hindered settling analysis is the required thickener cross-sectional area. The depth must be determined from a consideration of the clarification and compression functions of the thickener.

The total solids flux can be expressed three ways for an efficient thickener, each of which yields the same numerical value. First, it is the total solids loading in the influent flow divided by the plan area of the clarifier. For an activated sludge plant or a lime-soda plant with solids recycling, this would be calculated as

$$F_t = \frac{(Q + Q_r)X_i}{A} \tag{9.213}$$

where A = the thickener plan area (m^2 or ft^2)
F_t = the total solids flux ($kg/m^2 \cdot s$ or $lb/ft^2 \cdot sec$)
Q = the design water or wastewater flow rate (m^3/s or ft^3/sec)
Q_r = the recycle flow rate (m^3/s or ft^3/sec)
X_i = the suspended solids' concentration in the flow entering the thickener (kg/m^3 or lb/ft^3)

Second, it can be calculated as the flux through the sludge blanket inside the thickener divided by the plan area. In a continuous flow thickener, this consists of the flux due to the water movement through the tank plus the flux due to the settling of particles through the moving water. If sludge is wasted from the thickener underflow, the total water flow through the sludge blanket and in the underflow is $Q_r + Q_w$:

$$F_t = \frac{(Q_r + Q_w)X_c + v_{X_c}X_c}{A} \tag{9.214}$$

where Q_w = the waste sludge flow rate (m^3/s or ft^3/sec)
v_{Xc} = the settling velocity at a suspended solids' concentration X_c (m/s or ft/sec)
X_c = the suspended solids' concentration in the sludge blanket in the thickener (kg/m^3 or lb/ft^3)

Third, it is equal to the solids in the underflow divided by the tank area:

$$F_t = \frac{(Q_r + Q_w)X_u}{A} \tag{9.215}$$

where X_u = the suspended solids' concentration in the clarifier underflow (kg/m^3 or lb/ft^3).

Two design methods for continuous flow thickeners that are in common use are the Coe–Clevenger (1916) procedure and the Yoshioka et al. (1957) graphical method. These procedures are mathematically equivalent, but the Yoshioka method is easier to use.

The Yoshioka construction is shown in Fig. 9.11. First, the calculated batch fluxes are plotted against their respective suspended solids concentrations. Then, the desired underflow concentration is chosen, and a straight line is plotted (1) from the underflow concentration on the abscissa, (2) through a point of tangency on the batch flux curve, and (3) to an intercept on the ordinate. The intercept on the ordinate is the total flux that can be imposed on the thickener, F_t. Equation (9.213), (9.214), or (9.215) is then used to calculate the required plan area. Parker (1983) recommends that the peak hydraulic load rather than the average hydraulic load be used in the calculation.

If the right-hand side of Eq. (9.214) is plotted for all possible values of X_c, it will be found that F_t is the minimum of the function (Dick, 1970). Consequently, Eq. (9.212) may be used to eliminate v_{Xc} from Eq. (9.214), and the minimum of the total flux formula may be found by differentiating with respect to X_c (Dick and Young, no date):

$$F_t = \left[a(b-1)\right]^{1/b}\left(\frac{b}{b-1}\right)\left(\frac{Q_r + Q_w}{A}\right)^{(b-1)/b} \tag{9.216}$$

Clarification Zone

Clarification is impaired if the sludge blanket comes too close to the water surface and if the overflow rate is too high. If effluent suspended solids concentrations must be consistently below about 20 mg/L, then a clarifier side water depth must be at least 16 ft, and the overflow rate must be less than 600 gpd/ft^2 (Parker, 1983).

Compression Zone

If high sludge solids concentrations are required, a compression zone may form. Its depth can be estimated from the Roberts–Behn formula in terms of the suspension dilution, D, which is defined to be the mass of water in the sludge divided by the mass of particles (Roberts, 1949; Behn, 1957),

$$D_t - D_\infty = \left(D_o - D_\infty\right)e^{-Kt} \tag{9.217}$$

where D_0 = the initial dilution (kg water/kg solids or lb water/lb solids)
D_t = the dilution at time t (kg water/kg solids or lb water/lb solids)
D_∞ = the ultimate dilution (kg water/kg solids or lb water/lb solids)
K = the rate constant (per sec)
t = the elapsed compression time (sec)

or, alternatively, in terms of the interface height, H, (Behn and Liebman, 1963),

$$H_t - H_\infty = \left(H_o - H_\infty\right)e^{-Kt} \tag{9.218}$$

where H_0 = the initial interface height (m or ft)
H_t = the interface height at time t (m or ft)
H_∞ = the ultimate interface height (m or ft)

These are connected by

$$D_t = \frac{\rho H_t}{X_o H_o} - \frac{\rho}{\rho_p} \tag{9.219}$$

where ρ = the water density (kg/m^3 or lb/ft^3)
ρ_p = the density of the particles (kg/m^3 or lb/ft^3)

The unknown is the time required to achieve the desired compressive thickening. The compression parameters are D_o (or H_o), D_8 (or H_8) and K, and these are determined from a batch settling test. The computational procedure is iterative. One selects a trial value for D_8 (or H_8) and plots the differences on semi-log paper. If the data come from the compression region, a value of the ultimate dilution factor or depth can be found that will produce a straight line.

The volume of the compression zone that produces the required underflow dilution factor, D_u, is given by (Behn and Liebman, 1963),

$$V_{cz} = \left(Q + Q_r\right)X_i\left(\frac{t_u}{\rho_p} + \frac{D_o - D_u}{\rho K} + \frac{D_\infty t_u}{\rho}\right) \tag{9.220}$$

where t_u = the compression time required to produce a dilution ratio of D_u (sec)
V_{cz} = the volume of the compression zone (m^3 or ft^3)
X_i = the suspended solids concentration in the influent flow (kg/m^3 or lb/ft^3)

The compression time to reach the underflow dilution factor, t_u, is calculated from Eq. (9.220) once D_u is selected. The depth of the compression zone is calculated by dividing the compression zone volume by the plan area determined from the hindered settling analysis.

In Behn's (1957) soil consolidation theory of compression, the parameter K depends on the depth at which compression begins, H_o:

$$K = \frac{k(\rho_p - \rho)g}{\gamma H_o} \tag{9.221}$$

where k = Darcy's permeability coefficient (m/s or ft/sec).

This relationship arises because the force that expels water from the sludge is the net weight of the solids. Consequently, one can expect the parameter K to vary with the depth of the compression zone in the thickener. An iterative solution is required. The value of K determined from the batch settling test is used to get a first estimate of the compression zone volume and depth. The calculated depth is then compared with the value of H_o that occurred in the test, and K is adjusted accordingly until the calculated depth matches H_o.

Rules of Thumb

Commonly used limits on total solids fluxes on activated sludge secondary clarifiers for the maximum daily flow and maximum return rate are (Wastewater Committee, 1990):

- Conventional — F_t = 50 lb/ft^2·day
- Extended aeration — F_t = 35 lb/ft^2·day
- Second-stage nitrification — F_t = 35 lb/ft^2·day

Current practice for average flow conditions is around 20 to 30 lb/ft^2·day (Joint Task Force, 1992).

9.6 Filtration

Granular Media Filters

Particle Removal Mechanisms

The possible removal mechanisms are as follows (Ives, 1975; Tien, 1989):

- Mechanical straining — Straining occurs when the particles are larger than the local pore. It is important only if the ratio of particle diameter to pore size is larger than about 0.2 (Herzig, Leclerc, and Le Goff, 1970). Straining is undesirable, because it concentrates removed particles at the filter surface and reduces filter runs.
- Sedimentation — The effective horizontal surface in sand filters is roughly 3% of the surface area of the sand grains, and this amounts to nearly 400 times the plan area of the bed for each meter of sand depth (Fair and Geyer, 1954). Consequently, filters act in part like large sedimentation basins (Hazen, 1904).
- Inertial impact — Particles tend to persist in moving in a straight line, and if they are large enough, their momentum may overcome the liquid drag forces and lead to a collision with the media.
- Hydrodynamic diffusion — Because of the liquid velocity variation across the particle diameter, there is a net hydrodynamic force on the particle normal to the direction of flow. If the particles are spherical and the velocity gradient is linear (laminar flow), this force moves the particle toward high velocities and away from any media surface. However, if particle shape is irregular and the flow field is nonuniform and unsteady (turbulent flow), the particle drift appears to be random. In the first case, removals are reduced. In the second case, random movements produce a turbulent diffusion, with transport from high concentration to low concentration areas. Particle adsorption produces a low concentration region near the media surface, so the hydrodynamic diffusion transports particles to the media.
- Interception — If the liquid stream lines bring a particle center to within one particle radius of the media surface, the particle will strike the surface and may adhere.

- Brownian diffusion — Brownian diffusion will cause particles to move from high concentration zones to low concentration zones. Adsorption to the media surface creates a low concentration zone near the media, so Brownian diffusion will transport particles from the bulk flow toward the media.
- Electrostatic and London–Van der Waals attraction — Electrical fields due to electrostatic charges or to induced London–Van der Waals fields, may attract or repel particles and media.
- Adhesion — Once the particles collide with the media surface, they must adhere. Adhesion occurs with the clean media surface and with particles already collected on the surface. Consequently, particles that are to be removed must be colloidally unstable (Gregory, 1975).

Performance

In general, granular media filters remove particles that are much smaller than the pore opening. Also, transport to the media surface depends on the local particle concentration in the flow. The result is that particle removal is more or less exponential with depth. This is usually expressed as Iwasaki's (1937) Law:

$$\frac{X}{X_o} = e^{-\lambda H} \tag{9.222}$$

where H = the depth of filter media (m or ft)
X = the suspended solids concentration leaving the filter (kg/m^3 or lb/ft^3)
X_o = the suspended solids concentration entering the filter (kg/m^3 or lb/ft^3)
λ = the filter coefficient (per m or per ft)

Ives and Sholji (1965) and Tien (1989) summarized empirical data for the dependence of the Iwasaki filter coefficient upon diameter of the particle to be removed, d_p, the diameter of the filter media, d_m, the fitration rate, U_f, and the water viscosity, μ. The dependencies have the following form:

$$\lambda \propto \frac{d_p^{\alpha}}{U_f^{\beta} d_m^{\gamma} \mu^{\delta}} \tag{9.223}$$

The exponents on the variables are highly uncertain and system specific, but α appears to be on the order of 1 to 1.5; β appears to be on the order of 0.5 to 2; γ appears to be on the order of 0.5 to 2; and δ appears to be on the order of 1. A worst-case scenario may be estimated by adopting the most unfavorable exponent for a suggested process change.

For practical design purposes, γ is sometimes taken to be 1, and filter depth and media size are traded off according to (James M. Montgomery, Consulting Engineers, Inc., 1985),

$$\frac{H_1}{d_{m1}} = \frac{H_2}{d_{m2}} \tag{9.224}$$

The Committee of the Sanitary Engineering Division on Filtering Materials (1936) reported that the depth of penetration of suspended solids (silts and flocs) into filter media was more or less proportional to the square of the media particle diameter. In the Committee's studies, the coefficient of proportionality ranged from about 10 to 25 in./mm^2, and it appeared to be a characteristic of the specific sand source. They recommended Allan's procedure for formulating sand specifications, which reduces to

$$H_{\min} = \sum_{i=1}^{n} H_i \propto \frac{1}{\sum_{i=1}^{n} \frac{f_i}{d_{mi}^2}} \tag{9.225}$$

where d_{mi} = the grain diameter of media size class i (m or ft)
f_i = the fraction by weight of media size d_{mi} (dimensionless)
H_i = the depth of filter media size d_{mi} (m or ft)
$H_{\min}$ = the minimum depth of media (m or ft)

Equation (9.225) was derived by assuming that the penetration of suspended particles into the sand mixture should be equal to the penetration into any single grade.

Because the removal rate is exponential, there is no combination of filtration rate or media depth that will remove all particles. A minimum filtered water turbidity of 0.1 to 0.2 seems to be the best that can be expected; this minimum will be proportional to the influent turbidity.

For many years, the standard filtration rate in the U.S. was 2 gpm/ft^2, which is usually attributed to Fuller's (1898) studies at Louisville. Cleasby and Baumann (1962) have shown that increasing the filtration rate to 6 gpm/ft^2 triples the effluent turbidity, but that turbidities less than 1 TU were still achievable at the higher rate. Their filters held 30 in. of sand, either with an effective size of 0.5 mm and a uniformity coefficient of 1.89 or sieved to lie between 0.59 and 0.84 mm. The suspended particles were ferric hydroxide flocs. Reviewing a number of filtration studies, Cleasby (1990) concluded that filtration rates up to 4 gpm/ft^2 were acceptable as long as coagulation of the raw water is nearly complete and no sudden increases in filtration rate occur. Higher filtration rates required filter aids, but effluent turbidities of less than 0.5 NTU are achievable.

Fair and Geyer (1954) summarized whole-plant coliform removal data reported by the U.S. Public Health Service as Eq 322:

$$C_f = aC_o^b \tag{9.226}$$

where a,b = empirical coefficients
C_o = the concentration of total coliform bacteria in the raw, untreated water in no./100 mL
C_f = the finished water concentration of total coliform bacteria in no./100 mL

Values of the coefficients for different plant designs are shown in Table 9.4. Also shown is the concentration of bacteria in the filter influent, C_{pi}, that will permit achievement of a finished water concentration of 1/100 mL. The filtration rates, bed depths, and grain sizes were not specified.

Hazen's (1896) empirical rule for the proportion of bacteria passing through filters is

$$P_{pass} = \tfrac{1}{2}\frac{U_f^2 d_{es}}{\sqrt{H}} \tag{9.227}$$

where d_{es} = the effective size on the filter media in mm
H = the media depth (in.)
P_{pass} = the percentage of the bacteria passing through the filter
U_f = the filtration rate in mgd

TABLE 9.4 Coliform Removal Efficiencies For Different Water Treatment Plant Configurations

	Turbid River Water			Clear Lake Water		
Treatment Process	a	b	C_{pi}	a	b	C_{pi}
Chlorination only	0.015	0.96	80	0.050	0.76	50

Flocculation, settling, filtration, postchlorination	0.011	0.52	6000	0.040	0.38	4500

Source: Fair, G.M. and Geyer, J.C. 1954. *Water Supply and Waste-Water Disposal*, John Wiley & Sons, Inc., New York.

Hazen's formula appears to approximate the median of a log-normal distribution. Approximately 40% of the cases will lie between one-half and twice the predicted value. In somewhat less than one-fourth of the cases, the percentage passing will be greater than twice the predicted value. One-sixth of the cases will exceed four times the predicted value. The proportion of cases exceeding 10 times the predicted value is less than 1%.

Immediately after backwashing, the water in the filter pores is turbid, and the initial product following the startup of filtration must be discarded. Approximately 10 bed volumes must be discarded to obtain stable effluent suspended solids concentrations (Cleasby and Baumann, 1962).

Water Balance and Number of Filter Boxes

The water balance (in units of volume) for a rapid sand filter for a design period T is,

$$\underbrace{U_f A t_f}_{\text{gross product}} = \underbrace{U_b A t_b}_{\text{wash water}} + \underbrace{F_p P Q_{pc} T}_{\text{community demand}} \tag{9.228}$$

where A = the plan area of the filter media (m^2 or ft^2)
F_p = the peaking factor for the design period (dimensionless)
P = the projected service population (capita)
Q_{pc} = the per caput water demand ($m^3/s \cdot cap$ or $ft^3/sec \cdot cap$)
T = the design period (sec)
T_b = the time spent backwashing during the design period (sec)
T_f = the time spent filtering during the design period (sec)
U_b = the backwash rate (m/s or ft/sec)
U_f = the filtration rate (m/s or ft/sec)

The design period T is determined by balancing costs of storage vs. filtration capacity. It is typically on the order of one to two weeks. The peaking factor F_p corresponds to the design period. Typical values are given in Tables 8.11 and 8.12. The service population P is the projected population, usually 20 years hence.

A commonly used filtration rate is 4 gpm/ft^2. The duration of the filter run is determined by the required effluent quality. A rough rule of thumb is that the filter must be cleaned after accumulating 0.1 lbm suspended solids per sq ft of filter area per ft of headloss (Cleasby, 1990). Actual filters may capture between one-third and three times this amount before requiring cleaning.

Backwash rates depend on the media and degree of fluidization required. Full fluidization results in a bed expansion of 15 to 30%. Backwashing is continued until the wash water is visibly clear, generally about 10 min.

The economical number of filters is often estimated using the Morrill–Wallace (1934) formula:

$$n = 2.7\sqrt{Q_{des}} \tag{9.229}$$

where n = the number of filter boxes (dimensionless)
Q_{des} = the plant design flow in mgd

Filter Box Design

The usual requirement is that there be at least two filters, each of which must be capable of meeting the plant design flow (Water Supply Committee, 1987). If more than two filters are built, they must be capable of meeting the plant design flow with one filter out of service. The dimensions of rapid sand filters are more or less standardized and may be summarized as follows (Babbitt, Doland, and Cleasby, 1967; Joint Task Force, 1990; Culp/Wesner/Culp, Inc., 1986; Kawamura, 1991).

Vertical Cross Section

The vertical cross section of a typical rapid sand filter box is generally at least 8 to 10 ft deep (preferably deeper to avoid air binding) above the floor and consists of the following layers:

- At least 12 and more likely 16 to 18 in. of gravel and torpedo sand
- 24 to 30 in. of filter media, either fine or coarse sand or sand and crushed anthracite coal
- At least 6 ft of water, sufficient to avoid negative or zero guage pressures anywhere in the filter and consequent air binding
- At least 6 in. of freeboard, and preferably more, to accommodate surges during backwashing

The backwash troughs are placed sufficiently high that the top of the expanded sand layer is at least 18 in. below the trough inlets.

Plan Dimensions

The plan area of the sand beds of gravity filters generally does not exceed 1000 ft^2, and larger sand beds are constructed as two subunits with separate backwashing.

Filters are normally arranged side by side in two parallel rows with a pipe gallery running between the rows. The pipe gallery should be open to daylight to facilitate maintenance.

Wash Water Effluent Troughs

The design of wash water effluent troughs is discussed earlier in Section 9.5, "Sedimentation." The troughs are submerged during filtration.

Air Scour

A major problem with air scour systems is disruption of the gravel layer and gravel/sand mixing. The gravel layer is eliminated in the nozzle/strainer and porous plate false bottom systems, and special gravel designs are used in the perforated block with gravel systems.

In some European designs (Degrémont, 1965), wash water over flow troughs are dispensed with, and the wash water is discharged over an end wall. The sand bed is not fluidized, and air scour and backwash water are applied simultaneously. An additional, simultaneous cross-filter surface flow of clarified water is used to promote movement of the dirty wash water to the wash water effluent channel.

Floor Design

Filter floors serve three essential purposes: (1) they support the filter media, (2) they collect the filtrate, and (3) they distribute the backwash water. In some designs, they also distribute the air scour. The usual designs are as follows (Cleasby, 1990; Joint Task Force, 1990; Kawamura, 1991):

- *Pipe laterals with gravel* consist of a manifold with perforated laterals placed on the filter box floor in at least 18 in. of gravel. The coarsest gravel must be deeper than the perforated laterals (at least 6 in. total depth), and there must be at least 10 to 16 in. of finer gravel and torpedo sand above the coarsest gravel. Precast concrete inverted "V" laterals are also available. The lateral orifices are drilled into the pipe bottoms or "V" lateral sides and are normally about 1/4 to 3/4 in. in diameter and 3 to 12 in. apart.
- The usual rules-of-thumb regarding sizing are (1) a ratio of orifice area to filter plan area of 0.0015 to 0.005, (2) a ratio of lateral cross-sectional area to total orifice area served of 2 to 4, and (3) a ratio of manifold cross-sectional area to lateral cross-sectional area served of 1.5 to 3.
- These systems generally exhibit relatively high headlosses and inferior backwash distribution and are discouraged. Poor backwash distribution can lead to gravel/sand mixing. This is aggravated by air scour, and air scour should not be applied through the laterals.
- *Blocks with gravel* consist of ceramic or polyethylene blocks overlain by at least 12 in. gravel. The blocks are grouted onto the filter box flow and to each other. The blocks are usually about 10 in. high by 11 in. wide by 2 ft long. The tops are perforated with 5/32 to 5/16 in. orifices typically numbering about 45 per sq ft. The filtrate and backwash water flow along channels inside the

block that run parallel to the lengths. Special end blocks discharge vertically into collection channels built into the filter box floor.

- Special gravel designs at least 12 to 15 in. deep are required if air scour is applied through the blocks. Porous plates and nozzle/strainer systems are preferred for air scour.
- *False bottoms with gravel* consist of precast or cast-in-place plates that have inverted pyramidal 3/4 in. orifices at 1 ft internals horizontally that are filled with porcelain spheres and gravel. The plates are installed on 2 ft high walls that sit on the filter box floor, forming a crawl space. The gravel layer above the false bottom is at least 12 in. deep. The flow is through the crawl space between the filter box floor and the false bottom.
- *False bottom without gravel* consists of precast plates or cast-in-place monolithic slabs set on short walls resting on the filter box floor. The walls are at least 2 ft high to provide a crawl space for maintenance and inspection. Cast-in-place slabs are preferred, because they eliminate air venting through joints. The plates are perforated, and the perforations contain patented nozzle/strainers that distribute the flow and exclude the filter sand. These systems are commonly used with air scour, which is applied through the nozzle/strainers.
- The nozzle/strainer openings are generally small, typically on the order of 0.25 mm, and are subject to clogging from construction debris, rust, and fines in the filter media and/or gravel. The largest available opening size should be used, and the effective size of the filter media should be twice the opening size. Some manufacturers recommend a 6 in. layer of pea stone be placed over the nozzles to avoid sand and debris clogging of the nozzle openings.
- Plastic nozzle/strainers are easily broken during installation and placement of media. Nozzle-strainer materials must be carefully matched to avoid differential thermal expansion and contraction.
- *Porous plates* consist of sintered aluminum oxide plates mounted on low walls or rectangular ceramic saddles set on the filter box floor. These systems are sometimes used when air scour is employed.
- The plates are fragile and easily broken during installation and placement of media. They are subject to the same clogging problems as nozzle/strainers. They are not recommended for hard, alkaline water, lime-soda softening installations, iron/manganese waters, or iron/manganese removal installations.

Good backwash distribution requires that headloss of the orifices or pores exceed all other minor losses in the backwash system.

Hydraulics

Filter hydraulics are concerned with the clean filter headloss, which is needed to select rate-of-flow controllers, and the backwashing headloss.

Clean Filter Headloss

For a uniform sand, the initial headloss is given by the Ergun (1952) equation:

$$\frac{\Delta p}{\gamma} = h_L = f_m \left(\frac{H}{d_{eq}} \right) \left(\frac{1-\varepsilon}{\varepsilon^3} \right) \left(\frac{U_f^2}{g} \right) \tag{9.230}$$

where A_p = the cross-sectional area of a sand grain (m^2 or ft^2)
d_{eq} = the equivalent diameter of a nonspherical particle (m or ft)
$= 6\ (V_p/A_p)$
g = the acceleration due to gravity (9.80665 m/s^2 or 32.174 ft/sec^2)
f_m = the MacDonald–El-Sayed–Mow–Dullien friction factor (dimensionless)
H = the thickness of the media layer (m or ft)
h_L = the headloss (m or ft)

Δp = the pressure drop due to friction (Pa or lbf/ft^2)
U_f = the filtration rate (m/s or ft/sec)
V_p = the volume of a sand grain (m^3 or ft^3)
ε = the bed porosity (dimensionless)
γ = the specific weight of the water (N/m^3 or lbf/ft^3)

The friction factor f_m is given by the MacDonald–El-Sayed–Mow–Dullien (1979) equation:

$$f_m \geq 180\frac{1-\varepsilon}{\boldsymbol{Re}} + 1.8, \text{ for smooth media;} \tag{9.231}$$

$$f_m \leq 180\frac{1-\varepsilon}{\boldsymbol{Re}} + 4.0, \text{ for rough media;} \tag{9.232}$$

$$\boldsymbol{Re} = \frac{\rho U_f d_{eq}}{\mu} \tag{9.233}$$

where μ = the dynamic viscosity of water (N·s/m^2 or lbf·sec/ft^2)
ρ = the water density (kg/m^3 or lbm/ft^3)

For filters containing several media sizes, the Fair and Geyer (1954) procedure is employed. It is assumed that the different sizes separate after backwashing and that the bed is stratified. The headloss is calculated for each media size by assuming that the depth for that size is,

$$H_i = f_i H \tag{9.234}$$

where f_i = the fraction by weight of media size class i (dimensionless)
H = the depth of the settled filter media (m or ft)
H_i = the depth of filter media size class i (m or ft)

The Fair–Geyer method yields a lower bound to the headloss. Filters do not fully stratify unless there is a substantial difference in terminal settling velocities of the media sizes. In a partially stratified filter, the bed porosity will be reduced because of intermixing of large and fine grains, and the headloss will be larger than that predicted by the Fair–Geyer method. An upper bound can be found by assuming that the entire bed is filled with grains equal in size to the effective size.

Backwashing

The headloss required to fluidize a bed is simply the net weight of the submerged media:

$$\frac{\Delta p}{\gamma} = h_L = H(\rho_s - \rho)(1-\varepsilon) \tag{9.235}$$

where ρ_p = the particle density (kg/m^3 or lbm/ft^3).

During backwashing, the headloss increases according to Eq. (9.230) until the headloss specified by Eq. (9.235) is reached; thereafter, the backwashing headloss is constant regardless of flow rate (Cleasby and Fan, 1981).

The only effect of changing the flow rate in a fluidized bed is to change the bed porosity. The expanded bed porosity can be estimated by the Richardson–Zaki (1954) equation:

$$\varepsilon_e = \left(\frac{U_b}{v_s}\right)^{\boldsymbol{Re}^{0.03}/4.35}, \text{ for } 0.2 < \boldsymbol{Re} < 1 \tag{9.236}$$

$$\varepsilon_e = \left(\frac{U_b}{v_s}\right)^{Re^{0.1}/4.45}, \text{ for } 1 < \boldsymbol{Re} < 500 \tag{9.237}$$

where U_b = the backwashing rate (m/s or ft/sec)
v_s = the free (unhindered) settling velocity of a media particle (m/s or ft/sec)
ε_e = the expanded bed porosity (dimensionless)

The Reynolds number is that of the media grains in free, unhindered settling:

$$\boldsymbol{Re} = \frac{\rho v_s d_{eq}}{\mu} \tag{9.238}$$

The free settling velocity can be estimated by Stokes' (1856) equation,

$$C_D = \frac{24}{\boldsymbol{Re}}, \text{ for } \boldsymbol{Re} < 0.1 \tag{9.137}$$

$$v_s = \frac{g(\rho_p - \rho)d_{eq}^2}{18\mu} \tag{9.138}$$

or by Shepherd's equation (Anderson, 1941),

$$C_D = \frac{18.5}{\boldsymbol{Re}^{0.60}}; \text{ for } 1.9 < \boldsymbol{Re} < 500 \tag{9.144}$$

$$v_s = 0.153 d_{eq}^{1.143}\left[\frac{g(\rho_p - \rho)}{\rho^{0.40}\mu^{0.60}}\right]^{0.714} \tag{9.145}$$

Generally, the particle size greater than 60% by weight of the grains, d_{60}, is used. The Reynolds number for common filter material is generally close to 1, and because of the weak dependence of bed expansion on Reynold's number (raised to the one-tenth power), it is often set arbitrarily to 1.

The depth of the expanded bed may be calculated from

$$H_e = H\frac{1-\varepsilon}{1-\varepsilon_e} \tag{9.239}$$

where H_e = the expanded bed depth (m or ft).

The maximum backwash velocity that does not fluidize the bed, U_{mf} can be estimated by setting the expanded bed porosity in Eqs. (9.236) or (9.237) equal to the settled bed porosity. Alternatively, one can use the Wen–Yu (1966) correlation:

$$\boldsymbol{Ga} = \frac{\rho(\rho_p - \rho)g d_{eq}^3}{\mu} \tag{9.240}$$

$$U_{mf} = \frac{\mu\left(33.7^2 + 0.0408\boldsymbol{Ga}\right)^{0.5}}{\rho d_{eq}} - \frac{33.7\mu}{\rho d_{eq}} \tag{9.241}$$

where **Ga** = the Gallileo number (dimensionless)
U_{mf} = the minimum bed fluidization backwash rate (m/s or ft/sec).

In dual media filters, the expansion of each layer must be calculated, separated, and totalled. Each layer will experience the same backwash flow rate, but the minimum flow rates required for fluidization will differ.

The optimum expansion for cleaning without air scour is about 70%, which corresponds to maximum hydraulic shear (Cleasby, Amirtharajah, and Baumann, 1975).

Fluidization alone is not an effective cleaning mechanism, and fluidization plus air scour is preferred. Air scour is applied alone followed by bed fluidization or applied simultaneously with a backwash flow rate that does not fluidize the bed. The latter method is the most effective cleaning procedure.

For typical fine sands with an effective size of about 0.5 mm, air scour and backwash are applied separately. Generally, air is applied at a rate of about 1 to 2 scfm/ft^2 for 2 to 5 min followed by a water rate of 5 to 8 gpm/ft^2 (nonfluidized) to 15 to 20 gpm/ft^2 (fully fluidized) (Cleasby, 1990). Backwash rates greater than about 15 gpm/ft^2 may dislodge the gravel layer.

Simultaneous air scour and backwash may be applied to dual media filters and to coarse grain filters with effective sizes of about 1 mm or larger. Airflow rates are about 2 to 4 scfm/ft^2, and water flow rates are about 6 gpm/ft^2 (Cleasby, 1990).

Amirtharajah (1984) developed a theoretical equation for optimizing airflow and backwash rates:

$$0.45Q_a^2 + 100\left(\frac{U_b}{U_{mf}}\right) = 41.9 \tag{9.242}$$

where Q_a = the airflow rate (scfm/ft^2)
U_b = the backwash rate (m/s or ft/sec)
U_{mf} = the minimum fluidization velocity based on the d_{60} grain diameter (m/s or ft/sec)

Equation (9.242) may overestimate the water flow rates (Cleasby, 1990).

Water Treatment

U.S. EPA Surface Water Treatment Rule

Enteric viruses and the cysts of important pathogenic protozoans like *Giardia lamblia* and *Cryptosporidium parvum* are highly resistant to the usual disinfection processes. The removal of these organisms from drinking water depends almost entirely upon coagulation, sedimentation, and filtration. Where possible, source protection is helpful in virus control.

The U.S. Environmental Protection Agency (U.S. EPA, 1989; Malcolm Pirnie, Inc., and HDR Engineering, Inc., 1990) issued treatment regulations and guidelines for public water supplies that use surface water sources and groundwater sources that are directly influenced by surface waters. Such systems are required to employ filtration and must achieve 99.9% (so-called "three log") removal or inactivation of *G. lamblia* and 99.99% (so-called "four log") removal or inactivation of enteric viruses. Future treatment regulations will require 99% ("two log") removal of *Cryptosporidium parvum* (U.S. EPA, 1998). The current performance requirements for filtration are that the filtered water turbidity never exceed 5 TU and that individual filter systems meet the following turbidity limits at least 95% of the time:

- Conventional rapid sand filters preceded by coagulation, flocculation, and sedimentation — 0.5 TU
- Direct filtration — 0.5 TU
- Cartridge filters and approved package plants — 0.5 TU
- Slow sand filters — 1.0 TU
- Diatomaceous earth filters — 1.0 TU

Public supplies can avoid the installation of filters if they meet the following basic conditions (Pontius, 1990):

- The system must have an effective watershed control program.
- Prior to disinfection, the fecal and total coliform levels must be less than 20/100 mL and 100/100 mL, respectively, in at least 90% of the samples.
- Prior to disinfection, the turbidity level must not exceed 5 TU in samples taken every 4 hr.
- The system must practice disinfection and achieve 99.9 and 99.99% removal or inactivation of *G. lamblia* cysts and enteric viruses, respectively, daily.
- The system must submit to third-party inspection of its disinfection and watershed control practices.
- The system cannot have been the source of a water-borne disease outbreak, unless it has been modified to prevent another such occurrence.
- The system must be in compliance with the total coliform rule requirements.
- The system must be in compliance with the total trihalomethane regulations.

The *Guidance Manual* (Malcolm Pirnie, Inc., and HDR Engineering, Inc., 1990) lists other requirements and options.

Media

The generally acceptable filtering materials for water filtration are silica sand, crushed anthracite coal, and granular activated carbon (Water Supply Committee, 1987; Standards Committee on Filtering Material, 1989):

- Silica sand particles shall have a specific gravity of at least 2.50, shall contain less than 5% by weight acid-soluble material and shall be free (less than 2% by weight of material smaller than 0.074 mm) of dust, clay, micaceous material, and organic matter.
- Crushed anthracite coal particles shall have a specific gravity of at least 1.4, a Mohr hardness of at least 2.7, and shall contain less than 5% by weight of acid-soluble material and be free of shale, clay, and debris.

In addition, filters normally contain a supporting layer of gravel and torpedo sand that retains the filtering media. In general, the supporting gravel and torpedo sand should consist of hard, durable, well-rounded particles with less than 25% by weight having a fractured face, less than 2% by weight being elongated or flat pieces, less than 1% by weight smaller than 0.074 mm, and less than 0.5% by weight consisting of coal, lignin, and organic impurities. The acid solubility should be less than 5% by weight for particles smaller than 2.36 mm, 17.5% by weight for particles between 2.36 and 25.4 mm, and less than 25% for particles equal to or larger than 25.4 mm. The specific gravity of the particles should be at least 2.5.

The grain size distribution is summarized in terms of an "effective size" and a "uniformity coefficient:"

- The effective size (e.s.) is the sieve opening that passes 10% by weight of the sample.
- The uniformity coefficient (U.C.) is the ratio of the sieve opening that passes 60% by weight of the sample and then the opening that passes 10% by weight of the same sample.

Typical media selections for various purposes are given in Table 9.5.

Single Media Filters

The typical filter cross section for a single-media filter (meaning either sand, coal, or GAC used alone) is given in Table 9.6. The various media are placed coarsest to finest from bottom to top, and the lowest layer rests directly on the perforated filter floor. Various manufacturers recommend different size distributions for their underdrain systems; two typical recommendations are given in Table 9.7. Kawamura (1991) recommends a minimum gravel depth of 16 in. in order to avoid disruption during backwashing.

TABLE 9.5 Media Specification for Various Applications (Uniformity Coefficient 1.6 to 1.7 for Medium Sand and 1.5 for Coarse Sand or Coal)

Process	Media	Effective Size (mm)	Depth (ft)
Coagulation, settling, filtration; filtration rate = 4 gpm/ft^2	Medium sand	0.45–0.55	2.0–2.5
Coagulation, settling, filtration; filtration rate > 4 gpm/ft^2 with polymer addition	Coarse sand	0.8–2.0	2.6–7.0
Coagulation, settling, filtration; filtration rate > 4 gpm/ft^2	Coarse sand	0.9–1.1	1.0–1.5
	Anthracite	0.9–1.4	1.5–2.0
Direct filtration of surface water	Coarse sand	1.5	1.0–1.5
	Anthracite	1.5	1.5–2.0
Iron and manganese removal	Coarse sand	<0.8	2.5–3.0
Iron and manganese removal	Coarse sand	0.9–1.1	1.0–1.5
	Anthracite	0.9–1.4	1.5–2.0
Coarse single media with simultaneous air scour and backwash for coagulation, settling, and filtration	Coarse sand	0.9–1.0	3.0–4.0
Coarse single media with simultaneous air scour and backwash for direct filtration	Coarse sand	1.4–1.6	3.5–7.0
Coarse single media with simultaneous air scour and backwash for iron and manganese removal	Coarse sand	1.0–2.0	5.0–10.0

Dual Media Filters

The principle problem with single-media filters is that the collected solids are concentrated in the upper few inches of the bed. This leads to relatively short filter runs. If the solids can be spread over a larger portion of the bed, the filter runs can be prolonged. One way of doing this is by using dual media filters. Dual media filters consist of an anthracite coal layer on top of a sand layer. The coal grains are larger than the sand grains, and suspended solids penetrate more deeply into the bed before being captured.

The general sizing principle is minimized media intermixing following backwashing. The critical size ratio for media with different densities is that which produces equal settling velocities (Conley and Hsiung, 1969):

$$\frac{d_1}{d_2} = \left(\frac{\rho_2 - \rho_m}{\rho_1 - \rho_m} \right)^{0.625} \tag{9.243}$$

[b] Williams, R.B. and Culp, G.L., eds. 1986. *Handbook of Public Water Systems*, Van Nostrand Reinhold, New York.

where d_1, d_2 = the equivalent grain diameters of the two media (m or ft)
ρ_1, ρ_2 = the densities of the two media grains (kg/m^3 or lb/ft^3)
ρ_m = the density of a fluidized bed (kg/m^3 or lbm/ft^3)

The fluid density is that of the fluidized bed, which is a mixture of water and solids:

$$\rho_m = \varepsilon\rho + \tfrac{1}{2}(\rho_1 + \rho_2)(1-\varepsilon) \tag{9.244}$$

Kawamura (1991) uses the density of water, ρ, instead of ρ_m and an exponent of 0.665 instead of 0.625.

The media are generally proportioned so that the ratio of the weight fractions is equal to the ratio of the grain sizes:

$$\frac{d_1}{d_2} = \frac{f_1}{f_2} \tag{9.245}$$

where f_1, f_2 = the weight fractions of the two media (dimensionless).

Some intermixing of the media at the interface is desirable. Cleasby and Sejkora (1975) recommend the following size distributions of coal and sand:

- Sand — an effective size 0.46 mm and a uniformity coefficient of 1.29
- Coal — an effective size of 0.92 mm and an uniformity coefficient of 1.60
- Ratio of the diameter larger than 90% of the coal to the diameter larger than 10% of the sand was 4.05

An interfacial size ratio of coal to sand of at least 3 is recommended (Joint Task Force, 1990).

The coal layer is usually about 18 in. deep, and the sand layer is about 8 in. deep. A typical specification for the media is given in Table 9.8 (Culp and Culp, 1974).

Operating Modes

Several different filter operating modes are recognized (AWWA Filtration Committee, 1984):

- Variable-control, constant-rate — In this scheme, plant flow is divided equally among the filters in service, and each filter operates at the same filtration rate and at a constant water level in the filter box. Each filter has an effluent rate-of-flow controller that compensates for the changing headloss in the bed.

TABLE 9.8 Size Specifications for Dual Media Coal/Sand Filters

U.S. Sieve Size (mm)	Percentage by Weight Passing	
	Coal	Sand

- This is a highly automated scheme that requires only minimal operator surveillance. It requires the most instrumentation and flow control equipment, because each filter must be individually monitored and controlled.
- Flow control from filter water level — In this scheme, the plant flow is divided equally among the filters in service by a flow-splitter. Each filter operates at a constant water level that is maintained by a butterfly valve on the filtered water line. The water levels differ among boxes in accordance with the differences in media headloss due to solids captured.
- This is an automated scheme that requires little operator attention. Individual filters do not require flow measurement devices, so less hardware is needed than in the variable-control, constant-rate scheme.
- Inlet flow splitting (constant rate, rising head) — In this scheme, the plant flow is divided equally among the filters in service by a flow-splitter that discharges above the highest water level in each filter. Each filter operates at a constant filtration rate, but the rates differ from one filter to the next. Instead of a rate-of-flow controller, the constant filtration rate is maintained by allowing the water level in each filter box to rise as solids accumulate in the media. When a filter reaches its predetermined maximum water level, it is removed from service and backwashed. Automatic overflows between boxes are needed to prevent spillage. The filter discharges at an elevation above the media level, so that negative pressures in the media are impossible.
- The monitoring instrumentation and flow control devices are minimal, but the operator must attend to filter cleanings.
- Variable declining rate — In these schemes, all filters operate at the same water level (maintained by a common inlet channel) and discharge at the same level (which is maintained above the media to avoid negative pressure). The available head is the same for each filter, and the filtration rate varies from one filter to the next in accordance with the relative headloss in the media. When the inlet water level reaches some predetermined elevation, the dirtiest filter is taken out of service and cleaned. The flow rate on each filter declines step-wise as clean filters are brought on line that take up a larger share of the flow.
- This scheme produces a better filtrate, because the filtration rate automatically falls as the bed becomes clogged, which reduces shearing stresses on the deposit. It also makes better use of available head, because most of the water is always going through relatively clean sand. The control system is simplified and consists mainly of a flow rate limiter on each filter to prevent excessive filtration rates in the clean beds. The operator must monitor the water level in the filters and plant flow rate.

- Direct filtration — Direct filtration eliminates flocculation and settling but not chemical addition and rapid mixing. The preferred raw water for direct filtration has the following composition (Direction Filtration Subcommittee, 1980; Cleasby, 1990):
  - Color less than 40 Hazen (platinum-cobalt) units
  - Turbidity less than 5 formazin turbidity units (FTU)
  - Algae (diatoms) less than 2000 asu/mL (1 asu = 400 μm^2 projected cell area)
  - Iron less than 0.3 mg/L
  - Manganese less than 0.05 mg/L
- The coagulant dosage should be adjusted to form small, barely visible, pinpoint flocs, because large flocs shorten filter runs by increasing headlosses and promoting early breakthrough (Cleasby, 1990). The optimum dosage is determined by filter behavior and is the smallest that achieves the required effluent turbidity.
- Dual media filters are required to provide adequate solids storage capacity.
- Design filtration rates range from 4 to 5 gpm/ft^2, but provision for operation at 1 to 8 gpm/ft^2 should be made (Joint Task Force, 1990).

Wastewater Treatment

Granular media filters are used in wastewater treatment plants as tertiary processes following secondary clarification of biological treatment effluents. A wide variety of designs are available, many of them proprietary. The major problems in wastewater filters are the relatively high solids concentrations in the influent flow and the so-called "stickiness" of the suspended solids. These problems require that special consideration be given to designs that produce long filter runs and to effective filter cleaning systems.

Wastewater filters are almost always operated with the addition of coagulants. Provision should be made to add coagulants to the secondary clarifier influent, the filter influent, or both. Rapid mixing is required; it may be achieved via tanks and turbines or static inline mixers.

Filters may be classified as follows (Metcalf & Eddy, Inc., 1991):

- Stratified or unstratified media — Backwashing alone tends to stratify monomedia bed with the fines on top. Simultaneous air scour and backwash produces a mixed, unstratified bed. Deep bed filters almost always require air scour and are usually unstratified.
- Mono, dual or multimedia — Filter media may be a single layer of one material like sand or crushed anthracite, two separate layers of different materials like sand and coal, or multilayer filters (usually five) of sand, coal, and garnet or ilmenite.
- Continuous or discontinous operation — Several proprietary cleaning systems are available that permit continuous operation of the filter: downflow moving bed, upflow moving bed, traveling bridge, and pulsed bed.
  - In downflow moving beds, the water and the filter media move downward. The sand is removed below the discharge point of the water, subjected to air scouring, and returned to the top of the filter.
  - In upflow beds, the water flows upward through the media, and the media moves downward. The media is withdrawn continuously from the bottom of the filter, washed, and returned to the top of the bed.
  - In traveling bridge filters, the media is placed in separate cells in a tank, and the backwashing system is mounted on a bridge that moves from one cell to the next for cleaning. At any moment, only one of the cells is being cleaned, and the others are in service.
  - Pulsed bed filters are really semicontinuous filters. Air is diffused just above the media surface to keep solids in suspension, and periodically, air is pulsed through the bed that resuspends the surface layer of the media, releasing collected solids. Solids migrate into the bed, and eventually, the filtering process must be shut down for backwashing.
- Conventional filters, which are taken out of service for periodic cleaning, are classified as discontinuous.

TABLE 9.9 Media for Wastewater Effluent Filtration (Uniformity Coefficient: 1.5 for Sand and 1.6 for Other Materials)

Filter Type and Typical Filtration Rate	Media	Effective Size (mm)	Media Depth (in.)
Monomedia, shallow bed, 3 gpm/ft^2	Sand	0.35–0.60	10–12
Monomedia, shallow bed, 3 gpm/ft^2	Anthracite	0.8–1.5	12–20
Monomedia, conventional, 3 gpm/ft^2	Sand	0.4–0.8	20–30
Monomedia, conventional, 4 gpm/ft^2	Anthracite	0.8–2.0	24–36
Monomedia, deep bed, 5 gpm/ft^2	Sand	2.0–3.0	36–72
Monomedia, deep bed, 5 gpm/ft^2	Anthracite	2.0–4.0	36–84
Dual media, 5 gpm/ft^2	Sand	0.4–0.8	6–12
	Anthracite	0.8–2.0	12–30
Trimedia, trilayer 5 gpm/ft^2	Anthracite (top)	1.0–2.0	8–20
	Sand (middle)	0.4–0.8	8–16
	Garnet/ilmenite (bottom)	0.2–0.6	2–6

Metcalf & Eddy, Inc. 1991. *Waste Engineering: Treatment, Disposal, and Reuse,* 3rd ed., rev. by G. Tchobanoglous and F.L. Burton, McGraw-Hill, Inc., New York.

The most common designs for new facilities specify discontinuous service, dual media filters with coagulation, and flow equalization to smooth the hydraulic and solids loading. Older plants with space restrictions are often retrofitted with continuous service filters that can operate under heavy and variable loads.

Performance and Media

The liquid applied to the filter should contain less than 10 mg/L TSS (Metcalf & Eddy, 1991; Joint Task Force, 1991). Under this condition, dual media filters with chemical coagulation can produce effluents containing turbidities of 0.1 to 0.4 JTU. If the coagulant is aluminum or ferric iron salts, orthophosphate will also be removed, and effluent orthophosphate concentrations of about 0.1 mg/L as PO_4 can be expected. As the influent suspended solids concentration increases, filter efficiency falls. At an influent load of 50 mg/L TSS, filtration with coagulation can be expected to produce effluents of about 5 mg/L TSS.

Commonly used media are described in Table 9.9.

Backwashing

The general recommendation is that the backwashing rate expand the bed by 10% so that the media grains have ample opportunity to rub against one another (Joint Task Force, 1991). Preliminary or concurrent air scour should be provided. The usual air scour rate is 3 to 5 scfm/ft^2. If two or more media are employed, a Baylis-type rotary water wash should be installed at the expected media interface heights of the expanded bed. The rotary water washes are operated at pressures of 40 to 50 psig and water rates of 0.5 to 1.0 gpm/ft^2 for single-arm distributors and 1.5 to 2.0 gpm/ft^2 for double-arm distributors. Distributor nozzles should be equipped with strainers to prevent clogging.

9.7 Activated Carbon

Preparation and Regeneration

Pure carbon occurs as crystals of diamond or graphite or as fullerene spheres. The atoms in diamond are arranged as tetrahedra, and the atoms in graphite are arranged as sheets of hexagons. Activated carbon grains consist of random arrays of microcrystalline graphite. Such grains can be made from many different organic substances, but various grades of coal are most commonly used, because the product is hard, dense, and easy to handle.

The raw material is first carbonized at about 500°C in a nonoxidizing atmosphere. This produces a char that contains some residual organic matter and many small graphite crystals. The char is then subjected to a slow oxidation in air at about 500°C or steam or carbon dioxide at 800 to 950°C. The preferred activation atmospheres are steam and carbon dioxide, because the oxidation reactions are endothermic and more easily controlled. The slow oxidation removes residual organic matter and small graphite crystals and produces a network of microscopic pores. The higher temperature promotes the formation of larger graphite crystals, which reduces the randomness of their arrangement.

It is almost always economical to recover and regenerate spent carbon, unless the quantities are very small. This is true even of powdered carbon, if it can be easily separated from the process stream. The economic break point for on-site regeneration depends on carbon usage and varies somewhere between 500 and 2000 lb/day (Snoeyink, 1990). Larger amounts should be shipped to commercial regeneration plants.

Spent carbon can be regenerated as it was made by heating in rotary kiln, fluidized bed, multiple hearth, or infrared furnaces (von Dreusche, 1981; McGinnis, 1981). In multiple hearth furnaces, the required heat is supplied by the hot combustion gases of a fuel. The fuel is oxidized at only small excess

air to minimize the amount of oxygen fed to the furnace. In infrared furnaces, heating is supplied by electrical heating elements. This method of heating provides somewhat better control of oxygen concentration in the furnace, but some oxygen enters with the carbon through the feedlock.

The usual regeneration stages in any furnace are as follows (McGinnis, 1981; Snoeyink, 1990):

- Drying stage — usually operated at about 200 to 700°C, depending on furnace type
- Pyrolysis stage — usually operated at about 500 to 800°C
- Coke oxidation stage — usually operated at about 700°C for water treatment carbon and at about 900°C for wastewater treatment carbons (Culp and Clark, 1983)

The pyrolysis stage vaporizes and cokes the adsorbed organics. The vaporized material diffuses into the hot gases in the furnace and either reacts with them or is discharged as part of the furnace stack gas. The coked material is oxidized by water vapor or by carbon dioxide, and the oxidation products exit in the furnace stack gases:

$$C + CO_2 \rightarrow 2\,CO \tag{9.246}$$

$$C + H_2O \rightarrow CO + H_2 \tag{9.247}$$

For water treatment carbons, the pyrolysis and activation stages are operated at temperatures below those required to graphitize the adsorbate char. Consequently, the newly formed char is more reactive than the original, largely graphitized activated carbon, and it is selectively removed by the oxidation process. Wastewater treatment carbons are oxidized at temperatures that graphitize as well as oxidize the adsorbate char. Significant amounts of the original carbon are also oxidized at this temperature.

Regeneration losses are generally on the order of 5 to 10% by weight. This is due mostly to spillage and other handling and transport losses, not to furnace oxidation. There is usually a reduction in grain size, which affects the hydraulics of fixed bed adsorbers and the adsorption rates. However, the adsorptive capacity of the original carbon is little changed (McGinnis, 1981).

Characteristics

The properties of commercially available activated carbons are given in Table 9.10. For water treatment, the American Water Works Association requires that (AWWA Standards Committee on Activated Carbon, 1990a, 1990b):

- "No soluble organic or inorganic substances in quantities capable of producing deleterious or injurious effects upon the health of those consuming the water of that would otherwise render the water … unfit for public use."
- "The carbon shall not impart to the water any contaminant that exceeds the limits as defined by the U.S. Environmental Protection Agency."
- The moisture content shall not exceed 8% by weight when packed or shipped.
- The apparent density shall not be less than 0.36 g/cm^3.
- The average particle size shall be at least 70% of its original size after subjection to either the stirred abrasion test or the Ro-Tap abrasion test. (These are described in the standard.)
- The adsorptive capacity as determined by the iodine number shall not be less than 500.

Uses

Taste and Odor

The traditional use of activated carbon is for taste and odor control. The usage is generally seasonal, and PAC slurry reactors (actually flocculation tanks) have often been the preferred mode of application.

TABLE 9.10 Properties of Commerically Available Activated Carbons

Property	Granular Activated Carbon	Powdered Activated Carbon
Effective size (mm)	0.6–0.9	<0.01 (65–90% < 0.044)
Uniformity coefficient (dimensionless)	<1.9	Not applicable
Real density of carbon excluding pores (g/cm^3)	2.0–2.1	Same
Dry density of grains (g/cm^3)	0.9–1.4	Same
Wet density of grains (g/cm^3)	1.5–1.6	Same
Dry, bulk density of packed bed (g/cm^3) (apparent density)	0.4–0.5	Same
Pore volume of grains (cm^3/g)	0.6–0.95	Same
Specific surface area of grains (m^2/g)	600–1100	Same
Iodine number (mg I_2/g °C at 0.02 N I_2 at 20–25°C)	600–1100	Same

The principal sources of tastes and odors are (Thimann, 1963):

- Manufacturing — generally due to oils, phenols and cresols, ammonia and amines (especially diamines), sulfides and mercaptans, and volatile fatty acids (especially propionic, butyric and isobutyric, valeric and isovaleric, and caproic acids);
- Putrefaction of proteinaceous and fatty material — generally diamines (skatol, indole, γ-amino butyric acid, cadaverine, putrescine, tryptamine, and tyramine), sulfides and mercaptans, and volatile fatty acids
- Microbial and metazoan blooms — especially cyanobacterial blooms

The odors associated with algal and other blooms have been classified as shown in Table 9.11.

Odors are normally measured by the threshold odor number (TON). This is defined as the sample with the smallest diluted volume that retains an odor. The samples are diluted with distilled water, and the TON is calculated as follows (Joint Editorial Board, 1992),

$$\text{TON} = \frac{V_{of} + V_s}{V_s} \tag{9.248}$$

where TON = the threshold odor number (dimensionless)
V_{of} = the volume of odor-free water used in the threshold odor test (mL)
V_S = the volume of original sample used in the threshold odor test (mL)

Conventional water treatment processes such as coagulation and settling do not substantially reduce the TON. In fact, coagulation with lime or soda ash frequently increases it (Anonymous, 1942). Coagulant chemicals sometimes change the character of the odor. Rapid sand filtration partially reduces the TON in some cases.

Disinfection By-Product (DBP) Precursors

The naturally occurring humic substances in surface and groundwaters react with chlorine to form chloroform ($CHCl_3$), which is a known carcinogen (Joint Task Force, 1990), and other disinfection

TABLE 9.11 Taste- and Odor-Producing Organisms

Organism	Odor when Numbers are Moderate	Odor when Numbers are Abundant
	Cyanobacteria	
Anabaena circinalis	Grassy	Pigpen
Anabaena flos-aquae	Moldy, grassy, nasturtium	Pigpen

by-products. This problem presents itself continuously, so GAC-packed columns are the preferred mode of application. GAC will remove trihalomethanes (THMs), haloacetic acids (HAAs), and their precursor humic substances. The removal efficiency of the precursors is somewhat greater than that of the THMs. THM removal is best on fresh carbon, and removals are impaired by competitive adsorption on older carbons. The useful life of GAC replacement media in rapid sand filter boxes is about 2 months (Ohio River Valley Sanitation Commission, 1980).

Organic Poisons and Priority Pollutants

Water supply intakes on large rivers are subject to transport and processing spills of most industrial organic chemicals. Large spills are often detected early and tracked, so that utilities can shut down operations while they pass. However, many smaller spills go undetected, and medically significant concentrations of organic poisons can enter public water supplies. This problem is similar to the THM problem, and it requires continuous water treatment by GAC in packed columns. GAC filter adsorbers do not remove priority pollutants reliably, and desorption of small chlorinated organic molecules sometimes occurs (Ohio River Valley Water Sanitation Commission, 1980; Graese, Snoeyink, and Lee, 1987). GAC filter adsorbers also exhibit lower carbon capacities and earlier breakthrough due to pore clogging by water treatment chemicals and flocs.

Wastewater SOC

Stringent NPDES effluent permits may require GAC-packed columns to remove soluble organic carbon (SOC), like residual soluble BOD_5, priority pollutants, or THM precursors (Joint Task Force, 1991). The suspended solids content of biologically treated effluents usually must be removed by chemical coagulation, sedimentation, and filtration prior to carbon treatment. The Lake Tahoe results indicate that empty bed contacting times of 15 to 30 min can produce an effluent BOD_5, COD, and TOC of less than 1, 12, and 3 mg/L, respectively, if clear, biologically treated water is fed to the columns (Culp and Culp, 1971).

Equilibria

A nonpolar adsorbent like activated carbon will adsorb nonpolar solutes from polar solvents like water (Adamson, 1982). Furthermore, Traube's rule (Freundlich, 1922) is: The adsorption of a homologous series of organic substances from aqueous solution increases as the chain length increases.

Adsorption is an equilibrium process in which organic molecules dissolved in water displace water molecules from the surface of the activated carbon. The equilibrium depends on the water-phase activities of the organic molecules (a_o), the water-phase activity of the water (a_w), the mole fraction of the organic molecule in the adsorbed layer (x_o), and the mole fraction of water in the adsorbed layer (x_w), and it is characterized by a free energy of adsorption (Adamson, 1982):

$$K = \frac{a_w x_o}{a_o x_w} = e^{-\Delta G^o/RT} \tag{9.249}$$

where a_o = water-phase activity of organic molecules (mol/L)
a_w = water-phase activity of water (mol/L)
ΔG^o = the standard free energy of a reaction (J/mol or ft-lbf/lb mol)
K = the equilibrium constant (units vary)
R = the gas constant (8.314 510 J/K·mol or 1,545 ft·lbf/°R·lb mol)
T = the absolute temperature (K or °R)
x_o = the mole fraction of organic matter in the adsorbed layer (dimensionless)
x_w = the mole fraction of water in the adsorbed layer (dimensionless)

Langmuir

The Langmuir isotherm follows directly from the equilibrium constant if the following conditions are met:

- All adsorption sites on the carbon have equal free energies of adsorption.
- The solution is dilute so that concentrations are nearly equal to activities.
- The mole fraction of water is eliminated using the fact that the sum of the mole fractions ($x_o + x_w$) must be unity.
- The number of adsorption sites per unit mass of carbon can be estimated so that the mole fraction of adsorbed organic matter can be expressed as mass of organic matter per unit mass of carbon.

$$q_e = \frac{q_{\max} C_e}{K_C + C_e} \tag{9.250}$$

where C_e = the equilibrium concentration of organic matter in water (kg/m^3 or lb/ft^3)
K_C = the affinity constant for the Langmuir isotherm (kg/m^3 or lb/ft^3)
q_e = the mass of adsorbed organic matter per unit mass of activated carbon at equilibrium (kg/kg or lbm/lbm)
$q_{\max}$ = the maximum capacity of activated carbon to adsorb organic matter (kg/kg or lbm/lbm)

Freundlich

It is generally not true that the free energy of adsorption is equal for all sites, so the Langmuir isotherm fails to fit many data sets. However, good fits are usually obtained with the Freundlich isotherm. This can be derived from the Langmuir isotherm if it is assumed that the distribution of adsorption energies is a decaying exponential (Halsey and Taylor, 1947):

$$q_e = kC_e^{1/n} \tag{9.251}$$

where k = a positive empirical coefficient (units vary)
n = a positive empirical exponent (dimensionless).

The representation of the exponent on the concentration as a fraction is traditional and has no special meaning.

Three-Parameter Isotherm

Occasionally, it is convenient to use a purely empirical three-parameter adsorption isotherm formula (Crittenden and Weber, 1978):

$$q_e = \frac{q_{\max} C_e}{K_C + C_e^{\beta}} \tag{9.252}$$

where β = an empirical exponent (dimensionless).

Freundlich Parameter Values

Freundlich parameter values for a number of important organic contaminants are given in Table 9.12.

Kinetics

During operation, a packed column first becomes saturated at its inlet end, and the carbon grains are in equilibrium with the influent solute concentration, C_o. Downstream of the saturated zone is the mass transfer zone, in which the carbon is adsorbing solute from the pore water. In this zone, the pore water solute concentration varies from its influent value to some low nonzero value. The mass transfer zone moves through the bed at a constant velocity toward the outlet end, and as it does, the effluent concentration begins to rise. The so-called "breakthrough" curve is a plot of the effluent concentration vs. service time, and it is a mirror image of the concentration profile in the mass transfer zone. The breakthrough concentration, C_b, is set by the required product water quality, and when it is reached, the carbon must be taken out of service and replaced or regenerated.

Empirical Column Tests

In pilot studies, several small columns are connected in series, and sampling taps are installed in each column's outlet line (Wagner and Julia, 1981; Hutchins, 1981). The test solution is pumped through the columns at some controlled rate, and a plot of effluent concentration vs. service time is prepared for each column. The columns will become saturated in sequence from first to last. The sampling taps represent distances along the intended field column's depth, and the use of several columns in series permits determination of the rate at which the mass transfer zone moves through the bed. The service time, t_b, required to reach the specified breakthrough concentration, C_b, is determined for each column, and it is plotted against the cumulative hydraulic retention time (Hutchins, 1981):

$$t_b = a_1 \tau_h + a_o \tag{9.253}$$

where a_o = an empirical constant (sec)
a_1 = an empirical coeffcient (dimensionless)
C_b = the specified breakthrough concentration (kg/m^3 or lb/ft^3)
t_b = the service time to breakthrough (sec)
τ_h = the hydraulic retention of the carbon columns (sec)

Column hydraulic retention times are usually reported as Empty Bed Contacting Times (EBCT), which is simply the hydraulic retention time calculated, assuming the bed is empty. The ratio of the true HRT to the EBCT is equal to the bed porosity:

$$\varepsilon = \frac{\text{HRT}}{\text{EBCT}} = \frac{\varepsilon V/Q}{V/Q} \tag{9.254}$$

The abscissal intercept, $-a_0/a_1$, is the smallest possible EBCT that produces the required effluent quality. The ordinal intercept, a_0, represents that portion of the bed that is not exhausted when breakthrough occurs. It represents the length of the mass transfer zone. If the service time to column saturation, t_{sat}, is determined, the length of the MTZ is,

$$H_{mtz} = \frac{(t_{sat} - t_b)H}{t_{sat}} = \frac{a_o H}{t_b} \tag{9.255}$$

where H = the bed length (m or ft)
H_{mtz} = the length of the mass transfer zone (m or ft)
t_{sat} = the service time to bed saturation (sec)

It is desirable to minimize the MTZ so as to maximize the efficiency of carbon usage. The length of the MTZ can be reduced by reducing the flow rate, but this increases the required column size.

The carbon usage rate for conventional GAC columns can be estimated as follows:

$$R_C = \frac{\rho_C(1-\varepsilon)V}{t_b} \tag{9.256}$$

where R_C = the carbon usage rate (kg/s or lb/sec)
V = the empty bed volume (m^3 or ft^3)
ε = the bed porosity when filled with carbon (dimensionless)
ρ_C = the bulk density of the dry carbon (kg/m^3 or lb/ft^3)

In this case, a portion of the carbon removed from the adsorber (equal to the volume of the MTZ) is not saturated with adsorbate and does not require regeneration. Pulsed column operation overcomes this deficiency, and the "base carbon usage rate" for a pulsed column is calculated as follows:

$$R_{bcu} = \frac{\rho_C(1-\varepsilon)Q}{a_1} \tag{9.257}$$

where Q = the water flow rate (m^3/s or ft^3/sec)
R_{bcu} = the base carbon usage rate (kg/s or lb/sec).

The Logistic Model

A purely empirical procedure has been developed by Oulman (1980). His model is based on the observance that the breakthrough curve is sigmoidal and can be approximated by the logistic equation:

$$\frac{C}{C_o} = \frac{1}{1 + e^{-(a+bt)}} \tag{9.258}$$

where a = an empirical constant (dimensionless)
b = an empirical coefficient (per sec)
C = the effluent contaminant concentration at time t (kg/m^3 or lb/ft^3)
C_o = the influent contaminant concentration (kg/m^3 or lb/ft^3)
t = the service time (sec)

This is actually a rearrangement of the Bohart–Adams equation, and the parameters in the exponential can be related to column properties and hydraulic loading as follows:

$$a = -\frac{k_a q_b H}{v_i \varepsilon} \tag{9.259}$$

$$b = k_a C_o \tag{9.260}$$

where H = the bed depth (m or ft)
k_a = the Bohart–Adams adsorption rate coefficient (per s)
q_b = the adsorption capacity of a carbon bed at bed saturation (kg substance/kg C or lb substance/lb C)
v_i = the interstitial water velocity in a packed bed (m/s or ft/sec)

The logistic equation can be linearized by rearrangement, and the coefficients a and b are the intercept and slope of plot:

$$\ln\left(\frac{C/C_o}{1 - C/C_o}\right) = a + bt \tag{9.261}$$

The only unknowns are the adsorption rate coefficient, k_a, and the bed capacity, q_b, and these may be calculated from the slope and intercept of the plot.

Clark, Symons, and Ireland (1986) derived a modified logistic formula by assuming that mass transfer to the carbon was controlled by transport through the water film, and that the solute concentration at the grain surface was in equilibrium with the quantity of adsorbed material. Freundlich's isotherm was used to describe the equilibrium. The effluent concentration vs. service time plot is,

$$C = \left(\frac{C_o^{n-1}}{1 + Ae^{-rt}}\right)^{\frac{1}{n-1}} \tag{9.262}$$

$$A = \left(\frac{C_o^{n-1}}{C_b^{n-1}} - 1\right) e^{rt_b} \tag{9.263}$$

$$r = \frac{(n-1) k_\ell v_{az}}{v_i \varepsilon} \tag{9.264}$$

where k_ℓ = the liquid film mass transfer coefficient (m/s or ft/sec)
n = an empirical exponent in the Freundlich adsorption isotherm (dimensionless)
r = an empirical coefficient (per sec)
ν_{az} = the velocity of the adsorption zone through an activated carbon bed (m/s or ft/sec)

Equation (9.262) can be linearized as follows for curve fitting:

$$\ln\left[\left(\frac{C_o}{C}\right)^{n-1}-1\right]=\ln A-rt \tag{9.265}$$

The logistic equation assumes that the breakthrough curve is symmetrical. When this is not the case, the modified logistic equation may give a better fit. The derivation of the modified logistic model shows that the coefficients A and r will vary with the liquid velocity in the bed, and they do (Clark, 1987). However, because the model ignores the effect of surface diffusion with the carbon grain pores, which is probably the rate-limiting process, Eqs. (9.263) and (9.264) cannot be used to calculate A and r and they should be determined empirically.

Packed Column Theory

A commonly used model is homogeneous surface diffusion model (HSDM) developed by Crittenden and Weber. This model was developed for the adsorption of single components.

It is assumed that the rate of adsorption is controlled by the rate of diffusion of adsorbed molecules along the walls of the pores inside the carbon grains. The water phase is assumed to be dilute everywhere, so that bulk flow in the pores and concentration effects on diffusivities can be ignored. The pore surface area is supposed to be uniformly distributed throughout the carbon particles, and the mass balance for adsorbate adsorbed to the carbon surface is written in spherical coordinates as follows:

$$\frac{\partial q}{\partial t}=D_s\left(\frac{\partial^2 q}{\partial r^2}+\frac{2}{r}\cdot\frac{\partial q}{\partial r}\right) \tag{9.266}$$

where D_s = the surface diffusivity (m^2/s or ft^2/sec)
q = the mass of adsorbate per unit mass of carbon (kg adsorbate/kg C or lb adsorbate/lb C)
r = the radial distance from the center of the carbon grain (m or ft)
t = elapsed time (sec)

The water phase at any level in the bed is assumed to be of uniform composition (except for the boundary layer) and without channeling. Mass transfer from the interstitial water to the carbon grains is represented as transport across a surface film. The mass balance for the adsorbate dissolved in the water flowing through the bed is as follows (James M. Montgomery, Consulting Engineers, Inc., 1985),

$$\underbrace{\frac{\partial C}{\partial t}}_{\text{accumulation in water}}=\underbrace{D_p\frac{\partial^2 C}{\partial z^2}}_{\text{dispersive flux}}-\underbrace{v_i\frac{\partial C}{\partial z}}_{\text{advective flux}}-\underbrace{\frac{3k_\ell(1-\varepsilon)}{a_p\phi\varepsilon}(C-C_s)}_{\text{transfer to carbon}} \tag{9.267}$$

where a_p = the radius of an activated carbon grain (m or ft)
C = the bulk water phase adsorbate concentration (kg/m^3 or lb/ft^3)
C_S = the adsorbate concentration at the water–carbon interface (kg/m^3 or lb/ft^3)
D_p = the water phase dispersion coefficient (m^2/s or ft/sec)
k_ℓ = the liquid film mass transfer coefficient (m/s or ft/sec)
ν_i = the interstitial water velocity in a packed bed (m/s or ft/sec)
z = the distance from the inlet of a granular activated carbon bed (m or ft)

ε = the filter bed porosity (dimensionless)
ϕ = the sphericity, the ratio of the surface area of an equivalent volume sphere to the surface area (not counting internal pores) of the carbon grain (dimensionless)

At the interface between the carbon grain and the interstitial water, there is an equilibrium between the adsorbed material and the dissolved material, which can be represented by some suitable isotherm such as the Freundlich:

$$q_s = kC_s^{1/n} \tag{9.251}$$

The interfacial area per unit bed volume is $3(1 - \varepsilon)/a_p\phi$.

Equations (9.266) and (9.271) are connected by the requirement that solute disappearing from the water appears as adsorbate in the carbon. The transfer of solute to the carbon can be represented on an areal flux basis,

$$D_s\rho_p \left.\frac{\partial q}{\partial r}\right|_{r=a_p} = k_\ell\left(C - C_s\right) \tag{9.268}$$

where ρ_p = the particle density (kg/m^3 or lbm/ft^3), or a bed volume basis,

$$\frac{3k_\ell\left(1-\varepsilon\right)\left(C-C_s\right)}{a_p\phi} = \rho_p\left(1-\varepsilon\right)\frac{\partial}{\partial t}\left(4\pi\int_0^{a_p} qr^2 dr\right) \tag{9.269}$$

The value of $q(r,z,t)$ is given by Eq. (9.269) with the condition that $q(a_p,z,t)$ be q_s.

The relevant boundary conditions are as follows:

$$C\left(z,t\right) = C_o + \frac{D_p}{v_i}\cdot\frac{\partial C}{\partial z} \qquad \text{at} \qquad z = 0 \tag{9.270}$$

$$\frac{\partial C}{\partial z} = 0 \qquad \text{at} \qquad z = H \tag{9.271}$$

$$\frac{\partial q}{\partial r} = 0 \qquad \text{at} \qquad r = 0 \tag{9.272}$$

$$q\left(r,t\right) = 0 \qquad \text{at} \qquad t = 0 \tag{9.273}$$

$$C\left(z,t\right) = 0 \qquad \text{at} \qquad t = 0 \tag{9.274}$$

Numerical procedures for solving these equations are presented by Weber and Crittenden (1975) and by Roy, Wang. and Adrian (1993).

A number of parameters must be evaluated before the model can be used:

- Freundlich isotherms constants
- Liquid film mass transfer coefficient
- Liquid film diffusivity
- Surface diffusivity

These parameters can be estimated using various published correlations, which are listed below, or by analyzing batch or continuous flow adsorption tests.

The Freundlich isotherm parameters must be determined experimentally for the substance of interest and the intended carbon. Typical values for a variety of substances are given in Table 9.12.

The mass transfer coefficient can be estimated using any one of several correlations:

Williamson, Bazaire, and Geankoplis (1963):

$$\frac{k_\ell}{\varepsilon \nu_i} \cdot \boldsymbol{Sc}^{0.58} = 2.40 \cdot \boldsymbol{Re}^{-0.66}; \quad 0.08 \le \boldsymbol{Re} \le 125 \tag{9.275}$$

where D_ℓ = the molecular diffusivity of the adsorbate in the bulk water (m^2/s or ft^2sec)
d_p = the diameter of a carbon grain (m or ft)
Re = the particle Reynolds number (dimensionless)
$= \rho \nu_i d_p / \mu$
Sc = the Schmidt number (dimensionless)
$= \mu / \rho D_\ell$
μ = the dynamic viscosity of water ($N \cdot s/m^2$ or $lbf \cdot sec/ft^2$)
ρ = the water density (kg/m^3 or lbm/ft^3)

Wakao and Funazkri (1978):

$$\frac{k_\ell d_p}{D_\ell} = 2 + 1.1 \cdot \boldsymbol{Re}^{0.6} \boldsymbol{Sc}^{1/3}; \quad 3 \le \boldsymbol{Re} \le 10^4 \tag{9.276}$$

where **Re** = the modified particle Reynolds number (dimensionless), $= \rho \varepsilon \nu_i d_p / \mu$.

The liquid phase solute diffusivities can be estimated in several ways:

Stokes-Einstein (Einstein, 1956):

$$D_\ell = \frac{kT}{6\pi a_p \mu} \tag{9.277}$$

where k = Boltzmann's constant ($1.380\,658 \infty 10^{-23}$ J/K or approximately $0.5658 \infty 10^{-23}$ ft·lbf/°R)
T = the absolute temperature (K or °R).

Polson (1950):

$$D_\ell = 2.74 \times 10^{-5} \cdot M_r^{-1/3} \tag{9.278}$$

where D_ℓ = the diffusivity in cm^2/s
M_r = the relative molecular weight (dimensionless).

Wilke-Chang (Wilke and Chang, 1955; Hayduk and Laudie, 1974):

$$\frac{D_{\ell i} \mu}{T} = 7.4 \times 10^{-8} \times \frac{\sqrt{2.6 M_{r\ell}}}{\nu_{mbp}^{0.6}} \tag{9.279}$$

where $D_{\ell i}$ = the diffusivity of species i in water in cm^2/s
$M_{r\ell}$ = the molecular weight of water in g
$= 18$ g
ν_{mbp} = the molar volume of the liquid phase of species i at its boiling point in cm^3/g-mole
μ = the viscosity of water in centipoise (cp)

Note that 1 cp = 0.001 $N \cdot s/m^2$ (exactly).

TABLE 9.13 Components of the Molar Volume of Liquids

Structural Component	Molar Volumes[a] (cm^3/g-mol)	Molar Volumes[b] (cm^3/g-mol)
Bromine, add	27.0	—
Carbon, add	14.8	16.5
Chlorine, end (R-Cl), add	21.6	19.5
Chlorine, inner (R-Cl-R), add	24.6	19.5
Fluorine, add	8.7	—
Hydrogen, add	3.7	1.98
Iodine, add	37.0	—
Nitrogen, double bonded, add	15.6	5.69
Nitrogen, triple bonded, add	16.2	5.69
Nitrogen, primary amines (RNH_2), add	10.5	5.69
Nitrogen, secondary amines (R_2NH), add	12.0	5.69
Nitrogen, tertiary amines (R_3N), add	10.8	5.69
Oxygen, if not combined as follows, add	7.4	5.48
Oxygen, in methyl esters, add	9.1	5.48
Oxygen, in methyl ethers, add	9.9	5.48
Oxygen, in other esters or ethers, add	11.0	5.48
Oxygen, in acids, add	12.0	5.48
Oxygen, combined with N, P, or S, add	8.3	5.48
Phosphorus, add	27.0	—
Sulfur, add	25.6	17.0
3-Member rings, deduct	6.0	—
4-Member rings, deduct	8.5	—
5-Member rings, deduct	11.5	—
6-Member rings (benzene, cyclohexane), deduct	15.0	20.2
Anthracene ring, deduct	47.5	20.2
Naphthalene ring, deduct	30.0	20.2

[a] Le Bas, 1915. *The Molecular Volumes of Liquid Chemical Compounds*, Longmans, London. [Quoted in Perry, R.H. and Chilton, C.H. 1973. *Chemical Engineer's Handbook*, 5th ed., McGraw-Hill, Inc., New York.]

[b] Bennet, C.O. and Myers, J.E. 1974. *Momentum, Heat, and Mass Transfer,* 2nd ed., McGraw-Hill, Inc., New York.

Perry and Chilton (1973) recommend the Le Bas volumes in place of ν_{mbp} if values for the latter cannot be found. Table 9.13 gives the Le Bas volumes for common structural components of organic substances.

Surface diffusivities of volatile organic substances and polycyclic aromatic substances can be estimated by the Suzuki–Kawazoe (1975) correlation:

$$D_s = 1.1 \times 10^{-4} \cdot e^{-5.32 T_b / T} \tag{9.280}$$

where D_S = the surface diffusivity in cm^2/s
T = the adsorption temperature in K
T_b = the boiling point of the organic substance in K

It is expected that the coefficient in front of the exponential will depend only on the carbon used and not on the adsorbate. The correlation was developed using Takeda HGR 513™, which is derived from coconut shell and has a mean grain size of 3.41 mm and a specfic surface area of 1225 m^2/g.

A simplified approach has been developed by Hand, Crittenden and Thacker (1984) that eliminates the need for computer simulations. They fitted an empirical formula to the results of many computer solutions. The equations and boundary conditions are first nondimensionalized by introducing the following dimensionless variables and groups:

$$\overline{C} = \frac{C}{C_o} \tag{9.281}$$

$$\overline{C}_s = \frac{C_s}{C_o} \tag{9.282}$$

$$\overline{q} = \frac{q}{q_o} \tag{9.283}$$

$$\overline{r} = \frac{r}{a_p} \tag{9.284}$$

$$\overline{z} = \frac{z}{H} \tag{9.285}$$

$$\boldsymbol{Bi} = \frac{k_\ell a_p (1-\varepsilon)}{D_s D_g \varepsilon \phi} \tag{9.286}$$

$$D_g = \frac{q_o \rho_p (1-\varepsilon)}{C_o \varepsilon} \tag{9.287}$$

$$E_d = \frac{D_s D_g \tau_h}{a_p^2} \tag{9.288}$$

$$\boldsymbol{St} = \frac{k_\ell \tau_h (1-\varepsilon)}{a_p \varepsilon \phi} \tag{9.289}$$

$$T = \frac{t}{\tau_h (1+D_g)} \tag{9.290}$$

where **Bi** = the Biot number (dimensionless)
C_0 = the adsorbate's influent concentration (kg/m^3 or lb/ft^3)
D_g = the solute distribution parameter (dimensionless)
E_d = the diffusivity modulus, the ratio of the Stanton to Biot numbers (dimensionless)
H = the depth of the carbon bed (m or ft)
q_0 = the mass of adsorbate per unit mass of activated carbon at equilibrium with the influent concentration C_0 (kg adsorbate/kg C or lb adsorbate/lb C)
St = the modified Stanton number (dimensionless)
T = the throughput, the ratio of the adsorbate fed to the amount of adsorbate that may be adsorbed at equilibrium (dimensionless)

The resulting transport equations and boundary conditions are as follows (Hand, Crittenden, and Thacker, 1984):

$$\frac{1}{1+D_g} \cdot \frac{\partial \overline{C}}{\partial T} = -\frac{\partial \overline{C}}{\partial \overline{z}} - 3 \cdot \boldsymbol{St} \cdot \left(\overline{C} - \overline{C}_s\right) \tag{9.291}$$

$$\frac{\partial \bar{q}}{\partial T} = \left(1 + \frac{1}{1 + D_g}\right) \cdot \frac{E_d}{\bar{r}^2} \cdot \frac{\partial}{\partial \bar{r}} \left(\bar{r}^2 \frac{\partial \bar{q}}{\partial \bar{r}}\right) \tag{9.292}$$

$$\left.\frac{\partial \bar{q}}{\partial \bar{r}}\right|_{\bar{r}=1} = \boldsymbol{Bi} \cdot \left(\bar{C} - \bar{C}_s\right) \tag{9.293}$$

$$\left.\frac{\partial \bar{q}}{\partial \bar{r}}\right|_{\bar{r}=0} = 0 \tag{9.294}$$

$$\bar{C}\left(\bar{z} = 0, T \geq 0\right) = 1 \tag{9.295}$$

$$\bar{C}\left[T\left(1 + D_g\right) < \bar{z} \leq 1, T < \frac{1}{1 + D_g}\right] = 0 \tag{9.296}$$

$$\bar{q}\left(0 \leq \bar{r} \leq 1, 0 \leq \bar{z} \leq 1, T = 0\right) = 0 \tag{9.297}$$

The nondimensional Freundlich isotherm is

$$\bar{q}_s = \bar{C}_s^{1/n} \tag{9.298}$$

If the solute distribution parameter, D_g, is greater than about 50, the Biot number, **Bi**, is greater than about 0.5, and the Freundlich exponent, $1/n$, is less than 1, the numerical solution is controlled by **Bi**, $1/n$, and the Stanton number, **St**. Hand, Crittenden, and Thacker (1984) summarized the results of numerous computer simulations as parameters in the following empirical formula:

$$T = A_o + A_1 \left(\frac{C}{C_o}\right)^{A_2} + \frac{A_3}{1.10 - \left(\frac{C}{C_o}\right)^{A_4}} \tag{9.299}$$

Equation (9.299) gives the processing time in terms of the throughput parameter, T, required to achieve a specified effluent concentration, C. The breakthrough ratio, C/C_0, must lie between about 0.02 to 0.99. Values for the parameters are given in Table 9.14. There are several apparent discontinuities in the parameter values, which make interpolation hazardous. However, a three-dimensional plot of the coefficients reveals a smoother pattern, and it should be used as the basis of interpolation.

Equation (9.299) is valid only if the bed contacting time is deep enough to develop a mass transfer zone. Minimum bed contacting times depend on the minimum Stanton number, which can be estimated from empirical correlation:

$$\boldsymbol{St}_{\min} = B_o + B_1 \cdot \boldsymbol{Bi} \tag{9.300}$$

Values of the correlation parameters are given in Table 9.15. The minimum bed contacting time is given by:

$$\tau_{\min} = \frac{\boldsymbol{St}_{\min} a_p \varepsilon \phi}{k_\ell \left(1 - \varepsilon\right)} \tag{9.301}$$

The minimum processing time before regeneration or replacement is required is calculated from the throughput:

$$t_{\min} = \tau_{\min}\left(1 + D_g\right)T \tag{9.302}$$

If longer processing times are desired, the hydraulic retention time must be increased proportionately.

Rapid Small-Scale Column Test

The rapid small-scale column test (RSSCT) can be used to predict the performance of pilot- or full-scale GAC columns (Crittenden, Berrigan, and Hand, 1986; Crittenden et al., 1987, 1991; Summers et al., 1995). In this approach, a representative sample of activated carbon is crushed (typically to U.S. No. 60 × 80 mesh), washed and dried, and then placed in a small diameter (~1 cm) column for testing. Feed solution is then passed through the column, and the effluent is monitored as a function of time. By using small diameter columns, the RSSCT is performed in a fraction of the time as required for pilot-scale testing. However, the short duration of the RSSCT prevents simulation of biodegradation within the GAC column and does not allow for evaluation of long-term changes in water quality.

The RSSCT is based on the dispersed flow, pore surface diffusion model, which takes into account advection, dispersion, diffusion, liquid-phase mass transfer resistance, local adsorption equilibrium, surface diffusion, pore diffusion, and competition between solutes. Based on this model, a number of dimensionless parameters are developed that remain constant from the small-scale to the pilot- or full-scale. If diffusivity is independent of the size of activated carbon, the EBCT of a large-scale GAC adsorber is related to the EBCT of a small-scale column by:

$$\frac{\mathrm{EBCT}_{lc}}{\mathrm{EBCT}_{sc}} = \left[\frac{a_{p,lc}}{a_{p,sc}}\right]^2 \tag{9.303}$$

where *lc* and *sc* denote variables corresponding to the large column and the small column, respectively. The hydraulic loading of the full-scale adsorber is related to the hydraulic loading of the small-scale column as follows:

$$\frac{v_{lc}}{v_{sc}} = \frac{a_{p,sc}}{a_{p,lc}} \tag{9.304}$$

Alternative scaling relations can be developed if the diffusivity is proportional to the size of the activated carbon (Crittenden et al., 1987).

Batch and Ideal Plug Flow Reactors

The Biot number is the ratio of the mass flux through the liquid film surrounding a carbon grain to the mass flux due to surface diffusion within the grain. For Biot numbers greater than about 100, mass transfer is controlled by surface diffusion, whereas liquid film diffusion controls at small Biot numbers (Traegner and Suidan, 1989).

For large Biot numbers, the HSDM has an exact power series solution in closed, batch systems (Crank, 1956):

$$\frac{q(t)}{q_e} = 1 - \frac{6}{\pi^2} \cdot \sum_{i=1}^{\infty} \frac{1}{i^2} \cdot \exp\left(-\frac{i^2 \pi^2 D_s t}{a_p^2}\right) \tag{9.305}$$

where q_e = the mass of adsorbate per unit mass of activated carbon at equilibrium (kg adsorbate/kg C or lb adsorbate/lb C).

Note that the solution depends only on the grain size and the surface diffusivity. Particle size does not affect the equilibrium position or the surface diffusivity, but small particles adsorb solute more quickly (Najm et al., 1990). Consequently, batch tests are more quickly performed if powdered carbon is used.

Numerical solutions to the HSDM model for large Biot numbers have been summarized in the form of power series by Hand, Crittenden, and Thacker (1983).

If both liquid film transport and surface diffusion are important, only a numerical solution is possible. Traegner and Suidan (1989) have shown how the Levenberg–Marquardt nonlinear optimization procedure can be used to adjust D_S and k_ℓ so that model predictions match experimental data.

PAC Slurry Reactors

The batch adsorption solution may also be applied to turbulent, completely mixed reactors. Taking into account the residence time distribution for a continous flow stirred tank, one obtains (Nakhla, Suidan, and Traegner-Duhr, 1989; Najm et al., 1990; Adham et al., 1993),

$$C = C_o - X_{PAC} \cdot kC^{1/n} \cdot \left[1 - \frac{6}{\pi^2} \cdot \sum_{i=1}^{\infty} \frac{1}{i^2 \left(1 + \frac{i^2 \pi^2 D_s \tau_h}{a_p^2} \right)} \right] \tag{9.306}$$

Multicomponent Adsorption

In many applications of activated carbon, multiple solutes compete for sites on the adsorbent surface. Ideal adsorbed solution theory (IAST) can be used to predict solution- and solid-phase equilibrium concentrations for systems containing multiple solutes (Radke and Prausnitz, 1972; Crittenden et al., 1985; Najm et al., 1991; Qi et al., 1994).

The basic premise underlying the IAST is that the spreading pressure of the pure component system is equal to the spreading pressure of the mixture. Subsequently, single-solute adsorption information can be used to predict adsorption behavior in multisolute systems. Using the Freundlich isotherm to relate the solution-phase and solid-phase concentrations of pure components, it can be shown that:

$$C_{e,i} = \frac{q_{e,i}}{\sum_{j=1}^{N} q_{e,j} \left(\frac{\sum_{j=1}^{N} n_j q_{e,j}}{n_i k_i} \right)^{n_i}} \tag{9.307}$$

where $C_{e,i}$ = the equilibrium concentration of solute i in water
$q_{e,i}$ = the mass of adsorbed solute i per unit mass of activated carbon at equilibrium
$q_{e,j}$ = the mass of adsorbed solute j per unit mass of activated carbon at equilibrium
n_i = the single-solute Freundlich empirical exponent for component i
k_i = the single-solute Freundlich empirical coefficient for component i
n_j = the single-solute Freundlich empirical exponent for component j
N = the number of independent adsorbing solutes in the system

The equilibrium concentration of solute i can be replaced with the initial concentration of solute i by noting the following relationship valid for a batch adsorption experiment:

$$q_{e,i} = \frac{C_{o,i} - C_{e,i}}{C_c} \tag{9.308}$$

where $C_{0,i}$ = the initial concentration of solute i in water
C_c = the concentration of activated carbon used.

Combining the above equations gives:

$$C_{o,i} - C_c q_{e,i} - \frac{q_{e,i}}{\sum_{j=1}^{N} q_{e,j} \left(\frac{\sum_{j=1}^{N} n_j q_{e,j}}{n_i k_i} \right)^{n_i}} = 0 \tag{9.309}$$

which for a two-component system reduces to the following two equations:

$$C_{o,1} - C_c q_{e,1} - \left(\frac{q_{e,1}}{q_{e,1} + q_{e,2}} \right) \left(\frac{n_1 q_{e,1} + n_2 q_{e,2}}{n_1 k_1} \right)^{n_1} = 0 \tag{9.310}$$

$$C_{o,2} - C_c q_{e,2} - \left(\frac{q_{e,2}}{q_{e,1} + q_{e,2}} \right) \left(\frac{n_1 q_{e,1} + n_2 q_{e,2}}{n_2 k_2} \right)^{n_2} = 0 \tag{9.311}$$

For systems of more than two components, additional equations may be developed and the set of equations solved numerically, for example, using the Newton–Raphson technique.

Application

Powdered Activated Carbon

Powdered activated carbon is usually applied by adding it to the water or wastewater to be treated and mixing the carbon and water in a slurry reactor for the requisite contacting time. The carbon is subsequently removed from the liquid by settling or filtration. Unless the treated water is nearly free of other suspended solids, the spent carbon cannot be regenerated and is wasted. Carbon wasting is practicable only for intermittent, short duration treatment.

If the treated water is clear, settling, filtration, or both will recover a product suitable for regeneration. Furthermore, it is possible to operate a countercurrent flow of carbon and water so as to minimize carbon requirement. In such a system, several slurry reactors are constructed and operated in series. Each reactor is equipped with a filter or settler, and the solids captured are pumped to the next upstream reactor (Hutchins, 1981).

The required contacting times must be empirically determined; the homogeneous surface diffusion model (HSDM) described above is widely used as a design aid. The adsorption rate is inversely proportional to the square of the carbon grain size, so the required contacting time for equal removal efficiencies is proportional to the square of the grain diameter (Najm et al., 1990):

$$\tau_h \propto a_p^2 \tag{9.312}$$

The adsorptive capacity and surface diffusivity are independent of grain size (Randtke and Snoeyink, 1983; Najm et al., 1990).

Most reported carbon adsorption studies have employed pure solutions of single substances. Studies in complex natural waters indicate that the background organic matter may reduce the sorptive capacity for the test substance by about 50% (Najm et al., 1990).

Granular Activated Carbon

Granular activated carbon systems are usually preferred when continous carbon treatment is required, because carbon recovery for regeneration is easier. Plant surveys indicated several design deficiencies that require special attention (Culp and Clark, 1983; Graese, Snoeyink, and Lee, 1987; Akell, 1981):

- Wet carbon forms electrolytic cells and is corrosive.
- Wet carbon is abrasive to steel.
- Dry, fresh carbon in large piles adsorbs oxygen and can spontaneously ignite; the ignition temperature depends strongly on how the carbon was manufactured and is about 300°C for steam-activated carbons.
- Idle carbon beds loaded with ketones, aldehydes, and some organic acids are subject to "temperature excursions" and occasional bed fires.

- Carbon dust is explosive if it contains more than 8% by weight organic matter; most steam-activated carbons are well below this limit.
- Adsorbers are generally devoid of oxygen and cannot be entered without respirators and/or ventilation.
- Wastewater adsorbates may undergo anaerobic decomposition, producing explosive gases like methane and poisonous gases like hydrogen sulfide; control of column-dissolved oxygen levels is necessary.
- GAC and slurry transfer and feed equipment is often undersized.
- Backwash lines must be vented.
- Backwash nozzles subject to breakage or clogging must be avoided. (See Chapter 9, Section 9.6, "Filtration.")
- Regeneration furnace feeds must be uniform to avoid temperature fluctuations and inconsistent reactivation.
- Control systems and drive motors must be protected from the weather and from furnace emissions and radiant heat.

Granular activated carbon systems come in three general types:

- *Packed columns* are large steel or reinforced concrete tanks, generally pressurized to maximize throughput rates (Culp and Clark, 1983; Culp/Wesner/Culp, Inc., 1986; Snoeyink, 1990; Joint Task Force, 1990). Prefabricated tanks must be less than 12 ft in diameter for transport. Larger tanks are constructed on site.
- In water treatment plants, the columns are installed after the rapid sand filters and operated downflow. Filtration rates between 3 and 7 gpm/ft^2 and depths of 2.5 to 15 ft are employed. The governing variable is contact time. This should be determined by pilot studies and model studies as described above. The most important restriction is that the contacting time be long enough to establish a mass transfer zone. Contacting times longer than this are needed to provide adequate service life, and the actual value chosen depends on the economics of the particular application. An empty bed contacting time (EBCT) of 10 to 20 min is common; 5 min suffices for taste and odor control. However, some applications may require an EBCT of a few hours.
- *Pulsed columns* are designed to permit intermittent replacement of carbon in operating columns (Hutchins, 1981; Snoeyink, 1990). Liquid flow is upward, and carbon is withdrawn from the column bottom at specified intervals. Fresh carbon is added at the top of the column. The columns have no freeboard, so the carbon cannot move during operation or cleaning, unless it is being withdrawn. This prevents vertical mixing of the bed.
- The carbon discharged from pulsed beds is always saturated with adsorbate at the raw water solute concentration. This is the most efficient way to use carbon. Carbon usage rates are calculated as "base rate," discussed above (Hutchins, 1981).
- *Rapid sand filters* are used, but it has become common to remove the sand from rapid sand filters and replace it with activated carbon (Culp and Clark, 1983; Graese, Snoeyink, and Lee, 1987; Joint Task Force, 1990). Unless the filter box is extended, the contacting time will be short (usually less than 9 min) and may not be sufficient to establish a mass transfer zone. Such installations are normally restricted to taste and odor control. Taste and odor control systems may be in service for 1 to 5 years before the carbon must be replaced.
- Because the carbon also acts as a particle filter, several operational problems must be considered:
  - Backwashing rates sufficient to remove accumulated solids and prevent mudball formation may lead to carbon loss; careful carbon sizing and backwash control are needed.
  - Carbon grain pores may be fouled by deposition of calcium carbonate, magnesium hydroxide, and ferric and manganic oxides, all of which reduce adsorptive capacity.

9.8 Aeration and Gas Exchange

Equilibria and Kinetics of Unreactive Gases

Equilibria

According to Henry's Law, at equilibrium, the concentration of a dissolved gas in a liquid is proportional to the partial pressure of the gas in the gas phase (Brezonik, 1994):

$$C = K_H p \tag{9.313}$$

where C = the concentration of dissolved gas in the liquid (kg/m^3 or lb/ft^3)
K_H = the Henry's Law constant (kg/m^3·Pa or lb·ft/lbf)
p = the partial pressure of the dissolved gas in the gas phase (Pa or lbf/ft^2)

Equation (9.313) can be written in a variety of ways. The pressure on the right-hand side can be replaced by a concentration, in which gas the Henry's Law constant takes on the units of a volume ratio, e.g., m^3 gas/m^3 liquid. This is frequently (and incorrectly) called the dimensionless Henry's Law constant. Also, it is often convenient to work in moles or pound-moles instead of kilograms or pounds. Other variants are discussed later in the section entitled "Air Stripping of Volatile Organic Substances."

Equation (9.313) is often written with the constant on the left-hand side:

$$p = HC \tag{9.314}$$

where H = the (reciprocal) Henry's Law constant (Pa·m^3/kg or lbf/lb·ft).

Equation (9.313) will be used in order that the symbol H may be used without confusion for depth in various mass transfer formulae.

Mass Transfer Kinetics

The simplest model of mass transfer between two phases is the Lewis–Whitman two-film theory (Brezonik, 1994). It is assumed that a "stagnant" film exists on each side of the phase interface. Each film exists only statistically. Its fluid properties may differ from the bulk fluid only on average and not at each instant. Its thickness depends on the details of the flow regime in the bulk fluid. Mass transport through each film is supposed to occur by molecular diffusion, and Fick's Law applies. If the films are in steady state (which does not mean that the bulk fluids are, although they may be), the total mass flux through each film will be the same, and the fluxes will be proportional to the pressure or concentration differences across the films:

$$\underbrace{F}_{\text{total flux}} = \underbrace{k_g\left(\frac{p - p_i}{RT}\right)}_{\text{flux through gas film}} = \underbrace{k_\ell\left(C_i - C\right)}_{\text{flux through liquid film}} \tag{9.315}$$

where C = the gas concentration in the bulk liquid (mol/m^3 or lb mol/ft^3)
C_i = the gas concentration in the liquid at the gas/liquid interface (mol/m^3 or lb mol/ft^3)
F = the total flux through the two films (mol/m^2·s or lb mol/ft^2·sec)
k_g = the gas film mass transfer coefficient (m/s or ft/sec)
k_ℓ = the liquid film mass transfer coefficient (m/s or ft/sec)
p = the partial pressure of the dissolving gas in the bulk gas phase (Pa or lbf/ft^2)
p_i = the partial pressure of the dissolving gas at the gas/liquid interface (Pa or lbf/ft^2)
R = the gas constant (8.314 510 J/mol·K or 1,545.356 ft·lbf/lb mol·°R)
T = the absolute temperature (K or °R)

Henry's law connects the interfacial partial pressure and the interfacial dissolved gas concentration, and it also allows the bulk gas-phase partial pressure to be expressed as the equivalent gas solubility:

$$C_i = K_H p_i \tag{9.316}$$

$$C_s = K_H p \tag{9.317}$$

where C_s = the dissolved gas concentration equivalent to the gas's partial pressure in the gas phase, its equilibrium concentration (kg/m^3 or lb/ft^3).

The overall concentration difference, $C_s - C$, may be partitioned as follows:

$$C_s - C = (C_s - C_i) + (C_i - C) \tag{9.318}$$

$$C_s - C = K_H(p - p_i) + (C_i - C) \tag{9.319}$$

The pressures and concentrations may be eliminated via the flux relationships in Eq. (9.315), and the overall liquid film mass transfer coefficient may be defined as follows:

$$\frac{1}{K_\ell} = \frac{RTK_H}{k_g} + \frac{1}{k_\ell} \tag{9.320}$$

where K_ℓ = the overall liquid film mass transfer coefficient (m/s or ft/sec); = $F/C_s - C$.

A similar analysis, which starts by writing the overall pressure difference analogously to Eq. (9.318), yields,

$$\frac{RT}{K_g} = \frac{RT}{k_g} + \frac{1}{k_\ell K_H} \tag{9.321}$$

where K_g = the overall gas film mass transfer coefficient (m/s or ft/sec)
$= F/p - p_{eq}$
p_{eq} = the gas partial pressure equivalent to the bulk liquid-phase concentration (Pa or lbf/ft^2)
$= K_H C$

If the Henry's law constant and the flux are defined in terms of molar concentration in the gas and liquid phases, the product RT does not appear in Eqs. (9.341), (9.347) or (9.348).

Note that the two overall transfer coefficients are connected by the Henry's Law constant:

$$K_H = \frac{K_g}{K_\ell} = \frac{RT(C_s - C)}{p - p_{eq}} \tag{9.322}$$

It is a matter of convenience as to which overall mass transfer coefficient is employed. If K_H is small, then K_ℓ is approximately equal to k_ℓ. Similarly, if K_H is large, then K_g is nearly equal to k_g. Furthermore, a large Henry's Law constant means that K_g is larger than K_ℓ, the mass transfer rate is limited by diffusion through the water film, and the concentration gradient across the water film is large. Conversely, a small Henry's Law constant means that mass transfer is controlled by diffusion through the gas film, and the pressure gradient across the gas film is large.

The underlying film mass transfer coefficients are supposed to depend upon the molecular diffusivities of the substances. Depending on whether the fluid regime is laminar, transitional, or turbulent (which affects the film structure), the dependency is to the first power of the diffusivity or to its square root. The diffusivity depends on the reciprocal square root of the relative molecular weight. Consequently, if the mass transfer coefficient for one substance is known, the coefficient for another can be estimated (Brezonik, 1994):

$$\frac{k_{\ell 1}}{k_{\ell 2}} = \left(\frac{D_{\ell 1}}{D_{\ell 2}}\right)^n = \left(\frac{M_{r2}}{M_{r1}}\right)^{n/2} \tag{9.323}$$

$$\frac{k_{g1}}{k_{g2}} = \left(\frac{D_{g1}}{D_{g2}}\right)^n = \left(\frac{M_{r2}}{M_{r1}}\right)^{n/2} \tag{9.324}$$

where D_{ij} = the diffusivity of the j-th substance in the i-th phase (m^2/s or ft^2/sec)
M_{rj} = the relative molecular weight of the j-th substance (g/mol or lb/lb-mol).

The exponent n in Eq. (9.324) varies from 0.5 under turbulent conditions to 1 under laminar and must be determined experimentally (Brezonik, 1994).

The diffusivities can be estimated by using Eqs. (9.277), (9.278), or (9.279), presented above.

K_g and K_ℓ are areal mass transfer coefficients, because the flux must be multiplied by the interfacial area to get the total rate of mass transfer. In many systems, the interfacial area cannot be determined, but the gas or liquid volumes can. It is then easier to use an overall volumetric mass transfer coefficient. The areal and volumetric coefficients are related by,

$$K_\ell a = \frac{K_\ell A}{V} \tag{9.325}$$

where A = the (possibly unknown) interfacial area (m^2 or ft^2)
$K_\ell a$ = the overall volumetric mass transfer coefficient (per sec).

Oxygen Transfer

Oxygen is an unreactive, high Henry's Law constant gas, with gas transfer kinetics that are liquid film limited.

Oxygen Solubility

The solubility of oxygen depends on the temperature of the water, the humidity of the air, and the mean submergence of the gas bubbles as they rise from the diffusers to the tank surface. Henry's Law for oxygen solubility is as follows:

$$C_s = K_H p_{O_2} \tag{9.326}$$

where C_s = the solubility of oxygen in water (kg/m^3 or lb/ft^3)
K_H = the Henry's Law equilibrium constant ($kg/m^3 \cdot Pa$ or $lb/ft \cdot lbf$)
p_{O2} = the partial pressure of oxygen in the gas phase (Pa or lbf/ft^2)

Because dry air is 20.946% by volume oxygen (Weast, Astle, and Beyer, 1983), Henry's Law can also be written as,

$$C_s = 0.20946 K_H p_{da} \tag{9.327}$$

where p_{da} = the pressure of dry air (Pa or lbf/ft^2).

Air usually contains some water vapor, and Henry's Law for humid air is,

$$C_s = 0.20946 K_H \left(p_{ha} - p_v\right) \tag{9.328}$$

where p_v = the pressure of the water vapor (Pa or lbf/ft^2).

By convention, tabulated values of oxygen solubility are given for standardized condtions of 1 atmosphere (101.325 kPa or 2116.22 lbf/ft^2) total humid air pressure and 100% relaltive humidity in the gas phase:

$$C_s' = 0.20946 K_H \left(p_{sa} - p_{vsat}\right) \tag{9.329}$$

where C_s' = oxygen's solubility in pure water under standard conditions or 20°C and 1 atm total pressure of water-saturated air (kg/m^3 or lb/ft^3) and p_{vsat} = the vapor pressure of water at 20°C (Pa or lbf/ft^2).

TABLE 9.16 Solubilities of Oxygen in Pure Water in Contact with Water Saturated Air at 1 atm Total Pressure

Temp. (°C)	Oxygen Solubility (mg/L) for Salinity (g/kg) of					
	0.0	0.5	1.0	1.5	2.0	2.5
0	14.62	14.57	14.52	14.47	14.42	14.37
5	12.77	12.73	12.69	12.64	12.60	12.56
10	11.29	11.25	11.22	11.18	11.14	11.11
15	10.08	10.05	10.02	9.99	9.96	9.93
20	9.09	9.07	9.04	9.01	8.99	8.96

40	6.41	6.40	6.38	6.36	6.35	6.33
45	5.93	5.92	5.90	5.89	5.87	5.86
50	5.49	5.48	5.47	5.45	5.44	5.43

Computed from formula of Joint Editorial Board. 1992. *Standard Methods for the Examination of Water and Wastewater*, 18th ed. American Public Health Association, Washington, DC.

Because the vapor pressure of water depends only on temperature, one can also write,

$$p_{sa} - p_{vsat} = c \cdot p_{sa} \tag{9.330}$$

$$C_s' = 0.20946 \cdot c \cdot K_H p_{sa} \tag{9.331}$$

The value of c varies from about 0.993 to 0.905 as the temperature increases from 0 to 45°C.

Standard values of the oxygen solubility are given in Table 9.16. These concentrations may be calculated from (Joint Editorial Board, 1992):

$$\ln C_s' = -139.444\ 11 + \frac{157.570\ 1 \times 10^3}{T} - \frac{66.423\ 08 \times 10^6}{T^2} + \frac{12.438\ 00 \times 10^9}{T^3} - \frac{862.1949 \times 10^9}{T^4} - S(‰)\left[0.017674 - \frac{10.754}{T} + \frac{2140.7}{T^2}\right] \tag{9.332}$$

where $S(0/00)$ = the salinity (g "dissolved solids"/kg water)
T = the absolute temperature in K.

The salinity is discussed below.

Salinity and Chlorinity

The solubilities of dissolved gases are reduced by the presence of dissolved salts, which is called the "salting out" effect (Glasstone, 1947).

The original definition of "salinity" was "mass of salt per unit mass of seawater." This proved to be a difficult chemical determination, because simple drying leads to loss of hydrogen chloride and carbon dioxide, and the residue readily aborbs moisture from the atmosphere (Riley and Chester, 1971). The definition due to Knudsen is that the salinity is the grams of dissolved inorganic matter in 1 kg of water after the carbonate has been replaced by oxide, and bromide and iodide have been replaced by chloride. This would be approximately equivalent to the ash left in a volatile solids test of fresh water.

It is simpler to measure the total halides by a silver titration. The "chlorinity" is defined to be the grams of silver needed to precipitate all the halides in 328.5233 g of water. With this definition, the empirical relationship between salinity and chlorinity is as follows (Riley and Chester, 1971):

$$S(‰) = 0.03 + 1.805 Cl(‰) \tag{9.333}$$

Nowadays, salinity is determined via conductance measurements. The currently accepted formula is below (Lewis, 1980; Perkin and Lewis, 1980):

$$S(‰) = \sum_{j=0}^{5} \left[a_j + b_j f(T)\right] R_T^{j/2} \tag{9.334}$$

$$R_T = \frac{R}{R_p r_T} \tag{9.335}$$

$$R_p = 1 + \frac{A_1 p + A_2 p^2 + A_3 p^3}{1 + B_1 T + B_2 T^2 + B_3 R + B_4 R T} \tag{9.336}$$

$$r_T = c_o + c_1 T + c_2 T^2 + c_3 T^3 + c_4 T^4 \tag{9.337}$$

where $A_1, A_2, A_3 = 2.070 \times 10^{-5}$, -6.370×10^{-10}, 3.989×10^{-15}

$a_0, a_1, a_2, a_3, a_4, a_5 = 0.0080, -0.1692, 25.3851, 14.0941, -7.0261, 2.7081$

$B_1, B_2, B_3, B_4 = 3.426 \times 10^{-2}$, 4.464×10^{-4}, 4.215×10^{-1}, 3.107×10^{-3}

$b_0, b_1, b_2, b_3, b_4, b_5 = 0.0005, -0.0056, -0.0066, -0.0375, 0.0636, 0.0144$

$c_0, c_1, c_2, c_3, c_4 = 0.6766097, 0.0200564, 1.104259 \times 10^{-4}$, 6.6698×10^{-7}, 1.0031×10^{-9}

$f(T) = T - 15/1 + 0.0162(T - 15)$

p = the gage pressure of the *in situ* sample in decibars

R = the ratio of the measured *in situ* conductivity of the sample to the conductivity of a solution containing 32.4356 g KCl in 1 kg solution at 15°C and 1 atm total pressure

R_p = a pressure correction factor (dimensionless)

r_T = a temperature correction factor (dimensionless)

T = the *in situ* sample temperature in °C

Equation (9.334) is valid for salinities ranging from 2 to 39 g/kg, temperatures from –2 to 35°C, and pressures form 0 to about 2000 decibars. The pressure correction factor can be ignored in most treatment plant designs.

For the lower salinities normally encountered in water and wastewater treatment (0 to 1 g/kg), the following formula may be used (Hill and Dauphinee, 1986):

$$S(‰) = \sum_{j=0}^{5} \left[a_j + b_j f(T)\right] R_T^{j/2} - \frac{0.0080}{1 + 600 R_T + 1.6 \times 10^5 R_T^2} - \frac{0.0005 f(T)}{1 + 10 R_T + 1000 R_T^{3/2}} \tag{9.338}$$

Effect of Pressure

An air bubble just released from a diffuser is subjected to a total pressure equal to the local barometric pressure plus the hydrostatic head due to the submergence, $p_b + \gamma h$. Air bubbles in contact with water quickly reach the water temperature and become saturated with water vapor, so the dry air pressure in the bubble is $p_b + \gamma h - p_{vsat}$. The partial pressure of oxygen near the diffuser would be $0.20946(p_b + \gamma h - p_{vsat})$.

The hydrostatic head falls as the bubble rises. Moreover, the volume percentage of oxygen in the bubble declines as oxygen is absorbed by the surrounding water. Consequently, one needs to average hydrostatic pressure and bubble oxygen pressure to get an average aeration tank solubility. The result would be as follows:

$$C_s = 0.20946 \bar{f} K_H \left(p_b + \tfrac{1}{2}\gamma h - p_{vsat}\right) \tag{9.339}$$

TABLE 9.17 Densities of Pure Water at Selected Temperature

Temperature (°C)	Mass Density (kg/m³)	Weight Density (N/m³)	Temperature (°C)	Mass Density (kg/m³)	Weight Density (N/m³)

where $\bar{f}$ = the depth-averaged ratio of the oxygen partial pressure at any depth to the initial oxygen partial pressure (dimensionless)
h = the depth of submergence of the diffuser (m or ft)
ν = the weigh density of water (N/m³ or lbf/ft³)

The oxygen transfer efficiency is typically around 10%, so $\bar{f}$ is typically around 0.95.

The mean oxygen solubility in an aeration tank, corrected for all these effects, is related to the standard oxygen solubility by,

$$\overline{C}_s = C'_s \cdot \frac{\bar{f}}{c} \cdot \frac{p_b + \frac{1}{2}\gamma h - p_{vsat}}{p_{sa}} \tag{9.340}$$

where $\overline{C}_s$ = the depth-averaged oxygen solubility (kg/m³ or lb/ft³).

The ratio $\bar{f}/c$ ranges from about 0.96 to 1.05 as the temperature increases from 0 to 45°C, but under summer conditions in the temperate zone, which usually control the design, the ratio is about 0.99.

Density and vapor pressure data for water are given in Tables 9.17 and 9.18, respectively. Air properties versus elevation above or below sea level are given in Table 9.19.

Gas Diffusers

There are two broad classes of air diffusion devices, based on bubble size — coarse bubble and fine bubble. Coarse bubble diffusers produce air bubbles that are 6 to 10 mm in diameter, and new fine bubble diffusers produce bubbles that are 2 to 5 mm in diameter.

The standard oxygen transfer efficiencies of several kinds of diffusers are given in Table 9.20. It should be noted that the fine bubble systems are generally two to three times as efficient as coarse bubble systems. The cost of the increased efficiency is additional maintenance; the benefit is reduced energy usage. Nowadays, fine bubble systems are cost-effective.

Coarse Bubble Diffusion

The most common coarse bubble diffusers consist of perforated pipes and valved orifices. Such devices have low transfer efficiencies, but they resist clogging. Coarse bubble diffusers are generally installed along the bottom of one or both walls to develop spiral flow.

TABLE 9.19 Properties of the Standard Atmosphere vs. Altitude

Altitude Above Mean Sea Level (m)	Pressure (kPa)	Density (kg/m^3)	Absolute Viscosity ($N \cdot s/m^2$)	Temperature (K)
–1000	113.93	1.3470	1.8206×10^{-5}	294.65
–500	107.47	1.2849	1.8050×10^{-5}	291.40

The "oxygen transfer rate" (OTR) for a completely mixed reactor is,

$$R = \alpha \cdot K_\ell a \cdot \left(\beta \cdot C_s - C\right) \cdot V \tag{9.341}$$

where C = the oxygen concentration in the aeration tank (kg/m^3 or lb/ft^3)

C_s = the oxygen solubility in the aeration tank under the given temperature and diffusers submergence (kg/m^3 or lb/ft^3)

$K_\ell a$ = the volumetric mass transfer coefficient (per sec)

R = the oxygen transfer rate (kg/s or lb/sec)

V = the aeration tank volume (m^3 or ft^3)

Source: Joint Task Force of the Water Pollution Control Federation and the American Society of Civil Engineers. 1988. *Aeration: A Wastewater Treatment Process,* WPCF Manual of Practice No. FD-13, ASCE Manuals and Reports on Engineering Practice No. 68. Water Pollution Control Federation, Alexandria, VA; American Society of Civil Engineers, New York.

α = the ratio of the mass transfer coefficient under conditions in the aeration tank to the mass transfer coefficient under standard conditions (dimensionless)

β = the ratio of the oxygen solubility for the salinity in the aeration tank to the oxygen solubility in pure water (dimensionless)

The alpha and beta values depend on water composition, and alpha also depends on the aeration equipment. They should be determined by field testing.

Beta is generally near 1, unless the salinity of the water is high. The effect is accounted for by Eq. (9.315) and Table 9.16. And, if oxygen solubilities are calculated from Eq. (9.315), beta should be set to unity.

Some aeration field data are given in Table 9.21 (Joint Task Force, 1988). For diffused air and oxygen systems, the alpha value for raw and settled municipal wastewater is about 0.2 to 0.3; it rises to about 0.5 to 0.6 for conventional, unnitrified effluents and to about 0.8 to 0.9 for highly treated, nitrified effluents. Alpha values for fine bubble diffusers are smaller than those for coarse bubble systems. For surface aeration systems, the alpha value for raw and settled municipal wastewater is about 0.6; it may rise to 1.2 for clean water.

The volumetric mass transfer coefficient is temperature dependent (Stenstrom and Gilbert, 1981):

$$\frac{K_\ell a(T_1)}{K_\ell a(T_o)} = 1.024^{T_1 - T_o} \tag{9.342}$$

where T_0 = the reference temperature in °C

T_1 = the aeration tank temperature in °C.

The usual reference temperature is 20°C.

The so-called "standard oxygen transfer rate" (SOTR) of equipment is usually reported under standard conditions of clean water, zero dissolved oxygen, 20°C, 1 standard atmosphere (101.325 kPa or 2116.22 lbf/ft^2) of ambient air pressure, and a specified depth of submergence. The SOTR is calculated as,

$$R_{std} = K_\ell a \cdot C_s \cdot V \tag{9.343}$$

where R_{std} = the standard oxygen transfer rate (kg/s or lb/sec).

The conversion of SOTRs to OTRS is as follows:

$$\frac{R}{R_{std}} = \cdot \frac{\alpha \cdot 1.024^{T-20} \cdot \left[\beta \cdot C_s(T) - C\right]}{C_s(20°C)} \tag{9.344}$$

The oxygen transfer efficiency (OTE) is the ratio of the oxygen absorbed to the oxygen supplied in the airflow through the diffuser:

$$E_{O_2} = \frac{R}{0.20946 Q_a \rho_a M_{rO_2}} \tag{9.345}$$

where E_{O2} = the oxygen transfer efficiency (dimensionless)
M_{rO2} = the relative molecular weight of oxygen (31.998, either g/mol or lb/lb-mol)
Q_a = the airflow rate under standard conditions of 1 atm pressure and 0°C (m^3/s or ft^3/sec)
ρ_a = the molar oxygen density (mol/m^3 or lb-mol/ft^3)

The standard oxygen transfer efficiency (SOTE) is the efficiency for clean water at 20°C and 1 atm pressure at a specified submergence.

The molar density of oxygen can be calculated from the ideal gas law:

$$\rho_a = \frac{n}{V} = \frac{P}{RT} \tag{9.346}$$

Fine Bubble Diffusers

There are three types of fine bubble diffusers (ASCE Committee on Oxygen Transfer, 1989):

- Sintered ceramic plates made from alumina, aluminum silicate, and silica
- Rigid porous plastic plates and tubes, usually made from high-density polyethylene (HDPE) and styrene-acrylonitrile
- Nonrigid porous plates and tubes made from rubber and HDPE
- Perforated plastic membrane, both discs and tube sheaths, usually made from polyvinyl chloride (PVC) with added plasticizer

Presently, only the first and last types are in widespread use. The diffusers are installed as plate holders and air manifolds set on the aeration tank floor or as disc, dome, or tube diffusers attached to air manifolds that cover the tank floor and are set somewhat above it.

Fine bubble diffusers gradually lose oxygen transfer effciency. This is usually modeled as (ASCE Committee on Oxygen Transfer, 1989),

$$R = \alpha \cdot F \cdot K_\ell a \cdot \left(\beta \cdot C_s - C\right) \cdot V \tag{9.347}$$

where F = the fouling factor (dimensionless).

The fouling factor decreases with time of service. This occurs because the diffuser pores accumulate airborne particulates and precipitates from the water (Type I) or because biofilm grows on the diffuser surface (Type II). For design purposes, the rate of fouling may be taken as constant so that the fouling factor may be modeled as,

$$F = 1.0 - k_f t \tag{9.348}$$

where k_f = the fouling rate (per sec), and t = the service time (sec).

Typical values for k_f range from 0.03 to 0.07 per month.

TABLE 9.22 Effect of Airflow Rate on Diffuser Oxygen Transfer Efficiency

Diffuser System	m
Ceramic dome grid	0.150
Ceramic disc grid	0.133
Ceramic disc grid	0.126
Rigid porous disc grid	0.097
Rigid porous tube in double spiral roll	0.240
Nonrigid tube in spiral roll	0.276
Perforate membrane disc grid	0.195
Perforated membrane disc grid (9 in.)	0.11
EPDM perforated membrane tube grid	0.150

Source: ASCE Committee on Oxygen Transfer. 1989. *Design Manual: Fine Pore Aeration Systems*, EPA/625/1–89/023. U.S. Environmental Protection Agency, Office of Research and Development, Center for Environmental Research Information, Risk Reduction Engineering Laboratory, Cincinnati, OH.

The standard oxygen transfer efficiencies of fine bubble diffusers depend somewhat on airflow rate (ASCE Committee on Oxygen Transfer, 1989):

$$\frac{E_{stdO_2,2}}{E_{stdO_2,1}} = \left(\frac{Q_{ad1}}{Q_{ad2}}\right)^m \tag{9.349}$$

Values of m for various diffusers are given in Table 9.22.

Air Piping

The volumetric airflow rate for the piping temperature and pressure can be esitmated from the ideal gas law:

$$\frac{p_2 Q_{a2}}{T_2} = \frac{p_{sa} Q_{Ra}}{T_{sc}} \tag{9.350}$$

where p_2 = the blower outlet pressure (Pa or lbf/ft^2)
p_{sa} = the pressure of the standard atmosphere (101.325 kPa or 2,116.22 lbf/ft^2)
Q_a = the airflow rate (m^3/s or ft^3/sec)
Q_{Ra} = the required process airflow rate at standard conditions of 1 atm pressure and 0°C (m^3/s or ft^3/sec)
T_2 = the blower outlet temperature (K or °R)
T_{sc} = the temperature for standard conditions for gases (273.15 K or 491.67°R)

The piping inlet temperature may be estimated from the adiabatic polytropic process (Perry and Chilton, 1973),

$$T_2 = T_1\left(\frac{p_2}{p_1}\right)^{(n-1)/n} \tag{9.351}$$

where n = the exponent for the polytropic process (dimensionless)
= 1.40, for air
p_1 = the blower intake pressure (N/m^2 or lbf/ft^2);

p_2 = the blower outlet pressure (N/m^2 or lbf/ft^2)
T_1 = the blower intake temperature (K or °R)
T_2 = the blower outlet temperature (K or °R)

The blower power requirement is (Perry and Chilton, 1973),

$$P = \left(\frac{n}{n-1}\right)\rho_a Q_a R T_1 \left[\left(\frac{p_2}{p_1}\right)^{(n-1)/n} - 1\right] \tag{9.352}$$

where P = the blower power (W or ft-lbf/sec)
Q_a = the airflow rate (m^3/s or ft^3/sec)
R = the gas constant 8314.510 J/mol·K or 1545.356 ft·lbf/lb-mol·°R)
ρ_a = the mass density of the air (mol/m^3 or lb-mol/ft^3)

The blower power is the power in the compressed air, and the power required by the blower motor will be larger in inverse proportion to the blower efficiency.

For small temperature and pressure changes (less than 10%), air may be treated as an incompressible fluid (Metcalf & Eddy, Inc., 1991). The priniciple difference from water distribution is that the blower exit gas is hot (about 140°F to 180°F), and allowances must be made for piping expansion and contraction.

The headloss may be calculated using the Darcy–Weisbach equation and friction factors from the Moody diagram. The air density may be calculated from the ideal gas law. The viscosity of air is given by the Chapman–Enskog formula (Blevins, 1984):

$$\mu_a = 26.69 \times 10^{-7} \frac{M_{ra}^{1/2} T^{1/2}}{\sigma^2 \Omega_v} \tag{9.353}$$

$$\Omega_v = 1.147\left(\frac{T}{T_e}\right)^{-0.145} + \left(\frac{T}{T_e} + 0.5\right)^{-2.0} \tag{9.354}$$

where M_{ra} = the relative molecular weight for air (28.966 g/mol, for air)
T = the air temperature in K
T_e = the effective temperature of the force potential in K (78.6 K, for air)
μ_a = the dynamic viscosity of air in N·s/m^2
σ = the collision diameter in Å (3.711 Å, for air)

Surface Aerators

The common surface aerators are the Kessener brush and its derivatives (brushes or discs mounted on a horizontal shaft and normally found in oxidation ditches), low-speed radial flow turbines and high-speed axial flow turbines (usually equipped with draft tubes and found in aerated lagoons).

Surface aerators are rated in terms of mass of oxygen transferred per unit time per unit power, e.g., kg/kW·s or lb/hp·hr. The design equation is shown below (Joint Task Force, 1988):

$$\frac{R/P}{R_{std}/P} = \cdot \frac{\alpha \cdot 1.024^{T-20} \cdot \left[\beta \cdot C_s(T) - C\right]}{C_s(20°C)} \tag{9.355}$$

Both alpha and beta values are often reported to be about 1 in municipal wastewater. The usual theta value, 1.024, applies. Standard aeration rates for low-speed radial flow systems range from about 2 to 5 lb O_2/hp·hr; for high-speed axial flow aerators, from 2 to 3.6 lb O_2/hp·hr; and for brushes, from 1.5 to 3.6 lb O_2/hp·hr (Metcalf & Eddy, 1991).

TABLE 9.23 Acid Ionization Constants for Selected Gases (pK_a Values)

	Temperature (°C)									
Acid	0	5	10	15	20	25	30	35	40	50

Absorption of Reactive Gases

Some gases react with water or with other solutes in it. If the reactions are fast (like most acid/base reactions), the reaction increases the amount of gas that is adsorbed and its adsorption rate.

Equilibria

Henry's Law applies only to the dissolved gas molecule and not to any of its reaction products.

Ammonia

Ammonia chemistry is outlined in Chapter 8. Ammonia reacts with water to form the ammonium ion, NH_4^+:

$$NH_3 + H_2O \leftrightarrow NH_4^+ + OH^- \tag{9.356}$$

The molar fraction of the total ammonia concentration that is unprotonated ammonia is,

$$f = \frac{[NH_3]}{[NH_3]+[NH_4^+]} = \frac{1}{1+\dfrac{[H^+]}{K_a}} = \frac{1}{1+\dfrac{K_b}{[OH^-]}} \tag{9.357}$$

where K_a = the acid ionization constant (mol/L)
K_b = the base ionization constant (mol/L).

Values of the acid ionization constant for various temperatures are given in Table 9.23.

Carbon Dioxide

Atmospheric carbon dioxide goes into solution, forming aqueous carbon dioxide, and this reacts with water to form carbonic acid (Stumm and Morgan, 1970):

$$CO_2(g) \rightarrow CO_2(aq) \tag{9.358}$$

$$CO_2(aq) + H_2O \rightarrow H_2CO_3 \tag{9.359}$$

The reaction in Eq. (9.358) goes virtually to completion, and dissolved carbon dioxide and carbonic acid are not distinguished by the usual analytical methods. Therefore, it is customary to define a "composite carbonic acid" concentration:

$$\left[H_2CO_3^*\right] = \left[H_2CO_3\right] + \left[CO_{2(aq)}\right] \tag{9.360}$$

At equilibrium, the ratio of $CO_2(aq)$ to H_2CO_3 is constant, depending only on temperature, so this convention merely introduces a constant factor into the equilibrium constants. The composite carbonic acid ionizes to produce bicarbonate, and bicarbonate ionizes to make carbonate:

$$H_2CO_3^* \leftrightarrow H^+ + HCO_3^- \tag{9.361}$$

$$HCO_3^- \leftrightarrow H^+ + CO_3^{2-} \tag{9.362}$$

The system is completed by the ionization of water:

$$H_2O \leftrightarrow H^+ + OH^- \tag{9.363}$$

The equilibrium constants for this system may be written as:

$$K^*_{H_{CO_2}} = \frac{\left[H_2CO_3^*\right]}{p_{CO_2}} \tag{9.364}$$

$$K_1 = \frac{\left[H^+\right]\left[HCO_3^-\right]}{\left[H_2CO_3^*\right]} \tag{9.365}$$

$$K_2 = \frac{\left[H^+\right]\left[CO_3^{2-}\right]}{\left[HCO_3^-\right]} \tag{9.366}$$

$$K_w = \left[H^+\right]\left[OH^-\right] \tag{9.367}$$

where [X] = the activity of species X (moles/L), usually approximated as the molar concentration in dilute solutions

p_{CO2} = the partial pressure of carbon dioxide in the atmosphere (atm).

Numerical values for these constants at several temperatures are given in Table 9.23.

The molar concentrations of the various species can be written in terms of the proton concentration and the equilibrium constants by using Eq. (9.364) through (9.367) to eliminate variables:

$$f_o = \frac{\left[H_2CO_3^*\right]}{\left[H_2CO_3^*\right] + \left[HCO_3^-\right] + \left[CO_3^{2-}\right]} = \frac{1}{1 + \dfrac{K_1}{\left[H^+\right]} + \dfrac{K_1K_2}{\left[H^+\right]^2}} \tag{9.368}$$

$$f_1 = \frac{\left[HCO_3^-\right]}{\left[H_2CO_3^*\right] + \left[HCO_3^-\right] + \left[CO_3^{2-}\right]} = \frac{1}{1 + \dfrac{\left[H^+\right]}{K_1} + \dfrac{K_2}{\left[H^+\right]}} \tag{9.369}$$

TABLE 9.24 Distribution of Alkaline Species for the Carbonate System

Ratio of Phenolphthalein to Total Alkalinity P/T	Bicarbonate (meq/L)	Carbonate (meq/L)	Hydroxide (meq/L)
0	T	0	0
<1/2	$T - 2P$	$2P$	0
1/2	0	$2P$ or T	0
>1/2	0	$2(T - P)$	$2P - T$
1	0	0	T

Source: Hardenbergh, W.A. and Rodie, E.B. 1963. *Water Supply and Waste Disposal*. International Textbook Co., Scranton, PA.

$$f_2 = \frac{\left[CO_3^{2-}\right]}{\left[H_2CO_3^*\right]+\left[HCO_3^-\right]+\left[CO_3^{2-}\right]} = \frac{1}{1+\frac{\left[H^+\right]}{K_2}+\frac{\left[H^+\right]^2}{K_1K_2}} \tag{9.370}$$

where f_0 = the molar fraction of the carbonate species in the form of the composite acidity (dimensionless)
f_1 = the molar fraction of the carbonate species in the form of bicarbonate (dimensionless)
f_2 = the molar fraction of the carbonate species in the form of carbonate (dimensionless)

The rather wide separation in the values of K_1 and K_2 and the fact that significant quantities of bicarbonate and hydroxide do not occur together make possible a simple procedure for determining the distribution of hydroxide, carbonate, and bicarbonate. The alkalinity titrated to pH 8.3 is called the "phenolphthalein alkalinity" (because phenolphthalein is used to detect the endpoint), and the total quantity of acid needed to reduce the pH from the original sample value past pH 8.3 down to pH 4.5 is traditionally called the "methyl orange alkalinity," or total alkalinity (which is better, because bromcresol green is the preferred indicator). The ratio of these two values determines the distribution of carbonate forms, as indicated in Table 9.24.

Chlorine

Chlorine gas readily dissolves in water according to Henry's Law (Stover et al., 1986):

$$\left[Cl_2(aq)\right] = K_H p_{Cl_2} \tag{9.371}$$

$$K_H = 4.805 \times 10^{-6} e^{2818.48/T} \tag{9.372}$$

where $[Cl_2(aq)]$ = the concentration of molecular chlorine in mol/L
K_H = Henry's Law constant in mol/L·atm
p_{Cl_2} = the partial pressure of molecular chlorine in the gas phase in atm
T = the absolute temperature in K

Dissolved chlorine reacts strongly with water to form hypochlorous acid (White, 1986):

$$Cl_2(aq) + H_2O \leftrightarrow HOCl + H^+ + Cl^- \tag{9.373}$$

$$K_o \frac{\left[H^+\right]\left[Cl^-\right]\left[HOCl\right]}{\left[Cl_2(aq)\right]} \tag{9.374}$$

$$pK_o = -0.579 + \frac{1190.7}{T} \tag{9.375}$$

where T = the absolute temperature in K.

In pure water, the total concentration can be written as follows (Stover et al., 1986):

$$\left[Cl_2(aq)\right]+\left[HOCl\right]=K_H p_{Cl_2}+\left(K_o K_H p_{Cl_2}\right)^{1/3} \tag{9.376}$$

In buffered water with significant background chloride concentrations, the total solubility is as shown:

$$\left[Cl_2(aq)\right]+\left[HOCl\right]=K_H p_{Cl_2}\left[1+\frac{K_o}{\left[H^+\right]\left[Cl^-\right]}+\frac{K_o K_a}{\left[H^+\right]^2\left[Cl^-\right]}\right] \tag{9.377}$$

The hypochlorous acid ionizes to form hypochlorite ion:

$$HOCl \leftrightarrow H^+ + OCl^- \tag{9.378}$$

$$K_a=\frac{[H^+][OCl^-]}{[HOCl]} \tag{9.379}$$

$$pK_a=-10.069+0.025T-\frac{3000}{T} \tag{9.380}$$

where T = kelvin.

The molar fraction of hypochlorous acid depends strongly on pH and can be estimated from,

$$f=\frac{\left[HOCl\right]}{\left[HOCl\right]+\left[OCl^-\right]}=\frac{1}{1+\frac{K_a}{\left[H^+\right]}} \tag{9.381}$$

Below pH 7, a mixture of hypochlorous acid and hypochlorite is found in nearly all un-ionized acid, but at about pH 9, hypochlorous acid comprises nearly all of the ion.

Values of the acid ionization constants are given in Table 9.23.

Chlorine Dioxide

The solubility of chlorine dioxide follows Henry's Law (Haas, 1990):

$$C_{ClO_2}=K_H p_{ClO_2} \tag{9.382}$$

$$\ln K_H=58.84621+\frac{47.9133}{T}-11.0593\ln T \tag{9.383}$$

where C_{ClO_2} = the mole fraction of chlorine dioxide in water (dimensionless)
K_H = the Henry's Law constant per atm
P_{ClO_2} = the partial pressure of chlorine dioxide in the gas phase in atm
T = the absolute temperature in K

Above pH 9, chlorine dioxide disproportions according to,

$$2\,ClO_2+2\,OH^- \leftrightarrow ClO_3^-+ClO_2^-+H_2O \tag{9.384}$$

An equilibrium constant is not yet available.

Hydrogen Chloride

The solubility of hydrogen chloride in pure water ranges from 823 g/L at 0°C to 633 g/L at 40°C (Dean, 1992).

Hydrogen chloride is a strong acid with an acid ionization constant of about 1.3×10^6 (Dean, 1992) and is nearly completely ionized in water:

$$HCl \leftrightarrow H^+ + Cl^- \tag{9.385}$$

Hydrogen Cyanide

The solubility of hydrogen cyanide is virtually unlimited. The cyanide ion forms complexes with many metals, which further enhances the solubility.

Hydrogen cyanide is a weak acid:

$$HCN \leftrightarrow H^+ + CN^- \tag{9.386}$$

$$K_a = \frac{[H^+][CN^-]}{[HCN]} \tag{9.387}$$

Values of the acid ionization constant for several temperatures are given in Table 9.23.

Hydrogen Sulfide

The solubility of hydrogen sulfide in pure water ranges from about 7.1 g/L at 0°C to about 1.9 g/L at 50°C (Dean, 1992).

Hydrogen sulfide is a weak acid, and it dissociates twice as the pH is raised:

$$H_2S \leftrightarrow HS^- + H^+ \tag{9.388}$$

$$K_1 = \frac{[H^+][HS^-]}{[H_2S]} \tag{9.389}$$

$$HS^- \leftrightarrow S^{2-} + H^+ \tag{9.390}$$

$$K_2 = \frac{[H^+][S^{2-}]}{[HS^-]} \tag{9.391}$$

The sulfide ion forms highly insoluble precipitates with many metals, which greatly enhances its solubility. Values of the acid ionization constant are given in Table 9.23.

Ozone

The solubility of ozone follows Henry's Law (Joint Task Force, 1990):

$$C_{O_3} = K_H p_{O_3} \tag{9.392}$$

$$K_H = \frac{1.29 \times 10^6}{T} - 3720.5 \tag{9.393}$$

where C_{O_3} = the ozone concentration in mg/L
K_H = the Henry's Law constant in mg/L·%
P_{O_3} = the partial pressure of ozone in the gas phase in % of one atm
T = the temperature in K

The units of pressure are somewhat peculiar. For example, if the exit gas from the generator is at 1 atm total pressure and 20°C, and if it contains 0.05% ozone, the solubility of ozone is 0.34 mg/L.

Ozone decomposes spontaneously, even in the absence of reductants.

Sulfur Dioxide

Sulfur dioxide is used as a reductant to remove excess chlorine following disinfection.

The solubility of sulfur dioxide in pure water ranges from 798 g/L at 0°C to about 188 g/L at 45°C (Dean, 1992).

$$SO_2(g) \leftrightarrow SO_2(aq) \tag{9.394}$$

$$C_{SO_2} = K_H p_{SO_2} \tag{9.395}$$

The Henry's Law constant is approximately 247, 75, and 22.9 g/L·atm at 4, 16, and 27°C, respectively (Stover et al., 1986).

Sulfur dioxide reacts with water to form sulfurous acid, which ionizes step-wise to form bisulfite and sulfite ions (Stover et al., 1986):

$$SO_2 + H_2O \leftrightarrow H_2SO_3 \tag{9.396}$$

$$K_o = \frac{[H_2SO_3]}{[SO_2(aq)]} \tag{9.397}$$

$$H_2SO_3 \leftrightarrow HSO_3^- + H^+ \tag{9.398}$$

$$K_1 = \frac{[H^+][HSO_3^-]}{[H_2SO_3]} \tag{9.399}$$

$$HSO_3^- \leftrightarrow SO_3^{2-} + H^+ \tag{9.400}$$

$$K_2 = \frac{[H^+][SO_3^{2-}]}{[HSO_3^-]} \tag{9.401}$$

Acid ionization constants are given in Table 9.23.

Kinetics

The effect of fast reactions is to increase the concentration gradient in the interfacial layers and, consequently, the rate of gas absorption. This is expressed mathematically and experimentally by an increase in the liquid film mass transfer coefficient, k_ℓ (Sherwood, Pigford, and Wilke, 1975). The increase depends on the details of the reaction, including the other reactants, and must be determined empirically.

Air Stripping of Volatile Organic Substances

Nowadays, an important treatment process is the removal of volatile organic substances — many of which are toxic and/or carcinogenic — from water by air stripping in packed towers or by air diffusion or surface aeration in tanks.

Packed Towers

The common packing materials are 1 to 2 in Berl saddles, Pall rings, Rasching rings, plastic rods, spheres, and plastic Tellerettes. The air and water flow rates are countercurrent, with the water generally trickling down over the packing and the air being forced upwards through the bed by blowers.

If the contaminant concentration in water is dilute so that Henry's law governs its solubility, the required height of packing is given by the following (Sherwood, Pigford, and Wilke, 1975):

$$H = \left(\frac{Q_\ell / A}{K_\ell a}\right) \cdot \left(\frac{\dfrac{K_{HC} Q_a}{Q_\ell}}{\dfrac{K_{HC} Q_a}{Q_\ell} - 1}\right) \cdot \ln\left[\frac{\left(C_{\ell,i} - \dfrac{C_{a,i}}{K_{HC}}\right)\left(\dfrac{K_{HC} Q_a}{Q_\ell} - 1\right) + 1}{\left(C_{\ell,e} - \dfrac{C_{a,i}}{K_{HC}}\right)\left(\dfrac{K_{HC} Q_a}{Q_\ell}\right)}\right] \tag{9.402}$$

where A = the cross-sectional area of the packed tower (m^2 or ft^2)
$C_{a,i}$ = the concentration of contaminant in the influent air (kg/m^3 or lb/ft^3)
$C_{\ell,e}$ = the concentration of contaminant in the effluent water (kg/m^3 or lb/ft^3)
$C_{\ell,i}$ = the concentration of contaminant in the influent water (kg/m^3 or lb/ft^3)
H = the height of the packing (m or ft)
K_{HC} = the so-called "dimensionless" Henry's law constant (m^3 water/m^3 air or ft^3 water/ft^3 air)
$= C_a / C_\ell$
K_ℓ = the overall areal liquid phase mass transfer coefficient for clean water (m/s or ft/sec)
Q_a = the airflow rate (m^3/s or ft^3/sec)
Q_ℓ = the water flow rate (m^3/s or ft^3/sec)

In environmental engineering practice, the influent air has no contaminant in it, so $C_{a,i}$ in Eq. (9.402) is zero. Henry's Law constants are given in a variety of units, and one must be careful to use the appropriate numerical value.

The principal problem in using Eq. (9.402) is evaluation of the overall mass transfer coefficient. This has been the subject of numerous studies, and the Onda correlations are currently preferred (Roberts et al., 1985; Lamarche and Droste, 1989; Staudinger, Knocke, and Randall, 1990):

$$\frac{A_w}{A_v} = 1 - \exp\left\{-1.45 \cdot \left(\frac{\sigma_c}{\sigma_\ell}\right)^{0.45} \left(\frac{\rho_\ell Q_\ell / A}{A_v \mu_\ell}\right)^{0.1} \left[\frac{\rho_\ell^2 g}{A_v \left(\rho_\ell Q_\ell / A\right)^2}\right]^{0.05} \left[\frac{\left(\rho_\ell Q_\ell / A\right)^2}{\rho_\ell \sigma_\ell A_v}\right]^{0.2}\right\} \tag{9.403}$$

$$\frac{k_a}{A_v D_a} = 5.23 \cdot \left(\frac{\rho_a Q_a / A}{A_v \mu_a}\right)^{0.7} \left(\frac{\mu_a}{\rho_a D_a}\right)^{1/3} \tag{9.404}$$

$$k_\ell \left(\frac{\rho_\ell}{\mu_\ell g}\right)^{1/3} = 0.0051 \left(\frac{\rho_\ell Q_\ell}{A_w \mu_\ell}\right)^{2/3} \left(\frac{\mu_\ell}{\rho_\ell D_\ell}\right)^{0.5} \left(A_v d_p\right)^{0.4} \tag{9.405}$$

where A = the plan area of the packed tower (m^2 or ft^2)
A_v = the specific surface area of the packing (m^2/m^3 or ft^2/ft^3)
A_w = the wetted specific surface area of the packing (m^2/m^3 or ft^2/ft^3)
D_a = the diffusivity of the contaminant vapor in air (m^2/s or ft^2/sec)
D_ℓ = the diffusivity of the contaminant in water (m^2/s or ft^2sec)
d_p = the nominal packing size (m or ft)
g = the acceleration due to gravity (9.80665 m/s^2 or 32.174 ft/sec^2)
k_a = the air film mass transfer coefficient (m/s or ft/sec)
k_ℓ = the water film mass transfer coefficient (m/s or ft/sec)
Q_a = the airflow rate (m^3/s or ft^3/sec)
Q_ℓ = the water flow rate (m^3/s or ft^3/sec)
μ_a = the dynamic viscosity of air (N/m^2·s or lbf/ft^2·sec)

μ_ℓ = the dynamic viscosity of water (N/m^2·s or lbf/ft^2·sec)
ρ_a = the mass density of air (kg/m^3 or lb/ft^3)
ρ_ℓ = the mass density of water (kg/m^3 or lb/ft^3)
σ_c = the critical surface tension of the packing (N/m or lbf/ft)
σ_ℓ = the surface tension of water (N/m or lbf/ft)

Staudinger et al. (1990) estimated that the Onda correlations yield a ±30% error in the mass transfer rate, $K_\ell a$. LaMarche and Droste (1989) also found that the Onda predictions were uniformly too high, but their error was smaller. For design purposes, use 70% of the predicted $K_\ell a$.

Properties of Packings

Physical properties of common packing materials are given in Table 9.25.

The critical surface tension is that which produces a contact angle of zero between the solid surface and the liquid film surface that is in contact with air (Adamson, 1982). Table 9.26 lists some critical surface tensions.

Henry's Law Constants

Henry's Law can be written in several different ways, and each way assigns different units to the constant (Munz and Roberts, 1987):

$$p_i = K_{HXp} \cdot X_{\ell i} \tag{9.406}$$

$$p_i = K_{HCp} \cdot C_{\ell i} \tag{9.407}$$

$$C_{ai} = K_{HC} \cdot C_{\ell i} \tag{9.408}$$

The different constants are connected by the following:

$$K_{HC} = K_{HXp} \cdot \frac{\nu_\ell M_{r\ell}}{RT} \tag{9.409}$$

$$K_{HCp} = K_{HXp} \cdot \nu_\ell \tag{9.410}$$

where C_{ai} = the concentration of contaminant in the air (kg/m^3 or lbm/ft^3)
$C_{\ell i}$ = the concentration of contaminant in the water (kg/m^3 or lbm/ft^3)
K_{HC} = the so-called "dimensionless" Henry's law constant (m^3 water/m^3 air or ft^3 water/ft^3 air)
$= C_a/C_\ell$
K_{HCp} = the Henry's Law constant (Pa·m^3/kg or lbf·ft/lb)
K_{HXp} = the Henry's Law constant (Pa in lbf/ft^2)
$M_{r\ell}$ = the molecular weight of water (18 g/mol or 18 lb/lb-mol)
p_i = the partial pressure of species i in air (Pa or lbf/ft^2)
R = the gas constant (8.314 J/mol·K or 1545 ft-lbf/lb-mol·°R)
T = the absolute temperature (K or °R)
ν_ℓ = the specific volume of water (m^3/kg or ft^3/lb)
$X_{\ell i}$ = the mole fraction of species i in water (dimensionless)

Henry's Law constants for several important volatile organic compounds are listed in Table 9.27. The temperature dependency is represented by an empirical fit to the van't Hoff relationship. This is done separately for each form of the constant, e.g.,

$$\log K_{HXp} = a - \frac{b}{T} \tag{9.411}$$

TABLE 9.25 Physical Properties of Packings

Packing	Nominal Size (in.)	Bulk Density (lb/ft^3)	Specific Surface Area (ft^2/ft^3)	Porosity (%)
Berl saddles, ceramic	2	39	32	72

$$\log K_{HC} = a' - \frac{b'}{T} \tag{9.412}$$

$$\log K_{HCp} = a'' - \frac{b''}{T} \tag{9.413}$$

where a,a',a'' = empirical constants (dimensionless)
b,b',b'' = empirical constants (K or °R).

Diffused Air and Surface Aeration

Volatile organic contaminants can be removed by diffused and surface aeration. The laws governing oxygen transfer also apply. The gas and liquid film mass transfer coefficient s depends on molecular diffusivities, which in turn, depend on molecular weights. Therefore, if one knows k_ℓ and k_g for one substance in a particular mass transfer system, one can, in principal, calculate for any other substance. One needs to distinquish between surface aerators and diffused air, because the air bubbles accumulate contaminant as they rise through the liquid.

Surface Aerators

In the case of surface aerators, there is no contaminant concentration in the ambient air, so the solubility of the contaminant is zero. For a completely mixed reactor, the steady state mass balance is as follows (Roberts, Munz, and Dändliker, 1984):

$$Q_\ell\left(C_{\ell,i} - C_{\ell,e}\right) = K_\ell a_j \cdot C_{\ell,e} V \tag{9.414}$$

where $C_{\ell,e}$ = the concentration of contaminant in the effluent water (kg/m³ or lb/ft³)
$C_{\ell,i}$ = the concentration of contaminant in the influent water (kg/m³ or lb/ft³)
$K_\ell a_j$ = the overall volumetric liquid-phase mass transfer coefficient for species j (per sec)
Q_ℓ = the water flow rate (m³/s or ft³/sec)
V = the tank volume (m³ or ft³)

In the more general case of mixed-cells-in-series and in ideal plug flow, one gets the following:

$$\frac{C_{\ell,e}}{C_{\ell,i}} = \left[\frac{1}{1 + K_\ell a_j\left(V_1/Q_\ell\right)}\right]^n \tag{9.415}$$

$$\frac{C_{\ell,e}}{C_{\ell,i}} = \exp\left(-\frac{K_\ell a_j V}{Q_\ell}\right) \tag{9.416}$$

where n = the number of mixed-cells-in-series (dimensionless).

For relatively insoluble substances like oxygen and many volatile organics, the gas film resistance is small and may be neglected (Kavanaugh and Trussel, 1980). In that case, K_ℓ is nearly equal to k_ℓ. The organic vapor mass transfer coefficient for a particular system may be estimated from the coefficient for oxygen, if it is known, via Eq. (9.324).

Air Diffusion

Assuming a completely mixed reactor, the ratio of the liquid effluent to liquid influent concentrations of the volatile organic substance removal is given by Roberts, Munz, and Dändliker, 1984):

$$\frac{C_{\ell,e}}{C_{\ell,i}} = \frac{1}{1+\dfrac{Q_a K_{HCj}}{Q_\ell}\left[1-\exp\left(-\dfrac{K_\ell a_j V}{K_{HCj} Q_a}\right)\right]} \tag{9.417}$$

The concentration of the contaminant in the off-gas is,

$$C_{a,e} = K_{HCj} \cdot C_{\ell,e}\left[1-\exp\left(-\frac{K_\ell a_j V}{K_{HCj} Q_a}\right)\right] \tag{9.418}$$

where $C_{a,e}$ = the concentration of contaminant in the effluent air (kg/m^3 or lb/ft^3)
K_{HCj} = the "dimensionless" Henry's Law constant for species j (m^3 water/m^3 air or ft^3 water/ft^3 air)
$K_\ell a_j$ = the overall volumetric liquid-phase mass transfer coefficient for species j (per sec)
Q_a = the airflow rate (m^3/s or ft^3/sec)

10.1 Coagulation

Surface waters contain a variety of suspended, colloidal solids that have aesthetic, economic, or health impacts. Simple sedimentation and direct, unaided filtration are not practical in the case of clays and organic detritus, because the overflow and filtration rates required for their removal lead to facilities that are 100 to 200 times larger than those built today (Fanning, 1887; Fuller, 1898). Consequently, all surface water treatment plants incorporate processes that destabilize and agglomerate colloids into larger, fast-settling particles.

Colloids

Properties

Colloidal systems (dispersoids, colloidal dispersions, colloidal suspensions, colloidal solutions, and sols) consist of particles suspended in some sort of medium. The chemical composition of the particles is usually different from that of the medium, but examples where they are the same are known. Colloidal systems are distinguished from true solutions and mechanical suspensions by the following criteria (Voyutsky, 1978).

Opalescence

Colloidal systems scatter visible light. If a light beam is passed through a suspension of colloidal particles, some of the light beam will be scattered at right angles, and a cloudy streak will be seen running along its path. This is called a "Tyndall cone" after its discoverer.

A consequence of scattering is that colloidal systems do not transmit images of objects; when the transmitted light is viewed along its path, only a uniform glow is seen. This property is called "turbidity," and colloidal systems are said to be "turbid." By contrast, true solutions, even if they are colored, transmit clear images of objects.

Opalescence is the basis of colloid measurement. If light intensity measurements are made collinearly with the beam, the procedure is called "turbidimetry." If the measurements are made at right angles to the path of the beam, the procedure is called "nephelometry."

Turbidimetry requires subtraction of the light intensity leaving the sample from the light intensity entering the sample. For low turbidities, this difference is small, and its measurement is inherently inaccurate. Nephelometry is preferred at low turbidities, because only the intensity of the scattered light need be known, and very low light intensities can be measured accurately.

In Rayleigh's theory, the scattered light intensity is given by the following (Jirgensons and Straumanis, 1956):

$$H_s = 24\pi^3 \cdot \left(\frac{n_p^2 - n_m^2}{n_p^2 + 2n_m^2} \right) \cdot \frac{nV_p^2}{\lambda^4} \cdot I_o \tag{10.1}$$

where H_s = the total scattered light intensity summed over all angles from nonconducting, spherical particles (W or ft·lbf/sec)
I_0 = the irradiance of the incident beam (W/m^2 or ft·lbf/ft^2·sec)
n = the concentration of particles (number/m^3 or number/ft^3)
n_m = the refractive index of the suspending medium (dimensionless)
n_p = the refractive index of the particle (dimensionless)
λ = the wavelength of the incident beam (m or ft)

The observed intensity of scattered light varies with (a) the angle at which the light is measured, (b) the size and properties of the particles, (c) the properties of the suspending medium, (d) the wavelengths in the incident light, and (e) whether or not the light is polarized. Consequently, the units of turbidity are somewhat arbitrary, and the weight concentrations of particles in different waters may be different, even if the turbidities are the same.

The turbidity units used in environmental engineering are based on several different but related standards. The earliest standard was based on the silica frustules of diatoms (Committee on Standard Methods of Water Analysis, 1901). The shells were cleaned of organic matter and ground and sieved through a 200 mesh screen, so the particles were smaller than 74 μm. This means the original standard suspension includes some particles that were larger than colloids. A suspension containing 1 mg/L of these prepared particles was defined to have a turbidity of 1.

Nowadays, the clay kaolin, the organic colloid formazin, and styrene divinylbenzene beads are used instead of diatomaceous earth, but the concentrations of these materials are adjusted so that one turbidity unit of any of them produces approximately the same degree of scattering as 1 mg/L of diatomaceous earth (Joint Editorial Board, 1992). All these modern standards also include particles that are larger than colloids. However, many of the suspended particles in surface waters are supracolloidal, so the use of standards containing supracolloidal particles is not an error.

If the turbidity is between 25 and 1000 units, it is often measured using a Jackson Tube. This is an example of turbidimetry. In this device, a standardized candle is viewed through a layer of sample contained in a glass tube with opaque sides and a clear bottom. Sample can be added to or withdrawn from the tube until the image of the candle disappears and a uniformly illuminated field remains. The depth of sample is correlated with the turbidity. For example, if the turbidity is 100 units, the image of the candle disappears at a sample depth of 21.5 cm; it disappears at 39.8 cm, if the turbidity is 50 units. Turbidity measurements performed this way are reported as "JTU," i.e., Jackson turbidity units.

For turbidities less than 25 units, the scattered light intensity at 90° from the incident path is measured. Various commercial instruments are used, and they are calibrated against standard suspensions.

Measurement at 90° is called nephelometry, and the instruments are called nephelometers. The measured turbidity is reported as "NTU," i.e., nephelometric turbidity units.

The treatment goal for potable waters is to produce a final turbidity less than 0.5 units.

Dialysis

Colloidal particles can be dialyzed. This means that they cannot pass through a semipermeable membrane. True solutes of low molecular weight will. Consequently, if a system containing water, true solutes, and colloidal particles is placed on one side of a semipermeable membrane, and pure water is placed on the other side of the membrane, the true solutes pass through the membrane, equilibrating their concentrations on either side, but the colloids do not. This is one way of purifying colloidal systems from dissolved salts. The process is dependent on the sizes of the membrane's pores, and so this is another size classification scheme: colloids are larger than true solutes. The traditional membranes were animal tissues like bull's bladders and parchment, but nowadays, various synthetic membranes are used, and the pore sizes can be specified (Voyutsky, 1978).

Osmotic Pressure

If a colloidal system is dialyzed, it will exhibit an osmotic pressure on the dialysis membrane, just like a true solution. Osmotic pressure is proportional to the number of particles suspended in the dispersing medium. It does not depend on the size of the particles, so it does not matter whether the particles are single atoms, large molecules, or sols.

The osmotic pressure of the colloidal system is calculated using Einstein's formula, which is the same as the osmotic pressure equation for true solutes (Einstein, 1956):

$$p = \frac{RTn}{VN_A} \tag{10.2}$$

where N_A = Avogadro's number (6.022 136 7 × 10^{23} particles/mole)
n = the concentration of particles (number/m^3)
p = the osmotic pressure of the colloidal system (N/m^2)
R = the gas constant (8.314 510 J/mol·K)
T = the absolute temperature (K)

It is estimated that a 0.5% by wt. gold sol, which is about the highest concentration that can be achieved, consisting of particles about 1 nm in diameter, would develop an osmotic pressure of only 1 to 2 mm water head (Svedberg, 1924).

Brownian Movement

Colloidal particles exhibit the so-called "Brownian movement," which is visible in the case of the larger particles under a microscope. The Brownian movement is due to the momentum transmitted to the colloidal particles by the thermal motion of the suspending medium. The resulting paths of the colloidal particles consist of connected, broken straight lines oriented at random and with random lengths. The result is that the particles diffuse according to Fick's Law. Einsteins's formula for the diffusivity of colloidal particles is (Einstein, 1956):

$$D = \frac{RT}{6\pi N_A \mu r} \tag{10.3}$$

where D = the diffusivity of the suspended particles (m^2/s)
r = the radius of the suspended particle (m)
μ = the absolute viscosity of the suspending medium (N·s/m^2)

Colloidal particles have a small settling velocity, which may be estimated from Stoke's Law. Consequently, in a perfectly quiescent container, the particles will tend to settle out. This will establish a concentration gradient, with higher concentrations toward the bottom, and the resulting upward diffusion

will, at some point, balance the sedimentation. At equilibrium, the particles are distributed vertically in the container according to the "hypsometric" law, which was first derived for the distribution of gases in a gravitational field (Svedberg, 1924):

$$\frac{n_2}{n_1} = \exp\left\{-\frac{gN_A V_p\left(\rho_p - \rho\right)\left(z_2 - z_1\right)}{RT}\right\} \tag{10.4}$$

where g = the acceleration due to gravity (9.80665 m/s^2);
n_1 = the number (or concentration) of particles at height z_1
n_2 = the number (or concentration) of particles at height z_2
V_p = the volume of a single particle (m^3)
z_1 = the elevation of particle concentration n_1 (m)
z_2 = the elevation of particle concentration n_2 (m)
ρ = the mass density of the suspending medium (kg/m^3)
ρ_p = the mass density of the particles (kg/m^3)

Electrophoresis

If an electric field is applied to a colloidal system, *all* the particles will migrate slowly to *one* electrode. This means that the particles are charged and that they all have the same kind of charge, positive or negative, although the absolute values of the charges may differ. This should be contrasted with solutions of electrolytes, which contain equal numbers of positive and negative charges: when true solutions are electrolyzed, particles are attracted to both electrodes.

Stability

Many colloidal systems are unstable, and the particles can be coagulated in a variety of ways. In fact, one of the main problems of colloid chemistry is how to make the particles stay in suspension.

Composition

The particles usually have a different composition from the suspending medium. Therefore, the systems consist of more than one chemical phase, usually two but sometimes more, and they are heterogeneous. True solutions consist of a single phase.

Particle Size

The traditional range of sizes of colloidal particles was set by Zsigmondy (1914) at 1 to 100 nm. The upper size limit was chosen because it is somewhat smaller than the smallest particle that can be seen under a light microscope. Also, particles smaller than 100 nm do not settle out of suspension, even under quiescent conditions, but particles around 1 μm, the size of bacteria, will. The lower limit is somewhat smaller than can be detected by an ultramicroscope. Consequently, these are operational limits determined by the available instrumentation; they are not fundamental properties of colloidal systems.

These sizes may be compared to those of other particles:

- Atoms — 0.1 to 0.6 nm
- Small molecules — 0.2 to 5 nm
- Small polymers — 0.5 to 10 nm
- Colloids — 1 to 100 nm
- Clay — <2000 nm (Smaller clays are colloidal.)
- Bacteria — 250 to 10,000 nm (These and larger particles are settleable.)
- Silt — 2000 to 50,000 nm
- Visible particles — >50,000 nm
- Very fine sand — 50,000 to 100,000 nm

Dispersions of particles with diameters between 100 and 1000 nm are sometimes called "fine" dispersions; if the diameters are larger than 1000 nm, the dispersion is called "coarse." Fine and coarse dispersions are maintained by turbulence in the suspending medium, not by the random thermal motion of their molecules.

Kinds of Colloidal Dispersions

Colloids can also be classified according to chemistry. The simplest scheme, due to Ostwald (1915), is:

- Gas in gas (impossible)
- Liquid in gas (fogs, mists, clouds)
- Solid in gas [smokes, fumes (ammonium chloride)]
- Gas in liquid (foams)
- Liquid in liquid (emulsions, cream)
- Solid in liquid (colloidal gold)
- Gas in solid (meershaum, pumice)
- Liquid in solid [metallic mercury in ointments, opal (water in amorphous silica)]
- Solid in solid [ruby glass (gold in glass), cast iron (carbon in iron)]

The important colloids in water and sewage treatment are foams, emulsions, and solids-in-liquids. Smokes, fumes, fogs, and mists are important in air pollution.

Classification by Stability

Colloidal systems are traditionally divided into two broad groups:

- "Reversible," "lyo(hydro)philic," or "emulsoid"
- "Irreversible," "lyo(hydro)phobic," or"suspensoid"

The various terms used to describe each class are not exact synonyms, because they emphasize different aspects of colloidal stability. Furthermore, they are probably best thought of as endpoints on a continuous spectrum rather than separate groups. Lyophilic colloids are typically organic materials, especially naturally occurring ones, and lyophobic colloids are primarily inorganic materials.

The dichotomy reversible/irreversible, proposed by Zsigmondy (1914), is based on the idea of thermodynamic spontaneity. A colloidal system is called reversible if after drying it can be reformed simply by adding the dispersion medium. It is called irreversible if it does not reform spontaneously.

The distinctions lyophilic/lyophobic, introduced by Neumann (Ostwald, 1915), and hydrophilic/hydrophobic, which was introduced by Perrin (Ostwald, 1915), refer to the sensitivity of the system to the addition of electrolytes. A lyo(hydro)philic colloidal particle remains in suspension and uncoagulated over relatively wide ranges of electrolyte concentration, but lyo(hydro)phobic colloidal particles are stable only over narrow ranges of electrolyte concentration.

Suspensoid comprehends the ideas of irreversiblility and electrolyte sensitivity.

Emulsoid comprehends reversibility and insensitivity to electrolytes.

Because these definitions are not fully equivalent, they sometimes lead to contradictory classifications. For example, clays spontaneously form stable suspensions when mixed with natural waters, so they can be classified as reversible and, by extension, hydrophilic (Fridrikhsberg, 1986). On the other hand, the stability of clay suspensions is sensitive to the electrolyte concentration, so they can also be classified as hydrophobes (James M. Montgomery, Consulting Engineers, Inc., 1985). Aluminum hydroxide and ferric hydroxide, which are discussed below, also exhibit these contrary tendencies (Voyutsky, 1978). Furthermore, some colloid scientists maintain that organic substances like cellulose and protein are not properly classified as any kind of colloid; they are really high molecular weight molecules in true solution (Voyutsky, 1978). By implication, the only true colloids are suspensoids. Most workers, however, continue to include organic materials among the colloids.

Stability

Colloidal dispersions are said to be stable, if the particles remain separated from one another for long times. If the particles coalesce, the dispersion becomes unstable. There are two phenomena that affect stability: solvation and surface charge (Kruyt, 1930).

Hydrophilic colloids are naturally stabilized by solvation and surface charge. Hydrophobic colloids are not solvated and depend entirely on surface charge for stability. Clays and metallic hydroxides are partially solvated but are stabilized in part by surface charges.

A particle is solvated if its surface bonds to water. The particular kind of bonding involved is called "hydrogen bonding." This is a sort of weak electrostatic bonding. It occurs whenever the system contains surfaces that have strongly electronegative atoms like O, N, or F. Even when these atoms are covalently bonded into molecules, their attraction for electrons is so strong that the electron cloud is distorted and concentrated in their vicinity. This produces a region of excess negative charge. Hydrogen atoms tend to be attracted to these zones of excess negativity, and this attraction leads to a weak bonding between molecules. For example, water molecules hydrogen bond both to each other and to ammonia:

$$\begin{array}{ccc} \text{H–O}\cdots\text{H–O} & \text{and} & \text{H–O}\cdots\text{H–N–H} \\ \quad | \quad | & & \quad\;\; | \quad\;\; | \\ \quad \text{H} \quad \text{H} & & \quad\;\; \text{H} \quad\;\; \text{H} \end{array}$$

Here the solid lines indicate normal covalent bonds, and the three dots indicate hydrogen bonds. Typical hydrogen bond energies are about 5 kcal/mole, compared to about 50 to 100 kcal/mole for covalent bonds.

Hydrogen bonding leads to a competition between water molecules and other colloids for the particle surface, and in the case of hydrophilic colloids, the water wins. Consequently, the particles are prevented from coalescing, because they are coated with a film of water that cannot be displaced.

The surface charge on colloids is developed in three ways. Some colloids contain surface groups that readily ionize in water or take up protons, e.g., (Stumm and Morgan, 1970):

$$-\text{OH} \rightarrow -\text{OH}^-$$

$$-\text{NH}_2 \rightarrow -\text{NH}_3^+$$

$$-\text{COOH} \rightarrow -\text{COO}^-$$

These ionizations and protonations are strongly pH dependent, and the resulting surface potential varies with the pH.

The second method is selective bonding of ions from the surrounding solution. This occurs because the plane of the crystal lattice that forms the particle surface has unsatisfied electrostatic and covalent bonds that ions in the suspending medium can complete. The bonding is very specific and depends on the detailed chemistry of the particle surface and the kinds of ions dissolved in the water.

The third method is ion exchange. Some ions, usually cations, diffuse out of the crystal lattice of the colloidal particle into the surrounding medium, and they are replaced by other ions that diffuse from the medium into the particle. If the two ions have different charges, the lattice will acquire or lose charge. Ion exchange is not very specific, except that small, highly charged ions tend to replace large, weakly charged ions.

All three mechanisms may occur on a single particle. The net result is the surface potential, ψ_0.

The surface potential influences the remaining ions in the suspending medium by electrostatic repulsion and attraction; the result is the so-called "electrical double layer" (Voyutsky, 1978). If the particle has a net negative charge (which is typical of clays), positive ions in the suspending medium adsorb electrostatically to the exterior of the particle surface in a layer one or more ions thick. This adsorbed layer is called the "Stern" layer, and it reduces the net potential on the particle from ψ_0 to ψ_δ. The reduced electrostatic field repels and attracts ions in the suspending medium depending on whether they are of

like or unlike sign, respectively. Consequently, the solution is not electrically neutral near the particle surface, and any given thin layer of solution will contain an excess of charge opposite in sign to ψ_δ. The ions in the solution layer bearing the charges of opposite sign are called the counterions, and the layer itself is called the "diffuse" or "Gouy" layer. Away from the particle surface, the net observed charge is the sum of the charges due to the particle surface charge, the Stern layer and the intervening Gouy layer. It falls off with distance, until at large distances, the system appears to be electrically neutral.

The surface potential of colloids is usually determined by measuring their velocity in an electrical field. Because moving particles have an attached boundary layer of water, what is actually determined is the net of the voltage on the particle and the counterions in the boundary layer. The result is called the electrokinetic potential or the zeta potential, and it is calculated using the Helmholtz–Smoluchowski equation (Voyutsky, 1978):

$$\zeta = \frac{k\pi\mu\nu}{\varepsilon \cdot \boldsymbol{E}} \tag{10.5}$$

where E = the imposed potential gradient (V/m)
k = a constant in the Helmholtz–Smoluchowski equation that depends on the particle shape and imposed electric field, generally between 4 and 8 (dimensionless)
ν = the particle velocity (m/s)
ε = the dielectric constant of the suspending medium (dimensionless)
μ = the absolute viscosity of the suspending medium ($N \cdot s/m^2$)
ζ = the zeta potential (V)

The ratio ν/E is called the electrophoretic mobility.

The thickness of the boundary layer will depend upon the velocity of the particle. Consequently, the volume of water and the number of counterions associated with a moving colloid varies with the imposed electric field and other factors. This means that ζ also varies with these conditions, and it cannot be identified with ψ_δ. Nevertheless, as long as the experimental conditions are standardized, the zeta potential remains a useful index of the surface potential on the particles. Furthermore, many colloids coagulate spontaneously if the Stern layer potential, ψ_δ, is near zero, and the zeta potential is also zero in this case.

Coagulation Chemistry

Coagulation Mechanisms

Colloidal particles can be coagulated in four ways:

- Surface potential reduction
- Compression of the Gouy layer
- Interparticle bridging
- Enmeshment

Reduction of surface potential is effective only against hydrophobic colloids. If the surface potential arises because of ionization or protonation of surface groups, a change in pH via the addition of acid or base will eliminate it. Addition of counterions that adsorb to the surface of the particles also can reduce the surface potential.

Compression of the Gouy layer permits colloidal particles to approach each other closely before experiencing electrostatic repulsion, and their momentum may overcome the residual repulsion and cause collision and adhesion. The Gouy layer can be compressed by the addition of counterions that do not adsorb to the particles. The compression is greatest for highly charged ions, because the electrostatic attraction per ion increases with its charge. According to the Schulze–Hardy Rule (Voyutsky, 1978), the molar concentration of an ion required to coagulate a colloid is proportional to the reciprocal of its charge raised to the sixth power. Consequently, the relative molar concentrations of mono-, di-, tri-, and tetravalent ions required to coagulate a colloid are in the ratios $1:(1/2)^6:(1/3)^6:(1/4)^6$ or 1:0.016:0.0013:0.00024.

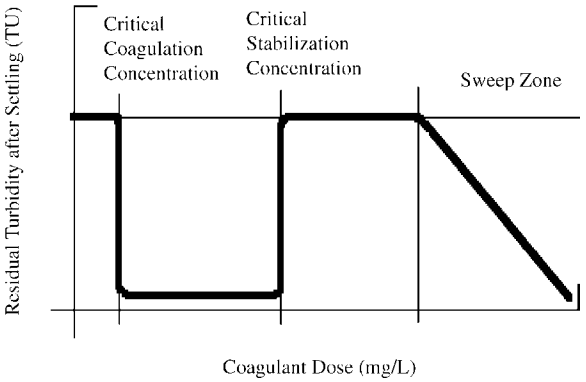

FIGURE 10.1 Residual turbidity after settling vs. coagulant dose.

Interparticle bridging is accomplished by adding microscopic filaments to the suspension. These filaments are long enough to bond to more than one particle surface, and they entangle the particles forming larger masses. The filaments may be either uncharged in water (nonionic), positively charged (cationic), or negatively charged (anionic).

Enmeshment occurs when a precipitate is formed in the water by the addition of suitable chemicals. If the precipitate is voluminous, it will surround and trap the colloids, and they will settle out with it.

Coagulant Dosage

A typical example of coagulation by aluminum and iron salts is shown in Fig. 10.1, in which residual turbidity after settling is plotted against coagulant dose. At low coagulant dosages, nothing happens. However, as the dosage is increased a point is reached at which rapid coagulation and settling occurs. This is called the "critical coagulation concentration" (CCC). Coagulation and settling also occur at somewhat higher concentrations of coagulant. Eventually, increasing the dosage fails to coagulate the suspension, and the concentration marking this failure is called the "critical restabilization concentration" (CSC). At still higher coagulant dosages, turbidity removal again occurs. This second turbidity removal zone is called the "sweep zone."

Figure 10.1 can be explained as follows. Between the CCC and the CSC, aluminum and iron salts coagulate silts and clays by surface charge reduction (Dentel and Gossett, 1988: Mackrle, 1962; Stumm and O'Melia, 1968). Aluminum and iron form precipitates of aluminum hydroxide [$Al(OH)_3$] and ferric hydroxide [$Fe(OH)_3$], respectively. These precipitates are highly insoluble and hydrophobic, and they adsorb to the silt and clay surfaces. The net charge on the aluminum hydroxide precipitate is positive at pHs less than about 8; the ferric hydroxide precipitate is positive at pHs less than about 6 (Stumm and Morgan, 1970). The result of the hydroxide adsorption is that the normally negative surface charge of the silts and clays is reduced, and so is the zeta potential. Coagulation and precipitation of the silts and clays occurs when enough aluminum or iron has been added to the suspension to reduce the zeta potential to near zero, and this is the condition between the CCC and the CSC.

At dosages below the CCC, the silts and clays retain enough negative charge to repel each other electrostatically.

As the aluminum or iron dosage approaches the CSC, aluminum and ferric hydroxide continue to adsorb to the silts and clays, the silts and clays become positive, and they are stabilized again by electrostatic repulsion, although the charge is positive.

If large amounts of aluminum or iron salts are used, the quantity of hydroxide precipitate formed will exceed the adsorption capacity of the silt and clay surfaces, and free hydroxide precipitate will accumulate in the suspension. This free precipitate will enmesh the silts and clays and remove them when it settles out. This is the sweep zone.

When the coagulant dosages employed lie between the CCC and the CSC, the coagulation mechanism is surface charge reduction via adsorption of aluminum or ferric hydroxides to the particle surfaces. Consequently, there should be a relationship between the raw water turbidity and the dosage required to destabilize it. Examples of empirical correlations are given in Stein (1915), Hopkins and Bean (1966), Langelier, Ludwig, and Ludwig, (1953), and Hudson (1965). For particles of uniform size, regardless of shape, the surface area is proportional to the two-thirds power of the concentration. This rule is also true for different suspensions having the same size distribution. Hazen's (1890) rule of thumb, Eq. (10.6), follows this rule very closely:

$$C_{Alum} = 0.349 + 0.0377 \cdot C_{TU}^{2/3}; \qquad R^2 = 0.998 \tag{10.6}$$

where C_{Alum} = the filter alum dosage in grains/gallon
C_{TU} = the raw water turbidity in JTU

However, when waters from several different sources are compared, it is found that the required coagulant dosages do not follow Hazen's rule of thumb. The divergences from the rule are probably due to differences in particle sizes in the different waters. For constant turbidity, the required coagulant dosage varies inversely with particle size; the required dosage nearly triples if the particle size is reduced by a factor of about ten (Langelier, Ludwig, and Ludwig, 1953).

The Jar Test

Although Eq. (10.6) is useful as a guideline, in practice, coagulant dosages must be determined experimentally. The determination must be repeated on a frequent basis, at least daily but often once or more per work shift, because the quantities and qualities of the suspended solids in surface waters vary. The usual method is the "jar test."

The jar test attempts to simulate the intensity and duration of the turbulence in key operations as they are actually performed in the treatment plant: i.e., chemical dosing (rapid mixing), colloid destabilization and agglomeration (coagulation/flocculation), and particle settling. Because each plant is different, the details of the jar test procedure will vary from facility to facility, but the general outline, developed by Camp and Conklin (1970), is as follows:

- Two-liter aliquots of a representative sample are placed into each of several standard 2L laboratory beakers or specially designed 2L square beakers (Cornwall and Bishop, 1983). Typically, six beakers are used, because the common laboratory mixing apparatus has space for six beakers. Beakers with stators are preferred because there is better control of the turbulence. The intensity of the turbulence is measured by the "root-mean-square velocity gradient," "*G*." (The r.m.s. characteristic strain rate, $\overline{\Gamma}$, is nowadays preferred.)
- The mixer is turned on, and the rotational speed is adjusted to produce the same r.m.s. velocity gradient as that produced by the plant's rapid-mixing tank.
- A known amount of the coagulant is added to each beaker, usually in the form of a concentrated solution, and the rapid mixing is allowed to continue for a time equal to the hydraulic detention time of the plant's rapid mixing tank.
- The mixing rate is slowed to produce a r.m.s. velocity gradient equal to that in the plant's flocculation tank, and the mixing is continued for a time equal to the flocculation tank's hydraulic detention time.
- The mixer is turned off, and the flocculated suspension is allowed to settle quiescently for a period equal to the hydraulic detention time of the plant's settling tanks.
- The supernatant liquid is sampled and analyzed for residual turbidity.

Hudson and Singley (1974) recommend sampling the contents of each beaker for residual suspended solids as soon the turbulence dies out, in order to develop a settling velocity distribution curve for the flocculated particles.

The supernatant liquid should be clear, and the floc particles should be compact and dense, i.e., "pinhead" floc, so-called because of its size. Large, feathery floc particles are undesirable, because they are fragile and tend to settle slowly, and they may indicate dosage in the sweep zone, which may be uneconomic.

If the suspension does not coagulate or if the result is "smokey" or "pinpoint" floc, either:

- More coagulant is needed.
- The raw water has insufficient alkalinity, and the addition of lime or soda ash is required. (This necessitates a more elaborate testing program to determine the proper ratios of coagulant and base.)
- The water is so cold that the reactions are delayed. (The test should be conducted at the temperature of the treatment plant.)

The jar test is also used to evaluate the performance of various coagulant aids, as well as the removal of color, disinfection by-product precursors, and taste and odor compounds.

Finally, it should be noted that the jar test simulates an ideal plug flow reactor. This means that it will not accurately simulate the performance of the flocculation and settling tanks unless they exhibit ideal plug flow, too. In practice, flocculation tanks must be built as mixed-cells-in-series, and settling tanks should incorporate tube modules.

Aluminum and Iron Chemistry

The chemistries of aluminum and ferric iron are very similar. Both cations react strongly with water molecules to form hydroxide precipitates and release protons:

$$Al^{3+} + 3\,H_2O \rightarrow Al(OH)_3(s) + 3\,H^+ \tag{10.7}$$

$$Fe^{3+} + 3\,H_2O \rightarrow Fe(OH)_3(s) + 3\,H^+ \tag{10.8}$$

Furthermore, at high pHs both precipitates react with the hydroxide ion and redissolve, forming aluminate and ferrate ions:

$$Al(OH)_3(s) + OH^- \rightarrow Al(OH)_4^- \tag{10.9}$$

$$Fe(OH)_3(s) + OH^- \rightarrow Fe(OH)_4^- \tag{10.10}$$

Both cations also form a large number of other dissolved ionic species, some of which are polymers, and many of yet unknown structure.

The dissolution of aluminum and ferric hydroxide at high pH is not a significant problem in water treatment, because the high pHs required do not normally occur. However, the hydrolysis reactions of Eqs. (10.7) and (10.8) are. Both reactions liberate protons, and unless these protons are removed from solution, only trace amounts, if any, of the precipitates are formed. In fact, if aluminum salts are added to pure water, no visible precipitate is formed. There are also many natural waters in which precipitate formation is minimal. These generally occur in granitic or basaltic regions.

Filter Alum

The most commonly used coagulant is filter alum, also called aluminum sulfate. Filter alum is made by dissolving bauxite ore in sulfuric acid. The solution is treated to remove impurities, neutralized, and evaporated to produce slabs of aluminum sulfate. The product is gray to yellow-white in color, depending on the impurities present, and the crystals include variable amounts of water of hydration: $Al_2(SO_4)_3(H_2O)_n$, with n taking the values 0, 6, 10, 16, 18, and 27. It is usually specified that the water-soluble alumina [Al_2O_3]

content exceed 17% by weight. This implies an atomic composition of $Al_2(SO_4)_3(H_2O)_{14.3}$. The commercial product also should contain less than 0.5% by wt insoluble matter and less than 0.75% by wt iron, reported as ferric oxide [Fe_2O_3] (Hedgepeth, 1934; Sidgwick, 1950).

Filter alum can be purchased as lumps ranging in size from 3/4 to 3 in., as granules smaller than the NBS No. 4 sieve, as a powder, or as a solution. The solution is required to contain at least 8.5% by wt alumina. The granules and powder must be dissolved in water prior to application, and the lumps must be ground prior to dissolution. Consequently, the purchase of liquid aluminum sulfate, sometimes called "syrup alum," eliminates the need for grinders and dissolving apparatus, and these savings may offset the generally higher unit costs and increased storage volumes and costs.

The dissolution of filter alum and its reaction with alkalinity to form aluminum hydroxide may be described by,

$$Al_2(SO_4)_3(H_2O)_{14.3}(s) + 6\ HCO_3^- \rightarrow 2\ Al(OH)_3(s) + 6\ CO_2 + 3\ SO_4^{2-} + 14.3\ H_2O \qquad (10.11)$$

The aluminum hydroxide precipitate is white, and the carbon dioxide gas produced will appear as small bubbles in the water and on the sides of the jar test beaker. The sulfate released passes through the treatment plant and into the distribution system. One mole of filter alum releases six moles of protons, so its equivalent weight is 1/6 of 600 g or 100 g. The alkalinity consumed is six equivalents or 300 g (as $CaCO_3$). This is the source of the traditional rule-of-thumb that *1 g of filter alum consumes 0.5 g of alkalinity.*

The acid-side and base-side equilibria for the dissolution of aluminum hydroxide are (Hayden and Rubin, 1974):

$$Al^{3+} + H_2O \leftrightarrow Al(OH)_3(s) + 3\ H^+ \qquad (10.12)$$

$$K_{s1} = \frac{[H^+]^3}{[Al^{3+}]} = 10^{-10.40} \quad (25°C) \qquad (10.13)$$

$$Al(OH)_3(s) + OH^- \leftrightarrow Al(OH)_4^- \qquad (10.14)$$

$$K_{s2} = \frac{[Al(OH)_4^-]}{[OH^-]} = 10^{1.64} \quad (25°C) \qquad (10.15)$$

Substituting the ionization constant for water produces:

$$K_{s2} \cdot K_w = [Al(OH)_4^-] \cdot [H^+] = 10^{-12.35} (25°C) \qquad (10.16)$$

Equations (10.13) and (10.16) plot as straight lines on log/log coordinates. Together they define a triangular region of hydroxide precipitation, which is shown in Fig. 10.2. Figure 10.2 shows the conditions for the precipitation of aluminum hydroxide. However, it is known that this triangular region also corresponds to the region in which silts and clays are coagulated (Dentel and Gossett, 1988; Hayden and Rubin, 1974). The rectangular region in the figure is the usual range of pH levels and alum dosages seen in water treatment. It corresponds to Hazen's recommendations.

Other aluminum species not indicated in Fig. 10.2 are $AlOH^{2+}$ and $Al_8(OH)_{20}^{4+}$. These species are significant under acid conditions. The general relationship among the aluminum species may be represented as (Rubin and Kovac, 1974):

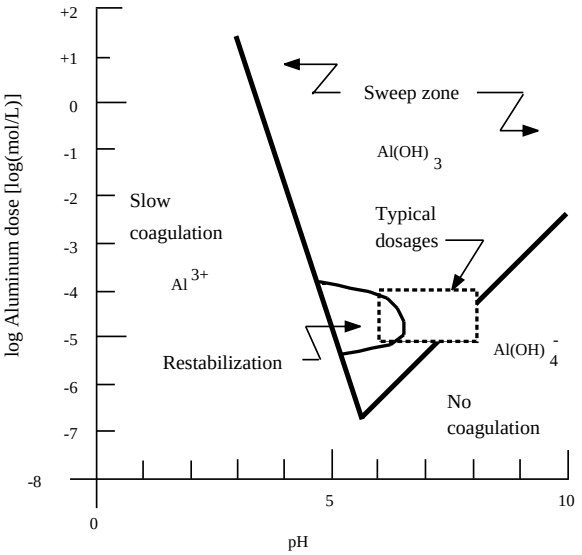

FIGURE 10.2 Alum hydroxide precipitation zone (Hayden and Rubin, 1974).

$$Al^{3+} \leftrightarrow \left\{ \begin{array}{c} AlOH^{2+} \\ Al_8(OH)_{20}^{4+} \end{array} \right\} \leftrightarrow Al(OH)_3(s) \leftrightarrow Al(OH)_4^-$$

$$\updownarrow$$

$$AlOOH(s)$$

$$\updownarrow$$

$$Al_2O_3(s)$$

The aluminum ion, Al^{3+}, is the dominant species below pH 4.5. Between pH 4.5 and 5, the cations $AlOH^{2+}$ and $Al_8(OH)_{20}^{4+}$ are the principal species. Aluminate, $Al(OH)_4^-$ is the major species above pH 9.5 to 10. Between pH 5 and 10, various solids are formed. The fresh precipitate is aluminum hydroxide, but as it ages, it gradually loses water, eventually becoming a mixture of bayerite and gibbsite. As the solid phase ages, the equilibrium constants given in Eqs. (10.13) and (10.15) change. The values given are for freshly precipitated hydroxide.

The usual aluminum coagulation operating range intersects the restabilization zone, so coagulation difficulties are sometimes experienced. These can be overcome by (Rubin and Kovac, 1974):

- Increasing the alum dosage to get out of the charge reversal zone (This is really a matter of increasing the sulfate concentration, which compresses the Gouy layer.)
- Decreasing the alum dosage to get below the CSC (The floc is generally less settleable, and the primary removal mechanism is filtration, which is satisfactory as long as the total suspended solids concentration is low.)
- Adding lime to raise the pH and move to the right of the restabilization zone
- Adding polyelectrolytes to flocculate the positively charged colloids or coagulant aids like bentonite or activated silica, which are negatively charged and reduce the net positive charge on the silt-clay-hydroxide particles by combining with them (Bentonite and activated silica also increase the density of the floc particles, which improves settling, and activated silica improves flow toughness.)

The same problems arise with iron coagulants, and the same solutions may be employed.

Ferrous and Ferric Iron

The three forms of iron salts usually encountered in water treatment are ferric chloride [$FeCl_3 \cdot 6H_2O$], ferric sulfate [$Fe_2(SO_4)_3(H_2O)_9$], and ferrous sulfate [$FeSO_4(H_2O)_7$]. Anhydrous forms of the ferric salts are available.

Ferrous sulfate is known in the trade as "copperas," "green vitriol," "sugar sulfate," and "sugar of iron." Ferrous sulfate occurs naturally as the ore copperas, but it is more commonly manufactured. Copperas can be made by oxidizing iron pyrites [FeS_2]. The oxidation yields a solution of copperas and sulfuric acid, and the acid is neutralized and converted to copperas by the addition of scrap iron or iron wire. However, the major source is waste pickle liquor. This is a solution of ferrous sulfate that is produced by soaking iron and steel in sulfuric acid to remove mill scale. Again, residual sulfuric acid in the waste liquor is neutralized by adding scrap iron or iron wire. The solutions are purified and evaporated, yielding pale green crystals. Although the heptahydrate [$FeSO_4(H_2O)_7$] is the usual product, salts with 0, 1, or 4 waters of hydration may also be obtained. Copperas is sold as lumps and granules. Because of its derivation from scrap steel, it should be checked for heavy metals.

Ferrous iron forms precipitates with both hydroxide and carbonate (Stumm and Morgan, 1970):

$$Fe(OH)_2(s) \leftrightarrow Fe^{2+} + 2\ OH^- \tag{10.17}$$

$$K_{OH^-} = \left[Fe^{2+}\right] \cdot \left[OH^-\right] = 2 \times 10^{-15} \quad (25°C) \tag{10.18}$$

$$FeCO_3(s) \leftrightarrow Fe^{2+} + CO_3^{2-} \tag{10.19}$$

$$K_{CO_3^{2-}} = \left[Fe^{2+}\right] \cdot \left[CO_3^{2-}\right] = 2.1 \times 10^{-11} \quad (25°C) \tag{10.20}$$

In most waters, the carbonate concentration is high enough to make ferrous carbonate the only solid species, if any forms.

The alkalinity of natural and used waters is usually comprised entirely of bicarbonate, and copperas will not form a precipitate in them. This difficulty may be overcome by using a mixture of lime and copperas, the so-called "lime-and-iron" process. The purpose of the lime is to convert bicarbonate to carbonate so a precipitate may be formed:

$$Fe^{2+} + HCO_3^- + OH^- \rightarrow FeCO_3 + H_2O \tag{10.21}$$

If the raw water has a significant carbonate concentration, less lime will be needed, because the original carbonate will react with some of the copperas. If the raw water has a significant carbonic acid concentration, additional lime will be required to neutralize it. In either case, enough lime should be used to form an excess of carbonate and, perhaps, hydroxide, which forces the reaction to completion. Hazen's (1890) rule-of-thumb for raw water with carbonate (pH > 8.3) is as follows:

$$\{CaO\} = 1.16 \cdot \{FeSO_4(H_2O)_7\} - \{\text{phenolphthalein alkalinity}\} + 0.6 \tag{10.22}$$

For raw water without carbonate (pH < 8.3),

$$\{CaO\} = 1.16 \cdot \{FeSO_4(H_2O)_7\} + 0.50 \cdot \{H_2CO_3^*\} + 0.6 \tag{10.23}$$

The curly braces indicate that the concentration units are equivalents per liter. One mole of ferrous sulfate is two equivalents.

The lime-and-iron process produces waters with a pH of around 9.5, which may be excessive and may require neutralization prior to distribution or discharge. Consequently, copperas is normally applied in

combination with chlorine. The intention is to oxidize the ferrous iron to ferric iron, and the mixture of copperas and chlorine is referred to as "chlorinated copperas:"

$$FeSO_4(H_2O)_7 + \tfrac{1}{2}\ Cl_2 \rightarrow Fe^{3+} + Cl^- + SO_4^{2-} + 7\ H_2O \tag{10.24}$$

The indicated reaction ratio is about 7.84 g ferrous sulfate per g of chlorine, but dissolved oxygen in the raw water will also convert ferrous to ferric iron, and the practical reaction ratio is more like 7.3 g ferrous sulfate per g chlorine (Hardenbergh, 1940).

Ferric sulfate [$Fe_2(SO_4)_3 \cdot 9H_2O$] is prepared by oxidizing copperas with nitric acid or hydrogen peroxide. Evaporation produces a yellow crystal. Besides the usual nonahydrate, ferric sulfates containing 0, 3, 6, 7, 10, and 12 waters of hydration may be obtained (Sidgwick, 1950).

Ferric chloride is made by mixing hydrochloric acid with iron wire, ferric carbonate, or ferric oxide. The solid is red-yellow in color. The usual product is $FeCl_3 \cdot 6H_2O$, but the anhydrous salt and salts with 2, 2.5, and 3.5 waters of hydration are also known (Hedgepeth, 1934; Sidgwick, 1950).

Both ferric salts produce ferric cations upon dissolution:

$$Fe_2(SO_4)_3(H_2O)_9 \rightarrow 2\ Fe^{3+} + 3\ SO_4^{2-} + 9\ H_2O \tag{10.25}$$

$$FeCl_3(H_2O)_6 \rightarrow Fe^{3+} + 3\ Cl^- + 6\ H_2O \tag{10.26}$$

The chemistry of the ferric cation is similar to that of the aluminum cation, except for the species occurring under acidic conditions (Rubin and Kovac, 1974):

$$Fe^{3+} \leftrightarrow \left\{ \begin{array}{c} FeOH^{2+} \\ Fe(OH)_2^+ \\ Fe_2(OH)_2^{4+} \end{array} \right\} \leftrightarrow Fe(OH)_3(s) \leftrightarrow Fe(OH)_4^-$$

$$\updownarrow$$

$$FeOOH(s)$$

$$\updownarrow$$

$$Fe_2O_3(s)$$

In the case of iron, the equilibrium involving $Fe(OH)_2^+$ must be considered, as well as Eqs. (10.27) and (10.29) (Stumm and Morgan, 1970):

$$Fe^{3+} + 3\ H_2O \leftrightarrow Fe(OH)_3(s) + 3\ H^+ \tag{10.27}$$

$$K_{so} = \frac{[H^+]^3}{[Fe^{3+}]} = 10^{-3.28} \quad (25°C) \tag{10.28}$$

$$Fe(OH)_3(s) + OH^- \leftrightarrow Fe(OH)_4^- \tag{10.29}$$

$$K_{s1} = \frac{[Fe(OH)_4^-]}{[OH^-]} = 10^{-4.5} \quad (25°C) \tag{10.30}$$

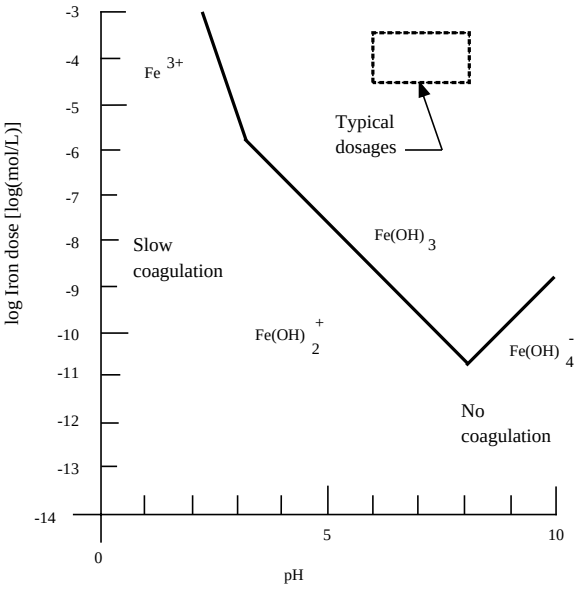

FIGURE 10.3 Ferric hydroxide precipitation zone (Stumm and Morgan, 1970).

$$\mathrm{Fe(OH)_3(s) \leftrightarrow Fe(OH)_2^+ + OH^-} \tag{10.31}$$

$$K_{s2} = \left[\mathrm{Fe(OH_2^+)}\right]\cdot\left[\mathrm{OH^-}\right] = 10^{-16.6} \quad (25°\mathrm{C}) \tag{10.32}$$

The lines defined by Eqs. (10.28), (10.30), and (10.32) are plotted on log/log coordinates in Fig. 10.3. They define a polygon, which indicates the region where ferric hydroxide precipitate may be expected.

Lime

Lime is usually purchased as "quick lime" [CaO] or "slaked lime" [$Ca(OH)_2$]. The former is available as lumps or granules, the latter is a white powder. Synonyms for quick lime are "burnt lime," "chemical lime," "unslaked lime," and "calcium oxide." If it is made by calcining limestone or lime/soda softening sludges, quick lime may contain substantial amounts of clay. The commercial purity is 75 to 99% by wt CaO. The synonyms for slaked lime are "hydrated lime" and "calcium hydroxide." The commercial product generally contains 63 to 73% CaO.

Lime is used principally to raise the pH to change the surface charge on the colloids and precipitates or provide the alkalinity needed by aluminum and iron.

The lime dosage required for the formation of aluminum and ferric hydroxide, in equivalents per liter, is simply the aluminum or ferric iron dosage less the original total alkalinity:

$$\{\mathrm{CaO}\} + \{\mathrm{Ca(OH_2)}\} = \{\mathrm{Al^{3+}}\} + \{\mathrm{Fe^{3+}}\} - \{\text{total alkalinity}\} \tag{10.33}$$

All concentrations are in meq/L.

As a practical matter, the coagulant and the lime dosages are determined experimentally by the jar test; the calculation suggested by Eq. (10.33) cannot be used to determine lime dosages, although it may serve as a check on the reasonableness of the jar test results. Equation (10.33) also does not take into account finished water stability and issues associated with corrosion and scale.

The jar test is also used to determine the lime dosage needed to reduce the surface charge. The charge reduction is usually checked by an electrophoresis experiment to measure the zeta potential associated with the particles.

It is possible to coagulate many waters simply by adding lime. In a few instances, chiefly anoxic groundwaters, the coagulation occurs because the raw water contains substantial amounts of ferrous iron, and one is really employing the lime-and-iron process. Usually, the precipitate formed with lime is calcium carbonate, perhaps with some magnesium hydroxide. This is the lime/soda softening process.

Coagulant Aids

The principal coagulant aids are lime, bentonite, fuller's earth, activated silica, and various organic polymers. These aids are used to perform several functions, although any given aid will perform only one or a few of the functions:

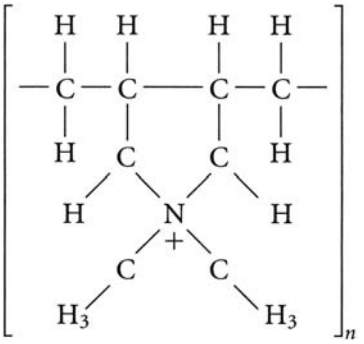
- They may change the pH of the water, which alters the surface charge on many colloids.
- They may provide the alkalinity needed for coagulation by aluminum and ferric iron.
- They may reduce the net surface charge on the colloids by adsorbing to the colloid surface; this is especially useful in escaping the restabilization zone.
- They may link colloidal particles together, forming larger masses; in some cases, the coagulant aid may totally replace the coagulant, but this is often expensive.
- They may increase the strength of the flocculated particles, which prevents floc fragmentation and breakthrough during filtration.
- They may increase the concentration of particles present, thereby increasing the rate of particle collision and the rate of flocculation.
- They may increase the density of the flocculated particles, which improves settling tank efficiencies.

Bentonite and fuller's earth are clays, and both are members of the montmorrillonite-smectite group. The clays are used during periods of low turbidity to increase the suspended solids concentration and the rate of particle collision and to increase the density of the floc particles. Because they carry negative charges when suspended in water, bentonite and fuller's earth may also be used to reduce surface charges in the restabilization zone. Clay dosages as high as 7 gr/gal (120 mg/L) have been used (Babbitt, Doland, and Cleasby, 1967). The required coagulant dosages are also increased by the added clay, and voluminous, fluffy flocs are produced, which, however, settle more rapidly than the floc formed from aluminum hydroxide alone.

Activated silica is an amorphous precipitate of sodium silicate [Na_2SiO_3]. Sodium silicate is sold as a solution containing about 30% by wt SiO_2. This solution is very alkaline, having a pH of about 12. The precipitate is formed by diluting the commercial solution to about 1.5% by wt. SiO_2 and reducing the alkalinity of the solution to about 1100 to 1200 mg/L (as $CaCO_3$) with sulfuric acid. Chlorine and sodium bicarbonate have also been used as acids. The precipitate is aged for 15 min to 2 hr and diluted again to about 0.6% by wt. SiO_2. This second dilution stops the polymerization reactions within the precipitate. The usual application rate is 1:12 to 1:8 parts of silica to parts of aluminum hydroxide. The activated silica precipitate bonds strongly to the coagulated silts/clays/hydroxides and strengthens the flocs. This reduces floc fragmentation due to hydraulic shear in sand filters and limits floc "breakthrough" (Vaughn, Turre, and Grimes, 1971; Kemmer, 1988).

The organic polymers used as coagulant aids may be classified as nonionic, anionic, or cationic (James M. Montgomery, Consulting Engineers, Inc., 1985; O'Melia, 1972; Kemmer, 1988):

- Nonionic — polyacrylamide, $[–CH_2–CH(CONH_2)–]_n$, mol wt over 10^6; and polyethylene oxide, $[–CH_2–CH_2–]_n$, mol wt over 10^6
- anionic — hydrolyzed polyacrylamide, $[–CH_2–CH(CONH_2)CH_2CH(CONa)–]$, mol wt over 10^6; polyacrylic acid, $[–CH_2–CH(COO^-)–]_n$, mol wt over 10^6; polystyrene sulfonate, $[–CH_2–CH(øSO_{3^-})–]_n$, mol wt over 10^6
- cationic — polydiallyldimethylammonium, mol wt below 10^5; polyamines, $[–CH_2–CH_2–NH_{2^-}]_n$, mol wt below 10^5; and quarternized polyamines, $[–CH_2–CH(OH)–CH_2–N(CH_3)_2\text{-}]_n$, mol wt below 10^5



These materials are available from several manufacturers under a variety of trade names. The products are subject to regulation by the U.S. EPA. They are sold as powders, emulsions, and solutions.

All polymers function by adsorbing to the surface of colloids and metal hydroxides. The bonding may be purely electrostatic, but hydrogen bonding and van der Waals bonding occur too, and may overcome electrostatic repulsion.

Anionic polymers will bind to silts and clays, despite the electrostatic repulsion, if their molecular weight is high enough. The bonding is often specific, and some polymers will not bind to some colloids.

The charges on cationic and anionic polymers are due to the ionization and protonation of amino [$-NH_2$], carboxyl [–COOH] and amide [$-CONH_2$] groups and are pH dependent. Consequently, cationic polymers are somewhat more effective at low pHs, and anionic polymers are somewhat more effective at high pHs.

Cationic polymers reduce the surface charge on silts and clays and form interparticle bridges, which literally tie the particles together. Cationic polymers are sometimes used as the sole coagulant. Anionic and nonionic polymers generally function by forming interparticle bridges. Anionic and nonionic polymers are almost always used in combination with a primary coagulant. Dosages are generally on the order of one to several mg/L and are determined by jar testing.

Coagulant Choice

The choice of the coagulants to be employed and their dosages is determined by their relative costs and the jar test results. The rule is to choose the least cost combination that produces satisfactory coagulation, flocculation, settling, and filtration. This rule should be understood to include the minimization of treatment chemical leakage through the plant and into the distribution system. The important point here is that the choice is an empirical matter, and as such, it is subject to change as the raw water composition changes and as relative costs change.

Nevertheless, there are some differences between filter alum and iron salts that appear to have general applicability:

- Iron salts react more quickly to produce hydroxide precipitate than does alum, and the precipitate is tougher and settles more quickly (Babbitt, Doland, and Cleasby, 1967).
- Ferric iron precipitates over a wider range of pHs than does alum, 5 to 11 vs. 5.5 to 8. Ferrous iron precipitates between pH 8.5 and 11 (Committee on Water Works Practice, 1940).
- Alum sludges dewater with difficulty, especially on vacuum filters; the floc is weak and breaks down so that solids are not captured; the sludge is slimy, requiring frequent shutdowns for fabric cleaning; and the volume of sludge requiring processing is larger than with iron salts (Rudolfs, 1940; Joint Committee, 1959).
- Iron salts precipitate more completely, and the iron carryover into the distribution system is less than the aluminum carryover. The median iron concentration in surface waters coagulated with iron salts is about 80 μg/L, and the highest reported iron concentration is 0.41 mg/L (Miller et al., 1984). The median aluminum concentration in finished waters treated with alum is about 90 to 110 μg/L, and nearly 10% of all treatment plants report aluminum concentrations in their product

in excess of 1 mg/L (Letterman and Driscoll, 1988; Miller et al., 1984). Aluminum carryover is a problem because of indications that aluminum may be involved in some brain and bone disorders in humans, including Alzheimers disease (Alfrey, LeGendre, and Kaehny, 1976; Crapper, Krishnan, and Dalton, 1973; Davison et al., 1982; Kopeloff, Barrera, and Kopeloff, 1942; Klatzo, Wismiewski, and Streicher, 1965; Platts, Goode, and Hislop, 1977). The aluminum may be present as Al^{3+}, and its concentration in finished waters appears to increase with increases in flouride (caused by fluoridation) and dissolved organic matter, both of which form soluble complexes with Al^{3+} (Driscoll and Letterman, 1988).

- Alum is easy to handle and store, but iron salts are difficult to handle. Iron salts are corrosive, and they absorb atmospheric moisture, resulting in caking. This precludes feeding the dry compound (Rudolfs, 1940; Babbitt, Doland and Cleasby, 1967).
- There is no marked cost advantage accruing to either alum or iron salts.

Iron salts are often recommended for the coagulation of cold, low turbidity waters. However, a recent study suggests there is no substantial advantage for iron coagulation under these conditions (Haarhoff and Cleasby, 1988). There is an optimum aluminum dosage of about 0.06 mmol/L (1.6 mg Al^{3+}/L), and dosages above this degrade settling and removal. Iron does not exhibit such an optimum.

Sludge handling practices are also important. Water treatment sludges do not usually require processing prior to disposal. This situation arises because water treatment sludges consist of relatively inert inorganic materials, and in the past (but no longer), plants were often permitted to dispose of their sludges by discharge to the nearest stream. Nowadays, the sludges are simply lagooned or placed in landfills. In contrast, sewage treatment sludges are putrescible and require processing prior to disposal. This usually involves a dewatering step. The comparative ease and economy of dewatering iron sludges results in iron salts being the coagulant of choice in sewage treatment. Ferric iron also precipitates the sulfides found in sewage sludges, reducing their nuisance potential.

There are important disadvantages to ferric iron. First, ferric iron solutions are acidic and corrosive and require special materials of construction and operational practices. Second, any carryover of ferric hydroxide into a water distribution system is immediately obvious and undesirable. Alum hydroxide carryover would not be noticed.

10.2 Softening, Stabilization, and Demineralization

Hardness

The natural weathering of limestone, dolomite, and gypsum produces waters that contain elevated levels of calcium and magnesium (and bicarbonate):

$$CO_2 + H_2O + CaCO_3 \rightarrow Ca^{2+} + 2\ HCO_3^- \tag{10.34}$$

$$2\ CO_2 + 2\ H_2O + CaMg(CO_3)_2 \rightarrow Ca^{2+} + Mg^{2+} + 4\ HCO_3^- \tag{10.35}$$

$$CaSO_4(H_2O)_2 \rightarrow Ca^{2+} + SO_4^{2-} + 2\ H_2O \tag{10.36}$$

In the case of limestone and dolomite, weathering is an acid/base reaction with the carbon dioxide dissolved in the percolating waters. In the case of gypsum, it is a simple dissolution that occurs whenever the percolating water is unsaturated with respect to calcium sulfate.

Waters that contain substantial amounts of calcium and magnesium are called "hard." Waters that contain substantial amounts of bicarbonate are called "alkaline." Hard waters are usually also alkaline. For reasons connected to Clark's lime/soda softening process, the "carbonate hardness" is defined to be that portion of the calcium and magnesium that is equal to (or less than) the sum of the concentrations of bicarbonate and carbonate, expressed as meq/L. The "noncarbonate hardness" is defined to be the excess of calcium and magnesium over the sum of the concentrations of bicarbonate and carbonate, expressed as meq/L. Except for desert evaporite ponds, the concentrations of carbonate and hydroxide are negligible in natural waters.

Hardness is undesirable for two reasons:

- Hard waters lay down calcium and magnesium carbonate on hot surfaces, which reduces the heat transfer capacity of boilers and heaters and the hydraulic capacity of water and steam lines.
- Hard waters precipitate natural soaps; the precipitation consumes soaps uselessly, which increases cleaning costs, and the precipitate accumulates on surfaces and in fabrics, which requires additional cleaning and which reduces the useful life of fabrics.

It is generally believed that these costs become high enough to warrant municipal water softening when the water hardness exceeds about 100 mg/L (as $CaCO_3$).

Modern steam boilers require feedwaters that have mineral contents much lower than what can be achieved via lime/soda softening. Feedwater demineralization is usually accomplished via ion exchange or reverse osmosis.

Some scale deposition is desirable in water distribution systems in order to minimize lead and copper solubility.

Lime/Soda Chemistry

The excess lime process for the removal of carbonate hardness and the practice of reporting hardness in units of calcium carbonate were introduced by Thomas Clark in 1841 and 1856, respectively (Baker, 1981). The removal of noncarbonate hardness via the addition of soda ash or potash was introduced by A. Ashby in 1876.

The underlying principle is that calcium carbonate and magnesium hydroxide are relatively insoluble. Magnesium hydroxide is more insoluble than magnesium carbonate. The solubility products for dilute solutions of calcium carbonate are as follows (Shock, 1984):

$$K_{sp} = \left[\mathrm{Ca}^{2+}\right] \cdot \left[\mathrm{CO}_3^{2-}\right] \tag{10.37}$$

Calcite:

$$\log K_{sp} = -171.9065 - 0.077993T + \frac{2839.319}{T} + 71.595 \log T \tag{10.38}$$

Aragonite:

$$\log K_{sp} = -171.9773 - 0.077993T + \frac{2903.293}{T} + 71.595 \log T \tag{10.39}$$

Vaterite:

$$\log K_{sp} = -172.1295 - 0.077993T + \frac{3074.688}{T} + 71.595 \log T \tag{10.40}$$

where T = the absolute temperature in K.

For the magnesium solutions, one has the following (Stumm and Morgan, 1970),

$$\begin{aligned} K_{sp} &= \left[Mg^{2+}\right]\cdot\left[OH^{-}\right]^{2} \\ &= 10^{-9.2}\ \left(\text{active, } 25°C\right) \\ &= 10^{-11.6}\ \left(\text{brucite, } 25°C\right) \end{aligned} \tag{10.41}$$

$$\begin{aligned} K_{sp} &= \left[Mg^{2+}\right]\cdot\left[CO_3^{2-}\right] \\ &= 10^{-4.9}\ \left(\text{magnesite, } 25°C\right) \\ &= 10^{-5.4}\ \left(\text{nesquehonite, } 25°C\right) \end{aligned} \tag{10.42}$$

The solubility product for calcite varies nearly linearly with temperature from $10^{-8.09}$ at 5°C to $10^{-8.51}$ at 40°C. This is the basis of the "hot lime" process (Powell, 1954).

The reactions involved can be summarized as follows. First, a slurry of calcium hydroxide is prepared, either by slaking quick lime or by adding slaked lime to water. When this slurry is mixed with hard water, the following reactions occur in sequence:

1. Reaction with carbon dioxide and carbonic acid:

$$Ca(OH)_2 + H_2CO_3 \rightarrow \underline{CaCO_3} + H_2O \tag{10.43}$$

2. Reaction with bicarbonate:

$$Ca(OH)_2 + 2\,HCO_3^- \rightarrow \underline{CaCO_3} + CO_3^{2-} + H_2O \tag{10.44}$$

3. Reaction with raw water calcium:

$$Ca^{2+} + CO_3^{2-} \rightarrow \underline{CaCO_3} \tag{10.45}$$

4. Reaction with magnesium:

$$Ca(OH)_2 + Mg^{2+} \rightarrow \underline{Mg(OH)_2} + Ca^{2+} \tag{10.46}$$

5. Reaction with soda ash:

$$Na_2CO_3 + Ca^{2+} \rightarrow \underline{CaCO_3} + 2\,Na^{+} \tag{10.47}$$

The reaction with carbon dioxide is a nuisance, because it consumes lime and produces sludge but does not result in any hardness removal. Carbon dioxide concentrations are generally negligible in surface waters but may be substantial in groundwaters. In that case, it may be economical to remove the carbon dioxide by aeration prior to softening.

Equations (10.44) and (10.45) are the heart of the Clark process. First, hydrated lime reacts with bicarbonate to form an equivalent amount of free carbonate. The calcium in the lime precipitates out as calcium carbonate, and the free carbonate formed reacts with an equivalent amount of the raw water's original calcium, removing it as calcium carbonate, too. The net result is a reduction in the calcium concentration.

Equation (10.46) is called the "excess lime" reaction, because a substantial concentration of free, unreacted hydroxide is required to drive the precipitation of magnesium hydroxide. The net result is the

replacement of magnesium ions by calcium ions. If there is any free carbonate left over from Eq. (10.45), it will react with an equivalent amount of the calcium removing it.

Equation (10.47) is Ashby's process for the removal of noncarbonate hardness. Any calcium left over from Eq. (10.45) is precipitated with soda ash or potash.

Calcium Removal Only

Unless the magnesium concentration is a substantial portion of the total hardness, say more than one-third, or if the total hardness is high, say more than 300 mg/L (as $CaCO_3$), only calcium is removed. The traditional rule of thumb is that cold water softening can reduce the calcium concentration to about 0.8 meq/L (40 mg/L as $CaCO_3$) (Tebbutt, 1992). The magnesium concentration is unchanged.

The reactions are most easily summarized as a bar chart. First, all the ionic concentrations and the concentration of carbon dioxide/carbonic acid are converted to meq/L. Carbon dioxide/carbonic acid acts like a diprotic acid, so its equivalent weight is one-half its molecular weight. The bar chart is drawn as two rows with the cations on top and the anions on the bottom. Carbon dioxide/carbonic acid is placed in a separate box to the left. The sequence of cations from left to right is calcium, magnesium, and all others. The sequence of anions from left to right is carbonate, bicarbonate, and all others:

CO_2	Ca^{2+}		Mg^{2+}	Other cations
	CO_3^{2-}	HCO_3^-	Other anions	

The lime requirement for calcium removal is the sum of the carbon dioxide/carbonic acid demand and the lime required to convert bicarbonate to carbonate. If the calcium concentration exceeds the carbonate and bicarbonate concentrations combined (as shown), then all the bicarbonate is converted. However, if the sum of carbonate and bicarbonate is greater than the calcium concentration, only enough bicarbonate is converted to remove the calcium. The calculation is,

$$\{CaO\} = \{CO_2 + H_2CO_3\} + \min\left[\{\text{original } Ca^{2+} - CO_3^{2-}\} \text{ or } \{HCO_3^-\}\right] \tag{10.48}$$

where $\{x\}$ = the concentration of species x in meq/L.

The soda ash requirement is calculated as the calcium that cannot be removed by the original carbonate plus the bicarbonate converted to carbonate:

$$\{Na_2CO_3\} = \{\text{original } Ca^{2+}\} - \{CO_3^{2-}\} - \{HCO_3^-\} \tag{10.49}$$

For the bar diagram shown, the calcium concentration is larger than the sum of the carbonate and bicarbonate, and therefore, the soda ash requirement is not zero.

The sludge solids produced consist of calcium carbonate. The concentration in suspension just prior to settling is,

$$X_{ss} = 50.04\left[\{CaO\} + \{\text{original } Ca^{2+}\}\right] \tag{10.50}$$

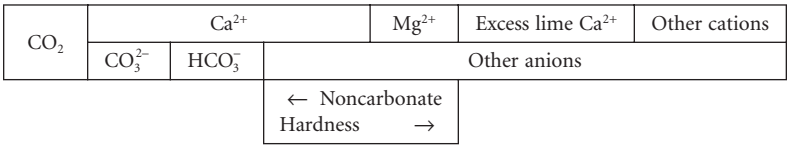
where X_{ss} = the concentration of suspended solids in mg/L.

If the raw water contains any suspended solids, these will be trapped in the precipitate, and they must be included.

Calcium and Magnesium Removal

If magnesium must be removed, excess lime treatment is required. The traditional rule of thumb is that cold water excess lime softening will reduce the calcium concentration to about 0.8 meq/L and the magnesium concentration to about 0.2 meq/L.

The bar chart relevant to excess lime treatment would look as follows:



The required lime dosage is,

$$\{CaO\} = \{CO_2 + H_2CO_3\} + \{HCO_3^-\} + \{Mg^{2+}\} + \{\text{excess lime}\} \tag{10.51}$$

where $\{x\}$ = the concentration of species x in meq/L.

Note that all the carbon dioxide/carbonic acid, all the bicarbonate, and all the magnesium must be reacted. The quantity of excess lime influences the concentration of magnesium that can be achieved and the rate of reaction. In cold water, a free hydroxide concentration of about 1 meq/L is required to reduce the magnesium concentration to 50 mg/L (as $CaCO_3$), and about 1.4 meq/L is required to produce a magnesium concentration of 8 mg/L (as $CaCO_3$) (Powell, 1954). The equivalent pHs are 11 and 11.2, respectively.

The soda ash requirement is,

$$\begin{aligned}\{Na_2CO_3\} &= \{Ca^{2+}\} + \{Mg^{2+}\} + \{\text{excess lime Ca}\} - \{CO_3^{2-}\} - \{HCO_3^-\} \\ &= \{\text{noncarbonate hardness}\} + \{\text{excess lime Ca}\}\end{aligned} \tag{10.52}$$

The solids formed consist of calcium carbonate and magnesium hydroxide and any silts and clays in the raw water. The total suspended solids concentration in mg/L prior to settling is,

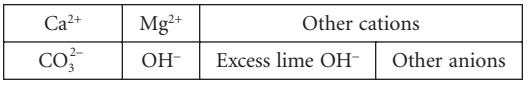
$$X_{ss} = 50.04\left[\{CaO\} + \{\text{original } Ca^{2+}\}\right] + 29.16\{\text{original } Mg^{2+}\} \tag{10.53}$$

Any silts and clays in the raw water will be trapped in the precipitates and should be added to get the total suspended solids.

Recarbonation

When only calcium is removed, the settled water has a pH between 10 and 10.6, is supersaturated with respect to calcium carbonate, and contains suspended calcium carbonate crystals that did not settle out. The traditional rule of thumb is that the residual calcium hardness is about 0.8 meq/L, and the magnesium hardness is unchanged. In the case of excess lime treatment, the settled water is supersaturated with respect to calcium carbonate and magnesium hydroxide and contains suspended particles of both crystals. The final pH is between 11 and 11.5. Such waters will deposit hard scales in sand filters and distribution systems and corrode lead and copper. The usual practice is to convert carbonate and hydroxide to bicarbonate by reacting with carbon dioxide gas.

Consider the following bar chart that represents excess lime-softened water after sedimentation:



It is convenient to use concentration units of mmol/L, because the carbonate and carbon dioxide are both converted to bicarbonate and so behave as a monoprotic base and acid. The carbon dioxide requirement is in mmol/L,

$$\left[CO_2\right]=\left[CO_3^{2-}\right]+\left[OH^-\right]+\left[\text{excess lime } OH^-\right] \tag{10.54}$$

In the case of excess lime softening, the carbonate and hydroxide concentrations associated with calcium and magnesium would be about 0.4 and 0.2 mmol/L, respectively, and the excess lime hydroxide (which is associated with other cations) would be about 1 to 1.5 mmol/L. Therefore, the expected carbon dioxide dosage is about 1.6 to 2.1 mmol/L. In the case of calcium removal only, there is no hydroxide residual, so the expected carbon dioxide dosage would be about 0.4 mmol/L.

In either case, the final water pH will be 8.3 or a little higher. Whether or not such waters will deposit scale can be estimated by using the Larson–Buswell (1942) correction to Langelier's (Langelier, 1936, 1946; Hoover, 1938) equilibrium pH_{eq},

$$pH_{eq}=-\log\left\{\frac{K_2\left(Ca^{2+}\right)\left(\text{Alkalinity}\right)}{K_{sp}}\right\}+9.30+\frac{2.5\sqrt{\mu}}{1+5.3\sqrt{\mu}+5.5\mu} \tag{10.55}$$

or the formula derived by Singley et al. (1985):

$$pH_{eq}=-\log\left\{\frac{K_2\left[Ca^{2+}\right]\cdot\left[\text{Alkalinity}\right]}{K_{sp}}\right\}+\frac{2.5\sqrt{\mu}+3.63\mu}{1+3.30\sqrt{\mu}+2.61\mu} \tag{10.56}$$

Langelier's saturation index, I_{sat}, is calculated as,

$$I_{sat}=pH_{act}-pH_{eq} \tag{10.57}$$

where I_{sat} = Langeliers's saturation index
pH_{act} = the measured pH of the water
pH_{eq} = the equilibrium pH at which a water neither deposits nor dissolves calcium carbonate
K_2 = the second acid dissociation constant for carbonic acid
K_{sp} = the solubility product of calcium carbonate
(Ca^{2+}) = the calcium ion concentration in mg/L as $CaCO_3$
$[Ca^{2+}]$ = the calcium ion concentration in mol/L
(Alkalinity) = the total alkalinity in mg/L as $CaCO_3$
[Alkalinity] = the total alkalinity in eq/L
μ = the ionic strength in mol/L
≈ Total Dissolved Solids (mg/L)/40,000

The values of the calcium carbonate solubility product were given above. The second acid ionization constant of carbonic acid can be estimated by (Shock, 1984),

$$\log K_2=-107.8871-0.03252849T+\frac{5151.79}{T}+38.92561\log T-\frac{563713.9}{T^2} \tag{10.58}$$

where T = the absolute temperature in K.

A water is stable if its measured pH is equal to pH_{eq}. It will deposit calcium carbonate scale if its measured pH is greater than pH_{eq}, and it will dissolve calcium carbonate scale if its measured pH is less than pH_{eq}.

More information is provided by Ryznar's (1944) stability index, I_{stab}:

$$I_{stab}=2pH_{eq}-pH_{act} \tag{10.59}$$

A stability index between about 6.3 and 6.8 will result in virtually no calcium carbonate scale or iron corrosion. Indices below 6 result in scale deposition from hot water, and the deposition is heavy below an index of 5. Indices above 7 produce iron corrosion, and indices above 8 indicate very corrosive water.

Lead and Copper Control

The action level for lead is 0.015 mg/L, and the maximum contaminant level goal (MCLG) for lead is zero. The action level for copper is 1.3 mg/L, and the MCLG for copper is also 1.3 mg/L. If 10% of the taps sampled exceed either of the action levels, one or more of the following must be done to the water system (EPA, 1991):

- Install corrosion control for the distribution system
- Treat the raw water to remove lead and copper
- Replace lead service lines
- Conduct public education to help the public reduce their exposure to lead

The general corrosion reaction is an oxidation in which the metallic element becomes an ion that may react with other solution ions:

$$Me \rightarrow Me^{n+} + ne^{-} \tag{10.60}$$

Corrosion can be discussed under three heads (Schock, 1990):

- Immunity — Immunity to corrosion means that the water chemistry is such that the metal is thermodynamically stable and will not corrode and go into solution. However, lead metal in contact with water is unstable and will corrode. Immunity generally requires some kind of cathodic protection, and the protected metal survives only as long as the sacrificial metal exists. In potable waters, zinc, aluminum, steel, and iron provide cathodic protection to lead, lead-tin solders, and copper.
- Passivation — Metal surfaces may be passivated by the deposition of a stable, nonporous film that protects the thermodynamically unstable metal from corrosion. In waters containing carbonate ion, the lead surface may be coated with a layer of plumbous carbonate (cerrusite, $PbCO_3$), hydroxy-plumbous carbonate [hydrocerrusite, $Pb(CO_3)_2(OH)_2$], or plumboacrite [$Pb_{10}(CO_3)_6(OH)_6O$] (Schock, 1990). The minimum equilibrium lead concentration is 0.069 mg/L, and it occurs at pH 9.8 and a dissolved carbonate concentration of 4.8 mg/L as C (Schock, 1990). The equilibrium lead concentrations for pHs between 8 and 9 and carbonate concentrations of less than 10 mg/L are less than 0.2 mg Pb/L. At pH 9.8, lead concentrations increase as carbonate concentrations increase or decrease. At a carbonate concentration of 4.8 mg C/L, lead concentrations increase as the pH increases or decreases.
- All of these lead concentrations are above the action level of 0.015 mg/L, but water in distribution systems is seldom in equilibrium with the piping and appurtenances, and measured lead concentrations may be less than the equilibrium values.
- Lead surfaces can also be passivated by zinc orthophosphate. Typical dosages are 0.4 to 0.6 mg/L as PO_4^{3-}. Theoretically, an equilibrium lead concentration of 0.01 mg/L can be achieved if the pH is adjusted to 7.6, the phosphate dosage is 4.5 mg/L as PO_4^{3-}, and the bicarbonate concentration is 5 to 10 mg/L as C (Schock, 1989). Zinc concentrations should not exceed 5 mg/L (for aesthetics), and this may limit the usefulness of zinc orthophosphate.
- Polyphosphate solubilizes lead, but it is slowly hydrolyzed to orthophosphate.
- In low alkalinity waters, sodium silicate at concentrations above 20 mg/L as SiO_2 and pHs around 8.2 slowly forms protective coatings on lead surfaces.
- Protection — Protection occurs when a layer of material is deposited that reduces the diffusion of material to and from the metal surface. The most common protective layer is calcium carbonate scale. This would require recarbonation to stop at a positive Langelier saturation index or a Ryznar stability index less than 6.

It should be noted that corrosion is not inhibited at Langelier indices as high as 2. The corrosion rate is more strongly influenced by dissolved oxygen and total dissolved solids than by water stability. For mild steel, the empirical formula for the rate of penetration is (Singley et al., 1985),

$$R_{pen} = \frac{C_{TDS}^{0.253} \cdot C_{DO}^{0.820}}{10^{0.0876 I_{sat}} \cdot t^{0.373}} \tag{10.61}$$

where C_{DO} = the dissolved oxygen concentration in mg/L
C_{TDS} = the total dissolved solids concentration in mg/L
I_{sat} = Langelier's saturation index (dimensionless)
R_{pen} = the mild steel corrosion penetration rate in mils per year
t = the exposure time in days

Ion Exchange

Materials

An ion exchanger is a solid that adsorbs certain dissolved ions from solution and replaces them with other ions. Some materials exchange cations, and others exchange anions. The exchange maintains the electroneutrality of the exchanger and the solution, so the number of equivalents of cations or anions released is equal to the number of equivalents of cations or anions adsorbed.

The property of ion exchange is widely known among many kinds of naturally occurring and synthetic solid materials. However, the most useful ion exchange materials are synthetic organic polymers consisting of polystyrene chains cross-linked with divinylbenzene and various attached functional groups. The functional groups may be divided into four classes. Letting *R* represent the resin lattice, the groups are (Abrams and Beneza, 1967):

- Strong acid cation (SAC) exchangers that contain the sulfonate ($R\text{-}SO_3^-$) group — These exchangers operate over a wide pH range and can remove all cations from solution, replacing them with protons, or all doubly and triply charged cations, replacing them with sodium.
- Weak acid cation (WAC) exchangers that contain the carboxylate ($R\text{-}COO^-$) group — These exchangers operate in neutral to alkaline pHs, where the carboxylate group is ionized and can remove doubly charged and triply charged ions, if carbonate or bicarbonate is present in sufficient quantities to neutralize the protons released.
- Strong base anion (SBA) exchangers that contain the quarternary amine [$R\text{–}N(CH_3)_3^+$] group — These exchangers can operate over a wide range of pHs and can remove all anions, replacing them with hydroxide or chloride ions.
- Weak base anion (WBA) exchangers that contain a primary, secondary, or tertiary amine ($R\text{-}NH_3^+$, $R = NH_3^+$, $R{+}NH^+$) group — These exchangers operate in the acidic range where the amino group is protonated.

Most commercial resins are homogeneous gels (Abrams and Beneza, 1967). The solid consists of an open crystalline matrix that adsorbs water and permits the free diffusion of ions. The charge of the functional groups is balanced by the diffusing ions. The degree of cross-linking influences the ionic diffusion rate, and large ions may be excluded from the gel.

Macroporous, highly cross-linked resins are available (Abrams and Beneza, 1967). In these materials, ion exchange is limited to the interior surfaces of the macropores. However, ionic diffusion in the macropores is rapid. Macroporous resins are largely limited to nonaqueous processes.

Equilibria

The exchange process can be described as a two-phase equilibrium involving ion *X* with charge *n* and ion *Y* with charge *m*:

$$R - X_m^n + nY^m \leftrightarrow R - Y_n^m + mX^n \tag{10.62}$$

$$K = \frac{\left[\mathrm{R} - \mathrm{Y}_n^m\right]^n \left[\mathrm{X}^n\right]^n}{\left[\mathrm{R} - \mathrm{X}_m^n\right]^m \left[\mathrm{Y}^m\right]^n} \tag{10.63}$$

Note that the terms $[\mathrm{R} - \mathrm{X}_m^n]$ and $[\mathrm{R} - \mathrm{Y}_n^m]$ refer to the activities of ions in the solid phase, while the terms $[X^n]$ and $[Y^m]$ refer to the ionic activities in water. In practice, concentrations rather than activities are used, and the equilibrium constant is called a selectivity coefficient. The selectivity coefficient varies with the ionic strength of the solution. Concentrations of ions in the exchanger are generally reported as a mass-to-mass ratio, whereas concentrations in water are reported as a mass-to-volume ratio.

Sometimes another constant called the separation factor is used:

$$\alpha = \frac{\left[\mathrm{R} - \mathrm{Y}_\mathrm{n}^\mathrm{m}\right]\left[\mathrm{X}^\mathrm{n}\right]}{\left[\mathrm{R} - \mathrm{X}_\mathrm{m}^\mathrm{n}\right]\left[\mathrm{Y}^\mathrm{m}\right]} = K \cdot \frac{\left[\mathrm{R} - \mathrm{X}_\mathrm{m}^\mathrm{n}\right]^{m-1}\left[\mathrm{Y}^\mathrm{m}\right]^{n-1}}{\left[\mathrm{R} - \mathrm{Y}_\mathrm{n}^\mathrm{m}\right]^{n-1}\left[\mathrm{X}^\mathrm{n}\right]^{m-1}} \tag{10.64}$$

Note that the separation factor is not an equilibrium constant and will vary significantly with water composition. Some separation factors relative to sodium are given in Table 10.1.

In general, ion exchangers preferentially adsorb more highly charged ions over less highly charged ions, and smaller ions over larger ions. The general preference sequence for cation exchangers is (Kemmer, 1988),

$$\mathrm{Fe}^{3+} > \mathrm{Al}^{3+} > \mathrm{Pb}^{2+} > \mathrm{Ba}^{2+} > \mathrm{Sr}^{2+} > \mathrm{Cd}^{2+} > \mathrm{Zn}^{2+} > \mathrm{Cu}^{2+} > \mathrm{Fe}^{2+} >$$

$$\mathrm{Mn}^{2+} > \mathrm{Ca}^{2+} > \mathrm{Mg}^{2+} > \mathrm{K}^{+} > \mathrm{NH}_4^{+} > \mathrm{Na}^{+} > \mathrm{H}^{+} > \mathrm{Li}^{+}$$

In most natural waters, ferric iron and aluminum form precipitates, which should be removed prior to the ion exchange bed to prevent clogging. Ferrous iron may be oxidized by dissolved oxygen after exchange and precipitate in or on the resin beads. This can be prevented by applying a reductant like sodium sulfite to the raw water or mixing it with the regenerant.

TABLE 10.1 Separation Factors Relative to Sodium and Chloride for Various Ions (N = 0.01; TDS = 500 mg/L as $CaCO_3$)

Strong Acid Cation Exchangers		Strong Base Anion Exchangers	
Cation	α	Anion	α
Ammonium, NH_4^+	1.3	Acetate, $CHCOO^-$	0.14
Barium, Ba^{2+}	5.8	Arsenate, $HAsO_4^{2-}$	1.5
Calcium, Ca^{2+}	1.9	Bicarbonate, HCO_3^-	0.27
Copper, Cu^{2+}	2.6	Bisulfate, HSO_4^-	4.1
Hydronium, H^+	0.67	Bisulfite, HSO_3^-	1.2
Iron, Fe^{2+}	1.7	Bromide, Br^-	2.3
Lead, Pb^{2+}	5	Chloride, Cl^-	1
Magnesium, Mg^{2+}	1.67	Chromate, CrO_4^{2-}	100
Manganese, Mn^{2+}	1.6	Fluoride, F^-	0.07
Potassium, K^+	1.67	Nitrate, NO_3^-	3.2
Radium, Ra^{2+}	13	Nitrite, NO_2^-	1.1
Sodium, Na^+	1	Selenate, SeO_4^{2-}	17
Strontium, Sr^{2+}	4.8	Selenite, SeO_3^{2-}	1.3
Zinc, Zn^{2+}	1.8	Sulfate, SO	9.1

For anion exchangers, the preference sequence is,

$$CrO_4^{2-} > SO_4^{2-} > SO_3^{2-} > HPO_4^{2-} > CNS^- > CNO^- > NO_3^- >$$

$$NO_2^- > Br^- > Cl^- > CN^- \; HCO_3^- > HSiO_3^- > OH^- > F^-$$

These sequences are affected by the ionic strength of the solution and the chemical composition of the ion exchanger.

Operating parameters and important resin properties are summarized in Table 10.2. Note that the operating exchange capacity varies with the concentration of the regenerant solution. This is a consequence of the equilibrium nature of the process.

Sodium Cycle Softening

Health and Ecology Notes

The sodium concentration in the finished water is equal to the original hardwater sodium concentration plus the sodium required to replace the calcium and magnesium hardness removed:

$$C_{Naf} = C_{Nao} + \tfrac{23}{50} C_{HCao} + \tfrac{23}{50} C_{HMgo} \tag{10.65}$$

where C_{HCao} = the original calcium hardness [eq/m^3 or gr (as $CaCO_3$)/ft^3]
C_{HMgo} = the original magnesium hardness [eq/m^3 or gr (as $CaCO_3$)/ft^3]
C_{Naf} = the final sodium concentration [eq/m^3 or gr (as $CaCO_3$)/ft^3]
C_{Nao} = the original sodium concentration [eq/m^3 or gr (as $CaCO_3$)/ft^3]

If a hard water is softened, the resulting sodium concentration will be high, and drinking water may comprise a significant fraction of the dietary sodium intake. This may be of concern for people on restricted sodium diets.

A zero-hardness water is corrosive, because of the lack of scale-forming calcium ions. Such waters are not suitable for household use without further treatment, because lead and copper will be dissolved from plumbing fixtures. Zinc orthophosphate additions and pH adjustment may be required. Partially softened waters may be acceptable if the final pH and carbonate concentration are carefully adjusted.

Sodium cycle softening produces a waste brine that may adversely affect fresh water biota. Many states have restrictions on the increase in total dissolved solids concentration that they will permit in receiving waters. Common restrictions are an increase in TDS of 100 mg/L and an absolute upper limit of 750 mg/L.

Waste brines do not adversely affect the biological wastewater treatment processes (including septic tanks) at chloride concentrations up to several thousand mg/L (Ludzack and Noran, 1965).

Operating Cycle

The sodium cycle ion exchange softening process consists of the following cycle:

- Hard water is passed through a bed of fresh ion exchange resin that is preloaded with sodium ions; calcium and magnesium ions are adsorbed from solution and replaced by a charge-equivalent amount of sodium ions.
- At the end of the ion exchange service run (which is indicated by a preset timer or by effluent monitoring), the ion exchange bed is backwashed to remove sediment, and the washwater is run to waste.
- The ion exchange material is then regenerated by slowly pumping through it a sodium chloride brine; the required brine volume normally exceeds the pore spaces in the bed; the spent regenerant brine is run to waste; and the concentration of the brine determines the exchange capacity of the resin.
- The bed is then flushed with several empty bed volumes of hard water to remove the spent regenerant brine, and the flushing water is run to waste; the bed is put back in service.

The design problem is to determine the following:

- Required bed volume and dimensions
- Duration of a cycle
- Mass of salt required for regeneration in each cycle
- Volume of regenerant brine required each cycle
- Volume of waste brine produced each cycle
- Composition of the waste brine

Bed Volume and Salt Requirement

For all intents and purposes, the removal of calcium and magnesium is nearly complete. Thus, the required ion exchange bed volume, V, can be calculated as follows:

$$V = \frac{Qt_s C_{Ho}}{q_{iec}} \tag{10.66}$$

where C_{Ho} = the hardness of the raw water [eq/m³ or gr (as $CaCO_3$)/ft³]
Q = the raw water flow rate (m³/s or ft³/sec)
q_{iec} = the capacity of the ion exchange resin [eq/m³ or gr (as $CaCO_3$)/ft³]
t_s = the time-in-service of the bed (sec)
V = the volume of the bed (m³ or ft³)

The time-in-service, t_s, is a design choice. The hard water flow rate, Q, the raw water hardness, C_{Ho}, and the bed exchange capacity, q_{iec}, are determined by the design problem.

The service flow rate in Table 10.2 yields a minimum bed volume, service time, and hydraulic detention time. The minimum depth requirement yields a maximum cross-sectional area, which is intended to control short-circuiting. Sometimes the service flow rate is given as an areal rate (approach velocity). In that case, the service flow rate and minimum depth combine to yield a minimum bed volume, service time, and hydraulic detention time.

Regeneration Scheduling

The cycle time is the sum of the required service time, backwash time, regeneration time, flushing time, and down time for valve opening and closing and pump startup and shutdown:

$$t_c = t_s + t_b + t_r + t_f + t_d \tag{10.67}$$

where t_b = the backwashing time (sec)
t_c = the cycle time (sec)
t_d = the down time for valve and pump adjustments (sec)
t_f = the flushing time (sec)
t_r = the regeneration time (sec)
t_s = the time-in-service of the bed (sec)

The last four components of the cycle time are more or less fixed, and the service time is freely adjustable (by adjusting the bed volume) and can be chosen so that the cycle time fits comfortably into a convenient work schedule.

Partial Softening

It is usually desirable to produce a finished hardness C_{Hf} greater than zero, in order to facilitate corrosion control. This is accomplished by bypassing some of the raw water around the exchanger and mixing it with softened water, as shown in Fig. 10.4. The finished water hardness is,

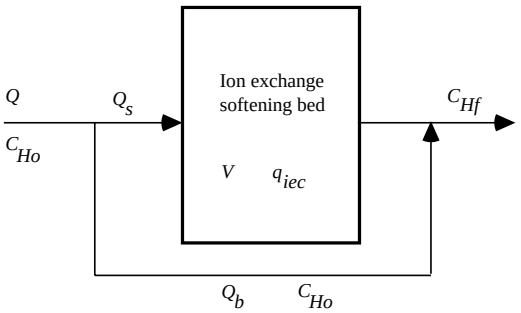

FIGURE 10.4 Flow scheme for partial ion exchange softening.

$$C_{Hf} = \frac{Q_b C_{Ho}}{Q_s + Q_b} = \frac{Q_b C_{Ho}}{Q} \tag{10.68}$$

where C_{Ho} = the hardness of the raw water [eq/m³ or gr (as $CaCO_3$)/ft³]
C_{Hf} = the hardness of the finished water [eq/m³ or gr (as $CaCO_3$)/ft³]
Q = the raw water flow rate (m³/s or ft³/sec)
Q_b = the raw water flow bypassed around the softener (m³/s or ft³/sec)
Q_s = the raw water flow processed through the softener (m³/s or ft³/sec)

The fractions of the raw water flow that are softened and bypassed are as follows:

$$f_s = \frac{Q_s}{Q} = 1 - \frac{C_{Hf}}{C_{Ho}} \tag{10.69}$$

$$f_b = \frac{Q_b}{Q} = \frac{C_{Hf}}{C_{Ho}} \tag{10.70}$$

where f_b = the fraction of the raw water that is bypassed (dimensionless)
f_s = the fraction of the raw water that is softened (dimensionless).

The bed volume is sized based on the volume of water softened, Q_s.

The salt requirement per cycle, M_{NaCl}, is the manufacturer's recommended dosage rate per unit bed volume, m_{NaCl}, times the bed volume:

$$M_{NaCl} = m_{NaCl} V \tag{10.71}$$

where M_{NaCl} = the mass of salt required to regenerate an ion exchange bed per cycle (kg or lb)
m_{NaCl} = the salt dosage per unit bed volume (kg/m^3 or lb/ft^3).

This will vary with the desired bed ion exchange capacity. The salt efficiency is defined to be the sodium exchanged divided by the sodium supplied. If equivalents are used to express masses, the efficiency is,

$$E_{Na} = \frac{V q_{iec}}{M_{NaCl}/58.5} \tag{10.72}$$

where E_{Na} = the salt efficiency (dimensionless).

Large ion exchange capacities require disproportionate salt dosages, which significantly reduce the salt efficiency.

Waste Brine

The waste brine is composed of the wash water, the spent regenerant brine, and the flushing water.

The wash water volume is merely the backwash rate, U_b, times the backwash duration and bed cross-sectional area, A:

$$V_{ww} = U_b A t_b \tag{10.73}$$

where A = the cross-sectional area of the bed (m^2 or ft^2)
t_b = the backwash duration (sec)
U_b = the backwash rate (m/s or ft/sec)
V_{ww} = the wash water volume (m^3 or ft^3)

The regenerant brine volume is equal to the mass of salt that is required for regeneration, divided by the weight fraction of salt in the brine, and the density of the brine:

$$V_{rb} = \frac{M_{NaCl}}{\rho_{rb} f_{NaCl}} \tag{10.74}$$

where f_{NaCl} = the mass fraction of salt in regenerant brine (dimensionless)
M_{NaCl} = the mass of salt required to regenerate an ion exchange bed per cycle (kg or lb)
ρ_{rb} = the density of regenerant brine (kg/m^3 or lbm/ft^3)

Densities for various brine concentrations and compositions are given in standard handbooks like the *CRC Handbook of Chemistry and Physics*.

The amount of flushing water is equal to the empty bed volume times the number of bed volumes used for flushing:

$$V_f = nV \tag{10.75}$$

where n = the number of empty bed volumes of flushing water needed to remove spent brine from an ion exchange bed (dimensionless)
V = the empty bed volume (m^3 or ft^3)
V_f = the flushing water volume (m^3or ft^3)

The total waste brine volume per cycle is,

$$V_{wb} = V_{ww} + V_{rb} + V_f \tag{10.76}$$

The waste brine contains the following:

- All the calcium and magnesium removed
- All the chloride in the regenerant brine
- All the sodium not exchanged during regeneration

The composition is most easily calculated if the units are equivalents. If the equivalent fraction of calcium in the hard water is f_{Ca}, the masses of the various ions in the waste brine are as follows:

$$M_{Ca} = f_{Ca} V q_{iec} \left(\frac{20 \text{ g Ca}}{\text{eq}} \right) \left(\frac{1 \text{ kg}}{10^3 \text{ g}} \right) \quad (\text{as Ca}) \tag{10.77}$$

$$M_{Mg} = (1 - f_{Ca}) V q_{iec} \left(\frac{12.16 \text{ g Mg}}{\text{eq}} \right) \left(\frac{1 \text{ kg}}{10^3 \text{ g}} \right) \quad (\text{as Mg}) \tag{10.78}$$

$$M_{Na} = M_{NaCl} \left(\frac{23 \text{ g Na}}{58.5 \text{ g NaCl}} \right) \left(\frac{1 \text{ kg}}{10^3 \text{ g}} \right) - V q_{iec} \left(\frac{23 \text{ g Na}}{\text{eq}} \right) \left(\frac{1 \text{ kg}}{10^3 \text{ g}} \right) \quad (\text{as Na}) \tag{10.79}$$

$$M_{Cl} = M_{NaCl} \left(\frac{35.5 \text{ g Cl}}{58.5 \text{ g NaCl}} \right) \left(\frac{1 \text{ kg}}{10^3 \text{ g}} \right) \quad (\text{as Cl}) \tag{10.80}$$

where f_{Ca} = the equivalents fraction of calcium in the hard water (dimensionless)
M_{Ca} = the mass of calcium in waste brine from ion exchange in kg
M_{Cl} = the mass of chloride in waste brine from ion exchange in kg
M_{Mg} = the mass of magnesium in waste brine from ion exchange in kg
M_{Na} = the mass of sodium in waste brine from ion exchange in kg

Chloride Cycle Dealkalization and Desulfurization

Strong base anion exchange resins will release chloride ions and adsorb bicarbonate, carbonate, and sulfate. The regenerant is a sodium chloride brine, but the chloride is the exchangeable ion, and the sodium ion is passive. The calculations parallel those for sodium cycle softening.

Demineralization

Waters may be nearly completely demineralized by a combination of strong acid hydrogen cycle and strong base hydroxide cycle resins.

Raw waters are first processed through the hydrogen cycle resin, which removes all cations and replaces them with protons. The result is a dilution solution of mineral acids and carbonic acid. The pH will depend on the total amount of cations removed: each equivalent of cations is replaced by one equivalent of protons.

The carbonic acid is derived from the carbonate and bicarbonate originally present in the raw water. Carbonic acid decomposes to form carbon dioxide gas until it is in equilibrium with the gas-phase partial pressure of CO. If the initial alkalinity is high enough, a vacuum degassifier will be required after the hydrogen cycle exchanger to remove the carbon dioxide gas.

The initial bicarbonate and carbonate ions are removed by conversion to carbon dioxide gas and degassification. The remaining anions (Cl^-, SO_4^{2-}, NO_3^-, etc.) can be removed by hydroxide cycle ion exchange. Note that the hydrogen cycle exchanger must precede the hydroxide cycle exchanger in order to avoid the formation of calcium carbonate and magnesium hydroxide deposits.

The design calculations for hydrogen cycle and hydroxide cycle exchangers parallel those for sodium cycle softening, the differences being that H^+ and OH^- are being released to the water rather than Na^+, and that the regenerants are strong acids (H_2SO_4 or HCl) and strong bases (NaOH or KOH). The waste products are fairly strong acid and base solutions. The wastes do not exactly neutralize each other, because the acid and base efficiencies are usually different.

Strong acid hydrogen cycle exchangers are usually regenerated with sulfuric acid. However, the acidity required to drive the regeneration is generally on the order of 2 to 8% acid by wt, and in this range, sulfuric acid is only partially ionized. The result is a low acid efficiency, generally on the order of 30%. Furthermore, in hard waters, the calcium sulfate solubility limit in the waste acid may be exceeded, and a gypsum sludge may be produced. Both problems can be avoided by using hydrochloric acid, but it is expensive, and HCl vapors pose a venting problem.

If the removal of weak acid anions like HCO_3^-, $HSiO_3^-$ or $CH_3\,COO^-$ is not required or if such anions are absent, weak base anion exchanger resins can be used instead of strong base anion resins. WBA resins can be regenerated with a wide variety of bases.

Mixed-bed exchangers contain SAC and SBA resins. Cation exchange and anion exchange occur at every level of the bed. The proportions of the two resin types depend on their relative ion exchange capacities. SBA resins have much lower densities than SAC resins, so they can be separated by backwashing. Regeneration is accomplished by down-flowing base through the upper SBA resin and up-flowing acid through the lower SAC resin. The wastes are drawn off at the interface between the separated resins. A mechanism for remixing the beads after regeneration must be included in the bed design.

10.3 Chemical Oxidation

Chemical Oxidants

Chemical oxidants are used in water and wastewater treatment for a variety of purposes, including disinfection; oxidation of iron and manganese; oxidation of recalcitrant, refractory, or toxic organic compounds; taste, odor, and color removal; prevention of algal growth within the treatment plant; control of nuisance species; and improvement of coagulation and flocculation efficiency (EPA, 1999). The most common oxidants for water treatment are chlorine, chlorine dioxide, ozone, permanganate, and advanced oxidation processes (AOPs). The oxidation-reduction half-reactions and standard reduction potentials, E^0, of common water treatment oxidants are shown in Table 10.3. A larger E^0 indicates a thermodynamically stronger oxidant; however, the kinetics of the reaction may control whether a reaction occurs. For example, although chlorine dioxide may react with a reductant producing Cl^-, it often only gains $1e^-$ rather than $5e^-$ forming ClO_2^-.

Chlorine

Chlorine can be purchased as pressurized liquid chlorine or as solid hypochlorite salts of calcium or sodium. Liquid chlorine is preferred for reasons of economy, but solid hypochlorite salts are preferred for reasons of safety.

TABLE 10.3 Standard Reduction Potentials of Common Oxidants

Reduction Half-Reaction	Standard Reduction Potential, E^0, V
$Cl_{2\,(aq)} + 2e^- = 2Cl^-$	+1.40
$HOCl + H^+ + 2e^- = H_2O + Cl^-$	+1.48
$OCl^- + 2H^+ + 2e^- = H_2O + Cl^-$	+1.71
$NH_2Cl + 2H^+ + 2e^- = Cl^- + NH_4^+$	+1.40
$ClO_2 + 5e^- + 2H_2O = Cl^- + 4OH^-$	+1.91
$ClO_2 + e^- = ClO_2^-$	+0.95
$ClO^- + 2H_2O + 4e^- = Cl^- + 4OH^-$	+0.76
$MnO_4^- + 4H^+ + 3e^- = MnO_2\,(s) + 2H_2O$	+1.68
$O_3 + 2e^- + 2H^+ = O_2 + H_2O$	+2.07
$H_2O_2 + 2H^+ + 2e^- = 2H_2O$	+1.77
$^{\bullet}OH + e^- = OH^-$	+2.80

Snoeyink, V.L. and Jenkins, D. 1980. *Water Chemistry,* John Wiley and Sons, New York.

Water Chemistry of Chlorine

Aqueous, often termed free chlorine, refers to elemental chlorine, Cl_2, as well as hypochlorous acid, HOCl, and hypochlorite, OCl^-. Combined chlorine is composed of monochloramine, NH_2Cl, and dichloramine, $NHCl_2$ (called chloramines). Combined chlorine is a relatively poor oxidant; thus, it is used primarily as a disinfectant. Cl_2 hydrolyzes in water, resulting in disproportionation (i.e., one Cl atom is oxidized, the other is reduced):

$$Cl_{2(aq)} + H_2O \leftrightarrow HOCl + H^+ + Cl^-; \qquad K_h = 4 \times 10^{-4} \tag{10.81}$$

Hypochlorous acid is a weak acid that dissociates to hypochlorite under moderate pH values:

$$HOCl \leftrightarrow H^+ + OCl^-; \qquad pK_a = 7.5 \tag{10.82}$$

Chlorine readily reacts with synthetic and naturally occurring organic compounds in water. Commonly, chlorine reacts with organic compounds by substitution for a hydrogen atom or addition, producing chlorinated organic products. However, chlorine may also oxidize a compound without chlorinating it (Snoeyink and Jenkins, 1980).

Chlorine Dioxide

Chlorine dioxide is an unstable greenish-yellow gas. Because of its instability, it cannot be stored or transported and is prepared on-site immediately prior to use. The usual methods are the reaction between hydrochloric acid and sodium chlorite and the reaction of sodium chlorite with chlorine, both in aqueous solution (Katz, 1980; Haas, 1990):

$$4\,HCl + 5\,NaClO_2 \rightarrow 4\,ClO_2 + 5\,NaCl + 2\,H_2O \tag{10.83}$$

$$Cl_2 + 2\,NaClO_2 \rightarrow 2\,ClO_2 + 2\,NaCl \tag{10.84}$$

Excess chlorine is used to drive the chlorine/chlorite reaction to completion. The normal recommendation is 1 kg pure chlorine per kg pure sodium chlorite (1.3 mol/mol), but even this excess produces conversion of only about 60%. Some facilities use more chlorine, and others acidify the reaction. Chlorine dioxide can also be formed from sodium hypochlorite and sodium chlorite in aqueous solution:

$$NaOCl + 2\ NaClO_2 + H_2O \rightarrow 2\ ClO_2 + 3\ Na^+ + Cl^- + 2\ OH^- \quad (10.85)$$

In all these reactions, chloride, chlorite, and chlorate are formed in side reactions.

Chlorine dioxide is an oxidant; it acts as a one-electron acceptor forming chlorite:

$$ClO_2 + e^- \leftrightarrow ClO_2^- \quad (10.86)$$

Chlorite may gain four electrons, forming Cl^-:

$$ClO_2^- + 4e^- + 2H_2O \leftrightarrow Cl^- + 4OH^- \quad (10.87)$$

However, chlorite is less reactive; thus, the second reaction does not proceed readily. Large doses of chlorite cause anemia, therefore, EPA has established an MCL for chlorite of 1 mg/L (EPA, 2001a).

Ozone

Ozone is very unstable, thus it is prepared on-site by passing a dry, oil-free, particulate-free oxygen-containing gas between two high-voltage electrodes (generally 7500 to 20,000 volts) (Katz, 1980).

$$3\ O_2 \leftrightarrow 2\ O_3 \quad (10.88)$$

The yields are generally 1 to 3% ozone by volume in air and 2 to 6% in oxygen. The reaction liberates heat, and decomposition of ozone to oxygen is favored at high temperatures, so the ozone generators must be cooled (Weavers and Wickramanayake, 2000).

Ozone decomposes in water to yield free radicals including hydroxyl radical ($OH^\bullet$) and hydroperoxyl radical ($HO_2^\bullet$).

$$O_3 + OH^- \rightarrow HO_2^\bullet + O_2^{\bullet-} \quad (10.89)$$

$$HO_2 \leftrightarrow O_2^{\bullet-} + H^+ \quad (10.90)$$

$$O_3 + O_2^{\bullet-} \rightarrow O_3^{\bullet-} + O_2 \quad (10.91)$$

$$O_3^{\bullet-} + H^+ \rightarrow HO_3^\bullet \quad (10.92)$$

$$HO_3^\bullet \rightarrow OH^\bullet + O_2 \quad (10.93)$$

These, particularly $OH^\bullet$, are strong and reactive oxidants, typically resulting in diffusion-limited reactions with organic species. However, due to this reactivity, concentrations of $OH^\bullet$ in water reach concentrations up to 10^{-12} M, whereas concentrations of ozone reach concentrations of 10^{-3} M (EPA, 1999).

The rate of decomposition of ozone varies from hours to seconds, depending on water conditions such as temperature, pH, UV light, O_3 concentration, and concentration of radical scavengers (i.e., alkalinity and organic matter). Gurol and Singer (1982) developed the following empirical equation to incorporate some of these parameters:

$$-\frac{d[O_3]}{dt} = k[O_3][OH^-]^{-0.55} \quad (10.94)$$

where $[O_3]$ and $[OH^-]$ are O_3 and hydroxide ion concentrations, respectively, and k is the temperature-dependent rate constant.

Permanganate

Potassium permanganate is commercially available in a deep purple solid crystalline form that dissolves in water to form a pink or purple solution. Typically, 1 to 4% solutions of permanganate are generated on-site prior to application to a treatment stream.

As shown in Table 10.3, permanganate (MnO_4^-) contains oxidized manganese (+VII) that is reduced to manganese (+IV) in the form of manganese dioxide solid (MnO_2). Permanganate oxidizes a wide variety of organic and inorganic compounds in the pH 4 to 9 range. Typically, oxidation is more rapid under alkaline than acid conditions (Hazen and Sawyer, 1992). Unlike the other oxidants described above, permanganate is not an effective disinfectant at concentrations typically employed, and therefore, it is used strictly as an oxidizing agent (EPA, 1999). Permanganate is added prior to sedimentation in treatment to allow for removal of manganese dioxide solids.

Advanced Oxidation Processes

Advanced oxidation processes (AOPs) have been shown to be effective for the elimination of organic and inorganic pollutants from water (Glaze, 1987; Masten and Davies, 1994; Legrini et al., 1993; Hoffmann et al., 1995). AOPs are generally grouped together, because they all result in the *in situ* formation of radicals or, more specifically, hydroxyl radicals ($OH^\bullet$), in sufficient quantity to affect water treatment (Glaze, 1987). These processes are often needed when conventional approaches to water and wastewater treatment are ineffective. Examples of AOPs include ozone at high pH (O_3/OH^-), ozone combined with hydrogen peroxide (O_3/H_2O_2), photolysis of ozone (O_3/UV), photolysis of ozone and hydrogen peroxide (O_3/H_2O_2/UV), photo-Fenton reaction (Fe(II)/H_2O_2/UV), and semiconductor photocatalysis (TiO_2/UV). Hoffmann et al., 1995; Langlais et al., 1991; Legrini et al., 1993; and Masten and Davies, 1994 form an abbreviated list of review papers and books on various AOPs.

The effectiveness of AOPs is dependent on chemical components in water other than target compounds. Alkalinity, pH, NOM, and particulates may cause significant deviations in treatment time required. For example, alkalinity and NOM react with $OH^\bullet$ radicals formed, reducing the concentration available to react with target species. In addition, particulates and light-absorbing species in water limit light penetration in ultraviolet irradiation AOPs.

Nondisinfection Uses Of Oxidants

Chemical oxidants other than chlorine are playing an increasing role in minimizing disinfection byproducts (DBPs). These oxidants may be used as primary disinfectants at the beginning or middle of the treatment process. Employing disinfectants other than chlorine early in the treatment process results in less trihalomethane (THM) formation due to oxidation of THM precursors and minimization of the interaction of chlorine with THM precursors.

Potassium permanganate is commonly used to control treatment plant fouling by nuisance aquatic species such as zebra mussels and Asiatic clams (EPA, 1999). Monochloramine is also effective at killing Asiatic clams without producing THMs.

Reduced iron (II) and manganese (II) are problematic in many groundwater sources but are uncommon in surface waters. Many oxidants may be used to remove iron and manganese from water sources. Oxidants act to oxidize iron (II) to iron (III) and manganese (II) to manganese dioxide [manganese (IV)]. The oxidized species are relatively insoluble and thus are removed in sedimentation treatment steps. Table 10.4 shows concentrations of various oxidants necessary to oxidize iron and manganese.

Taste and odor problems are more common in surface water than groundwater sources. This is due to the presence of algae and other microorganisms along with adequate nutrients from sources such as agricultural runoff. In addition, decaying vegetation is attributed to taste and color problems (James M. Montgomery, 1985). Moreover, disinfection can result in taste and odor. Taste and odor are extremely source specific, thus different oxidants may be effective, depending on factors such as location and season. Taste and odor associated with microorganisms and decaying vegetation are often resistant to traditional oxidation, thus ozone-containing AOPs such as ozone/hydrogen peroxide, ozone at high pH, or ozone/UV may be employed, although other oxidants may be effective as well.

TABLE 10.4 Oxidant Concentrations Required to Oxidize Reduced Iron and Manganese

Oxidant	Iron (II) mg/mg Fe	Manganese (II), mg/mg Mn
Chlorine, Cl_2	0.62	0.77
Chlorine dioxide, ClO_2	1.21	2.45
Ozone, O_3	0.43	0.88
Oxygen, O_2	0.14	0.29
Potassium permanganate, $KMnO_4$	0.94	1.92

Source: Environmental Protection Agency. 1999. "Alternative Disinfectants and Oxidants Guidance Manual," *EPA 815-R-99–014*.

Chemical oxidants are used in the removal of recalcitrant and toxic organic compounds when destruction rather than displacement into another phase (i.e., GAC or air stripping) is desired. Reactions are highly dependent on the target organic compound, the oxidant used, pH, temperature, and other constituents in the water (AWWA, 1999). In addition, the extent of oxidation is important to monitor. The oxidation of a target organic compound such as phenol will result in daughter products such as catechol, hydroquinone, and benzoquinone. These daughter products will vary depending on the oxidant, extent of oxidation, ratio of oxidant to target compound, and other constituents in water. Toxicity issues that may be present with parent compounds need to be considered for potential products formed.

10.4 Disinfection

Waterborne Diseases

The principal waterborne diseases in the U.S. are listed in Table 10.5. Almost all of these diseases are transmitted via fecal contamination of water and food, but a few are more commonly transmitted by direct person-to-person contact or by inhalation of microbially contaminated air. Most of these diseases are actually quite rare, there being only one or a few cases a year, and some like cholera have not been observed for decades. However, all of these diseases have permanent reservoirs among humans or wild animals both in the U.S. and abroad, and all of them have the potential to cause outbreaks unless careful sanitation is maintained.

For the last 30 years, the U.S. has averaged about 33 outbreaks of waterborne disease per year, and each outbreak has involved about 220 cases (Craun, 1988). The majority of the outbreaks occur in noncommunity and individual systems, but the majority of the cases occur in community systems. About one-fifth of the outbreaks occur in surface water systems that either do not treat the raw water or that provide only disinfection (Craun, 1988). About two-fifths of the outbreaks occur in groundwater systems that do not provide any treatment (Craun and McCabe, 1973). Only half of the outbreaks can be attributed to a specific organism, and in recent years, *Giardia lamblia* is the one most often identified, displacing *Salmonella*. However, *Cryptosporidium parvum*-induced diarrhea may be as common as giardiasis (Rose, 1988). In recent years, the U.S. has experienced nearly one proven *Cryptosporidium* outbreak per year (Pontius, 1993). In 1989–1990, there were 26 outbreaks of waterborne disease reported in the U.S. Of these, the causative organism was not identified in 14 outbreaks. *Giardia* was responsible in seven outbreaks, hepatitis A in two, and Norwalk-like viruses, *E. coli* O157:H7, and cyanobacteria were responsible for one each (Herwaldt et al., 1992). In 1993, over 400,000 people became ill as a result of contamination of drinking water by *Cryptosporidium* in Milwaukee, WI (Rowan and Behm, 1993).

The Total Coliform Rule

In the past, the sanitary quality of drinking water was judged by a most probable number (MPN) or membrane filter count (MFC) of coliform bacteria, and the maximum contaminant level was set at 1 total coliform per 100 mL. The U.S. Environmental Protection Agency (1989) has abandoned this method and now uses the following rule (Pontius, 1990):

- Total coliform must be measured in 100 mL samples using the multiple tube fermentation technique, the membrane filter technique, or the presence-absence coliform test [all of which are described in *Standard Methods for the Examination of Water and Wastewater*, 18th ed., American Public Health Association, Washington, DC. (1992)] or the Colilert™ System [MMO-MUG test, approved *Federal Register*, 57:24744 (1992)].
- The number of monthly samples depends on system size as prescribed in Table 10.6.
- No more than 5% of the monthly samples can test positive if 40 or more samples are analyzed each month.
- No more than one sample can test positive if less than 40 samples are analyzed each month.
- Unfiltered surface water systems must sample the first service connection each day that the final turbidity exceeds 1 NTU, and service connection samples must be included in the positive and negative counts.
- Coliform-positive samples must be analyzed to determine whether fecal coliform are present.
- Repeat samples must be collected within 24 hr of the laboratory report of a coliform-positive result; the number of repeat samples depends on system size as prescribed in Table 10.7.

When the Total Coliform Rule is violated, immediate corrective action is required. The public must be notified of the violation. The method of notification includes the public media and mail. The notification

41,001–50,000	50	3,020,001–3,960,000	450
50,001–59,000	60	3,960,001 or more	480

[a] In lieu of the frequency specified in this table, a noncommunity water system using groundwater and serving 1000 persons or fewer may monitor at a lesser frequency specified by the state until a sanitary survey is conducted, and the state reviews the results. Thereafter, noncommunity water systems using groundwater and serving 1000 persons or fewer must monitor each calendar quarter during which the system provides water to the public unless the state determines that some other frequency is more appropriate and notifies the system (in writing). Five years after promulgation, noncommunity water systems using groundwater and serving 1000 persons or fewer must monitor at least once per year.

A noncommunity water system using surface water or groundwater under the direct influence of surface water, regardless of the number of persons served, must monitor at the same frequency as a like-sized public water system. A noncommunity water system using groundwater and serving more than 1000 persons during any month must monitor at the same frequency as a like-sized community water system, except that the state may reduce the monitoring frequency for any month the system serves 1000 persons or fewer.

[b] Includes public water systems that have at least 15 service connections but serve fewer than 25 persons.

[c] For a community water system serving 25 to 1000 persons, the state may reduce this sampling frequency, if a sanitary survey conducted in the last 5 years indicates that the water system is supplied solely by a protected groundwater source and is free of sanitary defects. However, in no case, may the state reduce the sampling frequency to less than once per quarter.

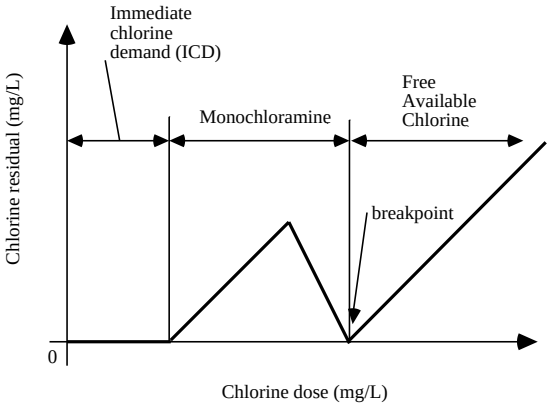

FIGURE 10.5 The chlorine breakpoint curve.

must conform to federal regulations regarding language and must include a description of the Total Coliform Rule, the public health significance of the violation, precautions consumers should take, a description of the corrective actions being taken by the utility, and telephone numbers for additional information. Corrective measures include flushing mains, increasing disinfectant doses, and improving filtration performance.

Community water systems collecting fewer than five samples per month are required to conduct a sanitary survey within 5 years of the promulgation of the rule and every 5 years thereafter. Noncommunity water systems are required to conduct a sanitary survey within 10 years after the rule is promulgated and every 5 years thereafter. If the noncommunity water system uses protected and disinfected groundwater, the sanitary survey may be repeated every 10 years instead of every 5 years.

Disinfectants

Although chlorine has been primarily used throughout the U.S., other chemical oxidants are becoming more popular. These include chlorine dioxide, chloramines, and ozone. In addition, ultraviolet irradiation is rapidly gaining acceptance, particularly in smaller treatment facilities (Parrotta and Bekdash, 1998). The chemistry of the disinfectants is discussed above. The solubilities of the gaseous disinfectants and pH effects on their forms are discussed in a previous chapter.

Chlorine

Generally, the disinfecting power of hypochlorous acid is greater than that of hypochlorite. In addition, the presence of ammonia in water results in the formation of chloramines. Thus, the form of chlorine present in the water is critical in determining the extent of disinfection.

The Breakpoint Curve

The breakpoint curve is a plot of the measured chlorine residual vs. the chlorine dose. It consists of three regions (see Fig. 10.5):

- An initial region at low chlorine dosages where there is no measurable residual [This represents the immediate chlorine demand (ICD) due to the oxidation of reactive substances like ferrous iron and sulfide.]
- A second region at higher doses in which the measured residual first increases with chlorine dose and then decreases (This region occurs when the raw water contains ammonia or organic nitrogen. The measured residual consists mostly of monochloramine, and it is called the combined residual. Combined residual rises as ammonia is converted to monochloramine, and it declines as

monochloramine is converted to nitrogen gas and nitrate. The minimum point of the falling limb of the curve is the "breakpoint," which marks the elimination of the combined residual.)

- A final region in which the measured residual increases linearly 1:1 with chlorine dose [The measured residual is a mixture of molecular chlorine, hypochlorous acid, and hypochlorite, and it is called the free available chlorine (FAC) residual. (See Chapter 9, Section 9.8, "Aeration and Gas Exchange.")]

The existence of an ICD and a combined residual depends on raw water composition, and either or both may be absent. Ferrous iron and sulfide are common in groundwater but rare in surface water. Unless it has been nitrified, wastewater contains significant amounts of ammonia, but surface waters do not.

Monochloramine, hypochlorite, and hypochlorous acid differ greatly in their disinfecting power, and determination of the breakpoint curve is needed to know which form is present.

Combined Residual Chlorine (Chloramines)

Hypochlorous acid reacts with ammonia to form monochloramine (Palin, 1977; Wei and Morris, 1974; Saunier and Selleck, 1979):

$$HOCl + NH_3 \rightarrow NH_2Cl + H_2O \tag{10.95}$$

This is the only product formed until the ammonia is nearly exhausted. Then, hypochlorous acid reacts with monochloramine to form dichloramine. Small amounts of nitrogen trichloride may also be formed:

$$HOCl + NH_2Cl \rightarrow NHCl_2 \tag{10.96}$$

$$HOCl + NHCl_2 \rightarrow NCl_3 \tag{10.97}$$

Saunier and Selleck (1979) propose that mono- and dichloramine react with water and/or hydroxide to form hydroxylamine:

$$NH_2Cl + OH^- \rightarrow NH_2OH + Cl^- \tag{10.98}$$

$$NHCl_2 + H_2O + OH^- \rightarrow NH_2OH + HOCl + Cl^- \tag{10.99}$$

They further propose that the hydroxylamine is oxidized by hypochlorous acid to nitrosyl hydride. This intermediate was also suggested by Wei and Morris (1974). However, nitrosyl hydride has never been observed, and its existence may be impossible (Sidgwick, 1950).

$$HOCl + NH_2OH \rightarrow NOH + H_2O + H^+ + Cl^- \tag{10.100}$$

If nitrosyl hydride exists, it would react with mono- and dichloramine to form nitrogen gas or with hypochlorous acid to form nitrate:

$$NOH + NHCl_2 \rightarrow N_2 + HOCl + H^+ + Cl^- \tag{10.101}$$

$$NOH + NH_2Cl \rightarrow N_2 + H_2O + H^+ + Cl^- \tag{10.102}$$

$$NOH + HOCl \rightarrow HNO_2 + H^+ + Cl^- \tag{10.103}$$

$$HNO_2 + HOCl \rightarrow HNO_3 + H^+ + Cl^- \tag{10.104}$$

The net stoichiometry would be a mixture of Eqs. (10.105) and (10.106):

$$3\ HOCl + 2\ NH_3 \rightarrow N_2 + 3\ H_2O + 3\ H^+ + 3\ Cl^- \tag{10.105}$$

$$4\ HOCl + NH_3 \rightarrow HNO_3 + H_2O + 4\ H^+ + 4\ Cl^- \tag{10.106}$$

It appears that the formation of nitrogen gas predominates, and the molar ratio of hypochlorous acid to ammonia at the breakpoint is about 1.6 to 1.7 (Wei and Morris, 1974). This amounts to about 8.1 to 8.6 kg chlorine per kg of total kjeldahl nitrogen (TKN).

Required Chlorine Dose

Generally, it is desirable to produce a free available chlorine residual consisting of hypochlorous acid, because this is the most effective form of chlorine for inactivation of microorganisms. The free residual is related to the chlorine dose by,

$$D_{Cl_2} = \text{ICD} + 8.6\ \text{TKN} + C_{FAC} \tag{10.107}$$

where C_{FAC} = the free, available chlorine consisting of a mixture of dissolved chlorine, hypochlorous acid, and hypochlorite in mg/L
D_{Cl_2} = the required chlorine dose in mg/L
ICD = the immediate chlorine demand in mg/L
TKN = the total kjeldahl nitrogen concentration in mg/L

The pH dependency of the distribution of hypochlorous acid and hypochlorite is discussed in Chapter 9, Section 9.8 "Aeration and Gas Exchange."

Dechlorination

Chlorine is highly toxic to fish: the 96-hr-LC_{50} is about 10 μg/L for most freshwater fish and about 2 μg/L for salmonids (Criteria Branch, 1976). High concentrations are also undesirable in drinking water for aesthetic reasons.

The usual method of dechlorination is reaction with sulfur dioxide. Sulfur dioxide reacts with hypochlorous acid and monochloramine:

$$SO_2 + HOCl + H_2O \rightarrow 3\ H^+ + Cl^- + SO_4^{2-} \tag{10.108}$$

$$SO_2 + NH_2\ Cl + 2H_2O \rightarrow NH_4^+ + 2\ H^+ + Cl^- + SO_4^{2-} \tag{10.109}$$

Chlorine can also be removed by reaction with activated carbon. The initial reaction with fresh carbon (R) results in the formation of carbon-oxides (R = O) on the carbon surfaces (Stover et al., 1986):

$$R + HOCl \rightarrow R{=}O + H^+ + Cl^- \tag{10.110}$$

The surface oxides may eventually evolve into carbon monoxide or carbon dioxide. Monochloramine undergoes a similar reaction:

$$R + NH_2\ Cl + H_2O \rightarrow R{=}O + NH_4^+ + Cl^- \tag{10.111}$$

Chlorine Dioxide

The relative advantages and disadvantages of chlorine dioxide as a disinfectant are as follows (Katz, 1980):

- It destroys phenols rather than chlorinating them, and reducing taste and odor products compared to free chlorine.
- It destroys some algal taste and odor compounds.

TABLE 10.8 Specific Lethality Coefficients for 5°C

	K (L/mg min)			
Disinfectant	Amoebic Cysts	Enteric Bacteria	Spores	Viruses
Hypochlorite, OCl^-	0.0005	0.2	<0.0005	<0.02

Monochloramine, NH_2Cl	0.02	0.1	0.001	0.005
Ozone, O_3	0.5	500	2	5

Source: Morris, J.C. 1975. "Aspects of the Quantitative Assessment of Germicidal Efficiency," p. 1 in *Disinfection: Water and Wastewater*, J.D. Johnson, ed. Ann Arbor Science Publishers, Inc., Ann Arbor, MI.

- It does not hydrolyze, so its disinfecting power is not affected by pH.
- Because it does not hydrolyze, it can be removed from water by air-stripping.
- It does not react with ammonia.

Chlorine dioxide does not form trihalomethanes (Rav-Acha, 1984). However, the excess chlorine used to make it will form THMs. Also, some chlorine is released during chlorine dioxide reactions, and this chlorine may form trace amounts of THMs.

Disinfection Kinetics

The Chick–Watson Law

In batch disinfection systems, the die-away of microbes is often exponential, which implies a first-order decay law called the Chick (1908)–Watson (1908) Law:

$$\frac{dN}{dt} = kC^n N \tag{10.112}$$

$$N(t) = N_o e^{-kC^n t} \tag{10.113}$$

where C = the disinfectant concentration (kg/m^3 or lb/ft^3)
k = the coefficient of specific lethality (m^{3n}/kg^n·s or ft^{3n}/lb^n·sec)
N = the number concentration of microbes (number/m^3 or number/ft^3)
n = the coefficient of dilution (dimensionless)
t = elapsed time (sec)

The coefficient of dilution is frequently near 1, and Morris (1975) argues that quality of the data typically obtained does not warrant any other value. Some specific lethality coefficients reported by Morris are given in Table 10.8.

Effect of Microbial Clusters

Microorganisms frequently exist clustered together or with other suspended solids. This offers protection for those organisms imbedded within the cluster and changes the pattern of inactivation. Die-away curves may exhibit an initial lag (called a "shoulder") and/or a sharp reduction in slope as the contacting time increases (called a "tail"). This situation can be modeled as a multi-Poisson process in which microorganisms in individiual clusters are inactivated sequentially (Wei and Chang, 1975):

$$S_t = \sum_{i=1}^{n} \left[X_i^o e^{-kt} \sum_{r=0}^{i-1} \frac{(kt)^r}{r!} \right] \tag{10.114}$$

where i = the number of viable microorganisms in a cluster (dimensionless)
k = the inactivation rate for a single microorganism (per sec)
n = the maximum number of microorganisms in a cluster (dimensionless)
S_t = the concentration of clusters containing viable microorganisms at time t (number/m^3 or number/ft^3);
X_i^o = the initial concentration of clusters containing i viable microorganisms (dimensionless)
t = the contacting time (sec)

Equation (10.114) fits all of the observed die-away patterns.

Ct Products

The results of disinfection studies are frequently reported as *Ct* products. These products can be derived directly from the Chick–Watson Law. Their use implies that the Chick–Watson Law accurately describes the die-away curve, and that the dilution coefficient is 1:

$$Ct = \frac{\ln N_o / N(t)}{k} \tag{10.115}$$

The value of *Ct* depends on the ratio of initial to final microorganism concentrations. Generally, the products are reported for ratios that are multiples of 10, and the reduction in microbial counts is referred to as one-log (10:1 ratio), two-log (100:1 ratio), three-log (1000:1), etc. Alternatively, one speaks of viable count reductions of 90, 99, 99.9%, etc., respectively.

Strictly speaking, the concept of the *Ct* product does not apply if the dilution coefficient is not 1. When this situation occurs, reported *Ct* products vary with the disinfectant concentration, and the applicable concentration must be specified. The result is a specification of the required contacting time.

Ct products also do not apply when there is microbial clustering. However, this situation may be handled by estimating the initial lag period. The die-away curve is plotted semilogarithmically, and the linear portion is extrapolated back to the initial microorganism concentration. The initial lag period is then read off the time axis. During the lag period, there is no inactivation, so any disinfection system must provide a contacting time longer than this lag period.

Finally, it must be remembered that *Ct* products are obtained from batch disinfection experiments. If they are to be used in the design of continuous flow systems, the systems must achieve nearly ideal plug flow. In this regard, the U.S. Environmental Protection Agency requires that the contacting time for any system be calculated as the time that at least 90% of the water is held (EPA, 1989). This can be determined by tracer studies.

Ct products can be determined for any microorganism, but as a practical matter, only those microbes most resistant to disinfection are of interest. For design purposes, the critical organisms are the cysts of the protozoan *Giardia lamblia* and viruses. The U.S. Environmental Protection Agency (1989) requires that water treatment plants achieve an overall reduction of 99.9% (3-log) of *G. lamblia* cysts and 99.99% (4-log) of viruses. The Agency credits coagulation-flocculation-settling-filtration with most of the removal of these indicator organisms and requires chemical disinfection for the remainder of the 3-log and 4-log removals. Their requirements are shown in Table 10.9. Some *Ct* products for chemical disinfection of *G. lamblia* and viruses are given in Tables 10.10 and 10.11, respectively. See the EPA website for conditions other than those listed in these tables.

Chlorine

Because chlorine forms a weak acid in water and forms weak oxidants with ammonia, chlorination kinetics exhibit special features.

pH Effects

As Table 10.8 shows, the hypochlorite ion is a poor disinfectant compared to undissociated hypochlorous acid. Consequently, in a mixture of hypochlorite and hypochlorous acid, nearly all the inactivation is

Source: Environmental Protection Agency. 1989. "Drinking Water; National Primary Drinking Water Regulations; Filtration, Disinfection, Turbidity, *Giardia lamblia*, Viruses, *Legionella*, and Heterotrophic Bacteria. Final Rule," *Federal Register*, 54(124): 27485.

achieved by the undissociated acid. This means that the specific lethality coefficient reported for FAC will depend on pH.

A pH-independent specific lethality coefficient based on HOCl can be calculated from,

$$k_{FAC}C_{FAC}^{n} = k_{HOCl}C_{HOCl}^{n} \tag{10.116}$$

where C_{FAC} = the free available chlorine concentration (kg/m^3 or lb/ft^3)
C_{HOCl} = the hypochlorous acid concentration (kg/m^3 or lb/ft^3)
k_{FAC} = the coefficient of specific lethality based on the free available chlorine concentration (m^{3n}/kg^n·s or ft^{3n}/lb^n·sec)
k_{HOCl} = the coefficient of specific lethality based on the hypochlorous acid concentration (m^{3n}/kg^n·s or ft^{3n}/lb^n·sec)
n = the dilution coefficient (dimensionless)

The molar fraction of hypochlorous acid depends strongly on pH and can be estimated from the following (see Chapter 9, Section 9.8 "Aeration and Gas Exchange"):

$$pK_a = -10.069 + 0.025T - \frac{3000}{T} \tag{10.117}$$

$$f = \frac{[\mathrm{HOCl}]}{[\mathrm{HOCl}] + [\mathrm{OCl}^-]} = \frac{1}{1 + \dfrac{K_a}{[\mathrm{H}^+]}} \tag{10.118}$$

where T = Kelvin.

Consequently, the relationship of the HOCl-based coefficient to the pH-dependent FAC-based coefficient is,

$$k_{HOCl} = k_{FAC}\left\{\frac{K_a + [\mathrm{H}^+]}{[\mathrm{H}^+]}\right\}^n \tag{10.119}$$

Temperature Effects

The analysis of Fair and Geyer (1954) indicates that the Streeter–Phelps theta value for coliform inactivation by free available chlorine is approximately 1.04 at pH values below 8.5 and is 1.08 at pH values above 9:

$$k_{HOCl}(T_1) = k_{HOCl}(T_o)\cdot\theta^{T_1 - T_o} \tag{10.120}$$

where $k_{HOCl}(T_0)$ = the specific lethality coefficient at the reference temperature T_0 (m^{3n}/kg^n·s or ft^{3n}/lb^n·sec)
$k_{HOCl}(T_1)$ = the specific lethality coefficient at the chlorine contactor temperature T_1 (m^{3n}/kg^n·s or ft^{3n}/lb^n·sec)
T_0 = the reference temperature, frequently 5°C (K or °R)
T_1 = the chlorine contactor temperature (K or °R)
θ = the Streeter–Phelps temperature coefficient (dimensionless)
= 1.04, for pH less than 8.5
= 1.08, for pH greater than 9

Chloramines

Monochloramine occurs naturally in the disinfection of many wastewaters, because the wastewaters contain substantial amounts of ammonia. In water treatment, monochloramines are formed when anhydrous ammonia is added along with chlorine. Monochloramine, dichloramine, and nitrogen trichloride are oxidants, and they are usually reported as equivalent molecular chlorine and called the "combined available chlorine" or "combined residual chlorine."

Monochloramine is a relatively poor disinfectant. However, disinfection with monochloramine is sometimes practiced in order to reduce trihalomethane and phenolic odor formation. Best results are obtained with low pH values around 6 and rather low ammonia-to-chlorine weight ratios (around 2:1), which enhance the formation of dichloramine (Haas, 1990).

The Streeter–Phelps theta value for monochloramine inactivation is about 1.08.

Contactor Design

The Surface Water Treatment Rule requires that the specified inactivation of cysts and viruses be completed by the time the water reaches the first customary service at the peak hourly flow. The *Ct* product may be calculated using the detention times of all the tanks and piping between the point of application of the disinfectant and the first service. For the purpose of the calculation, the disinfectant residuals are measured at tank outlets and the downstream end of pipeline sections. The hydraulic detention time of pipe sections can be estimated by assuming ideal plug flow. The hydraulic detention of tanks is estimated as the time required for 10% of a tracer applied to the tank inlet to reach the outlet, T_{10}. In the case of cysts, the calculation is,

$$\frac{\sum_{i=1}^{n}\left(C_{eff}T_{10}\right)_i}{\left(Ct\right)_{99.9}} \geq 1 \tag{10.121}$$

where C_{eff} = the disinfectant concentration at the effluent end of the *i*-th sequential unit (kg/m^3 or lb/ft^3)
$(Ct)_{99.9}$ = the *Ct* product for 99.9% inactivation (m^3·s/kg or ft^3·sec/lb)
T_{10} = the detention time for 90% of the flow entering the *i*-th sequential unit (sec)

The detention should be determined by tracer studies. The best method of tracer application is step-input, because pulse-input tests require more work (Teefy and Singer, 1990). Suitable tracers are chloride (at drinking water concentrations less than 250 mg/L), fluoride (at drinking water concentrations less than 2 mg/L), and Rhodamine WT (at drinking water concentrations less than 0.1 μg/L). Fluoride adsorbs to aluminum hydroxide and ferric hydroxide flocs, reducing its usefulness. Rhodamine B is a suspected carcinogen and should not be used.

Mixed-Cells-in-Series

In the past, little attention has been paid to the hydraulic design of disinfectant contactors, and the residence time distributions of existing contactors are generally unknown. In this situation, tracer studies are mandatory in order to satisfy the requirements of the Surface Water Treatment Rule.

It is possible, however, to produce contactor designs that have predictable residence distributions and achieve predictable degrees of inactivation. The easiest way to do this is to build contactors as mixed-cells-in-series. Each cell should have a mixer and a disinfectant dosing device so that both the hydraulic regime and the disinfectant concentration are controllable.

For a contactor consisting of *n* completely-mixed-cells-in-series, each cell having the same volume V_1, the ratio of the outlet to inlet microorganism concentrations is,

$$\frac{N}{N_o} = \left[\frac{1}{1+kC\left(V_1/Q\right)}\right]^n \tag{10.122}$$

where C = the disinfectant concentration (kg/m^3 or lb/ft^3)
k = the specific lethality coefficient (m^3/kg·s or ft^3/lb·sec)
N = the required effluent microbial concentration (number/m^3 or number/ft^3)
N_0 = the influent microbial concentration (number/m^3 or number/ft^3)
n = the number of mixed-cells-in-series (dimensionless)

Q = the flow rate through the contactor (m^3/s or ft^3/sec)
V_1 = the volume of one cell (m^3 or ft^3)

It is assumed that the coefficient of dilution is 1, and that the cells are equivolume.

The ratio N/N_0 is determined by the required log inactivation: the ratio is 0.10 for a one-log inactivation, 0.01 for a two-log inactivation, etc. The specific lethality coefficient can be calculated from *Ct* product data by Eq. (10.115). In the case of chlorine, if the disinfectant concentration is reported in terms of free available chlorine $\{[Cl_2]+[HOCl]+[OCl^-]\}$, the specific lethality coefficient for the contactor pH must be used. If the concentration of the undissociated hypochlorous acid is reported, no pH correction is needed, but the specific lethality coefficient for HOCl is needed. The fraction of hypochlorous acid in the free available chlorine is given by Eq. (10.117). In any case, the specific lethality coefficient must be corrected for temperature using Eq. (10.118).

For a reactor consisting of mixed-cells-in-series, the value of T_{10} can be calculated theoretically. The exit age distribution for n mixed-cells-in-series is given by Eq. (10.123) (Wen and Fan, 1975):

$$E = \frac{n^n}{(n-1)!}\left(\frac{t}{nV_1/Q}\right)^{n-1}\exp\left(-\frac{t}{V_1/Q}\right) = \frac{C(t)nV_1}{M} \tag{10.123}$$

In a pulse input tracer test, E is also the ratio of the tracer concentration in the effluent times the tank volume to the mass of tracer injected. The cumulative exit age distribution is given by Eq. (10.124) (Wen and Fan, 1975):

$$F = 1-\exp\left(-\frac{t}{V_1/Q}\right)\sum_{i=1}^{n}\frac{1}{(i-1)!}\left(\frac{t}{V_1/Q}\right)^{i-1} = \frac{C(t)}{C_o} \tag{10.124}$$

This is also the dimensionless tracer response obtained in a step-input tracer test. In either equation, the value of T_{10} is the time for the first 10% of the tracer to appear in the effluent.

The computation recommended by the Surface Water Treatment Rule underestimates the inactivation actually achieved by mixed-cells-in-series if the dimensionless contacting number $KC(nV_1/Q)$ is less than 14, and the number of compartments is four or more (Lawler and Singer, 1993). For larger values of the parameter or fewer compartments, the SWTR overestimates the inactivation achieved.

Ultraviolet Irradiator Design

Ultraviolet radiation destroys nucleic acids, which inactivates mircroorganisms (Stover et al., 1986). Optimum disinfection occurs at UV wavelengths about 254 nm, and most commercial lamps are designed to emit near the optimum.

Ultraviolet disinfection units consist of parallel arrays of long emission lamps. The lamps are generally 0.9 m to 1.6 m long and 1.5 to 1.9 cm in diameter. They are usually spaced several cm apart (center line to center line), and are operated submerged. The liquid flow may be parallel to the lamp axes or normal to them. The tanks containing the arrays are designed with inlet and outlet baffles to control flow distribution.

The inactivation rate is directly proportional to the UV light intensity, generally expressed as $\mu W/cm^2$. However, water and suspended solids absorb UV light, so in any real reactor, the light intensity declines with distance from the lamp. Inactivation rates are expressed in terms of the average intensity, $\bar{I}$. Because the details of the intensity distribution vary from one design to the next, different designs achieve different inactivation rates even if they produce the same average intensity.

For batch systems, the inactivation rate would be represented by (Stover et al., 1986),

$$\frac{dN}{dt} = -a\bar{I}^b N \tag{10.125}$$

where a = an empirical rate coefficient ($cm^{2b}/\mu W^{b}\cdot s$)
b = an empirical exponent (dimensionless)
$\bar{I}$ = the volume-averaged light intensity ($\mu W/cm^2$)
N = the number concentration of microbes (number/m^3)
t = exposure time (sec)

Values of a are strongly dependent on the suspended solids content of the water being irradiated. Reported wastewater treatment plant values vary from 40×10^{-9} $(cm^2/\mu W)^{-b}\cdot s^{-1}$ to 0.10×10^{-3} $(cm^2/\mu W)^{-b}\cdot s^{-1}$. Reported values of b are less variable and range from 1.09 to 2.2.

Typical average UV light intensities are on the order of several thousand $\mu W/cm^2$, which corresponds to a UV power density of several W/L. Tubular arrays of lamps generally produce lower average intensities for the same power density than do uniform arrays.

The disinfection units may be analyzed as plug flow reactors with dispersion (Stover et al., 1986):

$$N = N_o \exp\left[\frac{UL}{2E}\left(1-\sqrt{1+\frac{4a\bar{I}^b E}{U^2}}\right)\right] + 0.26X_{SS}^{1.96} \tag{10.126}$$

where a = an empirical rate coefficient ($cm^{2b}/\mu W^{b}\cdot s$)
b = an empirical exponent (dimensionless)
E = longitudinal shear dispersion coefficient (m^2/s)
$\bar{I}$ = the volume-averaged light intensity ($\mu W/cm^2$)
L = the length of the irradiation chamber (m)
N = the effluent number concentration of microbes (coli/100 mL)
N_o = the influent number concentration of microbes (coli/mL)
U = the mean velocity in the irradiator (m/s)
X_{ss} = the suspended solids concentration (mg/L)

The first term on the right-hand side represents the residual microbial concentration that would be in the irradiator effluent if all the microorganisms were dispersed as single cells or cysts. The second term represents the microorganisms that are incorporated into suspended solids and that escape irradiation.

The coefficient and exponent on the suspended solids concentration X_{ss} represent the experience at the Port Richmond Water Pollution Control Plant on Staten Island, New York, for the disinfection of coliform bacteria. If the suspended solids concentration is given as mg/L, the resulting fecal coliform count is given as cells per 100 mL. Fecal coliform data from other wastewater treatment facilities are scattered widely around the Port Richmond correlation. Correlations for water treatment plants are not available.

Disinfection By-Products

A current challenge of water treatment facilities is to balance adequate disinfection with minimal disinfection by-product (DBP) formation. Disinfection by-products are formed from the reaction of disinfection oxidants with natural organic and inorganic matter in source water. Many of these DBPs are probable or possible human carcinogens (AWWA, 1999). Thus, these DBPs are regulated under the Total Trihalomethane Rule and Stage 1 Disinfectants and Disinfection By-products (D/DBP) Rule (EPA, 2001a). The Total Trihalomethane Rule, applying to water systems serving at least 10,000 people using a disinfectant, set an interim MCL for total trihalomethanes of 0.10 mg/L as an annual average.

In 1998, the U.S. EPA finalized Stage 1 of the Disinfectants/Disinfection By-products (D/DBP) Rule to regulate maximum residual concentrations of disinfectants; lower the MCL for total trihalomethanes (TTHMs); and establish a new MCL for 5 haloacetic acids (HAAs), chlorite, and bromate. This rule applies to community water supplies using disinfectants regardless of size (EPA, 2001b). In addition, this

rule specifies removal requirements for DBP precursor compounds. The removal requirements increase with increasing raw water total organic carbon (TOC) and decreasing alkalinity. Note that the Stage 1 DBP Rule supersedes the 1979 TTHM standard.

Halogenated DBPs

The chlorination of natural waters containing humic and fulvic acids results in the formation of chloroform and other halogenated methane derivatives. In test animals, chloroform causes central nervous system depression, hepatotoxicity, nephrotoxicity, teratogenicity. and carcinogenicity (Symons, et al., 1981). Chloroform in drinking water is suspected to cause cancer in humans.

Halogenated by-product formation may be minimized by removing the organic precursors with activated carbon prior to chlorination or by switching to an alternative disinfectant such as chlorine dioxide or ozone for primary disinfection (Symons et al., 1981).

The substances that comprise total trihalomethanes include chloroform ($CHCl_3$), bromoform ($CHBr_3$), bromodichloromethane ($CHCl_2Br$), and dibromochloromethane ($CHClBr_2$). Haloacetic acids included in Stage 1 DBP Rule include dichloroacetic acid ($Cl_2CHCOOH$), trichloroacetic acid ($Cl_3CHCOOH$), monochloroacetic acid ($ClCH_2COOH$), monobromoacetic acid ($BrCH_2COOH$), and dibromoacetic acid ($Br_2CHCOOH$).

Predictive, empirical models for the resulting THM or HAA have been developed by Watson (1993). In these models, the concentration of the DBP is given in μg/L; all other concentrations are in mg/L; the extinction coefficient for UV light at 254 nm is given in reciprocal cm; the contacting time is in hours:

Chloroform:

$$\mathrm{CHCl_3} = 0.064(\mathrm{TOC})^{0.329}(\mathrm{pH})^{1.161}(^{\circ}\mathrm{C})^{1.018}(\mathrm{Cl_2\ Dose})^{0.561} \times \times (\mathrm{Br^-} + 0.01)^{-0.404}(\mathrm{k_{ext,254}})^{0.874}(\mathrm{hr})^{0.269} \tag{10.127}$$

Bromodichloromethane, for $Cl_2/Br^- < 75$:

$$\mathrm{CHCl_2Br} = 0.0098(\mathrm{pH})^{2.550}(^{\circ}\mathrm{C})^{0.519}(\mathrm{Cl_2Dose})^{0.497}(\mathrm{Br^-})^{0.181}(\mathrm{hr})^{0.256} \tag{10.128}$$

Bromodichloromethane, for $Cl_2/Br^- > 75$:

$$\mathrm{CHCl_2Br} = 1.325(\mathrm{TOC})^{-0.725}(^{\circ}\mathrm{C})^{1.441}(\mathrm{Cl_2\ Dose})^{0.632}(\mathrm{Br^-})^{0.794}(\mathrm{hr})^{0.204} \tag{10.129}$$

Dibromochloromethane, for $Cl_2/Br^- < 50$:

$$\mathrm{CHClBr_2} = 14.998(\mathrm{TOC})^{-1.665}(^{\circ}\mathrm{C})^{0.989}(\mathrm{Cl_2\ Dose})^{0.729}(\mathrm{Br^-})^{1.241}(\mathrm{hr})^{0.261} \tag{10.130}$$

Dibromochloromethane, for $Cl_2/Br^- > 50$:

$$\mathrm{CHClBr_2} = 0.028(\mathrm{TOC})^{-1.078}(\mathrm{pH})^{1.956}(^{\circ}\mathrm{C})^{0.596}(\mathrm{Cl_2\ Dose})^{1.072} \times \ldots \ldots \times (\mathrm{Br^-})^{1.573}(\mathrm{k_{ext,254}})^{-1.175}(\mathrm{hr})^{0.200} \tag{10.131}$$

Bromoform:

$$\mathrm{CHBr_3} = 6.533(\mathrm{TOC})^{-2.031}(\mathrm{pH})^{1.603}(\mathrm{Cl_2\ Dose})^{1.057}(\mathrm{Br^-})^{1.388}(\mathrm{hr})^{0.136} \tag{10.132}$$

Monochloroacetic acid, for hr > 12:

$$ClCH_2COOH = 1.634(TOC)^{0.753}(pH)^{-1.124}(Cl_2\ Dose)^{0.509} \times \ldots$$
$$\ldots \times (Br^- + 0.01)^{-0.085}(hr)^{0.300} \quad (10.133)$$

Dichloroacetic acid:

$$Cl_2CHCOOH = 0.605(TOC)^{0.291}(°C)^{0.665}(Cl_2\ Dose)^{0.480} \times \ldots$$
$$\ldots \times (Br^- + 0.01)^{-0.568}(k_{ext,254})^{0.726}(hr)^{0.239} \quad (10.134)$$

Trichloroacetic acid:

$$Cl_3CCOOH = 87.182(TOC)^{0.355}(pH)^{-1.732}(Cl_2\ Dose)^{0.881} \times \ldots$$
$$\ldots \times (Br^- + 0.01)^{-0.679}(k_{ext,254})^{0.901}(hr)^{0.264} \quad (10.135)$$

Monobromoacetic acid:

$$BrCH_2COOH = 0.176(TOC)^{1.664}(pH)^{-0.927}(°C)^{0.450}(Br^-)^{0.795} \times \ldots$$
$$\ldots \times (k_{ext,254})^{-0.624}(hr)^{0.145} \quad (10.136)$$

Dibromoacetic acid:

$$Br_2CHCOOH = 84.945(TOC)^{-0.620}(°C)^{0.657}(Cl_2\ Dose)^{-0.200} \times \ldots$$
$$\ldots \times (Br^-)^{1.073}(k_{ext,254})^{0.651}(hr)^{0.120} \quad (10.137)$$

where Br^- = the bromide concentration in mg/L
°C = the reaction temperature in °C
Cl_2 Dose = the chlorine dose in mg/L
DBP = the disinfection by-product in μg/L
hr = the contacting time in hours
$k_{ext,254}$ = the extinction coefficient for ultraviolet light at 254 nm in cm^{-1}
pH = the contacting pH
TOC = the total organic carbon concentration in mg/L

Inorganic By-products

Bromate and hypobromate are formed from the reaction of ozone or hydroxyl radicals with bromide naturally occurring in source water (von Gunten and Hoigne, 1994). To date, this by-product is the only ozonation by-product to be regulated (Richardson et al., 1998). The level of bromate produced increases with increasing bromide concentration in the source water. However, lowering the pH or ozone exposure time reduces bromate formation (von Gunten and Hoigne, 1994).

Both chlorite and chlorate have been identified as DPBs from chlorine dioxide. Chlorite is the predominant product of ClO_2 disinfection [see Eq. (10.86)]. However, it can be minimized by the addition of a reducing agent such as ferric chloride to reduce ClO_2^- to Cl^- as shown in Eq. (10.87). Granular activated carbon filtration has also been shown to be effective in the removal of chlorite. Health risks

associated with chlorate are unclear; thus, it is not regulated, but formation may be minimized by optimizing ClO_2 generation (Richardson et al., 1998).

Other inorganic by-products of concern but not regulated include iodate, hydrogen peroxide, and ammonia. Iodate is formed from the oxidation of iodide in source water. Hydrogen peroxide may result from its direct addition as used with certain AOPs or from its formation *in situ* from the decomposition of ozone. Ammonia would be expected in conjunction with chloramine use.

Organic Oxidation By-products

Although not regulated, organic oxidation by-products are of growing concern. These by-products are formed from reactions between natural organic matter and any of the oxidizing agents (EPA, 1999). This would include compounds such as aldehydes, ketones, and organic acids.

11.1 Introduction

National Pollutant Discharge Elimination System (NPDES) permits limit the final effluent's total suspended solids (SS) and 5-day biochemical oxygen demand (BOD_5). Other quality parameters and sampling requirements are included as needed. However, most biological processes produce effluents that contain only a few mg/L of soluble BOD_5, or less, and the BOD_5 of the final effluent is mostly biomass that has escaped capture by the final clarifier. Thus, the NPDES permits control final clarifier design and operation, not the biological process itself. Some biological processes, like completely mixed activated sludge, produce flocs that settle slowly, and this should be a consideration in their selection and operation. If effluents containing much less than 10 mg/L of SS or BOD_5 are required, then additional effluent treatment like coagulation, settling, and filtration should be considered.

Because the permitted effluent BOD_5 does not control the biological process, the design procedure focuses on other considerations like waste sludge production, oxygen utilization, nitrification, and biological nutrient removal. The most common choice is whether or not to nitrify, and this choice determines the solids' retention time (SRT) in activated sludge plants and the hydraulic loading in trickling filter plants.

Most aerobic biological processes are capable of similar carbon removal efficiencies, and the criteria for choosing among them are largely economic and operational. Activated sludge plants tend to be capital-, labor-, and power-intensive but compact. They are usually adopted in urban areas. Ponds and irrigation schemes require little capital, labor, or power but need large land areas per caput. They are usually adopted in rural areas. Trickling filters and other fixed film processes fall between activated sludge and ponds and irrigation in their requirements.

Biological nutrient removal (BNR) is most developed and best understood in the activated sludge process. Therefore, most BNR facilities are modifications of the activated sludge.

The jargon of the profession now distinguishes between *aerobic*, *anoxic,* and *anaerobic* conditions. Aerobic means that dissolved oxygen is present (and nonlimiting). Both anoxic and anaerobic mean that dissolved oxygen is absent. However, anaerobic also means that there is no other electron acceptor present, especially nitrite or nitrate, whereas anoxic means that other electron acceptors are present, usually nitrate and sometimes sulfate. Most engineers continue to classify methanogenesis from hydrogen and carbon dioxide as an anaerobic process, but in the new jargon, it is better classified as an anoxic process, because carbon dioxide is the electron acceptor, and because energy is captured from proton fluxes across the cell membrane.

The following descriptions use the recommended notations of the International Water Association (Grau et al., 1982, 1987) and the International Union of Pure and Applied Chemistry (Mills et al., 1993). The *Système International d'Unités* (Bureau International, 1991) is strictly followed, except where cited authors use another. In those cases, the cited author's units are quoted.

11.2 Activated Sludge

The principal wastewater treatment scheme is the activated sludge process, which was developed by Ardern and Lockett in 1914. Its various modifications are capable of removing and oxidizing organic matter, of oxidizing ammonia to nitrate, of reducing nitrate to nitrogen gas, and of achieving high removals of phosphorus via incorporation into biomass as volutin crystals.

Biokinetics of Carbonaceous BOD Removal

Designs can be based on calibrated and verified process models, pilot-plant data, or the traditional rules of thumb. The traditional rules of thumb are acceptable only for municipal wastewaters that consist primarily of domestic wastes. The design of industrial treatment facilities requires pilot testing and careful wastewater characterization. Process models require calibration and verification on the intended wastewater, although municipal wastewaters are similar enough that calibration data for one facility is often useful at others.

Most of the current process models are based on Pearson's (1968) simplification of Gram's (1956) model with additional processes and variables proposed by McKinney (1962). Pirt's (1965) maintenance concept is also used below.

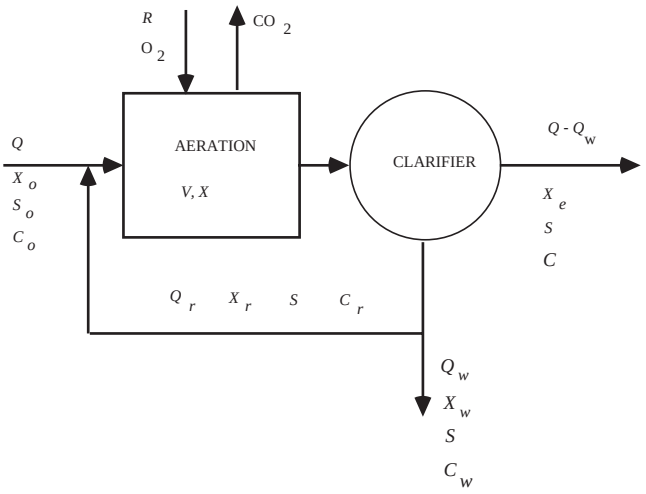

FIGURE 11.1 Generic activated sludge process.

State Variables and Kinetic Relations

A wide variety of state variables has been and is being used to describe the activated sludge process. The minimal required set is probably that proposed by McKinney (1962).

Refer to Fig. 11.1. A steady state mass balance on the secondary clarifier for any component of the suspended solids leads to Eq. (11.1):

$$Q_w X_w + (Q - Q_w) X_e = (Q + Q_r) X - Q_r X_r \tag{11.1}$$

where Q = the raw or settled wastewater flow rate (m^3/s)
Q_r = the recycle (return) activated sludge flow rate (m^3/s)
Q_w = the waste-activated sludge flow rate (m^3/s)
X = the suspended solids' concentration in the aeration tank, analytical method and model variable unspecified (kg/m^3)
X_e = the suspended solids' concentration in the final effluent, analytical method and model variable unspecified (kg/m^3)
X_r = the suspended solids' concentration in the return activated sludge, analytical method and model variable unspecified (kg/m^3)
X_w = the suspended solids' concentration in the waste-activated sludge, analytical method and model variable unspecified (kg/m^3)

Eq. (11.1) is used below to eliminate the inflow and outflow terms in the aeration tank mass balances.

The left-hand side of Eq. (11.1) represents the net suspended solids production rate of the activated sludge process. It also appears in the definition of the *solids' retention* (*detention, residence*) *time* (SRT):

$$\Theta_X = \frac{VX}{Q_w X_w + (Q - Q_w) X_e} \tag{11.2}$$

where V = the aeration tank volume (m^3)
Θ_X = the solids' retention time, SRT (s)

Synonyms for SRT are biological solids' residence time, cell residence time (CRT), mean cell age, mean (reactor) cell residence time (MCRT), organism residence time, sludge age, sludge turnover time, and

solids' age. Synonyms for the reciprocal SRT ($1/\Theta_X$) are cell dilution rate, fraction sludge lost per day, fraction rate of removal of sludge solids, net growth rate, and VSS wasting rate.

The SRT is the average time solids spend in the activated sludge system, and it is analogous to the hydraulic retention time (HRT). The solids in the secondary clarifier are often ignored on the grounds that they are a negligible portion of the total system biomass and are inactive, lacking external substrate. However, predation, endogenous respiration, cell lysis, and released nutrient uptake and denitrification may occur in the clarifier. So, if it holds a great deal of solids (as in the sequencing batch reactor process), they should be included in the numerator of Eq. (11.2). The amount of solids in the clarifier is under operator control, and the operator can force Eq. (11.2) to be true as written.

If the suspended solids have the same composition everywhere in the system, then each component has the same SRT.

Sludge age has been used to mean several different things: the ratio of aeration tank biomass to influent suspended solids loading (Torpey, 1948), the reciprocal food-to-microorganism ratio (Heukelekian, Orford, and Manganelli, 1951), the reciprocal specific uptake rate (Fair and Thomas, 1950), the aeration period (Keefer and Meisel, 1950), and some undefined relationship between system biomass and the influent BOD_5 and suspended solids loading (Eckenfelder, 1956).

The dynamic mass balances for McKinney's variables in the aeration tank of a completely mixed activated sludge system and their steady state solutions are given below. The resulting formulas were simplified using Eq. (11.1) above:

Active Biomass, X_{va}

$$\text{accumulation in aeration} = \text{inflow} - \text{outflow} + \text{reproduction} - \text{"decay"}$$

$$\frac{d\left(VX_{va}\right)}{dt} = Q_r X_{var} - \left(Q + Q_r\right)X_{va} + \mu V X_{va} - k_d V X_{va} \tag{11.3}$$

$$\frac{1}{\Theta_X} = \mu - k_d$$

where k_d = the "decay" rate (per s)
t = clock time (s)
X_{va} = the active biomass concentration in the aeration tank (kg VSS/m^3)
X_{var} = the active biomass in the recycle activated sludge flow (kg VSS/m^3)
μ = the specific growth rate of the active biomass (per s)

Eq. (11.3) is true for all organisms in every biological process. However, in some processes, e.g., trickling filters, the system biomass cannot be determined without destroying the facility, and Eq. (11.3) is replaced by other measurable parameters.

The "active biomass" is a model variable defined by the model equations. It is not the actual biomass of the microbes and metazoans in the sludge.

The "decay" rate replaces McKinney's original endogenous respiration concept; and it is more general. The endogenous respiration rate of the sludge organisms is determined by measuring the oxygen consumption rate of sludge solids suspended in a solution of mineral salts without organic substrate. The measured rate includes the respiration of algae, bacteria, and fungi oxidizing intracellular food reserves (true endogenous respiration) and the respiration of predators feeding on their prey (technically exogenous respiration). Wuhrmann (1968) has shown that the endogenous respiration rate declines as the solids' retention time increases.

The decay rate is determined by regression of the biokinetic model on experimental data from pilot or field facilities. It represents a variety of solids' loss processes including at least: (a) viral lysis of microbial and metazoan cells; (b) hydrolysis of solids by exocellular bacterial and fungal enzymes; (c) hydrolysis of solids by intracellular ("intestinal") protozoan, rotiferan, and nematodal enzymes; (d) simple dissolution;

(e) abiotic hydrolysis; and (f) the respiration of all the organisms present. The decay rate is a constant regardless of solids' retention time.

Dead Biomass, X_{vd}

$$\text{accumulation in aeration} = \text{inflow} - \text{outflow} + \text{"decay"}$$

$$\frac{d(VX_{vd})}{dt} = Q_r X_{vdr} - (Q + Q_r)X_{vd} + f_d k_d V X_{va} \tag{11.4}$$

$$X_{vd} = f_d k_d \Theta_X X_{va}$$

where f_d = the fraction of active biomass converted to dead (inert) suspended solids by the various decay processes (dimensionless)
X_{vd} = the dead (inert) biomass in the aeration tank (kg VSS/m^3)

In McKinney's original model, the missing part $(1 - f_d)$ of the decayed active biomass is the substrate oxidized during endogenous respiration. In some more recent models, the missing active biomass is assumed to be oxidized and converted to biodegradable and unbiodegradable soluble matter.

Particulate Substrate, X_s

$$\text{accumulation in aeration} = \text{inflow} - \text{outflow} - \text{hydrolysis}$$

$$\frac{d(VX_{vs})}{dt} = QX_{so} + Q_r X_{sr} - (Q + Q_r)X_s - k_h V X_s \tag{11.5}$$

$$\frac{X_s}{X_{so}} = \frac{\Theta_X}{(1 + k_h \Theta_X)\tau}$$

where k_h = the first-order particulate substrate hydrolysis rate (per s)
X_s = the particulate substrate concentration in the aeration tank (kg/m^3)
X_{so} = the particulate substrate concentration in the raw or settled wastewater (kg/m^3)
τ = the hydraulic retention time (s)
$= V/Q$

The particulate substrate comprises the bulk of the biodegradable organic matter in municipal wastewater, even after primary settling. The analytical method used to measure X_s will depend on whether it is regarded as part of the sludge solids (in which case, the units are VSS) or as part of the substrate (in which case, the units are BOD_5, ultimate carbonaceous BOD, or biodegradable COD). In Eq. (11.5), the focus is on substrate, and the analytical method is unspecified.

Inert Influent Particulate Organic Matter, X_{vi}

$$\text{accumulation in aeration} = \text{inflow} - \text{outflow}$$

$$\frac{d(VX_{vi})}{dt} = QX_{vio} + Q_r X_{vir} - (Q + Q_r)X_{vi} \tag{11.6}$$

$$\frac{X_{vi}}{X_{vio}} = \frac{\Theta_X}{\tau}$$

where X_{vi} = the concentration of inert organic suspended solids in the aeration tank that originated in the raw or settled wastewater (kg VSS/m^3)
X_{vio} = the concentration of inert organic suspended solids in the raw or settled wastewater (kg VSS/m^3)

Inert Particulate Mineral Matter, X_m

$$\text{accumulation in aeration} = \text{inflow} - \text{outflow}$$

$$\frac{d(VX_m)}{dt} = QX_{mo} + Q_r X_{mr} - (Q + Q_r)X_m \tag{11.7}$$

$$\frac{X_m}{X_{mo}} = \frac{\Theta_X}{\tau}$$

where X_m = the concentration of inert suspended mineral matter in the aeration tank (kg/m^3)
X_{mo} = the concentration of inert suspended mineral matter in the raw or settled wastewater (kg/m^3)

The influent suspended mineral matter is mostly colloidal clay. However, in many wastewaters, additional suspended inorganic solids are produced by abiotic oxidative processes (e.g., ferric hydroxide) and by carbon dioxide stripping (e.g., calcium carbonate).

The mixed liquor suspended solids (MLSS) concentration includes all the particulate organic and mineral matter,

$$X = X_{va} + X_{vd} + X_{vi} + X_{vs} + X_m \tag{11.8}$$

whereas, the mixed liquor volatile suspended solids (MLVSS) includes only the particulate organic matter,

$$X_v = X_{va} + X_{vd} + X_{vi} + X_{vs} \tag{11.9}$$

where X = the total suspended solids concentration in the aeration tank (kg/m^3)
X_v = the volatile suspended solids concentration in the aeration tank (kg VSS/m^3)

In Eq. (11.9), particulate substrate (X_{vs}) is measured as VSS for consistency with the other particulate organic fractions. The quantity of total suspended solids determines the capacities of solids handling and dewatering facilities, and the quantity of volatile suspended solids determines the capacity of sludge stabilization facilities.

Soluble Substrate, S_s

$$\text{accumulation in aeration} = \text{inflow} - \text{outflow} - \text{uptake for reproduction}$$
$$- \text{uptake for maintenance} + \text{hydrolysis}$$

$$\frac{d(VS_s)}{dt} = QS_{so} + Q_r S_s - (Q + Q_r)S_s - \frac{\mu V X_{va}}{Y_a} \tag{11.10}$$
$$- k_m V X_{va} + k_h V X_s$$

$$X_{va} = \frac{Y_a}{1 + (k_d + k_m Y)\Theta_X} \cdot \frac{\Theta_X}{\tau} \cdot \left[S_{so} - S_s + \left(\frac{k_h \Theta_X}{1 + k_h \Theta_X} \right) X_{so} \right]$$

where k_m = the specific maintenance energy demand rate of the active biomass (kg substrate per kg active biomass per s)
S_s = the concentration of soluble readily biodegradable substrate in the aeration tank, analytical method unspecified (kg/m^3)
S_{so} = the concentration of soluble readily biodegradable substrate in the raw or settled wastewater, analytical method unspecified (kg/m^3)
Y_a = the true growth yield of the active biomass from the soluble substrate (kg active biomass VSS per kg soluble substrate)

The soluble substrate is the only form of organic matter that can be taken up by bacteria, fungi, and algae. Its concentration and the concentration of particulate substrate should be measured as the ultimate carbonaceous biochemical oxygen demand ($CBOD_u$). If it is measured as COD, then the biodegradable fraction of the COD must be determined.

Weichers et al. (1984) describe a kinetic technique for determining the soluble readily biodegradable COD (S_{CODrb}) based on oxygen uptake rate (OUR). First, the OUR of the mixed liquor is measured under steady loading and operating conditions. This should be done at several different times to establish that the load is steady. Then the influent load is shut off, and the OUR is measured at several different times again. There should be an immediate drop in OUR within a few minutes followed by a slow decline. The immediate drop represents the readily biodegradable COD. The calculation is as follows:

$$S_{CODrb} = \frac{\left(R_{O_2 sl} - R_{O_2 nl}\right)V}{f_{ox}Q} \tag{11.11}$$

where f_{ox} = the fraction of the consumed COD that is oxidized by rapidly growing bacteria (dimensionless)
$= 1 - \beta_x Y_h$
≈ 0.334 (Weichers et al., 1984)
$R_{O_2 nl}$ = the oxygen uptake rate immediately after the load is removed (kg/s)
$R_{O_2 sl}$ = the oxygen uptake rate during the steady load (kg/s)
Q = the wastewater flow rate during loading (m^3/s)
S_{CODrb} = the soluble readily biodegradable COD (kg/m^3)
V = the reactor volume (m^3)

The maintenance energy demand is comprised of energy consumption for protein turnover, motility, maintenance of concentration gradients across the cell membrane, and production of chemical signals and products. In the absence of external substrates, the maintenance energy demand of single cells is met by endogenous respiration.

Eq. (11.10) can also be written:

$$1 = \frac{Y_a}{1 + \left(k_d + k_m Y\right)\Theta_X} \cdot \frac{Q\left[S_{so} - S_s + \left(\frac{k_h \Theta_X}{1 + k_h \Theta_X}\right) X_{so}\right]}{VX_{va}} \cdot \Theta_X \tag{11.12}$$

The first factor on the right-hand side of Eq. (11.12) can be thought of as an observed active biomass yield, Y_{ao}:

$$Y_{ao} = \frac{Y_a}{1 + \left(k_d + k_m Y\right)\Theta_X} \tag{11.13}$$

which is the true growth yield corrected for the effects of decay and maintenance. We can also define a specific substrate uptake rate by active biomass,

$$q_a = \frac{Q\left[S_{so} - S_s + \left(\frac{k_h \Theta_X}{1 + k_h \Theta_X}\right) X_{so}\right]}{VX_{va}} \tag{11.14}$$

where q_a = the specific uptake rate of substrate by the active biomass (kg substrate per kg VSS per s).

With these definitions, Eq. (11.12) becomes,

$$Y_{ao} q_a \Theta_X = 1 \text{ (dimensionless)} \tag{11.15}$$

Combining Eqs. (11.10) and (11.14) also produces,

$$q_a = \frac{\mu}{Y_a} + k_m \tag{11.16}$$

and

$$\frac{1}{\Theta_X} = Yq_a - \left(k_d + k_m Y_a\right) \tag{11.17}$$

which should be compared with Eq. (11.3).

Inert Soluble Organic Matter, S_i

$$\text{accumulation in aeration} = \text{inflow} - \text{outflow}$$

$$\frac{d\left(VS_i\right)}{dt} = QS_{io} + Q_r S_i - \left(Q + Q_r\right)S_i \tag{11.18}$$

$$S_i = S_{io}$$

where S_i = the inert soluble organic matter concentration in the aeration tank, analytical method unspecified (kg/m^3)

S_{io} = the inert soluble organic matter concentration in the raw or settled wastewater, analytical method unspecified (kg/m^3).

The results of model calibrations suggest that roughly a fifth to a fourth of the particulate and soluble organic matter in municipal wastewater is unbiodegradable. This is an overestimate, because the organisms of the sludge produce a certain amount of unbiodegradable organic matter during the decay process.

Input-Output Variables

Pilot plant and field data and rules of thumb are often summarized in terms of traditional input-output variables. There are two sets of such variables, and each set includes the SRT as defined by Eq. (11.2) above. Refer again to Fig. 11.1.

The first set is based on the organic matter removed from the wastewater and consists of an observed volatile suspended solids yield and a specific uptake rate of particulate and soluble substrate:

Observed Volatile Suspended Solids Yield, Y_{vo}

$$Y_{vo} = \frac{Q_w X_{vw} + \left(Q - Q_{vw}\right)X_{ve}}{Q\left(C_{so} - S_{se}\right)} \tag{11.19}$$

where Y_{vo} = the observed volatile suspended solids yield based on the net reduction in organic matter (kg VSS/kg substrate)

C_{so} = the total (suspended plus soluble) biodegradable organic matter (substrate) concentration in the settled sewage, analytical method not specified (kg substrate/m^3)

$= X_{so} + S_{so}$

S_{se} = the soluble biodegradable organic matter concentration in the final effluent (kg COD/m^3 or lb COD/ft^3).

Because the ultimate problem is sludge handling, stabilization, and disposal, the observed yield includes all the particulate organic matter in the sludge, active biomass, endogenous biomass, inert organic solids, and residual particulate substrate. Sometimes particulate mineral matter is included, too.

Specific Uptake (Utilization) Rate, q_v

$$q_v = \frac{Q(C_{so} - S_{se})}{VX_v} \tag{11.20}$$

where q_v = the specific uptake (utilization) rate of biodegradable organic matter by the volatile suspended solids (kg BOD_5/kg VSS·s).

The specific uptake rate is sometimes reported in units of reciprocal time (e.g., "per day"), which is incorrect unless all organic matter is reported in the same units (e.g., COD). The correct traditional units are kg BOD_5 per kg VSS per day.

As a consequence of these definitions,

$$Y_{vo} q_v \Theta_X \equiv 1 \text{ (dimensionless)} \tag{11.21}$$

This is purely a semantic relationship. There is no assumption regarding steady states, time averages, or mass conservation involved. If any two of the variables are known, the third can be calculated. Simple rearrangement leads to useful design formulas, e.g.,

$$\frac{VX_v}{\Theta_X} = Y_{vo} Q(C_{so} - S_{se}) \tag{11.22}$$

$$X_v = \frac{Y_{vo} \Theta_X (C_{so} - S_{se})}{\tau} \tag{11.23}$$

Note also that these variables can be related to the biokinetic model variables as follows:

$$Y_{vo} q_v = Y_{ao} q_a \tag{11.24}$$

The second set of variables defines the suspended solids yield in terms of the organic matter supplied. The specific uptake rate is replaced by a "food-to-microorganism" ratio. Refer to Fig. 11.1.

Observed Volatile Suspended Solids Yield, Y'_{vo}

$$Y'_{vo} = \frac{Q_w X_{vw} + (Q - Q_w) X_{ve}}{QC_{so}} \tag{11.25}$$

where Y'_{vo} = the observed yield based on the total (both suspended and soluble) biodegradable organic matter in the settled sewage (kg VSS/kg BOD_5).

Food-to-Microorganism ratio (F/M or F:M)

$$F_v = \frac{QC_{so}}{VX_v} \tag{11.26}$$

where F_v = the food-to-microorganism ratio (kg COD/kg VSS·s).

Synonyms for F/M are *loading*, *BOD loading*, *BOD loading factor*, *biological loading*, *organic loading*, *plant load,* and *sludge loading*. McKinney's (1962) original definition of F/M as the ratio of the BOD_5 and VSS *concentrations* (not mass flows) is still encountered. Synonyms for McKinney's original meaning are *loading factor* and *floc loading*.

The SRT is defined previously in Eq. (11.2), so,

$$Y'_{vo}F_v\Theta_X \equiv 1 \text{ (dimensionless)} \tag{11.27}$$

Again, rearrangement leads to useful formulas:

$$\frac{VX_v}{\Theta_X} = Y'_{vo}QC_{so} \tag{11.28}$$

$$X_v = \frac{Y'_{vo}\Theta_X QC_{so}}{\tau} \tag{11.29}$$

These two sets of variables are related through the removal efficiency:

$$E = \frac{C_{so} - S_{se}}{C_{so}} = \frac{q_v}{F_v} = \frac{Y'_{vo}}{Y_{vo}} \tag{11.30}$$

where E = the removal efficiency (dimensionless).

Pilot-plant data provide other useful empirical formulas:

$$\frac{1}{\Theta_X} = aq_v - b \tag{11.31}$$

$$\frac{1}{\Theta_X} = a'F_v - b' \tag{11.32}$$

$$q_v = a''F_v + b'' \tag{11.33}$$

where a, a', a'', b, b', b'' = empirical constants (units vary).

The input-output variables are conceptually different from the model variables, even though there are some analogies. F_v, q_v, Y_{vo}, and Y'_{vo} are defined in terms of the total soluble and particulate substrate supplied, and all the volatile suspended solids, even though these included inert and dead organic matter and particulate substrate. The model variables q_a and Y_{ao} include only soluble substrate, hydrolyzed (therefore, soluble) particulate substrate, and active biomass.

However, the input-output variables are generally easier and more economical to implement, because they are measured using routine procedures, whereas determination of the model parameters and variables requires specialized laboratory studies. The input-output variables are also those used to develop the traditional rules of thumb, so an extensive public data is available that may be used for comparative and design purposes.

Substrate Uptake and Growth Kinetics

If a pure culture of microbes is grown in a medium consisting of a single soluble kinetically limiting organic substrate and minimal salts, the specific uptake rate can be correlated with the substrate concentration using the Monod (1949) equation:

$$q = \frac{q_{\max}S_s}{K_s + S_s} \tag{11.34}$$

where q = the specific uptake rate of the soluble substrate by the microbial species (kg substrate per kg biomass per s)
$q_{\max}$ = the maximum specific uptake rate (kg substrate per kg microbial species per s)
K_s = the Monod affinity constant (kg substrate/m^3)

TABLE 11.1 Typical Parameter Values for the Conventional, Nonnitrifying Activated Sludge Process for Municipal Wastewater at Approximately 15 to 25°C

Parameter	Symbol	Units	Typical	Range (%)
True growth yield	Y_a	kg VSS/kg COD	0.4	±10
		kg VSS/Kg $CBOD_5$	0.7	±10
Decay rate	k_d	Per day	0.05	±100
Maintenance energy demand	k_m	kg COD/kg VSS d	0.2	±50
		kg $CBOD_5$/kg VSS d	0.07	±50
Maximum specific uptake rate	q_{max}	kg COD/kg VSS d	10	±50
		kg $CBOD_5$/kg VSS d	6	±50
Maximum specific growth rate	μ_{max}	Per day	4	±50
Affinity constant	K_s	mg COD/L	500 (Total COD)	±50
		mg COD/L	50 (Biodegradable COD)	±50
		mg $CBOD_5$/L	100	±50
First-order rate constant	k	L/mg VSS d	0.02 (Total COD)	±100
			0.2 (Biodegradable COD)	±100
			0.06 (BOD)	±100

Button (1985) has collected much of the published experimental data for K_s, q_{max}, and Y.

A number of difficulties arise when the Monod formula is applied to activated-sludge data. First, when pure cultures are grown on minimal media, K_s takes on a value of a few mg/L for organic substrates and a few tenths of a mg/L, or less, for inorganic nutrients. However, in the mixed culture, mixed substrate environment of the activated sludge, when lumped variables like VSS, $CBOD_5$, and COD are used, K_s typically takes on values of tens to hundreds of mg/L of $CBOD_5$ or COD. (See Table 11.1.) This is partly due to the number of different substrates present, because when single organic substances are measured as themselves, K_s values more typical of pure cultures are found (Sykes, 1999).

The apparent variation in K_s is also due to the neglect of product formation and the inclusion of unbiodegradable or slowly biodegradable microbial metabolic end-products in the COD test. If end-products and kinetically limiting substrates are measured together as a lumped variable, the apparent K_s value will be proportional to the influent substrate concentration (Contois, 1959; Adams and Eckenfelder, 1975; Grady and Williams, 1975):

$$K_s \propto C_{so} \tag{11.35}$$

This effect is especially important in pilot studies of highly variable waste streams. It is necessary to distinguish the substrate COD from the total soluble COD. The unbiodegradable (nonsubstrate) COD is usually defined to be the intercept of the q_v vs. S_{se} plot on the COD axis. The intercept is generally on the order of 10 to 30 mg/L and comprises most of the soluble effluent COD in efficient plants.

Mixing and flocculation also affect the apparent K_s value. This was first demonstrated theoretically by Powell (1967) and then empirically by Baillod and Boyle (1970).

Wastewater treatment plants are operated to produce low soluble substrate concentrations, and the correlation between soluble substrate and q_a can be approximated as a straight line (called "first-order" kinetics):

$$q_a = kS_s \tag{11.36}$$

where k = the first-order rate constant (m^3/kg VSS·s).

In pure cultures grown on minimal media, Eq. (11.36) is observed whenever S_s is much smaller than K_s, and k is approximately q_{max}/K_s. However, in activated sludge plants treating complex wastes, individual pure substances are removed at zero-order kinetics ($S_s \gg K_s$; $q \approx q_{max}$) down to very low concentrations. Individual substances are removed at different constant rates, and in batch cultures tend to disappear sequentially (Wuhrmann, 1956; Tischler and Eckenfelder, 1969; Gaudy, Komolrit, and Bhatia, 1963). If a lumped variable like COD is used to measure soluble organic matter, the overall pattern fits Eq. (11.36).

Biokinetic *Caveat*

From the discussion on the *Effect of Tank Configuration on Removal Efficiency* in Chapter 9, Section 9.2, it might be assumed that organic matter removal in plug flow aeration tanks and sequencing batch reactors would be greater than that in mixed-cells-in-series, which, in turn, would be more efficient than completely mixed reactors. Unfortunately, this is not true. In the case of mixed microbial populations consuming synthetic or natural wastewater, the effluent *soluble* organic matter concentration is *not* affected by reactor configuration (Badger, Robinson, and Kiff, 1975; Chudoba, Strakova, and Kondo, 1991; Haseltine, 1961; Kroiss and Ruider, 1977; Toerber, Paulson, and Smith, 1974). This is true regardless of how the organic matter is measured: biochemical oxygen demand, chemical oxygen demand, or total organic carbon. The appropriate design procedure is to assume that all reactors are completely mixed, regardless of any internal baffling.

Biological processes do not violate the laws of reaction kinetics. Instead, it is the simplistic application of these laws that is at fault. The soluble organic matter concentration in the effluents of biological reactors is not residual substrate (i.e., a reactant). Rather, it is a microbial product (Baskir and Spearing, 1980; Erickson, 1980; Grady, Harlow and Riesing, 1972; Hao and Lau, 1988; Rickert and Hunter, 1971).

It should not be assumed that reactor configuration has no effect. Sequencing batch reactors and mixed-cells-in-series reactors with short compartmental detention times (less than 10 min) suppress activated sludge filamentous bulking and are the preferred configuration for that reason.

Furthermore, in the case of *particulate* or *emulsified* substrates, ideal plug flow configurations, like SBRs, produce lower effluent substrate concentrations than do CSTRs (Cassidy, Efendiev, and White, 2000).

Return Sludge Flow Rate

The return sludge flow rate can be calculated using the Benefield–Randall (1977) formula:

$$\frac{Q_r}{Q} = \frac{1 - \dfrac{\tau}{\Theta_X}}{\dfrac{X_r}{X} - 1} \approx \frac{1}{\dfrac{X_r}{X} - 1} \tag{11.37}$$

where Q = the settled sewage flow rate (m^3/s)
Q_r = the return activated sludge (RAS) flow rate (m^3/s)
V = the aeration tank volume (m^3)
X = the concentration of volatile suspended solids in the aeration tank mixed liquor, MLVSS (kg VSS/m^3)
X_r = the concentration of volatile suspended solids in the return (or recycle) activated sludge (kg VSS/m^3)

Θ_X = the solids' retention time (s)
τ = the hydraulic retention time, V/Q (s)

This is another rearrangement of the clarifier solids balance, Eq. (11.1).

Steady State Oxygen Consumption

The steady state total oxygen demand balance on the whole system applicable to any activated sludge process is as follows:

$$R_{O_2} = Q\left(C_{so} - S_{se}\right) + 4.57Q\left(C_{TKNo} - S_{TKNe}\right) - 2.86R_{N_2} - 1.98\frac{VX_v}{\Theta_X} \tag{11.38}$$

where C_{so} = the influent soluble plus particulate substrate concentration (kg COD/m^3)
C_{TKNo} = the influent soluble plus particulate total kjeldahl nitrogen (TKN) concentration (kg N/m^3)
Q = the settled or raw sewage flow rate (m^3/s)
R_{N_2} = the nitrogen gas production rate (kg N_2/s)
R_{O_2} = the oxygen utilization rate (kg O_2/s)
S_{se} = the final effluent soluble organic matter concentration (kg COD/m^3)
S_{TKNe} = the final effluent soluble TKN concentration (kg N/m^3)
V = the aeration tank volume (m^3)
X_v = the volatile suspended solids concentration in the aeration tank (kg VSS/m^3)
Θ_X = the solids' retention time (s)
4.57 = the oxygen demand of the TKN for the conversion of TKN to HNO_3 (kg O_2/kg TKN)
2.86 = the oxygen demand of nitrogen gas for the conversion of nitrogen gas to HNO_3 (kg O_2/kg N_2)
1.98 = the oxygen demand of the VSS, assuming complete oxidation to CO_2, H_2O, and HNO_3 (kg O_2/kg VSS)

Some authors mistakenly use 1.42 as the oxygen demand of the biomass, but this ignores the oxygen demand of the reduced nitrogen in the biomass solids.

If there is no denitrification, the term for nitrogen gas production, R_{N_2}, is zero. In municipal wastewaters, there is no denitrification unless there is first nitrification, because all influent nitrogen is in the reduced forms of ammonia or organically bound nitrogen. However, some industrial wastewaters (principally explosives and some agricultural chemicals) contain significant amounts of nitrates.

If there is no nitrification, the influent TKN is merely redistributed between the soluble TKN output, QS_{TKNe}, and the nitrogen incorporated into the waste solids, VX/Θ_X. The oxygen demand of the nitrogen in the waste solids exactly cancels the oxygen demand of the TKN removed. In the case of the input-output variables, the oxygen utilization rate becomes,

$$R_{O_2} = Q\left(C_{so} - S_{se}\right) - 1.42\frac{VX_v}{\Theta_X} \tag{11.39}$$

$$R_{O_2} = \left(1 - 1.42Y_{vo}\right)Q\left(C_{so} - S_{se}\right) \tag{11.40}$$

where 1.42 = the oxygen demand of the VSS assuming oxidation to CO_2, H_2O, and NH_3 (kg O_2/kg VSS).

In the case of the Gram–Pearson–McKinney–Pirt model, the oxygen uptake rate in the aeration tank would be as follows:

$$\text{oxygen uptake} = \text{substrate oxidized} + \text{biomass oxidized} + \text{maintenance}$$

$$R_{O_2} = \left(\frac{1}{Y_{ca}} - 1\right)\mu VX_{ca} + \left(1 - f_d\right)k_d VX_{ca} + k_{mc}VX_{ca} \tag{11.41}$$

where k_{mc} = the maintenance energy demand as COD of substrate per COD of biomass (kg COD/kg COD s)
X_{ca} = the active biomass concentration in the aeration tank as COD rather than VSS (kg COD/m^3)
Y_{ca} = the true growth yield of the active biomass as COD on the substrate COD (kg COD/kg COD)

Substitution from Eqs. (11.3), (11.4), (11.5), and (11.10) produces,

$$R_{O_2} = Q\left(X_{cso} + S_{cso} - S_{cs}\right) - \frac{V\left(X_{ca} + X_{cd} + X_{cs}\right)}{\Theta_X} \tag{11.42}$$

And, if the inert influent organic solids are added [Eq. (11.6)], one gets again Eq. (11.36) (with all the particulate organics reported as COD):

$$\begin{aligned} R_{O_2} &= Q\left(X_{cio} + X_{cso} + S_{cso} - S_{cs}\right) - \frac{V\left(X_{ca} + X_{cd} + X_{cs} + X_{ci}\right)}{\Theta_X} \\ &= Q\left(C_{co} - S_{cs}\right) - \frac{VX_c}{\Theta_X} \end{aligned} \tag{11.43}$$

Minimum Oxygen Concentration

The rate of carbonaceous BOD_5 removal is reduced at oxygen concentrations below about 0.5 mg/L (Orford, Heukelekian, and Isenberg, 1963). However, most authorities require higher aeration tank DOs. For nonnitrifying systems, the Joint Task Force (1988) recommends a DO of 2 mg/L under average conditions and 0.5 mg/L during peak loads. The Wastewater Committee (1997) and the Technical Advisory Board (1980) require a minimum DO of 2 mg/L at all times.

Temperature

Field and laboratory data indicate that the BOD_5 removal efficiency increases from about 80–85% to 90–95% as the temperature increases from about 5 to 30°C (Benedict and Carlson, 1973; Hunter, Genetelli, and Gilwood, 1966; Keefer, 1962; Ludzack, Schaffer, and Ettinger, 1961; Sawyer, 1942; Sayigh and Malina, 1978). Increases above 30°C do not improve BOD_5 removal efficiency, and increases above 45°C degrade BOD removal efficiency (Hunter, Genetelli, and Gilwood, 1966).

The true growth yield coefficient, *Y*, does not vary with temperature.

The values of k_d and k_m are so uncertain that temperature adjustments may not be warranted; however, most engineers make temperature corrections to k_d. This is justified by the reduction in predation and consequent increase in solids' production that occurs at low temperatures (Ludzack, Schaffer, and Ettinger, 1961). Low-temperature operation also results in poorer flocculation and a greater amount of dispersed fine solids. This is also due to reduced predation. The temperature correction to the decay rate would be as follows (Grady, Daigger, and Lim, 1999; Joint Task Force, 1992):

$$\frac{k_d\left(T_1\right)}{k_d\left(T_o\right)} = 1.04^{T_1 - T_o} \tag{11.44}$$

The parameters of the Monod function vary with temperature approximately as follows (Novak, 1974; Giona et al., 1979):

$$\frac{\mu_{\max}(T_1)}{\mu_{\max}\left(T_o\right)} = \frac{q_{\max}\left(T_1\right)}{q_{\max}\left(T_o\right)} \cong 1.10^{T_1 - T_o} \tag{11.45}$$

$$\frac{K_s\left(T_1\right)}{K_s\left(T_o\right)} \cong 1.075^{T_1 - T_o} \tag{11.46}$$

Lin and Heinke (1977) analyzed 26 years of data from each of 13 municipal plants and concluded that the temperature dependence of the first-order rate coefficient was,

$$\frac{k(T_1)}{k(T_o)} \cong 1.125^{T_1 - T_o} \tag{11.47}$$

pH

The optimum pH for the activated sludge process lies between 7 and 7.5, but pH does not substantially affect BOD_5 removal between about 6 and 9 (Keefer and Meisel, 1951). BOD_5 removal falls sharply outside that range and is reduced by about 50% at pHs of 5 or 10.

Nutrients

Most municipal and many industrial wastewaters have a proper balance of nutrients for biological waste treatment. However, some industrial wastes may be deficient in one or more required elements. The traditional rule of thumb is that the BOD_5:N and BOD_5:P mass ratios should be less than 20:1 and 100:1, respectively (Helmers et al., 1951). Sludge yields and treatment efficiencies fall when the BOD_5:P ratio exceeds about 220 (Greenberg, Klein, and Kaufman, 1955; Verstraete and Vissers, 1980).

Some industrial wastes are deficient in metals, especially potassium. Table 11.2 is the approximate composition of bacterial cells, and it may be used as a guide to nutrient requirements.

Waste-activated sludge is typically about 70% volatile solids, and the volatile solids contain about 7% N and 3% P. (See Table 11.3.)

Poisons

Carbonaceous BOD_5 removal is not affected by salinity up to that of seawater (Stewart, Ludwig, and Kearns, 1962). Approximate concentrations at which some poisons become inhibitory are indicated in Tables 11.4 and 11.5.

Traditional Rules of Thumb

Nowadays, most regulatory authorities have approved certain rules of thumb. An example is shown in Table 11.6 (Wastewater Committee, 1997). The rules of thumb should be used in the absence of pilot-plant data or when the data are suspect.

Carbonaceous BOD Removal

Solids' Retention Time

The solids' retention time should be short enough to suppress nitrification but long enough to achieve essentially complete soluble CBOD removal. At 25°C, a solids' retention time of 1 to 2 days suffices for nearly complete soluble BOD_5 removal, but 5 days SRT will be needed at 15°C. Satisfactory flocculation may require 3 days SRT, and the hydrolysis of particulate BOD_5 may require 4 days SRT (Grady, Daigger, and Lim, 1999).

If conditions are otherwise favorable, nitrification can occur at SRTS less than 3 days at warmer temperatures. Under these circumstances, aeration tank dissolved oxygen concentrations less than 2 mg/L may partially inhibit nitrification (Mohlman, 1938), but the aeration tank DO should not be so small as to limit soluble BOD_5 uptake and metabolism. Regulators often specify an absolute minimum DO of 1 mg/L.

It should be noted that ammonia is toxic to fish at concentrations around 1 mg/L (Table 8.7), and in many cases, the regulatory authority will require nitrification to prevent fish kills. Nonnitrifying processes are acceptable only where the receiving water provides dilution sufficient to avoid toxicity.

System Biomass and Waste Solids Production

Once the SRT is determined, the system biomass and waste solids production rate may be calculated.

If pilot-plant data are available, the SRT determines the specific uptake rate and food-to-microorganism ratio via Eqs. (11.31) and (11.32). The definitions of q_v and F_v directly produce the required MLVSS,

TABLE 11.2 Approximate Composition of Growing Bacteria and Nutrient Requirements for Biological Treatment

VX_v. Furthermore, the assumption of perfect clarification ($X_e = 0$) produces an upper limit on the waste sludge production rate, $Q_w X_w$, via the definition of the SRT, Eq. (11.2).

If a calibrated model is available, the MLVSS can be calculated from Eq. (11.9) with substitutions from Eqs. (11.4), (11.5), (11.6), and (11.10):

$$VX_v = Q\Theta_X \left[\frac{Y_a\left(1 + f_d k_d \Theta_X\right)}{1 + \left(k_d + k_m Y_a\right)\Theta_X} \left(S_{so} - S_s + \frac{k_h \Theta_X X_{so}}{1 + k_h \Theta_X} \right) + \frac{X_{vso}}{1 + k_h \Theta_X} + X_{vio} \right] \tag{11.48}$$

Except for particulate substrate, the solids terms on the right-hand side must have units of VSS. In the case of particulate substrate, in its first appearance (in parentheses), it must have the units appropriate

to the true growth yield constant, Y_a, which are usually kg VSS per kg COD (or BOD_5). In its second appearance, in the numerator of the third fraction, it must have units of VSS. The calculation of the waste solids' production rate proceeds, as above, from the definition of the SRT.

Aeration Tank Volume and Geometry

The aeration tank volume should be adjusted so that it can carry between 160 and 240% of the suspended solids required to treat the annual average flow and load (Table 8.13).

Aeration tanks are normally rectangular in plan and cross-sectional and much longer than they are wide or deep. Width and depth are controlled by the aeration system employed, and the length determines the hydraulic retention time. Diffusers typically have submergence depths of 12 to 20 ft, with 15 ft being common. HRTs of a few to several hours are generally required. (See Table 11.6.) Substrate removal in batch systems is generally complete in ½ hr, and the longer HRTs are required to promote flocculation and the hydrolysis of particulate substrate. Smaller HRTs produce larger values of X, so the lower limit on HRT is set by the mass transfer limits of the aeration system and by the allowable mass flux on the secondary clarifier. Very large HRTs are uneconomical.

Many aeration tanks incorporate a plug-flow selector at the inlet end to control filamentous bulking. The usual design choices are mixed-cells-in-series and sequencing batch reactors. The objective of using a plug-flow selector is to create a zone of relatively high substrate concentration near the inlet, which favors the growth of zoogloeal species. Because of the speed of soluble substrate uptake, a selector consisting of mixed-cells-in-series must have very short HRTs in each cell, about 10 min maximum. Figure 11.2 shows a typical plug-flow tank with selector. POTWs are typically designed for a peak load some 20 years distant, so it is necessary to check the as-built selector HRTs to make sure they are short enough under the initial low hydraulic loads.

The Joint Task Force (1992) summarizes a number of design recommendations and notes that there is no consensus on the design details for selectors. Anoxic denitrification zones in semiaerobic (nitrification/denitrification) plants are effective selectors, because they deny the filamentous microbes access to oxygen.

Air Supply and Distribution

Air supply is generally based on the maximum 1-hr BOD_5 load on the aeration tank, which is about 280% of the annual average BOD_5 load (Table 8.13).

In mixed-cells-in-series, the oxygen uptake rate is highest in the inlet compartment and lowest in the outlet compartment. Consequently, the rate of oxygen supply must be "tapered." A commonly recommended air distribution is given in Table 11.7. This should be checked against the mixing requirements, which are about 10 to 15 scfm per 1000 cu ft of aeration volume for diffused air grid systems and 15 to 25 scfm per 1000 cu ft of aeration volume for spiral flow systems (Joint Task Force, 1988).

Secondary Clarifiers

Secondary clarifiers (not the bioprocess) control final effluent quality, and engineers must exercise special care in their design.

In order to avoid floc breakup, the Aerobic Fixed-Growth Reactors Task Force (2000) recommends that the outlets of aeration tanks should not have waterfalls higher than 0.2 m, and that all piping, channels, and structures between the aeration tank and the clarifier should have peak velocities less than 0.6 m/s. Transfer channels should not be aerated, and 5 min of hydraulic flocculation should be provided

"Design Protocol for Aeration Systems — U.K. Perspective," in *Proceedings — Seminar Workshop on Aeration System Design, Testing, Operation, and Control*, EPA 600/9–85–005, W.C. Boyle, ed. Environmental Protection Agency, Risk Reduction Engineering Laboratory, Cincinnati, OH.

as the mixed liquor enters the clarifier or just before it enters. In rectangular clarifiers, the flocculation chamber is separate and has a low headloss diffusion inlet. In circular clarifiers, the flocculator is part of or an extension of the feed well.

The Joint Task Force (1992) indicates that shape has little influence on annual average effluent SS concentration between surface overflow rates of 400 and 800 gallon per square foot per day.

The side water depth of circular clarifiers should be at least 11 ft if their diameter is about 40 ft and at least 15 ft if the diameter is about 140 ft. Increasing improvements in effluent SS quality accrue as side water depths increase to 18 ft. Rectangular tanks may be somewhat shallower.

Secondary activated sludge clarifiers accumulate solids during peak flows if their allowable solids flux is exceeded. The clarifier depth should include an allowance for the increased sludge blanket depth. The Aerobic Fixed-Growth Reactors Task Force (2000) recommends that the allowance be less than 0.6 to 0.9 m above the average top of the sludge blanket.

The side water depth is also related to the overflow rate. For primary clarifiers, intermediate clarifiers, and trickling filter clarifiers with floor slopes greater than 1:12, the relationships are as follows (Aerobic Fixed-Growth Reactors Task Force, 2000):

$$v_{\max} \le 0.182 H_{sw}^2; \quad 1.8 \text{ m} \le H_{sw} \le 3.0 \text{ m} \tag{11.49}$$

$$v_{ave} \le 0.092H_{sw}^2;\ \ 1.8\ \text{m} \le H_{sw} \le 3.0\ \text{m} \tag{11.50}$$

$$v_{\max} \le 0.556H_{sw};\ \ 3.0\ \text{m} \le H_{sw} \le 4.6\ \text{m} \tag{11.51}$$

$$v_{ave} \le 0.278H_{sw};\ \ 3.0\ \text{m} \le H_{sw} \le 4.6\ \text{m} \tag{11.52}$$

where H_{sw} = the side water depth (m)
v_{ave} = the average overflow rate (m/h)
$v_{\max}$ = the maximum overflow rate (m/n = h)

For activated sludge, trickling filter-activated sludge, and trickling filter-solids contacting with bottom slopes greater than 1:12, the relationships are as follows (Aerobic Fixed-Growth Reactors Task Force, 2000):

$$v_{\max} \le 0.182H_{cw}^2;\ \ 1.8\ \text{m} \le H_{cw} \le 3.0\ \text{m} \tag{11.53}$$

$$v_{ave} \le 0.092H_{cw}^2;\ \ 1.8\ \text{m} \le H_{cw} \le 3.0\ \text{m} \tag{11.54}$$

$$v_{\max} \le 0.556H_{cw};\ \ 3.0\ \text{m} \le H_{cw} \le 4.6\ \text{m} \tag{11.55}$$

$$v_{ave} \le 0.278H_{cw};\ \ 3.0\ \text{m} \le H_{cw} \le 4.6\ \text{m} \tag{11.56}$$

where H_{cw} = the clear water depth, the depth of supernatant water above the maximum elevation of the sludge blanket (m).

Weir loading is unimportant, but placement is important. In rectangular tanks, the effluent launders should be placed in the last one-fourth to one-third of the tank length. Circular tanks should have double launders placed seven-tenths of the radius from centerline. Wall-mounted launders should have baffles placed beneath them to deflect upward flows along the wall. Launders cantilevered inboard can also deflect the upward flows. Baffles should project horizontally at least 18 in. in a 30 ft diameter clarifier, and the projection should increase above 18 in. by about 0.2 in./ft of diameter up to a maximum projection of 48 in. from the clarifier wall. The effluent weirs should be protected from scum by vertical baffles.

Operational and Design Problems

The chief operational problem of the conventional activated-sludge process is filamentous bulking. The filamentous bacteria responsible for bulking are strict aerobes (some are microaerophilic) and are limited to the catabolism of small organic molecules (simple sugars, volatile fatty acids, and short-chain alcohols). They grow faster than the zoogloeal bacteria at low concentrations of oxygen, nutrients, and substrates, and come to dominate the activated sludge community under those conditions. When this happens, the flocs settle slowly, and the secondary clarifier may fail to achieve adequate solids/liquid separation.

Completely mixed aeration tanks are especially prone to bulking, because the substrate concentration is low everywhere in such a tank. However, high-rate completely mixed processes, which produce relatively high effluent BODs, do not usually bulk. Mixed-cells-in-series selectors can produce bulked sludges if the HRT of the first cell is longer than about 10 min. Ideal plug flow tanks (see "Sequencing Batch Reactors" below) may produce bulked sludges if the aeration system cannot maintain at least 1 or more mg/L of oxygen at the inlet or if the influent waste is weak and largely soluble. However, most filamentous microbes are strictly aerobic, even the microaerophilic species. For that reason, semiaerobic designs in which the initial biomass-sewage contacting chamber is anoxic have become almost standard practice.

Some facilities have inadequate return sludge and waste sludge capacity or lack of control over flow rates and monitoring of flow rates, or both. Excessive return flow may hydraulically overload the secondary clarifier. Inadequate sludge return or wasting may allow solids to reside too long in the clarifier, producing gases and rising sludge. This is a special problem in nitrification facilities. Pumps and pipes are susceptible to plugging from debris.

Porous diffusers occasionally clog on the air supply side or the mixed liquor side (Joint Task Force, 1988). Airside clogging is due to suspended solids in the flow. This may be derived from dust in the local atmosphere, corrosion of the air piping, dislodgement of air supply pipe liner, leftover construction debris, or leaks that admit mixed liquor during out-of-service periods. Clogs develop in the mixed liquor side because of high soluble BOD concentrations, high soluble iron concentrations, low mixed liquor DO, high C:N or C:P ratios in the feed, and low unit airflow (especially due to uneven air distribution).

Disc, brush, and surface aerators are liable to accumulate ice in cold weather and require protective enclosures. They also tend to accumulate debris that passes through the preliminary treatment process. In aeration tanks deeper than about 15 ft, draft tubes are necessary to ensure the whole depth is mixed (Joint Task Force, 1992). Otherwise, the MLSS may settle out, forming odor-generating sludge deposits and minimizing sewage-biomass contact.

All aeration systems (except bubbleless membranes) produce aerosols and strip volatile organic compounds. Buffer strips around the facility sometimes provide adequate dilution of the contaminants before breezes reach the surrounding community. In other cases, capture and treatment of the aeration tank off-gases may be required.

Aeration tanks generally emit a nonoffensive musty odor. Other odors may indicate inadequate aeration.

Sequencing Batch Reactors

In recent years, sequencing batch reactors (SBR) have become quit common. They combine high turbulence (which promotes high mass transfer rates from the sewage to the activated sludge flocs) with batch reaction conditions (which tends to suppress filamentous microbes). They operate as follows:

- Starting out empty, the tank is first filled; any needed chemicals are added during the filling.
- The full tank is then stirred and aerated (as needed), and the reactions proceed.
- After mixing and reacting, the tank is allowed to stand quiescently to settle out the MLSS.
- The tank supernatant is drained off.
- The tank may sit idle between the draining and filling operations, while valves and pumps are switched.

The SBR is the fill-and-draw operating mode used by Ardern and Lockett (1914) and many others studying the activated sludge process. It is also the mode of operation of what used to be called "contact beds," a form of sewage treatment employed around the turn of the century and a predecessor of the trickling filter (Dunbar, 1908; Metcalf and Eddy, 1916).

Phase Scheduling

The design problem is scheduling the filling, stirring, draining, and idle phases of the cycle so as to meet the plant design flow rate.

If water production is to be continuous, at least one tank must be filling and one draining at each moment. Consider the schedule shown in Fig. 11.3. The total cycle time for a single tank is the sum of the times for filling, reacting, settling, draining, and idling. The plant flow first fills Tank No. 1. Then the flow is diverted to Tank No. 2, and so on. Tank No. 1 is again available after its cycle is completed. Raw water will be available at that moment, if another tank has just completed filling. This means that the cycle time for a single tank must be equal to or less than the product of the filling time and the number of available tanks:

$$nt_f \geq t_f + t_r + t_s + t_d + t_i \tag{11.57}$$

where n = the number of tanks (dimensionless)
t_d = the (clear) supernatant decanting time (s)
t_f = the filling time (s)
t_i = the idle time (s)
t_r = the reaction time (s)
t_s = the settling time (s)

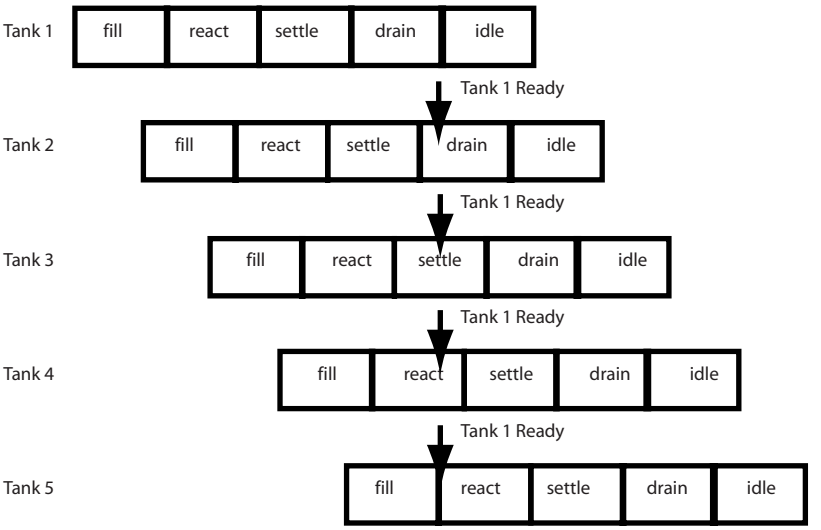

FIGURE 11.3 Schedule for sequencing batch reactor operation.

The idle time is freely adjustable, but the other times are set by the hydraulic capacity of the inlet and outlet devices and the time required for reaction and settling. A similar analysis of the draining operation leads to the conclusion that the product of the number of tanks and the draining time must equal the cycle time:

$$nt_d \geq t_f + t_r + t_s + t_d + t_i \tag{11.58}$$

The number of tanks in both equations must be the same, so the filling time must equal the draining time. They are otherwise freely adjustable within the limits of the hydraulic system.

An SBR may not be a viable option for very short phase time, say less than 30 min. With very short phase times, electric motors do not achieve a significant duration of steady state operation. Instead, they are always in the start-up mode or just recently exited from it, and they have not had sufficient time to cool from the heavy currents drawn during start-up. Under these conditions, the motors are prone to overheating and burnout. Also, a sequence of short-duration phases requires rapid valve and pump switching to occur within a few seconds. This is intrinsically difficult, because of the weights of the equipment parts, and it imposes high mechanical stresses on them. Finally, even if quick switching can be achieved, it may cause water hammer in the conduits.

The SBR is suitable where the duration of each phase is long, say several hours, so that only a few cycles are needed each day. This is the case in many activated sludge plants.

Headloss is a problem, too. In continuous flow tanks, the headloss amounts to several centimeters, at most. However, in SBRs, the headloss is the difference between the high water level and low water level, and this may amount to a few meters. In flat country, these headlosses become a significant problem, because they must be met by pumping.

Ideal plug flow tanks constructed as many-mixed-cells-in-series are more efficient than SBR systems. The total tankage in an SBR system is the product of the number of tanks, the filling time, and the flow rate. The tankage required for an ideal plug flow reactor is the product of the flow and processing time. If the same conversion efficiency is required of both systems, the processing times will be equal, and the ratio of the system volumes will be as follows:

$$\frac{V_{SBR}}{V_{PF}} = \frac{t_f + t_r + t_s + t_d + t_i}{t_r + t_s} > 1 \tag{11.59}$$

where V_{SBR} = the volume of the sequencing batch reactor (m^3)
V_{PF} = the volume of the equivalent plug flow reactor and associated clarifier (m^3).

Plug flow reactors do not incorporate settling; a separate clarifier is required for that. Consequently, the settling time of the clarifier associated with the plug flow reactor must be included in the denominator.

Volume, Plan Area, and Depth

The SBR volume must be sufficient to contain the required mass of MLSS for BOD_5 removal and to satisfy the maximum MLSS concentration limits of the aeration system and the subsequent settling/thickening phase. The desired SRT is chosen, and the required specific uptake rate, food-to-microorganism ratio or MLVSS mass is determined as described above for conventional BOD_5 removal. Aeration and settling/thickening determine the maximum MLVSS concentration, and the aeration volume follows directly.

The SBR tank must also function as a secondary clarifier/thickener, and all the design criteria applying to activated sludge settling and thickening apply to the SBR tank, too. This means that there will be a minimum plan area set by the design overflow rate and solids' flux and a minimum side water depth. The tank must also be large enough to store the sludge solids retained for the next filling phase and whatever the minimum clear supernatant depth is needed over the sludge. The settled/thickened sludge volume can be estimated from the sludge volume index (SVI). This is true only for batch settling processes; the SVI is not relevant to continuous flow clarifiers.

Solids' Wasting

In principal, solids can be wasted (to set the required SRT) at any point in the SBR cycle. However, it must be remembered that the secondary clarifier is a selector, too—one that selects for those microbes that can form activated sludge flocs. Therefore, solids should be wasted after the settling/thickening phase and before the filling phase.

Membrane Activated Sludge

Membrane Types and Uses

There are five basic types of membrane processes that are useful in wastewater treatment (Stephenson et al., 2000):

Hyperfiltration (reverse osmosis) — Selective separation of small solutes (relative molecular weights less than a few hundred; diameter less than 1 nm) by pressure differential; depends on differing solubilities of water and solutes in dense, polymeric membrane material

Electrodialysis — Selective separation of small ions (relative molecular weights less than a few hundred; diameters less than 1 nm) by voltage differential; depends on magnitude, density, and sign of electrical charge on ion and ion exchange properties of dense, polymeric membrane material

Nanofiltration (leaky reverse osmosis) — Separation of molecules and polymers (relative molecular weights a few hundred to 20,000; diameters 1 to 10 nm) by pressure differential; depends on solubility and diffusion of solutes in membrane material and sieving; dense or porous polymeric or porous inorganic membrane materials are available

Ultrafiltration — Separation of large polymers, colloids, and viruses (relative molecular weights 10,000 to 500,000; diameters 0.01 to 0.1 μm) by pressure differential; porous polymeric or inorganic membrane material separates suspended solids by size by sieving

Microfiltration — Separation of bacteria, protozoan cysts, eukaryotic cells, metazoa, and activated sludge flocs (relative molecular weights above 500,000; diameters above 0.1 μm) by pressure differential; porous polymeric or inorganic membrane material separates suspended solids by size by sieving

As the particle sizes increase, the pressure differential required for liquid/solid separation declines sharply, and operational and capital costs become more attractive.

The applications of membranes in biological treatment include the following:

- Solids/liquid separation, including protozoan cysts, bacteria, and viruses, (eliminating clarifiers, tertiary filters, and disinfection, and stabilizing operation via positive SRT control under widely varying loading conditions)
- Bubbleless oxygen transfer (yielding 100% gas transfer efficiency and no stripping of other gases or volatile organic carbon)
- Selective substrate removal from waste and/or isolation of biomass from poisons (eliminating some wastewater pretreatments)

At present, the best-established membrane application is the separation of activated sludge flocs from the mixed liquor.

System Configuration

Proprietary membrane activated sludge units are marketed by a number of companies (Stephenson et al., 2000), including AquaTech (BIOSUF), Bioscan A/S (BIOREK), Degremont (BRM), Eviroquip (Kubota MBR), Kubota (KUBOTA MBR), Membratek (ADUF and MEMTUF), Rhodia Group/Orelis (Pleiade and Ubis), Mutsui Chemicals, Inc. (AMSEX and Ubis), Vivendi Group/USF Gütling (Kopajet), Vivendi Group/USF Memcor (Membio), Vivendi Group/OTV (Biosep), Wehrle-Werk AG (Biomembrat), Weir Envig (ADUF), and Zenon Environmental (ZENOGEM and ZEEWEED). To date, most existing installations are relatively small and provide on-site treatment of gray water, night soil, landfill leachate, or high-strength industrial wastes, but municipal facilities are becoming common.

The usual membrane activated sludge process consists of an aeration tank and a microfiltration or ultrafiltration membrane system for solids/liquid separation; these processes are often called extractive membrane bioreactors (EMBR). The membrane replaces the secondary clarifier and any tertiary granular filtration units. Most installations can operate at MLSS concentrations up to 15,000 to 20,000 mg/L, which substantially reduces the aeration tank volume.

The membrane system may be external to the aeration tank (side stream) or submerged within it. The membranes may be hollow fiber, plate-and-sheet, tubular, or woven cloth. Except for hollow fiber membranes, operation is usually side stream. The majority of current industrial installations use tubular, side stream modules with pore sizes of 1 to 100 nm (Stephenson et al., 2000). Membranes operate with cross-flow velocities of 1.6 to 4.5 m/s to reduce fouling (Stephenson et al., 2000). Fouling, however, is inevitable due to biomass accumulation and accumulation of mineral solids, like calcium carbonate and ferric hydroxide, all of which are formed in the reactor. Mineral scale formation can sometimes be minimized by pretreatments such as pH reduction. Membrane systems usually include a cleaning mechanism that may include air scouring, back flushing, chlorination, and removal and cleaning and/or replacement. Membrane removal for cleaning and/or replacement is determined by the allowable maximum pressure differential and required minimal fluxes.

In industrial applications, specific fluxes range anywhere from 5 to 200 cu dm per sq m per bar per hour, and pressure differentials across the membrane range from 0.2 to 4 bar, depending on application (Stephenson et al., 2000). The usual industrial system employs pressures of 1.5 to 3 bar and achieves specific fluxes less than 100 cu dm per sq m per bar per hour.

The adoption of membrane activated sludge systems for municipal wastewater treatment involves several considerations (Günder, 2001). Operating fluxes are generally limited to 10 to 20 cu dm per sq m per hour at pressure differentials of 0.15 to 0.60 bar. The electric power requirements of municipal EMBR plants are generally twice that of conventional plants at an MLSS concentration of 15,000 mg/L and may be four times the conventional plant's usage if the MLSS concentration reaches 25,000 mg/L.

Mixed liquors become increasingly non-Newtonian as the concentration of SS exceeds a couple thousand mg/L. In the first instance, this shows up as rapidly increasing viscosity (35% greater than water at 3000 mg/L and double that of water at 7000 mg/L), and this, in turn, impairs all mass transfer processes dependent on viscosity, such as membrane flux rate, gas and heat transfer rates, settling/thickening, pumping, and transport via channels or pipes. The mixed liquor is gel-like and exhibits ductile flow behavior due to the extracellular polysaccharides excreted by the microbes and to the increased numbers

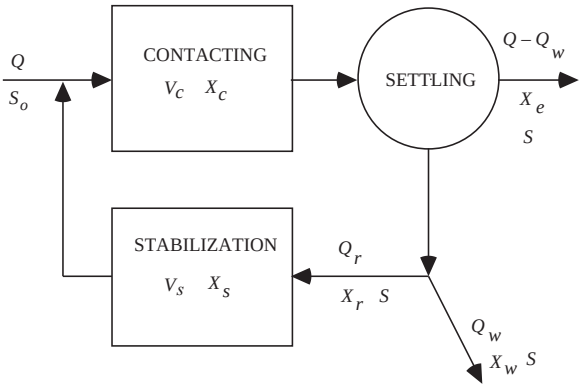

FIGURE 11.4 The contact-stabilization process.

of filaments in the sludge. Slowly rotating mixers produce a rotating core near the mixer axis and are surrounded by an unmixed stagnant zone. Gas bubbles tend to coalesce into very large bubbles, and small bubbles may remain trapped for long time periods in the mixed liquor.

Oxygen consumption, waste sludge production, fraction VSS in the MLSS, and soluble effluent COD appear to be similar to those in conventional plants, but the effluent BOD_5, coliform count, and plaque-forming units in the EMBR's effluent are much less than in a conventional plant's effluent.

Bubbleless aeration membrane systems called membrane aeration bioreactors (MABR) also are in use. These are more properly classified as fixed film reactors, because the biomass adheres to the wastewater side of the membrane.

Anaerobic membrane bioreactors are also available.

The Contact-Stabilization Process

Contact-stabilization (Zablatsky, Cornish, and Adams, 1959) is an important modification of the conventional, nonnitrifying activated sludge process. Synonyms are *sludge reaeration* (Ardern and Lockett, 1914a, 1914b), *bioflocculation* (Martin, 1927), *biosorption* (Ullrich and Smith, 1951) and *step-aeration* (Torpey, 1948). Variants are the *Hatfield Process* and the *Kraus Process* (Haseltine, 1961).

The distinguishing feature of contact-stabilization is the inclusion of a tank for the separate aeration of the return activated sludge (Fig. 11.4). The practical effect is that a much smaller total aeration tank volume is needed to hold the required system biomass, because the biomass is held at a higher average concentration.

The basic design principle proposed by Haseltine (1961) is that the distribution of activated sludge solids between the contacting and stabilization tanks does not affect the required system biomass. Haseltine's data, collected from 36 operating facilities, may be expressed mathematically as follows:

$$V_c X_{vc} + V_s X_{vs} = \frac{Q\left(C_{bo} - S_{be}\right)}{q_v} = \frac{QC_{bo}}{F} \tag{11.60}$$

where C_{bo} = the settled sewage total BOD_5 (kg BOD_5/m^3)
F = the food-to-microorganism ratio (kg BOD_5/kg VSS·s)
Q = the settled sewage flow rate (m^3/s)
q_v = the specific uptake rate (kg BOD_5/kg VSS·s)
S_{be} = the soluble effluent $CBOD_5$ (kg BOD_5/m^3)
V_c = the volume of the contacting tank (m^3)
V_s = the volume of the stabilization tank (m^3)
X_{vc} = the concentration of VSS in the contacting tank (kg/m^3)

X_{vs} = the concentration of VSS in the stabilization tank (kg/m^3)

The usual relationship between SRT, specific uptake rate, and decay rate applies, except the decay rate should be corrected for the distribution of solids between the contacting and stabilization tanks. Jenkins and Orhon (1973) recommend:

$$k_d = \beta \cdot \left[\frac{0.74q}{(1-\beta)3.2 + q_v} \right] \tag{11.61}$$

where k_d = the specific decay rate (per day)
q_v = the specific uptake rate (kg COD/kg VSS·d)
β = the weight fraction of the total activated sludge inventory that is in the stabilization basin (dimensionless)

Most engineers make the contacting and stabilization tanks of equal volume; some regulatory bodies require that at least one-third of the total aeration tankage be in the contacting tank (Wastewater Committee, 1997). Another rule of thumb is that the contacting period, counting recycle flows, should be less than 1 hr. Excessively long contacting periods negate the benefits of the process.

The contacting tank is usually constructed as mixed-cells-in-series. No particular design is used for the stabilization tank, because substrate removal does not occur in this tank.

The return sludge flow rate can be approximated using the Benefield–Randall formula [Eq. (11.37)].

Although there are some solids' losses in the stabilization tank due to microbial respiration (mostly from predation upon bacteria and fungi), the suspended solids' concentrations entering and leaving the stabilization tank are nearly equal.

The total oxygen consumption rate of a contact/stabilization system is the same as that of a conventional system operated at the same F/M ratio (Haseltine, 1961). The rate of oxygen consumption in the stabilization tank is probably about the same as that in the final 60 to 80% of the conventional, mixed-cells-in-series aeration tank. The recommendations of Boon and Chambers (1985), given in Table 11.7, would suggest that the stabilization tank could account for 25 to 40% of the total oxygen consumption. However, the uncertainties in this process require considerable flexibility in the capacity of the air distribution system. It is probably desirable to size the air piping and diffuser systems so that either the contacting tank or the stabilization tank could receive 100% of the estimated total air requirement.

The Extended Aeration Process

F. S. Barckhoff, the plant operator in East Palestine, OH, discovered the extended aeration process in about 1947 (Knox, 1958, 1959–60). Originally, it was called "aerobic digestion," because its purpose is to stabilize waste activated sludge in the aeration tank rather than in separate sludge digestion facilities. In older designs, there was no intentional wasting of activated sludge. The only solids to leave the system were those in the final effluent. The result was SRTs on the order of months to a year or more. The chief advantage of the extended aeration process was the elimination of waste sludge processing facilities. The chief disadvantages were the increase in oxygen consumption (needed to decompose the activated sludge solids) and the lack of kinetic control.

Full-scale plants fed dairy wastes have operated for periods up to a year without sludge wasting (Forney and Kountz, 1959; Kountz and Forney, 1959). Laboratory units fed glucose and soluble nutrients and managed so that no solids left the systems (other than those removed in sampling) have operated for periods of three years (SRT of 500 days) without net solids accumulation (Gaudy et al., 1970; Gaudy, Yang, and Obayashi, 1971). However, the MLSS in the laboratory units fluctuated widely during this time.

Nowadays, extended aeration plants normally incorporate solids wasting facilities, and the name really means plants with long aeration periods (usually 24 hr) and long SRTs (about 30 days).

In terms of the Gram–Pearson theory, the ideal extended aeration plant is operated so that sludge growth just equals sludge decay. Consequently, one has,

TABLE 11.8 Typical Parameter Values for the Extended Aeration Activated Sludge Process at Approximately 20°C

Parameter	Symbol	Units	Value
True yield	Y_v	kg VSS/kg COD	0.4
		kg VSS/kg BOD_5	0.7
Decay rate	k_d	Per day	0.012
Maximum specific growth rate	μ_{max}	Per day	0.04
Maximum uptake rate	q_{max}	kg COD/kg VSS d	0.05
Affinity constant	K_s	mg $CBOD_5$/L	10

$$\mu = k_d \tag{11.62}$$

$$S_s = \frac{k_d K_s}{Yq_{max} - k_d} \tag{11.63}$$

If there were no inert organic and inorganic solids inflow or production, all the biomass eventually would be oxidized, and the SRT would become infinite. However, no actual extended aeration facility can operate at infinite SRT. Most wastewaters contain significant amounts of clay and other inert inorganic solids, and various inert organic solids and inorganic precipitates are formed in the aeration tank. All of these gradually accumulate in the system, and in the absence of a clarifier, they must be discharged in the settled effluent.

Extended aeration plants accumulate suspended solids until the secondary clarifier fails, producing periods of very high effluent suspended solids concentrations (Morris et al., 1963). These sludge discharges usually are associated with high flows or bulking. Bulking is always a hazard, because most extended aeration plants incorporate completely mixed aeration tanks.

The SRTs employed in extended aeration are sufficient to permit year-round nitrification in most locales; however, traditional designs did not provide sufficient aeration capacity to support nitrification.

Extended aeration plants are frequently built as oxidation ditches or as aerated ponds. Both of these designs may incorporate anoxic zones. In the case of oxidation ditches that employ surface aerators for both aeration and mixing, the bottom may accumulate a deposit of activated sludge. In the case of ponds, the placement of surface aerators may result in unaerated zones (Nicholls, 1975; Price et al., 1973). These anoxic zones can be the sites of denitrification, and extended aeration plants may accomplish substantial nitrogen removal even in the absence of sludge wasting.

Some values of the Gram–Pearson kinetic model parameters are given in Table 11.8. It should be noted that the decay rate appears to decline at long SRTs. For SRTs up to about 40 days, Goodman and Englande (1974) recommend the following:

$$k_d = 0.48 \times 0.75^{\ln \Theta_X / \ln 2} \times 1.075^{T-20} \tag{11.64}$$

where k_d = the decay rate (per day)

T = the temperature (°C)
Θ_X = the solids' retention time (days)

For SRTs on the order of hundreds of days, the decay rate predicted by Eq. (11.64) may be high by a factor of about two.

Extended aeration plants have usually been recommended for small or isolated installations where regular, trained operating staffs are difficult to obtain. This practice results in serious operation and maintenance problems, most typically (Guo, Thirumurthi, and Jank, 1981):

- Clogging of comminutors
- Clogging of sludge return lines
- Clogging of air diffusers
- Failure of skimmers
- Icing of clarifier outlet weirs
- Insufficient biomass
- Insufficient aeration
- Offensive odors

Extended aeration plants are also subject to bulking and scum formation, but this is a result of the combination of completely mixed aeration tanks and long SRTs.

Nitrification

Nitrification is required to prevent fish kills due to ammonia toxicity and to prepare for nitrogen removal by denitrification. In single-sludge systems, the SRT required for nitrification also applies to the heterotrophs. This produces a large MLVSS inventory and large aeration tanks. Two-sludge processes separate CBOD removal from nitrification, and the resulting total system MLVSS and aeration tankage are substantially reduced. However, an additional, intermediate clarifier is needed.

Microbiology

Nitrification is the biological conversion of ammonia to nitrate. Aerobic, chemoautotrophic bacteria do it in two steps (Scheible and Heidman, 1993).

Nitrosomonas, Nitrosospira, Nitrosococcus, and Nitrosolobus:

$$\begin{aligned} &NH_4^+ + 1.44\ O_2 + 0.0496\ CO_2 = \\ &0.01\ C_5H_7O_2N + 0.990\ NO_2^- + 0.970\ H_2O + 1.99\ H^+ \end{aligned} \tag{11.65}$$

Nitrobacter, Nitrospina, and Nitrococcus:

$$\begin{aligned} &NO_2^- + 0.00619\ NH_4^+ + 0.50\ O_2 + 0.031\ CO_2 + 0.0124\ H_2O = \\ &0.00619\ C_5H_7O_2N + NO_3^- + 0.00619H^+ \end{aligned} \tag{11.66}$$

Overall:

$$\begin{aligned} &NH_4^+ + 1.89\ O_2 + 0.0805\ CO_2 = \\ &0.0161\ C_5H_7O_2N + 0.984\ NO_3^- + 0.952\ H_2O + 1.98\ H^+ \end{aligned} \tag{11.67}$$

The first step is slow and controls the overall rate of conversion. Consequently, in most systems, only small amounts of nitrite are observed, and the process can be represented as a one-step conversion of

ammonia to nitrate. Less than 2% of the ammonia-nitrogen is incorporated into new cells; the rest is oxidized.

Biokinetics

At low ammonia concentrations, the rate of growth of the rate-controlling *Nitroso-* genera can be correlated with the ammonia concentration using Monod kinetics:

$$\mu_n = \frac{\mu_{\max n} \cdot S_{na}}{K_{na} + S_{na}} \tag{11.68}$$

where K_{na} = the ammonia affinity constant (kg NH_3-N/m^3)
S_{na} = the total ammonia concentration (kg NH_3-N/m^3)
μ_n = the specific growth rate of the *Nitroso-* genera (per sec)
$\mu_{\max n}$ = the maximum specific growth rate of the *Nitroso-* genera (per sec)

The values of the kinetic parameters are usually estimated as follows (Knowles, Downing, and Barrett, 1965; Parker et al., 1975; Scheible and Heidman, 1993):

pH < 7.2

$$\mu_{\max n} = 0.47 \cdot \exp\{0.098(T-15)\} \cdot [1 - 0.833(7.2 - \text{pH})] \cdot \left(\frac{S_{O_2}}{S_{O_2} + 1.3}\right) \tag{11.69}$$

7.2 < pH < 9

$$\mu_{\max n} = 0.47 \cdot \exp\{0.098(T-15)\} \cdot \left(\frac{S_{O_2}}{S_{O_2} + 1.3}\right) \tag{11.70}$$

Any pH

$$K_{na} = 10^{0.051T - 1.158} \tag{11.71}$$

where K_{na} = the affinity constant (mg NH_3-N/L)
pH = the aeration tank pH (standard units)
S_{O_2} = the aeration tank dissolved oxygen concentration (mg/L)
T = the aeration tank temperature (°C)
$\mu_{\max N}$ = the maximum growth rate of the *Nitroso-* genera (per day)

Scheible and Heidman (1993) recommend a constant value of the affinity constant of 1 mg NH_3-N/L because of the high degree of variability in the reported values.

The maximum growth rate of the nitrifiers is much smaller than that of the heterotrophs, so nitrification is sensitive to SRT at cold temperatures.

At 20°C, the affinity coefficient is predicted to be about 0.73 mg N/L. This means that the rate of nitrification is independent of ammonia concentration (zero order) down to concentrations on the order of 1 mg NH_3-N/L. The practical consequence of this is that reactor configuration has little effect on overall ammonia removal. Aeration tanks are sized assuming complete mixing, which is conservative, because the effective ammonia specific uptake rate in mixed-cells-in-series is $\mu_{\max n}/Y_n$.

The maximum specific growth rates of the *Nitroso-* genera fall off sharply above pH 9, and the estimators do not apply above that pH.

The nitrification process produces nitric acid [Eq. (11.67)], and in poorly buffered waters, this may cause a significant decline in pH: 1 g NH_3-N reduces the alkalinity by 7.14 g (as $CaCO_3$).

The affinity constant for the DO correction, given here as 1.3 mg/L, may be as high as 2 mg/L in some systems. Scheible and Heidman (1993) recommend a value of 1 mg/L.

Ammonia Inhibition

Un-ionized ammonia, i.e., NH_3, is inhibitory to the *Nitroso-* and the *Nitro-* genera. The inhibition threshold concentrations of un-ionized ammonia for the *Nitroso-* group is about 10 to 150 mg NH_3/L; for the *Nitro-* group, it is about 0.1 to 1 mg NH_3/L. Inhibition of the *Nitro-* group results in the accumulation of nitrite.

The usual way to handle these effects is to adopt the Haldane kinetic model for the specific growth rate (Haldane, 1930):

$$\mu_n = \frac{\mu_{\max n} \cdot S_{na}}{K_{na} + S_{na} + \frac{S_{na}^2}{K_i}} \tag{11.72}$$

where K_i = the Haldane inhibition constant (kg NH_3-N/m^3).

In heterotroph-free cultures, the inhibition constant has been reported to be about 20 mg N/L at 19°C and pH 7 (Rozich and Castens, 1986). The basis here is the total ammonia concentration, both NH_3-N and NH_4^+-N. Under the given conditions, the ratio of total ammonia concentration to un-ionized ammonia would be about 250:1. At a full-scale nitrification facility treating landfill leachate, the observed inhibition constant was 36 mg/L of total ammonia nitrogen (Keenan, Steiner, and Fungaroli, 1979). The wastewater temperature varied from 0 to 29°C, and the pH varied from 7.3 to 8.6.

Other Inhibitors

A list of other inhibitors and the approximate threshold concentration for nitrification inhibition is given in Tables 11.4 and 11.5. The reduction in nitrification rate in some industrial wastewaters due to inhibitors can be severe. Adams and Eckenfelder (1977) give some laboratory data for nitrification rates for pulp and paper, refinery, and phenolic wastes that are only about 0.1% of the rates in municipal wastewater. The reported rates are low by an order of magnitude even if ammonia inhibition is accounted for.

Carbon:Nitrogen Ratio of Feed

The usual C:N ratio in municipal wastewater is about 10 to 15. However, in many industrial wastewaters, it may be higher or lower. In general, increasing the C:N ratio increases the heterotrophic biomass and the "endogenous" solids in the mixed liquor.

Because the heterotrophs can metabolize at much lower oxygen concentrations than can the nitrifiers, and at higher C:N ratios, the heterotrophs can reduce the aeration tank DO below the levels needed by the nitrifiers. Consequently, at least in plug flow tanks, the zone of active nitrification moves toward the outlet end of the aeration tank, and a longer aeration period may be needed.

The elevated MLSS concentrations also require larger aeration tanks, if for no other reason than the solids' flux on the secondary clarifier must be limited.

Design Solids' Retention Time

The minimum solids' retention required for nitrification ranges from about 3 days or less at 25°C to over 18 days at 12 to 15°C (Grady, Daigger, and Lim, 1999). The usual design procedure is to do the following (Metcalf & Eddy, Inc., 2002):

- Calculate the specific growth rate [Eqs. (11.68 through 11.71)] and the decay rate [Eq. (11.41) and Table 11.1] for the expected operating conditions and for the design load and permit conditions. Note that the design load includes a peaking factor (Table 8.13). If nitrification is required year-round, these calculations must be done for each distinct season.
- Calculate the required SRT [Eq. (11.3)].

- Multiply the calculated SRT by a safety factor of about 1.5 to obtain the design SRT. Note that when the peaking factor is accounted for, the design SRT will accommodate a loading that is at least three times the annual average load.

True Growth Yield

The yield of nitrifiers normally includes the *Nitroso-* and *Nitro-* genera and may be approximated by Eq. (11.67) (Scheible and Heidman, 1993). The estimated true growth yield coefficient for the nitrifiers as a whole is 0.13 g VSS/g NH_3-N or 0.028 g VSS/g NBOD. At least 98% of the ammonia-nitrogen is oxidized to nitrate.

The nitrifier "decay" rate is usually assumed to be the same as that of the heterotrophs. This is reasonable, because the so-called decay rate is really a predation/lysis effect.

Nitrifier Biomass

The nitrifier population is normally only a small portion of the MLSS. If it is assumed that the heterotrophs are carbon-limited and the nitrifiers are NH_3-N-limited, then the nitrifier biomass can be estimated from a simple nitrogen balance:

$$\underbrace{\frac{VX_{vn}}{Y_{on}\cdot\Theta_X}}_{\text{N consumed by nitrifiers}} = \underbrace{Q\left(C_{\text{TKN}o}-S_{\text{TKN}}\right)}_{\text{total N removed}} - \underbrace{f_{nh}\cdot\frac{VX_{vh}}{\Theta_X}}_{\text{N removed by heterotrophs}} \tag{11.73}$$

where f_{nh} = the fraction of nitrogen in the heterotrophs (kg N/kg VSS)
≈ 0.070 kg N/kg VSS (Table 11.3)
S_{TKN} = the soluble TKN (not ammonia) of the final effluent (kg TKN/m^3)
$C_{\text{TKN}o}$ = the TKN (soluble plus particulate) of the settled wastewater (kg TKN/m^3)
Q = the settled sewage flow rate (m^3/s or ft^3/sec)
V = the volume of the aeration tank (m^3 or ft^3)
X_{vh} = the concentration of heterotrophs in the aeration tank (kg VSS/m^3)
X_{vn} = the concentration of nitrifiers in the aeration tank (kg VSS/m^3)
Y_{on} = the observed yield for nitrifier growth on ammonia (kg VSS/kg NH_3-N)
Θ_X = the solids' retention time (sec)

Organic Nitrogen Production

NPDES permits are written in terms of ammonia-nitrogen, because of its toxicity. However, a substantial portion of the effluent TKN in nitrifying facilities is soluble organic nitrogen. As a rough guide, the ratio of TKN to NH_3-N in settled effluents is about 2:1 to 3:1 (Barth, Brenner, and Lewis, 1968; Beckman et al., 1972; Clarkson, Lau, and Krichten, 1980; Lawrence and Brown, 1976; Mulbarger, 1971; Prakasam et al., 1979; Stankewich, no date).

Two-Stage Nitrification

In the two-stage nitrification process, the nitrification step is preceded by a roughing step, either activated sludge or trickling filter, which is designed to remove about one-half to three-quarters of the settled sewage BOD_5. The benefits of this scheme are that the total biomass carried in the plant and the oxygen consumption are reduced. The costs are an additional clarifier and increased waste sludge production. The aeration tankage requirements of two-stage nitrification are comparable to those of nonnitrifying facilities, which suggests that most conventional plants can be readily upgraded to nitrification without major expense. Mulbarger (1971) estimates the increase in capital cost above that of a nonnitrifying facility to be about 10%.

The CBOD and TKN loads to the second stage are the expected effluent quality of the first stage. The first stage effluent BOD_5 is a semi-free design choice; it determines the specific uptake rate for the first

stage. The first stage effluent TKN is the TKN not incorporated into the first stage's waste activated sludge. It may be estimated by,

$$\underbrace{QS_{\mathrm{TKN}}}_{\text{1st stage soluble effluent TKN}} = \underbrace{QC_{\mathrm{TKN}o}}_{\text{settled sewage total TKN}} - \underbrace{f_{nh} \cdot \frac{VX_{vh}}{\Theta_X}}_{\text{TKN in 1st stage waste activated sludge}} \tag{11.74}$$

The EPA model described above can represent the nitrification kinetics of the second stage. The kinetics of CBOD removal in the second stage is not well known. The second-stage influent CBOD is a microbial product formed in the first stage, not residual settled sewage CBOD, and its removal kinetics may not be well represented by the data in Tables 11.1 and 11.8.

Denitrification

A variety of proprietary denitrification processes are being marketed, including A/O™ (U.S. Patent No. 4,056,465), Bardenpho™ (U.S. Patent No. 3,964,998), and BIO-DENITRO™ (U.S. Patent No. 3,977,965). The Joint Task Force (1992) lists other patents.

Microbiology

Many aerobic heterotrophic bacteria, especially pseudomonads, can utilize nitrate and nitrite as a terminal electron acceptor. The half-cell reactions are as follows:

$$NO_2^- + 3\,e^- + 4\,H^+ = \tfrac{1}{2}N_2 + 2\,H_2O \tag{11.75}$$

$$NO_3^- + 5\,e^- + 6\,H^+ = \tfrac{1}{2}N_2 + 3\,H_2O \tag{11.76}$$

The oxygen reduction half-cell is as shown:

$$O_2 + 4\,e^- + 4\,H^+ = 2\,H_2O \tag{11.77}$$

Consequently, the electronic equivalent weights of nitrite and nitrate are 1.713 and 2.857 g O_2/g NO_3-N, respectively. The nitrate equivalent weight is confirmed by Wuhrmann's (1968) data.

Growth Stoichiometry

The energy available to the denitrifiers is sharply reduced, from about 1 ATP per electron pair for oxygen-based oxidations to about 0.4 ATP per electron pair (Sykes, 1975). This substantially reduces waste activated sludge production.

Smarkel (1977) gives the theoretical growth stoichiometry for the anoxic growth of heterotrophic bacteria growing on methanol and nitrate plus nutrient salts as the following:

$$13.7CH_3OH + 1.8NHO_3 = C_5H_7O_2N + 8.67CO_2 + 5.40N_2 + 29.8H_2O \tag{11.78}$$

This closely approximates the empirical formula given by McCarty, Beck, and St. Amant (no date):

$$1.08CH_3OH + NO_3^- + H^+ = 0.065C_5H_7O_2N + 0.76CO_2 + 0.47N_2 + 2.44H_2O \tag{11.79}$$

The calculated true growth yields for organic matter and nitrate nitrogen are 0.172 g VSS per g COD and 0.684 g VSS per g NO_3-N.

Growth Kinetics

The denitrifier growth rate can be limited by the nitrate concentration or the COD concentration, and values of the Gram model kinetic parameters have been reported for both cases. Laboratory results for

TABLE 11.9 Typical Parameter Values for Laboratory-Scale Denitrifying Activated Sludge Processes Using Methanol at Approximately 20°C

Parameter	Symbol	Units	Typical
True growth yield	Y_{COD}	kg VSS/kg COD	0.17
	Y_{NO_3}	kg VSS/kg NO_3-N	0.68
Decay rate	k_d	Per day	0.04
Maximum specific growth rate	μ_{max}	Per day	0.3
Maximum uptake rate	q_{max}	kg COD/kg VSS·d	2
		kg NO_3-N/kg VSS·d	0.5
Affinity constant	K_s	mg BOD_5/L	150
		mg COD_{total}/L	75
		mg COD_{biodeg}/L	10
		mg NO_3-N/L	0.08

some of these parameters are summarized in Table 11.9. Scheible and Heidman (1993) give additional data. While the values for the true growth yields, the microbial decay, and perhaps the affinity coefficient for nitrate are reliable, the maximum specific growth rate and uptake rate are questionable. Large-scale pilot studies have produced maximum specific uptake rates that range from about 0.1 to 0.4 g NO_3-N per g MLVSS d at 20°C (Ekama and Marais, 1984; Parker et al., 1975).

A commonly used kinetic model for the rate of denitrification is as follows (Metcalf & Eddy, Inc., 2002):

$$r_{NO_3} = f_{dn} X_{va} \left(\frac{1 - 1.42 Y_{hox}}{2.86} \right) \left(\frac{q_{max} S_s}{K_s + S_s} \right) \left(\frac{S_{NO_3}}{K_{NO_3} + S_{NO_3}} \right) \left(\frac{K_{O_2}}{K_{O_2} + S_{O_2}} \right) \cdots + \frac{1.42 f_{nd} k_d X_{va}}{2.86} \tag{11.80}$$

where f_{dn} = the fraction of the active heterotrophic biomass that can denitrify (dimensionless)
K_{NO_3} = the affinity constant for nitrate-limited denitrification (kg NO_3-N/m^3)
K_{O_2} = the oxygen inhibition constant for denitrification (kg O_2/m^3)
K_s = the affinity constant for substrate-limited denitrification (kg COD/m^3)
k_d = the decay rate of the active biomass (per s)
r_{NO_3} = the volumetric nitrate-nitrogen consumption rate (kg NO_3-N/m^3 s)
S_{NO_3} = the nitrate-nitrogen concentration (kg N/m^3)
S_{O_2} = the aeration tank oxygen concentration (kg O_2/m^3)
S_s = the soluble rapidly biodegradable COD concentration in the aeration tank (kg COD/m^3)
Y_{hox} = the aerobic heterotrophic true growth yield (kg VSS/kg COD)
X_{va} = the active heterotrophic biomass (kg VSS/m^3)
1.42 = the oxygen equivalent of the biomass under nonnitrifying conditions (kg O_2/kg VSS)
2.86 = the oxygen equivalent of nitrate-nitrogen (kg O_2/kg N)

This formulation assumes that the MLVSS are partitioned as suggested by McKinney or the IWA's Activated Sludge Model. It includes the active biomass' growth and decay. The formulation of the rate as a product on Monod-like terms also assumes simultaneous kinetic limitation by the electron acceptors and the carbon substrate. This latter assumption is unproven empirically, but it may be qualitatively correct.

Oxygen

The threshold for oxygen inhibition of denitrification is about 0.1 mg/L, and the denitrification rate is reduced by 50% at oxygen concentrations around 0.2 to 0.3 mg/L (Focht and Chang, 1975). At 2.0 mg/L of oxygen, the denitrification rate is reduced by 90%.

Even conventional activated sludge processes denitrify if nitrate or nitrite is present, losing as much as 40% of the applied TKN (Johnson, 1959; Van Huyssteen, Barnard, and Hendrikz, 1990). This is generally believed to be due to microscale anoxic zones in the mixed liquor or inside the sludge flocs.

Inhibitors

The reduction of nitrite is inhibited by nitrite. In unacclimated cultures, the nitrite reduction rate falls by about 80% when the nitrite-nitrogen concentration exceeds about 8 mg/L (Beccari et al., 1983). This may be due to the accumulation of free nitrous acid, because there is an unusually sharp fall in the rate of nitrite reduction as the pH falls below 7.5.

Other reported inhibitors are as follows (Painter, 1970):

- Metal chelating agents (e.g., sodium diethyldithiocarbamate, orthophenanthroline, potassium cyanide, and 4-methyl-1:2-dimercaptobenzene)
- Cytochrome inhibitors (e.g., 2-*n*-heptyl-4-hydroxyquinoline-N-oxide)
- *P*-chloromercuribenzoate
- Hydrazine
- Chlorate
- Copper

Tables 11.4 and 11.5 summarize some quantitative data on inhibition.

Temperature

Focht and Chang (1975) reviewed Q_{10} data for a variety of nitrification processes (including mixed and pure cultures and suspended and film systems), and Lewandowski (1982) reviewed theta values for wastewater. The average theta for all these processes is about 1.095, and the type of reductant does not appear to affect the value.

pH

The optimum pH for the reduction of nitrate is about 7 to 7.5 (Beccari et al., 1983; Focht and Chang, 1975; Parker et al., 1975). The rate of nitrate reduction falls sharply outside that range to about half its maximum value at pHs of 6.0 and 8.0.

The optimum range of pH for nitrite reduction appears to be narrowly centered at 7.5. At pH 7.0, it is only 20% of its maximum value, and at pH 8.0, it is about 70% of its maximum (Beccari et al., 1983).

Semi-Aerobic Denitrification

The simplest denitrification facility is the "semi-aerobic" process developed by Ludzack and Ettinger (1962). This process is suitable for moderate removals of nitrate.

A schematic of the process train is shown in Fig. 11.5. In this process, mixed liquor from the effluent end of a nitrifying aeration tank is recirculated to an anoxic tank ahead of the aeration tank, where it is mixed with settled sewage. The anoxic tank is mixed but not aerated. The heterotrophs of the activated sludge utilize the nitrates in the mixed liquor to oxidize the CBOD of the settled sewage, and the nitrates are reduced to nitrogen gas.

The nitrate removal efficiency may be approximated by the following:

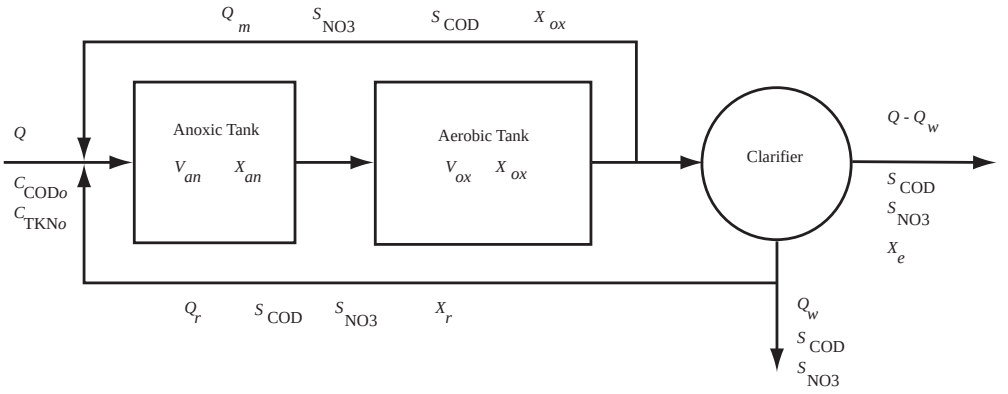

FIGURE 11.5 Ludzack-Ettinger (1962) semi-aerobic process.

$$E_{NO_3} = \frac{Q_m + Q_r}{Q + Q_m + Q_r} \tag{11.81}$$

where E_{NO_3} = the nitrate removal efficiency (dimensionless)
Q = the settled sewage flow (m^3/s or ft^3/sec)
Q_m = the mixed liquor return flow (m^3/s or ft^3/sec)
Q_r = the return sludge flow (m^3/s or ft^3/sec)

Because of economic limitations on the amount of return flows, the practical removal efficiency is limited to maybe 80%. If high removal efficiencies are needed, a separate stage denitrification facility must be built.

It is assumed that the CBOD of the settled sewage is sufficient to reduce the nitrate produced in the aerobic tank, and this is usually the case. However, it may be necessary to add additional reductant in some cases.

It is important to distinguish the anoxic SRT from the aerobic SRT, because nitrification occurs only under aerobic conditions. These may be estimated as follows:

$$\Theta_{Xs} = \Theta_{X,an} + \Theta_{X,ox} = \frac{V_{an}X_{an} + V_{ox}X_{ox}}{Q_w X_w + (Q - Q_w)X_e} \tag{11.82}$$

$$\Theta_{X,an} = \frac{V_{an}X_{an}}{Q_w X_w + (Q - Q_w)X_e} \tag{11.83}$$

$$\Theta_{X,ox} = \frac{V_{ox}X_{ox}}{Q_w X_w + (Q - Q_w)X_e} \tag{11.84}$$

where Q = the settled sewage flow (m^3/s)
Q_m = the mixed liquor return flow (m^3/s)
Q_r = the return sludge flow (m^3/s)
X_{an} = the volatile suspended solids' concentration in the anoxic tank (kg/m^3)
X_e = the volatile suspended solids' concentration in the settled effluent (kg/m^3)
X_{ox} = the volatile suspended solids' concentration in the aerobic (oxic) tank (kg/m^3)
$X_{w=}$ the volatile suspended solids' concentration in the waste activated sludge (kg/m^3)
$V_{an=}$ the volume of the anoxic compartment (m^3)
C_{ox} = the volume of the aerobic (oxic) compartment (m^3)
Θ_{Xs} = the system solids' retention time, SSRT (sec)

$\Theta_{X,an}$ = the anoxic SRT (sec)
$\Theta_{X,ox}$ = the aerobic (oxic) SRT (sec)

The MLVSS concentrations in the anoxic and aerobic compartments are nearly equal.

The presence of an anoxic zone ahead of the nitrification zone has no effect on the rate of nitrification (Jones and Sabra, 1980; Sutton, Jank, and Vachon, 1980). Consequently, the aerobic SRT may be chosen using the procedures for single-stage nitrification discussed above.

The anoxic HRT is normally 1 to 4 hr, and the anoxic SRT is generally about 30% of the system SRT. The maximum specific nitrate uptake rates observed in field units are about one-fourth to one-half of the rate quoted in Table 11.9. Also, $q_{\max NO3}$ declines as the anoxic and system SRT increases (Jones and Sabra, 1980).

Sutton et al. (1978) indicate that removal efficiency for filterable (soluble) TKN in a semiaerobic process can be estimated by the following:

At 24 to 26°C:

$$E_{TKNfilt} = \frac{0.98\Theta_{X,ox}}{0.26 + \Theta_{X,ox}} \tag{11.85}$$

At 14 to 16°C:

$$E_{TKNfilt} = \frac{1.05\Theta_{X,ox}}{1.00 + \Theta_{X,ox}} \tag{11.86}$$

At 7 to 8°C:

$$E_{TKNfilt} = \frac{1.11\Theta_{X,ox}}{5.04 + \Theta_{X,ox}} \tag{11.87}$$

where $E_{TKNfilt}$ = the removal efficiency for filterable total kjeldahl nitrogen (dimensionless).

These results are supported by the data of Sutton, Jank, and Vachon (1980) and by the data of Jones and Sabra (1980).

Burdick, Refling, and Stensel (1982) provide kinetic data for the removal of nitrate from municipal wastewater in the anoxic zone at 20°C:

$$q_{NO_3-N} = 0.03F_{an} + 0.029 \tag{11.88}$$

$$q_{NO_3-N} = 0.12\left(\frac{1}{\Theta_{Xs}}\right)^{0.706} \tag{11.89}$$

where q_{NO_3-N} = the anoxic zone specific nitrate consumption rate (kg NO_3-N/kg MLTSS·d)
F_{an} = the anoxic zone food-to-microorganism ratio (kg BOD_5/kg MLTSS·d).

Typical design values for the A/O™ and BARDENPHO™ processes are given in Table 11.10. Recent BARDENPHO™ designs are tending toward the lower limits tabulated.

A nitrogen/COD balance on the system and anoxic tank produces:

$$\begin{aligned} Q\left(C_{TKNo} - S_{TKN}\right) &= \left(Q + Q_m + Q_r\right)\left(S_{NO_3} - S_{NO_3an}\right) + \ldots \\ &\ldots + f_{Nh}\cdot\left\{Y_{oCODox}\cdot\left(C_{CODo} - S_s\right) + \ldots\right. \\ &\ldots + Y_{oNO_3an}\cdot\left(1 - \frac{Y_{oCODox}}{Y_{oCODan}}\right)\cdot\left.\left[\left(Q_m + Q_r\right)S_{NO_3} - \left(Q + Q_m + Q_r\right)S_{NO_3an}\right]\right\} \end{aligned} \tag{11.90}$$

TABLE 11.10 Typical Design Values for Commercial Semiaerobic Processes

Design Parameter	A/O™ Value	BARDENPHO™ Value
Anaerobic HRT (h)	0.5–1.0	0.6–2.0
First anoxic HRT (h)	0.5–1.0	2.2–5.2
Oxic HRT (h)	3.5–6.0	6.6–19.0
Second anoxic HRT (h)	—	2.2–5.7
Reaeration HRT (h)	—	0.5–2.0
Oxic SRT (d)	—	>10
F/M (kg BOD/kg MLVSS·d)	0.15–0.25	—
MLVSS (mg/L)	3000–5000	3000
Return sludge flow (% settled sewage flow)	20–50	—
Mixed liquor recycle flow (% settled sewage flow)	100–300	400

where C_{CODo} = the soluble plus particulate COD of the settled sewage (kg COD/m^3)
C_{TKNo} = the soluble plus particulate TKN in the settled wastewater (kg N/m^3)
f_{Nh} = the weight fraction of nitrogen in the heterotrophic biomass (kg N/kg VSS)
S_{NO_3} = the final effluent nitrate-nitrogen concentration (kg N/m^3)
S_{NO_3an} = the nitrate-nitrogen concentration in the effluent of the anoxic tank (kg N/m^3)
S_s = the soluble effluent COD (kg COD/m^3)
S_{TKN} = the soluble TKN in the final effluent (kg N/m^3)
Q = the settled sewage flow rate (m^3/s)
Q_m = the mixed liquor recirculation rate (m^3/s)
Q_r = the return sludge flow rate (m^3/s)
Y_{oCODan} = the observed heterotrophic yield from COD consumption under anoxic (denitrifying) conditions (kg VSS/kg COD)
Y_{oCODox} = the observed heterotrophic yield from COD consumption under aerobic conditions (kg VSS/kg COD)
Y_{oNO_3an} = the observed heterotrophic yield from nitrate-nitrogen consumption under anoxic (denitrifying) conditions (kg VSS/kg NO_3-N)

This ignores the nitrifying biomass on the grounds that it is small.

The observed yields can be estimated by,

$$Y_{oCODan} = \frac{Y_{CODan}}{1 + k_d \Theta_{Xan}} \approx \frac{0.17}{1 + k_d \Theta_{Xan}} \tag{11.91}$$

$$Y_{oCODox} = \frac{Y_{CODox}}{1 + k_d \Theta_{Xox}} \approx \frac{0.40}{1 + k_d \Theta_{Xox}} \tag{11.92}$$

$$Y_{oNO_3an} = \frac{Y_{NO_3an}}{1 + k_d \Theta_{Xan}} \approx \frac{0.68}{1 + k_d \Theta_{Xan}} \tag{11.93}$$

In Eq. (11.90), the settled sewage flow rate, the influent TKN, and the target effluent nitrate-nitrogen concentrations are known. The effluent soluble TKN can be estimated as in the designs for single-stage nitrification; it is two or three times the effluent ammonia-nitrogen concentration. The effluent ammonia-nitrogen concentration and the effluent soluble BOD_5 and COD are fixed by the aerobic SRT. The nitrate-nitrogen concentration in the effluent of the anoxic stage is often small, and in that case, it may be neglected. The return sludge flow rate may be estimated using the Benefield–Randall formula [Eq. (11.37)]. The observed anoxic and aerobic heterotrophic yields must be calculated using the anoxic and aerobic SRT, respectively.

The unknown in Eq. (11.90) is the required mixed liquor recirculation rate. Generally, recirculation rates of 100 to 400% of the settled sewage flow are employed. Higher rates produce more complete nitrate removal, but very high rates are uneconomical. If nearly complete nitrogen removal is required, then either a two- or three-sludge system fed external reductant like methanol should be constructed. These are discussed below.

Once the flow rates are known, simple mass balances around the system can be used to calculate the various mass conversions:

Anoxic consumption of nitrate and production of nitrogen gas:

$$R_{NO_3an} = R_{N_2an} = (Q_m + Q_r) S_{NO_3} - (Q + Q_m + Q_r) S_{NO_3an} \tag{11.94}$$

Anoxic consumption of COD:

$$R_{CODan} = QC_{CODo} + (Q_m + Q_r) S_{COD} - (Q + Q_m + Q_r) S_{CODan} \tag{11.95}$$

$$R_{CODan} = \frac{Y_{oNO_3an}}{Y_{oCODan}} \cdot R_{NO_3an} = 3.98 \cdot R_{NO_3an} \tag{11.96}$$

Aerobic consumption of COD:

$$R_{CODox} = Q(C_{CODo} - S_{COD}) - R_{CODan} \tag{11.97}$$

where
C_{CODo} = the total COD in the settled wastewater (kg/m^3)
R_{CODan} = the rate of COD consumption in the anoxic tank (kg/s)
R_{CODox} = the rate of COD consumption in the aerobic tank (kg/s)
R_{N2an} = the rate of nitrogen gas production in the anoxic tank (kg/s)
R_{NO3an} = the rate of nitrate-nitrogen consumption in the anoxic tank (kg/s)
S_{COD} = the soluble COD in the final effluent
S_{CODan} = the soluble COD in the effluent of the anoxic tank (kg/m^3)
S_{NO_3} = the concentration of nitrate-nitrogen in the settled effluent (kg/m^3)
S_{NO3an} = the concentration of nitrate-nitrogen in the effluent of the anoxic tank (kg/m^3)
Y_{oCODan} = the observed yield of heterotrophs from COD in the anoxic tank (kg VSS/kg COD)
Y_{oNO3an} = the observed yield of heterotrophs from nitrate-nitrogen in the anoxic tank (kg VSS/kg N)

Note that the effluent COD is fixed by the aerobic SRT. The COD in the effluent of the anoxic tank can be calculated using Eq. (11.95). If it is negative, supplemental reductant, usually methanol, is required.

The waste sludge production rate is given by,

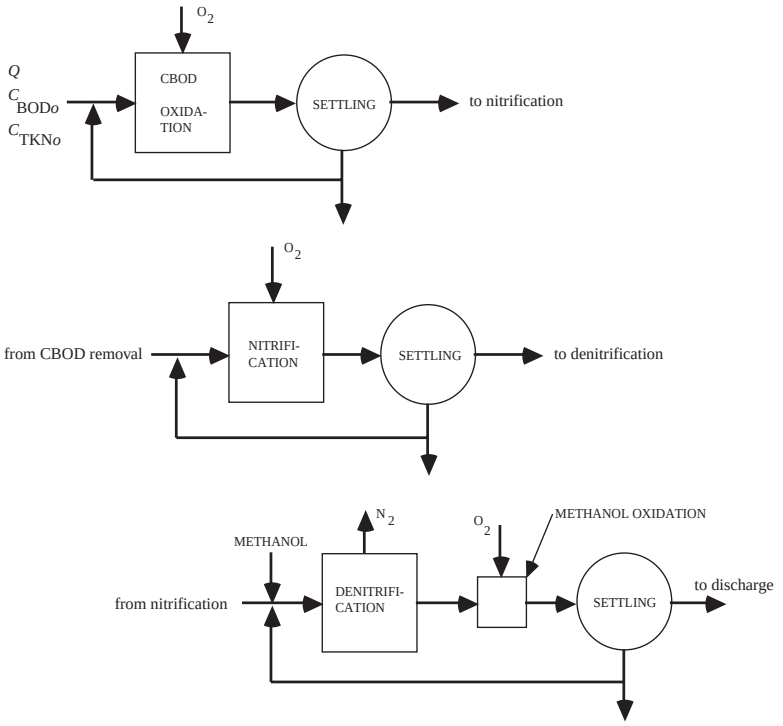

FIGURE 11.6 The three-sludge nitrogen removal scheme (Mulbarger, 1971).

$$Q_w X_w \le \frac{V_{an} X_{an}}{\Theta_{Xan}} + \frac{V_{ox} X_{ox}}{\Theta_{Xox}} = Y_{o\,\mathrm{COD}ox} \cdot R_{\mathrm{COD}ox} + Y_{o\,\mathrm{COD}an} \cdot R_{\mathrm{COD}an} \tag{11.98}$$

The aerobic SRT is fixed by the specified effluent ammonia-nitrogen concentration, and the anoxic SRT is set to minimize the nitrate-nitrogen concentration in the anoxic effluent. The MLSS is a semifree choice, so the only unknown is the total tankage.

Two- and Three-Stage Denitrification

If low effluent nitrate concentrations are needed, a separate stage denitrification process fed supplementary reductant is required. A schematic process train for separate stage denitrification is shown in Fig. 11.6, which is Mulbarger's (1971) three-sludge process. This scheme was modified and built by the Central Contra Costa Sanitary District and Brown and Caldwell, Engineers (Horstkotte et al., 1974). The principal changes are (1) the use of lime in the primary clarifier to remove metals and (2) the substitution of a single-stage nitrification process for the two-stage process used by Mulbarger.

The nitrification stage can be designed using the procedures described above.

The denitrification stage can be designed using the methanol and nitrate kinetic data in Table 11.11.

Any nonfermentable organic substance can be used as the reductant for nitrate. The usual choice is methanol, because it is the cheapest. Fermentable substances like sugar or molasses are not used, because a substantial portion of the reductant can be dissipated as gaseous end-products like hydrogen.

Disregarding microbial growth, the stoichiometry of methanol oxidation is as follows:

$$\mathrm{CH_3\,OH} + \tfrac{6}{5}\,\mathrm{HNO_3} = \mathrm{CO_2} + \tfrac{3}{5}\,\mathrm{N_2} + \tfrac{13}{5}\,\mathrm{H_2O} \tag{11.99}$$

TABLE 11.11 Separate Stage Denitrification Design Values [1–3]

Design Variable	Reference 1	Reference 2	Reference 3
Anoxic HRT (h)	3	1.6	0.82
Oxic HRT (h)	0.4	0.3	0.79
MLVSS (mg/L)	1390	2460	2600
F/M (kg COD/kg VSS·d)	0.73		0.79
Anoxic SRT (d)	38	7.6	29
Methanol/nitrate ratio (kg methanol/kg NO_3-N)	5.83	3.07	3.54
Effluent NO_3-N (mg/L)	0.9	0.7	0.8
System nitrogen removal (%)	91	>69	—
Temperature (°C)	12–22	10	16–19

[2] Mulbarger, M.C. 1971. "Nitrification and Denitrification in Activated Sludge Systems," *Journal of the Water Pollution Control Federation*, 43(10): 2059.

[3] Horstkotte, G.A., Niles, D.G., Parker, D.S., and Caldwell, D.H. 1974. "Full-Scale Testing of a Water Reclamation System," *Journal of the Water Pollution Control Federation*, 46(1): 181.

This suggests a methanol dosage of at least 1.9 g methanol per g nitrate-nitrogen. In order to account for growth and the presence of oxygen and nitrite in the feed, McCarty, Beck, and St. Amant (no date) recommend a dosage of the following:

$$S_{meth} = 2.47S_{NO_3o} + 1.53S_{NO_2o} + 0.87S_{O_2o} \tag{11.100}$$

where S_{meth} = the required methanol dosage (mg CH_3OH/L)
S_{NO_3o} = the initial nitrate-nitrogen concentration (mg NO_3-N/L)
S_{NO_2o} = the initial nitrite-nitrogen concentration (mg NO_2-N/L)
S_{O_2o} = the initial dissolved oxygen concentration (mg O_2/L)

In general, excess methanol is supplied to ensure that nearly complete nitrate removal is achieved. This means that the nitrate-limited kinetic parameters control. The excess methanol must be removed prior to discharge. This is accomplished by a short-detention aerobic stage inserted between the anoxic stage and the clarifier. The aerobic stage also serves as a nitrogen gas-stripping unit.

The sludge yield from the denitrification plant can be estimated via the formula suggested by McCarty, Beck, and St. Amant (no date):

$$X_v = 0.53S_{NO_3o} + 0.32S_{NO_2o} + 0.19S_{O_2o} \tag{11.101}$$

where X_v = the active heterotrophic biomass produced (mg VSS/L).

Biological Phosphorus Removal

The biochemical phosphorus removal process is called *polyphosphat überKompensation* or "polyphosphate overplus" (Harold, 1966). This is not to be confused with *luxury uptake*, which occurs when growth is inhibited by lack of an essential nutrient. Except for in the PHOSTRIP™ process, phosphorus is removed from wastewater by incorporation into the biomass and subsequent biomass wastage from the system. The steady state system phosphorus balance is as follows:

$$C_{Po} = S_P - f_{Ph}\frac{VX_v}{Q\Theta_X} \tag{11.102}$$

where C_{Po} = the total influent phosphorus concentration (kg/m^3)
f_{Ph} = the concentration of phosphorus in the volatile suspended solids (kg P/kg VSS)
Q = the settled sewage flow rate (m^3/s)
S_P = the soluble effluent phosphorus concentration (kg/m^3)
V = the aeration tank volume (m^3)
X_v = the mixed liquor volatile suspended solids' concentration (kg VSS/m^3)
Θ_X = the solids' retention time (s)

Growing bacteria typically contain about 3% by wt (dry) phosphorus, of which 65% is incorporated into deoxyribonucleic acid (DNA) and ribonucleic acid (RNA), 15% into phospholipids, and the remainder as acid-soluble phosphate esters (Roberts et al., 1955). Nearly all algae, bacteria, and fungi can accumulate more than that (Harold, 1966), and the bacterium Acinetobacter has been reported to contain as much as 16% phosphorus (Eagle et al., 1989). The increased phosphorus content consists of volutin granules. Volutin is a long-chain polymer of orthophosphate ions. The polymer is highly charged and is associated with K^+, Ca^{2+}, and Mg^{2+} ions, RNA, polybetahydroxybutyric acid (PHB), proteins, and phospholipids (Eagle et al., 1989).

Conventional activated sludge plants typically remove about 40% of the influent phosphorus (EPA, 1977). The phosphorus content of activated sludges with volutin-containing bacteria generally consists of 4 to 7% by wt of the total suspended solids, and the plants generally achieve better than 90% phosphorus removal (Scalf et al., 1969; Vacker, Connell and Wells, 1967).

A number of proprietary phosphorus removal processes are being marketed that induce volutin accumulation in bacteria, including A^2/O™ (U.S. Patent No. 4,056,465), BARDENPHO™ (U.S. Patent No. 3,964,998), PHOSTRIP™ and PHOSTRIP II™ (U.S. Patent No. 4,042,493; 4,141,822; 4,183,808; and 4,956,094) and VIP™ (U.S. Patent 4,867,883). The Joint Task Force (1992) lists several other patents and processes.

Microbiology

The underlying mechanism of volutin accumulation is the depression of the synthesis of three enzymes (Harold, 1966): alkaline phosphatase (which hydrolyzes extracellular phosphate esters), polyphosphate kinase (which synthesizes polyphosphate chains by transferring orthophosphate from adenosine triphosphate), and polyphosphatase (which hydrolyzes polyphosphate chains). Bacteria that are subjected to repeated anaerobic/aerobic cycles might have three to five times the normal amount of these enzymes..

Volutin formation occurs in activated sludge when it is exposed to an anaerobic/aerobic cycle (Wells, 1969). The currently accepted biochemical model for polyphosphate overplus is (Bowker and Stensel, 1987; Buchan, 1983; Fuhs and Chen, 1975; Marais, Loewenthal and Siebritz, 1983; Yall and Sinclair, 1971):

- During the anaerobic phase, volutin is hydrolyzed to orthophosphate, and the hydrolysis energy is used to absorb short-chain, volatile fatty acids (VFA, principally acetic acid) that are polymerized into polybetahydroxybutyric acid (PHB) and related substances like polybetahydroxyvaleric acid (PHV) (Bowker and Stensel, 1987). Orthophosphate is released to the surrounding medium, and cellular phosphorus levels fall to less than one-half normal (Smith, Wilkinson, and Duguid, 1954).
- Under subsequent aerobic conditions, the PHB (and PHV) are oxidized for energy and used for cell synthesis. The volutin is resynthesized by using some of the oxidation energy to reabsorb and polymerize the released orthophosphate.

Consequently, there is an alternation between volutin-rich aerobic and PHB-rich anaerobic states. Peak volutin levels are reached about 1 hr after re-exposure to oxygen or nitrate. Under prolonged aeration, the volutin is broken down and incorporated into DNA, RNA, and phospholipids.

The anaerobic phase shuts down the metabolism of most aerobic bacteria, except *Acinetobacter* spp. This permits *Acinetobacter* species to absorb volatile fatty acids without competition from other aerobic bacteria. The result is an activated sludge enriched in volutin-accumulating *Acinetobacter* bacteria. A *prolonged* anaerobic phase may encourage the growth of anaerobic and facultatively anaerobic bacteria that can ferment sewage organic matter to VFA and other small molecules for use by the *Acinetobacter*. However, if the raw wastewater lacks the required VFAs, acetate should be added from another source.

Kinetics

The kinetics of phosphorus uptake and release are poorly established in the public literature. In the early laboratory studies, it was reported that the release and subsequent uptake of orthophosphate each require about 3 hr for completion (Fuhs and Chen, 1975; Shapiro, 1967). The anaerobic phase in A/O™ systems generally has a hydraulic retention time of 30 to 90 min, BARDENPHO™ systems generally incorporate an anaerobic HRT of 1 to 2 hr, and PHOSTRIP™ plants operate with an anaerobic HRT of 5 to 20 hr (Bowker and Stensel, 1987). In PHOSTRIP™, the anaerobic phase is applied to settled sludge solids in a sidestream operation. It is nowadays recommended that the anaerobic phase HRT not exceed 3 hr (to avoid phosphorus releases not associated with VFA uptake), and that the anaerobic SRT be about 1 day (Grady, Daigger, and Lim, 1999).

BPR removal plants utilize system SRTs of 2 to 4 days (Grady, Daigger, and Lim, 1999). BPR plants remove phosphorus by incorporating it into active biomass, and longer SRTs result in lower active biomass concentrations and cells depleted in reserves of all kinds, which reduce overall phosphorus removal.

Because anaerobic conditions induce phosphorus release, it is important to waste sludge solids as soon after aerobic growth as possible and before the sludge enters any anaerobic environment.

Soluble Organic Matter Requirement

If effluent phosphorus concentrations less than 1 mg/L are desired, the settled wastewater should have a soluble BOD_5 to soluble P ratio of at least 15 or a total BOD_5 to total P ratio of at least 35 (Bowker and Stensel, 1987). Phosphorus-accumulating organisms preferentially consume acetate, and if the wastewater lacks acetate, consistent P removal will not occur.

Effects of Oxygen and Nitrate

Oxygen and nitrate (in nitrifying plants) are carried into the anaerobic zone by sludge and mixed liquor recycles. Airlift pumps, which are sometimes used for sludge recycle, will saturate water with oxygen. This permits some growth of aerobic bacteria in the anaerobic zone and reduces the competitive advantage of *Acinetobacter* spp. The net effect of oxygen and nitrate is to reduce the effective BOD_5:P ratio below that required for optimum phosphorus uptake. The reduction can be estimated from the initial oxygen or nitrate concentrations. The fraction of the removed COD that is actually oxidized is $1 - 1.42Y_o$. For rapidly growing bacteria, the observed yield is nearly equal to the true growth yield of 0.4 g VSS per g COD, so the fraction oxidized is about 43%. In the case of denitrification, the theoretical ratio is 3.53 kg COD removed for every kg of nitrate-nitrogen that is reduced (McCarty, Beck, and St. Amant, no date); reported values of the ratio range from 2.2 to 10.2 (Bowker and Stensel, 1987).

Chemical Requirements

Other than VFA in the influent, additional chemicals are not required for BPR. However, if the discharge permit has stringent limits on effluent phosphorus or if the VFA of the influent is variable, some provision for chemical precipitation of phosphate should be made. The preferred precipitant is alum, because, unlike ferric salts, the aluminum-phosphate precipitates (sterrettite, taranakite, and variscite) are insoluble under reducing conditions (Goldshmid and Rubin, 1978).

Lack of VFAs can be offset by the addition of acetate. Some facilities obtain acetate internally by an acid-phase-only anaerobic fermentation of sludge solids (Metcalf & Eddy, Inc., 2002). Unheated digesters with SRTs of 3 to 5 days (to inhibit methanogenesis) are fed primary solids only (to minimize phosphate in the recycle). The expected VFA yield is about 0.1 to 0.2 g VFA per g VSS fed to the digesters.

Phosphorus-Laden Recycle Streams

Sludge thickening and stabilization operations usually result in solubilization of phosphates. These streams should be pretreated with alum to remove soluble phosphate prior to admixture with the raw or settled sewage flow, and the alum-phosphate sludge should be dewatered and sent to final disposal.

Effluent Solids

Effluent solids are also enriched in phosphorus (beyond normal activated sludge levels), and tertiary solids removal may be needed to meet permit conditions.

Empirical Design

Weichers et al. (1984) recommend the following semiempirical formula for estimating phosphorus uptake:

$$\Delta C_{PoX} = C_{CODo}\left\{\left[\frac{\left(1 - f_{CODsu} - f_{CODpu}\right)Y_a}{1 + k_d\Theta_X}\right]\left(\gamma + f_{Pu}f_{X_au}k_d\Theta_X\right) + f_{Pu}\left(\frac{f_{CODpu}}{\beta_X}\right)\right\} \tag{11.103}$$

where C_{CODo} = the total influent COD (mg/L)
ΔC_{PoX} = the phosphorus removal from the wastewater by incorporation into the sludge (mg/L)
f_{CODpu} = the unbiodegradable fraction of the particulate influent COD (dimensionless)
≈ 0.13 for municipal wastewater (Weichers et al., 1984)
f_{CODsu} = the unbiodegradable fraction of the soluble influent COD (dimensionless)
≈ 0.05 for municipal wastewater (Weichers et al., 1984)
f_{Xan} = the anaerobic mass fraction of the MLSS (dimensionless)
f_{X_au} = the unbiodegradable fraction of the active biomass (dimensionless)
≈ 0.20 for municipal wastewater (Weichers et al., 1984)
f_{Pu} = the phosphorus concentration in the unbiodegradable volatile solids (mg P/mg VSS)
≈ 0.015 mg P/mg VSS for municipal wastewater (Weichers et al., 1984)
k_d = the decay coefficient of the heterotrophic bacteria, per day
≈ 0.24/day (Weichers et al., 1984)
$S_{CODanrb}$ = the readily biodegradable COD in the anaerobic reactor (mg/L)
Y_a = the true growth yield of the heterotrophic bacteria (mg VSS/mg COD)
≈ 0.45 mg VSS/mg COD (Weichers et al., 1984)
β_X = the COD of the VSS (mg COD/mg VSS)
≈ 1.48 mg COD/mg VSS (Weichers et al., 1984)
ϕ = the excess phosphorus removal propensity factor (dimensionless)
≈ $(S_{CODanrb} - 25)f_{Xan}$
γ = the fraction of phosphorus in the active biomass (mg P/mg VSS)
= $0.35 - 0.29\exp(-0.242\phi)$
Θ_X = the solids' retention time (days)

Eq. (11.103) distinguishes between the active biomass, which absorbs and releases phosphorus, and inert (endogenous) biomass. The phosphorus content of the active biomass is supposed to vary between about 3 and 35% by wt of the VSS. The phosphorus content of the inert biomass is estimated to be about 1.5% of VSS.

The anaerobic mass fraction is the fraction of the system biomass held in the anaerobic zone. Because MLSS concentrations do not vary substantially from one reactor to the next in a series of tanks, this is also approximately the fraction of the total system reactor volume in the anaerobic zone.

Flow Schematics and Performance

Flow schematics of the principal phosphorus removal processes are shown in Fig. 11.7.

The PHOSTRIP™ process removes phosphorus by subjecting a portion of the recycled activated sludge to an anaerobic holding period in a thickener. The phosphorus-rich supernatant is then treated with lime, and the phosphorus leaves the system as a hydroxylapatite [$Ca_5(PO_4)_3OH$] sludge. The phosphorus-

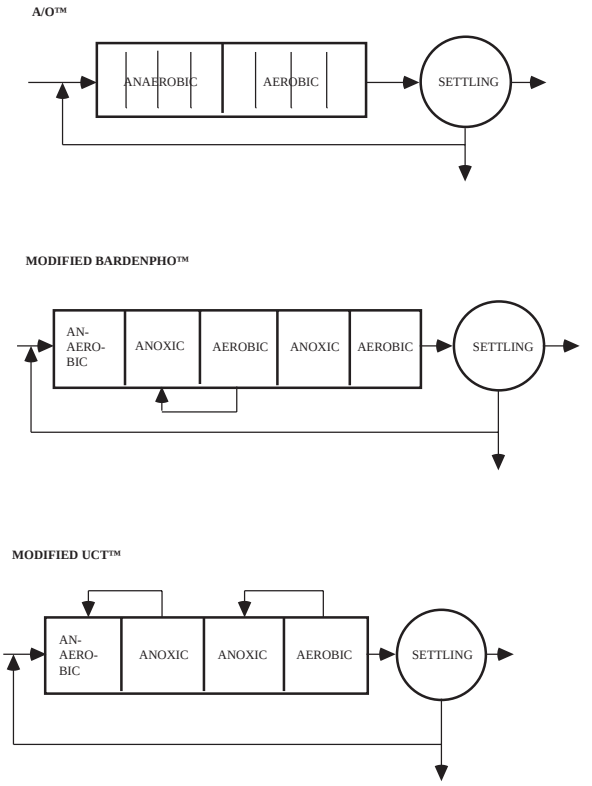

FIGURE 11.7(a) Biological phosphorus removal schemes.

depleted activated sludge solids in the thickener are returned to aeration. The PHOSTRIP™ process consistently produces soluble effluent phosphorus concentrations under 1 mg/L and usually produces total effluent phosphorus concentrations of about 1 mg/L, although excursions of effluent suspended solids sometimes degrade performance (Roy F. Weston, Inc., 1983). The process cannot be used to remove phosphorus from a nitrifying sludge, but it can be applied to the first stage of a two-stage nitrification plant. The PHOSTRIP™ process is best suited to low hardness waters so that the lime treatment step does not produce unwanted calcium carbonate sludges.

The A/O™ process nitrifies, partially denitrifies, and partially removes phosphorus. Total effluent phosphorus concentrations are generally 1.5 to 3.0 mg/L (Roy F. Weston, Inc., 1983). Phosphorus is removed from the system in the waste activated sludge.

The BARDENPHO™ process also nitrifies, partially denitrifies, and partially removes phosphorus. Supplemental methanol for denitrification and alum for phosphate precipitation may be required if consistently high removals of nitrogen and phosphorus are needed (Roy F. Weston, Inc., 1983). Phosphorus is removed from the system in the waste activated sludge.

Except for the PHOSTRIP™ process, all the schemes for biological phosphorus removal produce phosphorus-rich waste activated sludges. If these sludges are subjected to digestion, phosphorus-rich supernatants are produced, and the supernatants require a phosphorus removal treatment prior to recycle.

All the processes show degradation of total phosphorus removal when secondary clarifiers are subjected to hydraulic overloads. If consistently low total effluent phosphorus concentrations are required, effluent filters should be considered.

11.3 Aerobic Fixed-Film Processes

The fundamental problems of any percolation system are the hydraulic and pneumatic transmissibilities of the media. The initial solution to the relatively low transmissibility of natural soils was the intermittent sand filter, which was developed by Frankland in Great Britain and the Lawrence Experiment Station in

Massachusetts (Bruce and Hawkes, 1983). These filters are constructed of relatively coarse sands with controlled size grading. However, it was discovered at the Lawrence Experiment Station that high transmissibilities and good organic removals were obtainable by utilizing gravels. Latter studies increased the size of the media to crushed rock of a few inches diameter.

Trickling Filters

Trickling filters (*bacteria beds*, *biological filters*, *percolating filters*) consist of a thin film of wastewater flowing over a packing (media) that holds an aerobic surface biofilm. Aerobic conditions are maintained by the flow of air through the packing voids. Fig. 11.8 depicts a typical arrangement. The packing is supported by filter blocks that are slotted on top to admit the treated wastewater. The slots connect to a horizontal passageway in the lower part of the block. The passageways connect to a collection channel that gathers all wastewater leaving the filter. The drainage channel is also connected to the peripheral chimneys that admit air to the packing.

The first trickling filter plant was constructed in Salford, England, in 1892; the first American trickling filter was built in Atlanta, GA, in 1903 (Peters and Alleman, 1982). The traditional trickling filter classification by hydraulic and BOD_5 loading is given in Table 11.12. The Joint Task Force (1992) regards this classification scheme to be obsolete.

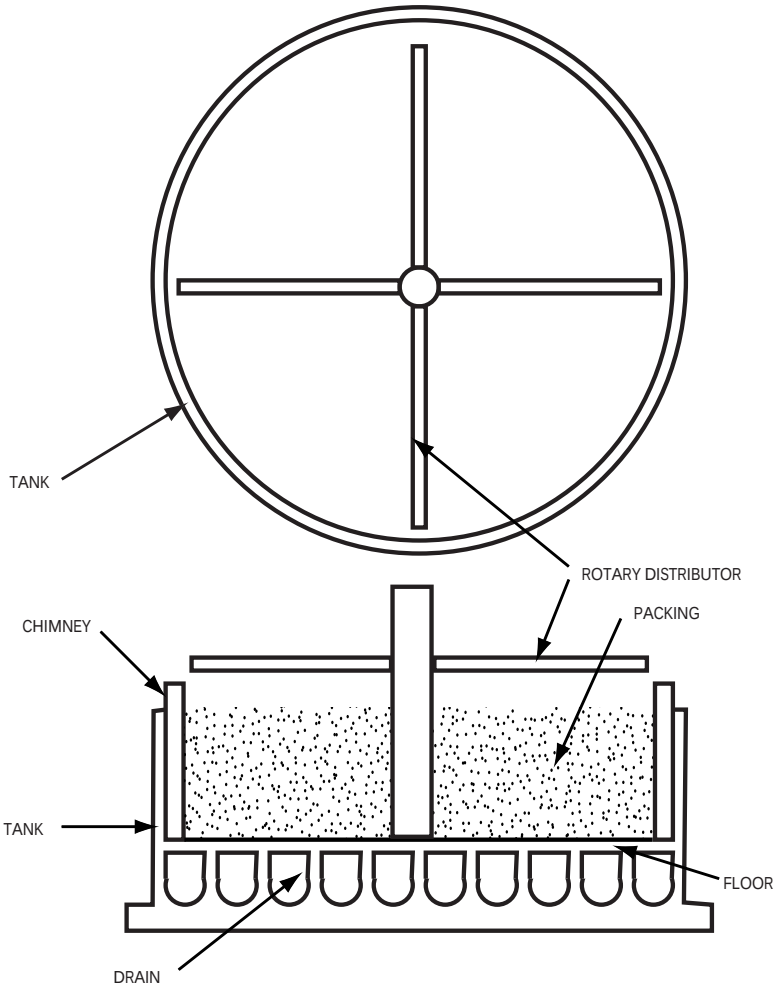

FIGURE 11.8 Trickling filter schematic.

TABLE 11.12 Trickling Filter Classification

Class	Media	Hydraulic Loading (mgad)	BOD_5 Loading (lb/d/1000 ft^3)	Depth (ft)	BOD_5 Removal [a] (%)	Recirculation/Nitrification
Low	Stone	1–4	5–20	5–10	75–85	No/fully
Intermediate	Stone	4–10	15–30	6–8	50–70	Yes/partial
High	Stone	10–40	30–60	3–8	40–80	Yes/none
Super	Plastic	15–90	30–150	<40	65–85	Yes/some
Roughing	Stone/plastic	60–180	<300	3–20	40–85	No/none

[a] After settling

Low-rate filters sometimes employ recirculation during low flow periods to keep the media wet. Low-rate and intermediate-rate filters produce nuisance flies. They also slough in the early spring when the filter fly larvae become active and disrupt the biofilm. During the sloughing, the filter effluent will contain more suspended solids than its influent. High-rate filters do not usually harbor filter flies, and they discharge solids at low rates more or less continuously. The low rate of solids discharge is not sloughing, because it is not larva-induced, seasonal, or flashy.

Packings (Media)

Trickling filter packings (media) can be classified as *random*, *stacked,* or *modular*:

- Random media consist of relatively small individual pieces of crushed stone or ceramic or plastic shapes that are gently poured into the filter box so that the orientations of the pieces are random.
- Stacked media consist of individual pieces that are placed by hand in a specified orientation.
- Modular media consist of relatively large integrated arrays of plates or channels. These are placed by hand in fixed orientations, and individual modules may be shaped in the field to fit.

Older filters built before 1960 consist almost entirely of crushed stone placed by hand-shovel and wheelbarrow and randomly oriented. Hand placement is required to avoid damage by dumping to the under drain system and to the media. The stone is usually sieved and washed on site to remove fines and long or flat shapes. The usual size range is 3 to 4 in. (76 to 114 mm). Stone must be durable against freeze-thaw cycles and chemically and biologically inert to the wastewater and microbes. Some furnace slags and burnt clays leach iron, which discolors the effluent. The usual test of durability is a loss of less than 10% by wt after 20 cycles of soaking for 16 to 18 hr in a saturated sodium sulfate solution at 70°F followed by drying at 230°F (Anonymous, 1936; ASTM Committee C-9, 1993).

Other random packings include ceramic, carbon, metal, or plastic rings (Raschig, Lessing, cross-partition, and spiral) and saddles (Berl and Intalox). Rings are short, hollow cylinders and different kinds have different designs for partition walls within the cylinder. For example, Rashig rings have no inner partitions, Lessing rings have a single cross-wall running down the axis of the cylinder, and cross-partitioned rings have two intersecting walls running down the axis. Saddles are strips of material that have been bent into a semicircular curve; the surface of the strip may be grooved or folded.

Stacked media are almost never used, because the careful hand labor required makes them expensive to install, because they are prone to channeling.

Modular media consist of arrays of parallel sheets of plastic joined together. Early designs used corrugated sheets with the corrugation channels aligned vertically. Two kinds are in use: vertical-flow, fully corrugated bundles (VFC) and vertical-flow, semicorrugated bundles (VFS). The latter alternate

TABLE 11.13 Physical Properties of Trickling Filter Media

Media	Unit Size (in.)	Specific Weight (lb/ft^3)	Specific Surface Area (ft^2/ft^3)	Void Space (%)
Modular plastic	24 × 24 × 48	2–6	25–35	94–97
Random plastic	Varies	2–5	25–50	>94
Redwood	47½ × 47½ × 35¾	10	14	76
Blast furnace slag	2–3	68	29	49
Rock (granite)	1–3	90	19	46
Rock (granite)	4	70	13	60

Source: Schwinn, D.E. and Gassett, R.B., eds. 1974. *Process Design Manual for Upgrading Existing Wastewater Treatment Plants.* Environmental Protection Agency, Technology Transfer, Washington, DC.

flat sheets with corrugated sheets. In recent years, the corrugations have been arranged so that the flow is diagonal through a bundle, with alternating layers directing the flow to opposite sides. This arrangement is called cross flow (XF). VFC is preferred for strong wastewaters and filters with high organic loadings. XF is preferred for weak wastewaters and low organic loadings (Joint Task Force, 1992). Plastic media must be resistant to ultraviolet radiation, disintegration, erosion, aging, all common acids and alkalis, organic compounds, and microbial attack (Wastewater Committee, 1997). The media must not be toxic to the biofilm or leach toxic materials. The media should be able to support foot traffic for distributor maintenance. If it cannot, walkways must be provided.

An important property of any media is the specific surface area, a, which is defined to be the total area available for biofilm attachment divided by the bulk volume of the media. The surface area actually covered by biofilm and wastewater depends on the hydraulic loading, and media-specific minimum flows are required to achieve the maximum treatment capacity. Some typical values of a are given in Table 11.13.

In order to promote free airflow, the Wastewater Committee (1997) specifies maximum specific surface areas of 30 sq ft per cu ft (100 m^2/m^3) for carbonaceous BOD_5 removal and 45 sq ft per cu ft (150m^2/m^3) for nitrification.

Rock media filters that depend on natural draft for aeration are usually limited to a maximum media depth of 10 ft (Wastewater Committee, 1990); the usual practice is to build them no deeper than 6 ft. Greater depths can be used if forced aeration is provided. Natural draft modular plastic media filters are typically 16 to 26 ft deep (Wastewater Committee, 1997).

Hydraulics and Pneumatics

Hydraulic Retention Time

The current model for the hydraulic regime in trickling filters is as follows (Suschka, 1987):

- There is a biofilm layer attached to the media surface.
- On the liquid side of the biofilm, there is a heterogeneous layer of porous biofilm and pore water; the biofilm is similar in morphology to a forest of microscopic mushrooms.
- Because of intermittent dosing, wastewater waves flow freely over the mixed biofilm-pore water layer.
- The remainder of the media voids are filled with air.

Most of the liquid on the media surface is in the heterogeneous layer, rather than in the freely flowing waves. The intermittent wastewater waves periodically disrupt and mix with the pore water in the biofilm, and this gives the flow a significant complete-mix and/or dispersed-flow character. Even in steady flow over biofilm-free filters, there is some dispersion, and it increases as the hydraulic load decreases, approaching complete mixing and streaming (Muslu, 1986).

For clean modular media, without a biofilm, the thickness of the freely flowing water film can be estimated by the following (Suschka, 1987):

$$h_{fl} = \sqrt[3]{\frac{3q}{\gamma \sin\alpha}} \tag{11.104}$$

where h_{fl} = the thickness of the free liquid (m)
q = the wastewater flow rate per unit width of media surface ($m^3/m \cdot s$)
α = the inclination of the media surface measured from the horizontal (rad)
γ = the unit weight of the liquid (N/m^3)

However, once the biofilm and its associated heterogeneous layer develop, the effective water layer thickness is determined by experiment to be approximately (Suschka, 1987),

$$h_{el} = 3.4 \times \sqrt[3]{\frac{3q}{\gamma \sin\alpha}} \tag{11.105}$$

where h_{el} = the effective water film thickness (m).

Suschka (1987) gives an order of magnitude estimate of the HRT of trickling filters with modular media:

$$\tau = \frac{2H}{(Q/V)^{0.75}} \tag{11.106}$$

where H = the depth of media (m)
Q = the total wastewater flow rate including recirculated flow (m^3/h)
V = the media volume (m^3)
τ = the HRT (min)

Equation (11.106) appears to be most representative of media with specific surface areas of about 100 to 120 m^2/m^3. The HRT of media with specific surface areas of about 40 m^2/m^3 is only about one-third of the HRT predicted by Eq. (11.106), and the HRT of media with specific surface areas around 200 m^2/m^3 is about three times the equation value.

Distributor Systems

The preferred distributor system consists of rotary sprinkler arms driven by variable speed electric motors (Joint Task Force, 1992). The wastewater should be distributed as uniformly as possible over the filter cross section; the maximum areal application rate should not vary by more than 10% from one point to another on the cross section (Wastewater Committee, 1990).

Impulse-driven arms are not desirable, because they fail to achieve adequate wetting. Fixed nozzles require high maintenance, and uniform distribution of the wastewater is nearly impossible (Joint Task Force, 1992).

Traditional designs attempted to provide a steady flow to each area of the filter cross section, but recent studies suggest that this results in poor wetting of the media surface, with perhaps as little as one-third of the media being used (Joint Task Force, 1992). Recent recommendations focus on the instantaneous dosing or flushing intensity (Ger. *spülkraft*) on a subarea due to the passage of a distributor arm. This is normally expressed as the total depth deposited on the area per passage of an arm and is calculated as follows (Joint Task Force, 1992):

$$I = \frac{Q + Q_r}{nfA} \tag{11.107}$$

where A = the plan area of the filter (m^2)
f = the rotational speed (frequency) of the distributor (Hz, rev/s)
I = the instantaneous dosing or flushing intensity (m/pass)
n = the number of distributor arms or passes per revolution (dimensionless)
Q = the settled sewage flow rate (m^3/s)
Q_r = the flow rate of the recirculated filter effluent (m^3/s or ft^3/sec)

Older practice results in flushing intensities on the order of 2 to 10 mm per pass, but field experience suggests it should be somewhere at least a few hundred mm per pass (Joint Task Force, 1992). The flushing intensity may be site-, media-, application-specific, or all, and the selection of the distributor motor and controller should allow maximum flexibility in the selection of rotational speeds.

The recommendation for high flushing intensities is supported by chemical engineering experience with packed beds for liquid/gas mass transfer operations (Leva, 1953). The efficiency of such units appears to increase with hydraulic loading nearly up to the point of flooding because of improved wetting. Packed towers are often operated in what is called the *loading region*, which occurs when the liquid rate is high enough that the gas pressure drop across the packing varies as a power of the gas flow rate that is greater than 2. In this region, Eqs. (11.109) and (11.112) do not apply.

Drainage

The usual requirements are (Wastewater Committee, 1997):

- The under-drain filter blocks should collect wastewater from the entire floor of the filter.
- The inlet slots in the top of the filter blocks must cover at least 15% of the filter plan area.
- The filter block passageways and collection drains may be only half full at instantaneous peak flows (to permit air flow), and they should be designed to provide a minimum velocity of 2 ft/sec (0.61 m/s) at an invert slope of 1%.

Aeration

The trickling filter is an aerobic process, and the oxygen needed is supplied by air flowing through the packed bed. This airflow is developed by natural convection due to density differences between the air inside and outside the bed or by blowers.

As long as the pressure drop is small, say 10% or less, air may be treated as an incompressible fluid, and the usual headloss equations apply. Piping losses may be estimated using the Darcy–Weisbach equation, and minor losses may be estimated as multiples of the velocity head. Conversion of headlosses to pressure drops requires the specific weight of air:

$$\Delta p = \gamma h_L \tag{11.108}$$

where g = the acceleration due to gravity (m/s^2)
h_L = the headloss experienced by the flowing air (m)
M_r = the relative molecular weight of air (28.96 g/mol)
Δp = the pressure drop (Pa)
p_{atm} = local atmospheric pressure (Pa)
R = the gas constant (8.314 510 J/mol·K)
T = the absolute temperature (K)
γ = the unit weight of air (N/m^3)
$= p_{atm} M_r g/\mathrm{RT}$

The pressure drop in the filter bed may be estimated using the MacDonald et al. (1979) modification of the Ergun (1952) equation [Eq. (9.234)]. For random and modular plastic media, this can be rewritten as follows:

$$\frac{\Delta p}{\gamma} = h_L = \tfrac{1}{6} f_m (Ha)\left(\frac{1}{\varepsilon^3}\right)\frac{v_s^2}{g} \tag{11.109}$$

where A_p = the surface area of a single media "particle"
a = the specific surface area of the filter media, i.e., the total media surface area divided by the total volume of the filter bed (m^2/m^3)
$= 6(1 - \varepsilon)/\, d_{eq}$ for granular media;
d_{eq} = the equivalent particle diameter (m)
$= 6\ (V_p/A_p)$

f_m = MacDonald–El-Sayed–Mow–Dullien (1979) friction factor (dimensionless)
$\geq 180\ (1 - \varepsilon/\mathbf{Re}) + 1.8$ (for smooth media)
$\leq 180\ (1 - \varepsilon/\mathbf{Re}) + 4$ (for rough media)
H = the height of the filter (m)
Re = the bed Reynold's number (dimensionless)
$= p\nu_s d_{eq}/\mu$ or $\rho\nu_s/\mu \cdot 6(1 - \varepsilon)/a$
V_p = the volume of a single media particle (m^3)
ν_s = the superficial (approach) velocity of the air (m/s)
ε = the bed porosity (dimensionless)
μ = the dynamic viscosity ($N \cdot s/m^2$)

In these relations,

$$Ra = \varepsilon \tag{11.110}$$

$$Aa = P \tag{11.111}$$

where A = the total cross-sectional plan area of the bed, including voids and media (m^2)
P = the wetted perimeter of the media in any planar cross section (m)
R = the bed hydraulic radius, i.e., the void volume divided by the surface area of the media (m)

The void volume in the bed must be reduced by the liquid and biomass volumes in the filter, and, in the case of crushed stone, the grain diameter should be increased by twice the film thickness.

If no blower is installed, the airflow is developed by the natural draft. The natural draft is the gas phase pressure difference developed between the air in the bottom of the trickling and the surrounding air. It may be estimated from the following (Schroeder and Tchobanoglous, 1976):

$$\Delta p = \frac{p_{atm} M_r g H}{R}\left(\frac{1}{T_1} - \frac{1}{T_2}\right) \tag{11.112}$$

where Δp = the natural draft developed by the temperature difference (Pa)
T_1 = the cooler absolute temperature (K)
T_2 = the warmer absolute temperature (K)

The airflow through natural draft filters may stagnate for temperature differences of less than 3°C (Joint Task Force, 1992). If temperature differences this small are expected to be common, forced air circulation is needed.

In natural draft systems, the air passages consist of the pore spaces in the media, the under drains, and "chimneys" placed around the periphery of the bed and connecting the under drains with the atmosphere. The under drains and effluent piping must have at least 50% of their cross-sectional area open to air movement at the peak instantaneous hydraulic flow rate (including the recirculated flow) (Wastewater Committee, 1997).

Plastic media filters for municipal wastewater should have at least 0.1 ft^2 of ventilation area for each 3 to 4.6 m of filter circumference and 1 to 2 m^2 of ventilation area per 1000 m^3 of media (Joint Task Force, 1992). The total cross-sectional area of the chimneys in stone filters must be at least 15% of the plan filter area (Wastewater Committee, 1997).

The minimum airflows recommended by the Joint Task Force (1992) are as follows:

Roughing filters loaded at 120 to 320 kg BOD_5/m^3/day

$$Q_{air} = 0.9 \cdot PF \cdot K \cdot Q \cdot \left(C_{\mathrm{BOD}i} - S_{\mathrm{BOD}}\right) \tag{11.113}$$

Standard rate filters loaded at 40 to 80 kg BOD_5/m^3 per day:

$$Q_{air} = PF \cdot K \cdot Q \cdot \left(C_{\mathrm{BOD}i} - S_{\mathrm{BOD}}\right) \tag{11.114}$$

where C_{BODi} = the total BOD_5 in the flow applied to the filter (kg/m^3)
K = the volumetric air requirement per unit mass of BOD_5 removed [75 m^3 air (1 atm, 0°C)/kg BOD_5]
PF = the load peaking factor (dimensionless)
Q = the total hydraulic flow rate applied to the filter, including recirculated flow (m^3/s)
Q_{air} = the airflow rate [m^3 air (1 atm, 0°C)/s or ft^3 air (SC)/sec]
S_{BOD} = the soluble BOD_5 in the filter effluent (kg/m^3)

The suggested volumetric air requirement amounts to an oxygen-to-BOD_5 mass ratio of about 21:1 and an implied oxygen transfer efficiency of 10%.

Empirical CBOD Removal Formulas

There are many empirical and semitheoretical formulas for the design of trickling filters (Roberts, 1973). The more commonly encountered ones are listed below in chronological order. Designers should bear in mind that the validity of these formulas is under active review, and it appears that all of them fail to account for (1) the fraction of the media that is wetted and (2) the liquid dosing pattern. It is recommended that trickling filter designs be based on large-scale pilot studies. In this regard, the older literature for stone and plastic media contains mainly data from filters that may have been hydraulically underloaded, and these reports may seriously underestimate filter capacities.

It should also be borne in mind that all the models assume that the effluent BOD_5 is merely residual influent BOD_5 that the microbes did not remove and metabolize. However, it has been shown that in laboratory-scale filters fed known, soluble substrates, about 85% of the soluble organic matter in the effluent is a high molecular weight ($M_r > 1000$) microbial product (Namkung and Rittman, 1986). This means that all trickling filter formulas, including those derived theoretically, have no mechanistic meaning, and the model parameter values can be expected to vary with wastewater composition and media configuration. All models should be treated as regression models.

National Research Council Formula

The NRC (Mohlman et al., 1946; Fair et al., 1948) formula was derived from correlations using data from stone media trickling filters at U.S. Army bases during World War II:

$$E = \frac{100}{1 + 0.0085\sqrt{\frac{W}{VF}}} \tag{11.115}$$

where E = the BOD_5 removal efficiency, settled influent sewage to settled effluent, not counting recycle (%)
F = the Mountfort (1924) recirculation factor (dimensionless)
$= (1 + R)/[1 + (1 - f_{av})R]^2$
f_{av} = the "available" fraction of the BOD_5, usually assumed to be about 0.9 (decimal fraction)
R = the recirculation ratio, i.e., the ratio of the settled sewage flow to the recycled treated flow (dimensionless)
V = the volume of the filter bed (ac·ft)
W = the BOD_5 load in the settled sewage not counting the recirculated flow (lb/day)

Note the traditional units. The settled effluent will contain some particulate BOD_5 depending on the efficiency of the final clarifier. The scatter about this formula is very large, and it is only a rough guide to trickling filter performance. The filter load, W, does not include adjustment for the recirculated flow. The Mountfort recirculation factor, F, accounts for any recirculation effect.

The NRC recommends the same formula for the second stage of two-stage filters with an adjustment for the reduced BOD of the effluent from the first filter. The second-stage efficiency is as follows:

$$E_2 = \frac{100}{1 + 0.0085\sqrt{\dfrac{W_1}{VF\left(1-e_1\right)^2}}} \tag{11.116}$$

where E_2 = the BOD_5 removal efficiency of the second stage (%)
e_1 = the fractional BOD_5 removal of the first-stage filter (decimal fraction)
W_1 = the BOD_5 load in the effluent of the first-stage clarifier (lb/day)

The data scatter about Eq. (11.116) is even worse for the second-stage plants.

Two-stage filtration is a solution to the structural and aeration problems associated with deep piles of stone. These include collapse of the pile, crushing of the deeper media layers, and low airflow rates. The second stage functions as the deeper layers of tall stone filter, not as a separate treatment process.

The Germain Formula

The Germain (1966) formula is the most commonly used design equation for plastic media. It is based on the theoretical and empirical work of Velz (1948), Howland (1958), and Schulze (1960):

$$\frac{C_{BODse}}{C_{BODo}} = \exp\left(-\frac{K_G H}{\left(Q/A\right)^{0.5}}\right) \tag{11.117}$$

where A = the plan area of the trickling filter (ft^2)
C_{BODo} = the BOD_5 in the settled sewage not including the recirculated flow (mg/L)
C_{BODse} = the BOD_5 in the settled effluent (mg/L)
K_G = the Germain treatability factor [$s^{-0.5} \cdot m^{-0.5}$ or $(gpm)^{0.5}/ft^2$]
≈ 0.088 $(gpm)^{0.5}/ft^2$ for settled domestic sewage
Q = the flow rate of the settled sewage not including any recirculated flow (gpm)

Equation (11.117) applies to trickling filters with and without recirculation. In both cases, Q is the settled sewage flow rate without any adjustment for the volume of the recirculated flow, and C_{BODo} is the BOD_5 of the settled sewage from the primary clarifier, again without any adjustment for the BOD_5 in the recirculated flow. In other words, Germain's experiments show no effect of recirculation upon filter performance.

Eckenfelder's Retardant Model

The Eckenfelder (1961) retardant formula was derived from the assumption that the rate of BOD_5 removal decreases as the contacting time increases. Eckenfelder applied his model to data from stone filters treating domestic sewage and obtained:

$$\frac{C_{BODse}}{C_{BODo}} = \frac{1}{1 + \dfrac{2.5H^{0.67}}{\left(Q/A\right)^{0.50}}} \tag{11.118}$$

where C_{BODo} = the settled sewage BOD_5 (mg/L)
C_{BODse} = the settled trickling filter effluent BOD_5 (mg/L)
A = the plan area of the filter (ac)
H = the depth of media (ft)
Q = the settled sewage flow rate (mgd)

Galler–Gotaas Correlation

Galler and Gotaas (1964) performed multiple linear (logarithmically transformed) regression on a large sample of published operating data and obtained the following formula, which is one of several versions they derived:

$$C_{BODse} = \frac{0.464 C_{BODi}^{1.19} \left(\frac{q + q_r}{q} \right)^{0.28} \left(q + q_r \right)^{0.13}}{\left(1 + H \right)^{0.67} T^{0.15}} \tag{11.119}$$

where C_{BODi} = the BOD_5 in the mixture of settled sewage and recirculated flow applied to the filter (mg/L)
C_{BODse} = the BOD_5 in the settled, final effluent (mg/L)
H = the depth of media (ft)
q = the settled sewage flow rate (mgad)
q_r = the recirculation rate (mgad)
T = the sewage temperature (°C)

The multiple correlation coefficient for the logarithmic form of Eq. (11.119) is 0.974.

Equation (11.119) was modified by Blain and McDonnell (1965) in order to account for strong correlations among the data set:

$$C_{BODse} = \frac{0.860 C_{BODo}^{1.31} q^{0.11}}{\left(\frac{q + q_r}{q} \right)^{0.35} H^{0.68} T^{0.57}} \tag{11.120}$$

where C_{BODo} = the BOD_5 of the settled sewage applied to the filter, not including the recirculated flow or BOD_5 (mg/L).

The logarithmic form of Eq. (11.120) has a multiple linear correlation coefficient of 0.869.

Bruce–Merkens Correlation

An empirical formula developed by Bruce and Merkens (1973) fits a variety of plastic and stone media:

$$\frac{C_{BODse}}{C_{BODi}} = \exp\left(-\frac{K_{15} \theta^{T-15} a}{Q/V} \right) \tag{11.121}$$

where a = the specific surface area of the media in m^2/m^3
C_{BODi} = the BOD_5 in the mixture of settled sewage and recirculated flow applied to the filter (mg/L)
C_{BODse} = the BOD_5 in the settled, final effluent (mg/L)
K_{15} = the reaction rate coefficient at 15°C
$\approx$ 0.037 m/d
Q = the settled sewage flow rate in m^2/d
V = the media volume in m^3
θ = the Streeter–Phelps temperature correction coefficient (dimensionless)
$\approx$ 1.08

Note that depth is not a factor in this model.

Institution of Water and Environmental Managers

The formula recommended by the Institution of Water and Environmental Management is as follows (Joint Task Force, 1992):

$$\frac{C_{BODse}}{C_{BODi}} = \frac{1}{1 + \frac{K \theta^{T-15} a_v^m}{\left(Q/V \right)^n}} \tag{11.122}$$

where a = the specific surface area of the filter media (m^2/m^3)
C_{BODi} = the BOD_5 in the mixture of settled sewage and recirculated flow applied to the filter (mg/L)
C_{BODse} = the BOD_5 in the settled, final effluent (mg/L)

$K = 0.0204\ m^{m+n}/d^n$ for stone and random media and $0.400\ m^{m+n}/d^n$ for modular plastic media
$m = 1.407$ for stone and random media and 0.7324 for modular plastic media
$n = 1.249$ for stone and random media and 1.396 for modular plastic media
Q = the settled sewage flow rate (m^3/d)
V = the filter volume (m^3)
θ = the Streeter–Phelps temperature coefficient, 1.111 for stone and random media and 1.089 for modular plastic media

Note that media depth is not a factor in this model.

Relative Reliability of Formulae

Benjes (1978) compared the predictions of the NRC formula, Eckenfelder's equation, and the Galler–Gotaas correlation to data from 20 treatment plants. Data from these treatment plants were not used in the original studies, so Benjes' work is a test of the predictive capabilities of the models. In general, the coefficient of determination (the correlation coefficient squared) was 0.50 for the NRC formula and the Galler–Gotaas correlation; it was 0.56 for the Eckenfelder equation. All of the formulas tend to predict better effluents than are actually achieved, especially when the effluent BOD_5 is large; the Eckenfelder formula yields the smallest predicted effluent BOD_5. The divergences from observed data are greatest for effluent BOD_5 above 30 mg/L. Below 30 mg/L, the three formulas are about equally accurate, but errors of plus or minus 50% in the predicted effluent BOD_5 should be expected.

Effect of Bed Geometry, Recirculation, and Hydraulic Load

Trickling filter models that incorporate Howland's HRT formula [like Eq. (11.117)] predict that if the media volume is held constant and the media depth is increased, the BOD_5 removal efficiency will improve. This occurs because the liquid film thickness increases as Q/A does, and the HRT increases because the total volume of liquid in the bed is larger. These models also predict that increasing recirculation will improve removal efficiency, for the same reason.

The NRC formula also predicts that recirculation will improve removal efficiency. Again, this is because of increased contact between the wastewater and the media.

In the case of empirical equations like the Galler–Gotaas correlation, the prediction falls out of the regression, and no mechanism is implied.

It is now believed that increased hydraulic loading improves removal efficiency, but the improvement is due to more complete wetting of the media surface and a resulting increase in the effective media surface area. The high-intensity, low-frequency dosing recommended by the Joint Task Force (1992) is intended to provide maximum wetting of the surface area.

The effects of wetting can be reported as changes in the Germain treatability constant, K_G, which increases with hydraulic loading up to some maximum value, at which it is supposed that the media is completely wet (Joint Task Force, 1992). In a study by Dow Chemical, Inc., the reaction rate constant increased with hydraulic load up to about 0.75 gpm/ft^2, above which the rate coefficient was constant (Joint Task Force, 1992). Albertson uses a Germain treatability constant of 0.203 $L^{0.5}/s^{0.5}\cdot m^2$ for fully wetted media at the reference conditions of 20°C, 6.1 m depth, and 150 mg/L influent BOD_5.

The Dow study also indicated that BOD_5 removal per unit media volume was independent of media depth for any given hydraulic load that achieved complete wetting of the media. This result was supported by Bruce and Merkens (1973) and by others (Joint Task Force, 1992), and the relationship between the Germain treatability coefficient and the media depth can be represented as follows:

$$\frac{K_{G1}}{K_{G2}} = \sqrt{\frac{H_2}{H_1}} \tag{11.123}$$

so that $K_G\sqrt{H}$ is a constant. The consequence of this is that the removal efficiency should depend on the volumetric rather than the areal hydraulic loading rate.

Albertson (Joint Task Force, 1992) recommends that the Germain constant also be corrected for the strength of the applied sewage:

$$K_G\left(H, C_{\text{BOD}o}, T\right) = 0.203\left(\frac{6.1}{H}\right)^{0.5}\left(\frac{150}{S_o}\right)^{0.5} 1.035^{T-20} \tag{11.124}$$

where $C_{\text{BOD}o}$ = the BOD_5 of the settled sewage not including the recirculated flow (mg/L)
H = the media depth (m)
$K_G\,(H, C_{\text{BOD}o}, T)$ = the Germain treatability constant at 20°C for the given filter depth and influent BOD_5, in $L^{0.5}/(s^{0.5} \cdot m^2)$
T = the wastewater temperature (°C)

Equation (11.124) only applies to vertical-flow, modular plastic media. The Germain treatability constant for shallow cross-flow media is significantly smaller.

Effect of Temperature on Carbonaceous BOD Removal

The BOD_5 removal efficiency of trickling filters depends on the temperature of the slime layer. In the case of continuously dosed, high-rate filters, this is probably the temperature of the applied wastewater. However, the slime layer in intermittently dosed, low-rate filters spends most of its time in contact with the air circulating through the filter, and the slime temperature will be somewhere between the air temperature and the water temperature. If recirculation is practiced, the applied wastewater temperature tends to approach the ambient air temperature.

Schroepfer et al. (1952) derived the following formulas for the effects of temperature on the BOD_5 removal efficiency of rock filters:

Low-rate, intermittently dosed filters:

$$E_2 - E_1 = 0.62\left(T_2 - T_1\right); \quad r \cong 0.7 \tag{11.125}$$

High-rate, continuously dosed filters:

$$E_2 - E_1 = 0.34\left(T_2 - T_1\right); \quad r \cong 0.6 \tag{11.126}$$

where E = the percentage BOD_5 removal efficiency of the combined filter and secondary clarifier based on the total BOD_5 load (%)
T = the wastewater temperature (°F).

Recirculation greatly increases the seasonal variation in BOD_5 removal efficiency. In a study of 17 stone filters in Michigan, Benzie, Larkin, and Moore (1963) found that the summer efficiency was 21 percentage points higher than the winter efficiency when recirculation was practiced but only 6 points higher without recirculation.

Tertiary Nitrification

A trickling filter may be classified as tertiary or nitrifying only as long as the soluble BOD_5 in the applied flow is less than about 12 mg/L and the BOD_5:TKN ratio is less than about 1 (Joint Task Force, 1992).

Nitrification in trickling filters is regarded to be mass transport limited as long as the ammonia concentration is greater than a few mg/L. The limiting flux may be that of oxygen or ammonia. According to the Williamson–McCarty (1976a, 1976b) analysis, the oxygen flux is rate limiting whenever

$$\frac{S_{\text{O}_2}}{S_{\text{NH}_3}} = \frac{S_{\text{O}_2 i}}{S_{\text{NH}_3 i}} < \frac{D_{f\text{NH}_3} \cdot \nu_{\text{O}_2} \cdot M_{r\text{O}_2}}{D_{f\text{O}_2} \cdot \nu_{\text{NH}_3} \cdot M_{r\text{NH}_3}} \tag{11.127}$$

where $D_{f\mathrm{NH_3}}$ = the diffusivity of ammonia nitrogen in the biofilm (m^2/s)
$D_{f\mathrm{O_2}}$ = the diffusivity of oxygen in the biofilm (m^2/s)
$M_{r\mathrm{NH_3}}$ = the relative molecular weight of ammonia nitrogen (17 g/mol)
$M_{r\mathrm{O_2}}$ = the relative molecular weight of oxygen (32 g/mol)
$S_{\mathrm{NH_3}}$ = the ammonia nitrogen concentration in the bulk liquid film (mg NH_3-N/L)
$S_{\mathrm{NH_3}i}$ = the ammonia nitrogen concentration at the interface of the liquid and biofilm (mg/L)
$S_{\mathrm{O_2}}$ = the oxygen concentration in the bulk liquid film (mg/L)
$S_{\mathrm{O_2}i}$ = the oxygen concentration at the interface of the liquid and biofilm (mg/L)
$\nu_{\mathrm{NH_3}}$ = the stoichiometric coefficient of ammonia nitrogen for nitrifier growth (dimensionless)
$\nu_{\mathrm{O_2}}$ = the stoichiometric coefficient of oxygen for nitrifier growth (dimensionless)

Williamson and McCarty estimate that nitrification will be oxygen limited whenever the oxygen:ammonia ratio in the liquid film is less than 2.7 kg O_2 per kg NH_3-N. As a practical matter, this means that tertiary nitrifying filters are oxygen-limited whenever the ammonia nitrogen concentration is larger than about 2 to 4 mg/L. In this range, the nitrification rate is also zero order with respect to ammonia.

Okey–Albertson Design Procedure

Okey and Albertson (Joint Task Force, 1992) developed an empirical procedure for tertiary nitrifying filters. They first define a transition ammonia concentration for the boundary between oxygen limitation and ammonia limitation of nitrification. This varies with oxygen saturation of the liquid film approximately as shown in Table 11.14 (Okey and Albertson, 1989). They then assume the filter depth can be divided into an upper oxygen-limited region and a lower ammonia-limited region. The volumes of the two regions are calculated separately and then added to get the total media volume. The filter area is calculated by assuming a minimum hydraulic loading rate, which includes recirculated flow. This procedure is restricted to applied wastewaters containing less than 12 mg/L of soluble BOD_5, a BOD_5:TKN ratio of less than 1 and a combined BOD_5 plus TSS concentration of 30 mg/L. It is assumed that modular media having a specific surface area of 138 m^2/m^3 is employed.

Oxygen-Limited Media Volume

Calculate the oxygen-limited media volume by assuming a nitrification rate of 1.2 g NH_3-N/m^2/d and a media-specific surface area of 138 m^2/m^3. The rate is constant between 10 and 30°C, and it is reduced below 10°C by using a Streeter–Phelps theta value of 1.035:

$$K_o\left(10°C \le T \le 30°C\right) = 1.2\,\frac{\mathrm{g\ NH_3 - N}}{\mathrm{m^2 \cdot d}}$$
$$K_o\left(T < 10°C\right) = 1.2\,\frac{\mathrm{g\ NH_3 - N}}{\mathrm{m^2 \cdot d}} \times 1.035^{T-10} \tag{11.128}$$

TABLE 11.14 Ammonia Concentrations for the Transition from Oxygen to Ammonia: Limitation of Nitrification in Trickling Filters

	Transition Ammonia Concentration (mg NH_3-N/L)		
Oxygen Saturation (%)	10°C	20°C	30°C
25	1.0	0.9	0.8
50	2.2	1.8	1.5
75	3.3	2.6	2.1
100	4.3	3.5	2.9

Source: Okey, R.W. and Albertson, O.E. 1989. "Diffusion's Role in Regulating Rate and Masking Temperature Effects in Fixed Film Nitrification," *Journal of the Water Pollution Control Federation*, 61(4): 500.

The oxygen-limited media volume will be

$$V_o = \frac{\left(Q + Q_r\right)\left(C_{\mathrm{TKN}o} - S_{\mathrm{NH_3}t}\right)}{K_o a} \tag{11.129}$$

where a = the specific surface area of the media (138 m^2/m^3)
$C_{\mathrm{TKN}o}$ = the total kjeldahl nitrogen concentration in the applied flow, including the TKN of the recirculated flow (mg TKN/L)
K_o = oxygen-limited nitrogen oxidation rate (g NH_3–N/m^2 d)
$Q + Q_r$ = the applied flow (m^3/d)
$S_{\mathrm{NH_3}t}$ = the transition ammonia nitrogen concentration obtained from Table 11.14 (mg NH_3-N/L)
V_o = the oxygen-limited media volume in (m^3)

Ammonia-Limited Media Volume

Use the empirical ammonia oxidation rate:

$$K_n\left(7°C \le T \le 30°C\right) = 1.2\left(\frac{S_{\mathrm{NH_3}e}}{S_{\mathrm{NH_3}t}}\right)^{0.75} \frac{\mathrm{g\ NH_3 - N}}{\mathrm{m^2 \cdot d}} \tag{11.130}$$

and calculate the required ammonia-limited volume by,

$$V_n = \frac{\left(Q + Q_r\right)\left(S_{\mathrm{NH_3}t} - S_{\mathrm{NH_3}e}\right)}{K_n a} \tag{11.131}$$

where K_n = the ammonia-limited nitrogen oxidation rate (g NH_3–N/$m^2 \cdot$d)
$S_{\mathrm{NH_3}e}$ = the required effluent ammonia nitrogen concentration (mg NH_3-N/L)
V_n = the ammonia-limited media volume (m^3)

Filter Depth

The filter depth is the total media volume divided by the required minimum hydraulic load, 47 m^3/m^2/d:

$$H = \frac{V_n + V_o}{\left(Q + Q_r\right)/q} \tag{11.132}$$

where q = the required hydraulic loading rate in $m^3/m^2 \cdot d \ge 0.54\ dm^3/m^2 \cdot s = 47\ m^3/m^2 \cdot d$.

Aeration and Dosing

Okey and Albertson recommend that forced ventilation be employed with a minimum oxygen supply of 50 kg O_2 per kg O_2 consumed, i.e., an oxygen transfer efficiency of 2%.

They also recommend instantaneous dosing intensity of 25 to 250 mm per pass and occasional flushing at greater than 300 mm per pass.

Combined BOD and TKN Removal

Heterotrophic bacteria grow more rapidly than nitrifiers and are less sensitive to low oxygen concentrations, so when the influent BOD_5 is high, the heterotrophs tend to displace the nitrifiers that become limited to the deep, low BOD_5 region of the filter. TKN removal rates decrease as the BOD_5:TKN ratio increases and as the temperature increases. At 15°C, the TKN oxidation rate is approximately

$$K_{\mathrm{TKN}}\left(15°C\right) \cong 1.086\left(\frac{C_{\mathrm{BOD_5}i}}{C_{\mathrm{TKN}i}}\right)^{-0.44} \tag{11.133}$$

where $K_{TKN}(15°C)$ = the total kjeldahl nitrogen removal rate (g TKN/m^2·d)
$C_{BOD_5 i}$ = the total BOD_5 concentration in the applied flow (mg TKN/L)
C_{TKNi} = the total TKN concentration in the applied flow (mg TKN/L)

At 25°C, the TKN oxidation rate is likely to be less than half that indicated by Eq. (11.133); at 10°C, the rate may be 50% higher. The scatter about Eq. (11.133) is large; the standard deviation of the estimate is 0.17 g TKN/m^2/d.

The Albertson–Okey (Joint Task Force, 1992) procedure for combined BOD_5 and ammonia removal is discussed below.

Media Volume

Assuming nitrification controls, determine the influent BOD_5 and TKN, and estimate the TKN oxidation rate for the indicated BOD_5:TKN ratio. Reduce this estimate by 1 standard deviation, i.e., 0.17 g TKN/m^2/d. Use the corrected oxidation rate to calculate the required media volume:

$$K_{TKNdes} \cong 1.086\left(\frac{C_{BOD_5 i}}{C_{TKNi}}\right)^{-0.44} - 0.17 \tag{11.134}$$

$$V_{TKN} = \frac{\left(Q + Q_r\right)\left(C_{TKNi} - S_{TKNse}\right)}{K_{TKNdes}\, a} \tag{11.135}$$

where a = the specific surface area of the media (m^2/m^3)
= 98 m^2/m^3, for design purposes
K_{TKNdes} = the design TKN oxidation rate for 15°C (g TKN/m^2·d)
S_{TKNse} = the required settled effluent TKN (mg TKN/L)
V_{TKN} = the total media volume required for combined BOD_5 and TKN removal (m^3)

Aeration and Distribution

Powered ventilation of the towers is required to prevent oxygen limitation. The oxygen requirement (at 2% transfer efficiency) is 50 kg O_2 per kg oxygen demand removed:

$$R_{O_2 des} = 50\left(Q + Q_r\right)\left[1.2\left(C_{BOD_5 i} - C_{BOD_5 e}\right) + 4.57\left(C_{TKNi} - C_{TKNe}\right)\right] \tag{11.136}$$

where $C_{BOD_5 e}$ = the total BOD_5 in the filter underflow (g/m^3)
$C_{BOD_5 i}$ = the total BOD_5 in the applied flow (g/m^3)
C_{TKNe} = the total TKN in the filter underflow (g/m^3)
C_{TKNi} = the total TKN in the applied flow (g/m^3)
$Q + Q_r$ = the applied flow (m^3/s)
$R_{O_2 des}$ = the design oxygen requirement in (g/s)

The minimum hydraulic application rate to ensure adequate wetting is 47 m^3/m^2/d. The wastewater application should be intermittent with an instantaneous dosing rate of 15 to 300 mm per pass.

Predator Control

Trickling filters mimic the physical ecology of brooks. Consequently, they become populated with significant numbers of insect larvae, worms, and snails that are adapted to eating microbial films. No steady state is possible in such an ecosystem, and the biofilm and its predators exhibit oscillations that are out of phase. All trickling filters exhibit such oscillations, but the oscillations in nitrifying filters are more pronounced, because the nitrifying bacteria grow more slowly than the heterotrophic bacteria. In fact, predator infestations can denude significant portions of the media surface, thereby preventing nitrification. Such denudation is followed by predator starvation and population decline, which permit reestablishment of the nitrifying film. There is, of course, no nitrification until the film has regrown.

Parker et al. (1989) recommend that tertiary nitrifying filters be flooded and then backwashed about once per week to kill and/or remove insect larvae, worms, and snails that consume the nitrifying biomass.

Effect of Temperature on Nitrification

The Joint Task Force (1992) concluded that temperature had little effect on the performance of tertiary nitrifying filters. The effects that are commonly reported were attributed instead to deficiencies in wetting, biofilm consumption by predators, overgrowth by heterotrophs, ammonia concentrations, and oxygen transfer limitations. In fact, if filters are liquid film mass transfer limited, as assumed in the Logan–Hermanowicz model, then the controlling rate process is diffusion, and the Streeter–Phelps (1925) temperature correction factor for the process is about 1.024, which leads to relatively small temperature effects.

The data for combined BOD_5 removal and nitrification is limited. It appears that the uncorrected TKN oxidation rate given by Eq. (11.134) should be decreased by about 50% if the temperature is 25°C or more, and that it may be increased by about 50% if the temperature is 10°C.

pH

The pH requirements of activated sludge apply to BOD_5 removal in trickling filters as well. Tertiary nitrifying filters may develop low pHs as a result of nitric acid formation. Limited data presented by Huang and Hopson (Parker et al., 1975) suggest that the nitrification rate actually increases up to about pH 8.4; at pH 7.1, the rate is only 50% of the maximum, and at pH 7.8, it is 90% of the maximum. This is somewhat contrary to the pH effect reported by Downing and Knowles for activated sludge, in which they indicated no increase in nitrification rate above pH 7.2.

Inhibitors

The list of inhibitors given for activated sludge in Tables 11.4 and 11.5 probably applies to trickling filter nitrification as well.

Secondary Clarifiers

See "Secondary Clarifiers" in Section 11.2.

Intermittent Sand Filters

The first treatment plant to incorporate the process was built in 1871 in Merthyr-Tydvil, Wales. The first American intermittent sand filter was installed in Medfield, MA, in 1887. Intermittent sand filters are still commonly used in rural or isolated areas where land costs are low and operating staff scarce. They also have been used to upgrade stabilization pond effluents.

Filtration Media

The earliest intermittent sand filters were constructed by removing the topsoil and vegetation from natural deposits of coarse sand and leveling the sand surface. Nowadays, the filtration media are engineered to specification.

Intermittent sand filtration fell out of favor after World War II, and current design regulations seldom include specific mention of them. However, the older standards of the Wastewater Committee (1968) and the Technical Advisory Board (1962) do. A combination of their more stringent limits and the recommendations of the Committee of the Sanitary Engineering Division on Filtering Materials (1936) produces media with the following characteristics:

- Depth: at least 36 in. (but not more than 48 in.)
- Effective size (d_{10}): if the wastewater is applied by flooding, 0.3 mm to 0.6 mm; if it is applied by rotating distributor, 0.4 mm to 1.0 mm
- Uniformity coefficient (d_{60}/d_{10}): less than 3.5
- Homogeneity of placement: media should be free of strata or veins of varying size
- Media cleanliness: practically free of clay, loam, soft limestone, or other material subject to disintegration; less than 1% organic matter; less than 3% acid-soluble matter

- Sand grain composition: siliceous sand without calcareous or argillaceous matter
- Shape: rounded, not angular; do not use crushed stone

The combinations of depth, effective size, and dosing method are intended to avoid short-circuiting of the flow through the filter. Especially in the case of flooding, if coarse sands are used, most of the flow will enter the bed near the inlet, and large parts of the bed will receive little or no flow.

A gravel layer supports and retains the filter media. A minimum of three gravel layers is required:

- Technical Advisory Board (1962)
  - From 2 in. below to 2 in. above the drains — grain sizes of 2 in. to 1.5 in.
  - From 2 to 4 in. above the drains — grain sizes of 1 in. to ½ in.
  - From 4 to 6 in. above the drains — grain sizes of ½ in. to ¼ in.
- Wastewater Committee (1968)
  - From below the drains to 6 in. above them, three layers declining in size upwards of — grain sizes of 1.5 in. to ¾ in.; grain sizes of ¾ in. to ¼ in.; and grain sizes of ¼ in. to ⅛ in.

Filter Size and Number

A minimum of two filters is needed to treat continuous raw sewage flow. Each filter should be less than ¾ to 1 acre in plan area (Metcalf and Eddy, 1930). The beds are normally rectangular and grouped around a central distribution box. Nowadays, they are constructed in filter boxes to avoid groundwater contamination. Unless the filter is covered, or is surrounded by a high curb, its surface needs to be protected from dirt and dust by a buffer strip of pavement around its edge, and the grounds farther away should be grassed and mowed regularly with collection of the clippings (Keefer, 1940). Vegetation will grow on the filter surface and must be periodically removed.

Dosing

Although early intermittent sand filters accepted raw sewage, nowadays, at least primary settling or microscreening is required. The BOD_5 and SS loading should not exceed 2.5 lb per 1000 ft^2/d (Technical Advisory Committee, 1962). The hydraulic loads should not exceed the following (Wastewater Committee, 1968):

- Normal settled sewage: 3 gal/ft^2/day
- Strong settled sewage: 1 gal/ft^2/day
- Settled trickling filter effluent: 10 gal/ft^2/day

Removal efficiencies are insensitive to small deviations from these recommendations (Furman, Calaway, and Grantham, 1955).

Wastewater is applied to the filter at least two to not more than four times per day in depths of at least 3 in each time (Keefer, 1940). An application rate of once per day impairs removal efficiency (Furman, Calaway, and Grantham, 1955). The higher dosing frequency is more appropriate in the south and to weaker sewages (Imhoff, Müller, and Thistlewaite, 1971). In the case of strong wastes, several days may be required between doses to avoid clogging. Babbitt and Baumann (1958) and Keefer (1940) cite Barbour's recommendation of an instantaneous dosing rate of 1 ft^3/sec for every 5000 ft^2 of surface for about 20 min. Imhoff, Müller, and Thistlewaite (1971) recommend that dosing by flooding be completed in less than 15 min.

The distribution system may be as follows:

- Impulse-driven rotary, perforated pipes like those used in trickling filters
- A manifold of different pipes discharging onto splash plates placed not more than 30 to 60 ft apart over the filter surface
- A ridge and furrow surface

Intermittency of flow may be achieved via dosing siphons (traditional) or pumps (modern and preferred).

Cleaning

Filter surfaces gradually accumulate a fibrous humus surface mat that must be removed by periodic raking. Cleaning may be indicated if the applied dose takes more than 20 to 30 min to infiltrate the surface. The rakings may be recycled to agricultural land like other sewage sludges if they pass the EPA's Rule 503 requirements (see below). The rakings may amount to 7 to 9 yd^3/mil gal (Keefer, 1940).

The bulk of the biological action occurs in the top 5 to 8 in. of the bed, and sometimes this part of the bed clogs. Clogging may be relieved by harrowing the surface or by removing and replacing the top ¾ to 2 in. of sand (Keefer, 1940; Babbitt and Baumann, 1958). If several filters are available, it may be feasible to relieve clogging by taking one unit at a time out of service.

In northern climates, ice accumulation may clog the filter surface. This may be alleviated by plowing the surface into ridges and furrows (Babbitt and Baumann, 1958), and by increasing the depth of dosage to 1 ft (Imhoff, Müller, and Thistlewaite, 1971). In extreme climates, the filters should be covered.

Drainage

The underdrains should be at least 4 in. in diameter, placed not more than 10 ft on centers and sloped to the outlet. They may be open-joint (1/4 to 3/8 in. spacing with tar paper cover over the top half of the diameter) or perforated, vitrified clay or concrete.

Aeration

Intermittent sand filters are aerated by the wave of sewage moving through the filter. This wave expels the deoxygenated air in the media pores and draws fresh air in behind it. Separate aeration systems are not needed.

Performance

If the average dosing rate for normal sewage is less than about 50,000 gal/ac/day, the effluent will be clear, odorless, colorless, and nitrified (Babbitt and Baumann, 1958). An effluent BOD_5 of a few mg/L and virtually no SS can be expected (Keefer, 1940).

Rotating Biological Contactors

The rotating biological contactor (RBC) is also known as *rotating biological disc*, *rotating biological surface* (RBS), *bio-disc*, *rotating filter*, and *rotating biological filter*, and is marketed under Aero-Surf™, Bio-Surf™, BioSpiral™, and Surfact™. It consists of a number of partially submerged discs mounted on a rotating shaft. The discs provide a surface for the attachment of microbes and their predators. The rotation mixes the tank contents, aerates, and promotes mass transfer to the attached biomass. Oxygen is also transferred to the biomass when it is lifted out of the tank by the rotation and exposed to the air. Nowadays, many RBC installations have supplemental diffused air aeration.

Weigand in Germany patented the earliest RBC in 1900 (Peters and Alleman, 1982). It consisted of a rotating, hollow cylinder made of wooden slats. In 1925, Doman used rotating galvanized steel discs for the biomass support. Lack of suitable materials delayed the further development of the RBC until the 1950s, when Popel and Hartmann made improved discs out of expanded polystyrene. The J. Conrad Stengelin Co. in Germany manufactured large discs for use in a municipal treatment plant in Stuttgart, which went operational in 1960. The first RBC application in the U.S. was at the Eiler Cheese Co. in DePere, WI, in 1970. The first full-scale municipal RBC plant was built in Pewaukee, WI (Joint Task Force, 1992).

Configuration

The usual process train consists of preliminary treatment, primary settling, staged RBC treatment, final clarification, and disinfection. Solids are not usually recycled from the final clarifier underflow to the RBC.

The combination biomass support-aeration system consists of shaft-mounted modules of corrugated, high-density polyethylene discs (Fig. 11.9). The shaft is usually square in cross section. The typical motor-driven module is about 12 ft in diameter, and 25 ft long and contains 2750 ft^3 of media (Aerobic

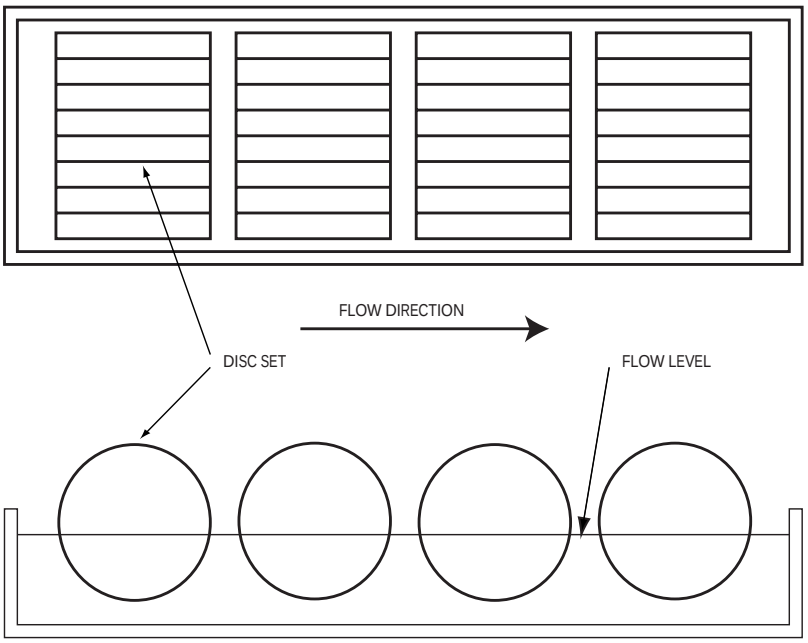

FIGURE 11.9 Rotating biological contactor.

Fixed-Growth Reactors Task Force, 2000). The surface area available for biofilm support on a single shaft will be between 100,000 ft^2 (low density, 36 ft^2/ft^3) to 150,000 ft^2 (high density, 55 ft^2/ft^3) depending on the intended use. Low-density media are used for the initial CBOD-removal-only stages in order to avoid clogging inside the discs; high-density media is used in later nitrification stages where thin biofilms are desired. Motor-driven systems sometimes include diffused air for supplemental air supply.

Diffused air drives are also available. Diffused air-driven modules have cups on their peripheries to capture the rising air bubbles and generate torque. They also have larger diameters, typically 16 ft, to increase the available torque. Rising air bubbles may improve mass transfer to the discs and scour excessive biomass from them.

The side water depth is typically 5 ft, and approximately 40% of the disc area is submerged. The disc rotational speed is about 1 to 1.6 rpm. The modules are usually rotated by constant-speed, variable-torque electric motors connected to the shafts by gearboxes, chain and sprocket, or V-belt and pulley transmissions.

The modules are installed in tanks configured as mixed-cells-in-series in order to prevent short-circuiting. Each cell may contain more than one module. If baffles are installed between modules in a single cell, they should be removable for maintenance. The inlet piping should allow for step-feed among the cells.

Modules may be installed with the shafts parallel to the flow (small tanks) or across the flow (large tanks).

Tanks are covered to avoid media deterioration by ultraviolet light, to avoid the accumulation of algal mats, and to protect the biofilm from excessive high or low temperatures.

The total area of the enclosed media determines tank liquid volumes. A common requirement is 0.12 gal/ft^2 of media (Aerobic Fixed-Growth Reactors Task Force, 2000). This results in a HRT of about 1.4 hr.

CBOD Removal Kinetics

The Benjes empirical formula is commonly used for RBC design. This model is conservative in that it predicts larger module volumes than do some other models. It is an adaptation of the Germain formula used in trickling filter design (Aerobic Fixed Growth Reactors Task Force, 2000):

$$\frac{C_{BODse}}{C_{BODo}} = \exp\left[-K_B\left(V/Q\right)^{0.5}\right] \tag{11.137}$$

where C_{BODo} = the BOD_5 in the settled primary sewage (mg/L)
C_{BODse} = the BOD_5 in the final settled effluent (mg/L)
K_B = the Benjes treatability constant ($gpm^{0.5}/ft^{1.5}$)
≈ 0.3 $gpm^{0.5}/ft^{1.5}$ at 13°C
≈ 0.2 $gpm^{0.5}/ft^{1.5}$ at 7°C
≈ 0.15 $gpm^{0.5}/ft^{1.5}$ at 5°C
Q = the settled sewage flow rate (gpm)
V = the total module volume (cu ft)

The value of 0.3 $gpm^{0.5}/ft^{1.5}$ for K_B represents the median of the scattered data. The envelope values are 0.2 and 0.4 $gpm^{0.5}/ft^{1.5}$.

The Streeter–Phelps theta value for temperature corrections to K_B is poorly known. Designers have used values between 1.01 and 1.05. Most manufacturers estimate that the removal rate per unit area falls by about one-third as the temperature declines from 18 to 6°C.

The settled effluent BOD_5 in mg/L also can be estimated as 15 times the areal organic loading on the discs in lb BOD_5/1000 ft^2/day.

Dissolved Oxygen

A dissolved oxygen level of at least 2 mg/L should be maintained in each cell.

Biofilm Control

The active biofilm thickness is limited to about 0.1 mm. Biofilm thickness on the media should be monitored by load cells or strain gages. Excessive biofilm thickness may be controlled by diffused air scouring, increasing rotational speed, reversing rotational direction, taking the module out of service (resting), removing baffles between modules to decrease BOD concentrations around a module, and chemical stripping.

Nitrification

The TKN available for nitrification is estimated by (Aerobic Fixed-Growth Reactors Task Force, 2000):

$$TKN_a = TKN_t - 0.055BOD_{5r} - 1 \tag{11.138}$$

where BOD_{5r} = the BOD_5 removed in the CBOD removal stages (mg/L)
TKN_a = the available TKN (mg/L)
TKN_t = the TKN in the influent of the RBC's first stage (mg/L)

The TKN of any recycle streams returned to the primary clarifier must be included.

The areal nitrification rate is normally represented by a Monod-like formula (Aerobic Fixed-Growth Reactors Task Force, 2000):

$$q_n = \frac{q_{n\max} S_{na}}{K_{na} + S_{na}} \tag{11.139}$$

where K_{na} = the Monod affinity constant for nitrification by RBC (mg NH_3–N/L)
≈ 0.4 mg NH_3–N/L
q_n = the areal ammonia nitrogen uptake rate (g NH_3–N/m^2 d)
$q_{n\,max}$ = the maximum areal ammonia nitrogen uptake rate (g NH_3–N/m^2 d)
≈ 1.5 g NH_3–N/m^2 d (0.3 lb NH_3–N/1000 ft^2/day) at 13°C
S_{na} = the ammonia nitrogen concentration in the stage (mg NH_3–N/L)

The temperature dependence of nitrification in RBCs is poorly known. The Wastewater Committee (1992) recommends that nitrification at 5°C requires 2.5 times the media area needed at 13°C. Temperatures higher than 13°C do not increase the nitrification rate.

Staging

Because Eq. (11.137) is a plug flow model, the RBC tankage must be compartmentalized as mixed-cells-in-series and the shafts distributed among the cells. A minimum of four stages should be constructed. Generally, several (at least two) parallel, multistage trains will be constructed. The design areal BOD load and the design peak influent flow and strength are used to determine the required number of first-stage shafts. Low-density media is assumed. The total influent is divided equally among the parallel trains.

Equation (11.137) is used to estimate the total media volume required for CBOD removal, and this is converted into the required number of shafts (at 2750 ft^3/shaft). This estimate is multiplied by a safety factor of 1.25.

The areal BOD load on the first stage should be less than 2.5 lb soluble BOD_5 per 1000 ft^2/day and 6.4 lb total BOD_5/1000 ft^2/day (Joint Task Force, 1992). A design first-stage loading of 6 lb total BOD_5/1000 ft^2/day is commonly used. Loadings above this level tend to produce excessive biofilm thickness and possible structural overloading, varying motor loads and rotational speed, oxygen limitation and odors, reduced BOD removal efficiency, and nuisance growths of *Beggiatoa* spp. If recycles are returned to the primary clarifier, their BOD load must be included. The first stage will remove the greatest amount of BOD, and it may require supplementary diffused air.

The remaining shafts calculated from Eq. (11.137) are distributed uniformly among the parallel trains. Staging is achieved by placing a removable baffle between each shaft in a train.

The nitrification staging proceeds similarly. The settled effluent of the CBOD removal process is the influent of the nitrification process. The media area is determined by the NPDES permit conditions, the expected available TKN determined by Eq. (11.138), and the areal nitrification rate determined by Eq. (11.139). This area is usually multiplied by a safety factor of 1.25. The use of Eq. (11.130) implies a completely mixed tank, but each shaft may be baffled, and this will give an additional safety factor.

Waste Solids Production

The Aerobic Fixed-Growth Reactors Task Force (2000) estimates waste solids production to be between 0.5 and 0.8 kg per kg BOD_5 removed, with the higher yields occurring in cold weather and at high organic loading rates.

The underflow from the secondary clarifier will contain about 2.5 to 3% solids and may be gravity thickened to about 5% solids.

Operation and Design Problems

Some of the early RBC installations exhibited an excessive rate of mechanical and structural failures, but newer installations do not.

Present-day operation and design problems include the following (Aerobic Fixed-Growth Reactors Task Force, 2000):

- Excessive first-stage loadings: remove baffles between first and second stages to reduce BOD concentrations in the first stage; increase aeration by increasing rotational speed or adding supplementary diffused air; bypass some influent to second or later stages
- Excessive or uneven biomass accumulation on the discs: reduce loadings on the discs as above; clean discs; take discs out of service to starve biomass
- Inadequate solids control and loss of fine SS in final effluent: reduce high hydraulic loadings by equalization; recirculate some secondary clarifier underflow sludge to the RBC first stage to promote flocculation of fines; add coagulant prior to secondary clarifier inlet
- Corrosion of metal supports

Anaerobic Rotating Biological Contactors

Tait and Friedman developed the anaerobic rotating biological contactor (AnRBC) at bench-scale in 1980 and studied it as a sludge digestion process.

Dimensional analysis indicates that the relevant process variables are as follows (Phoon, 1982):

- The dimensionless methane yield: mass of methane produced per mass of COD fed, R_{CH_4}/R_{COD}, kg/kg
- The disc Reynolds number: fd/D_l
- The product of the disc rotational speed and the hydraulic retention time: τf

In Phoon's study, the gas production and COD loading data for AnRBCs fed primary sewage sludge could be correlated by,

$$\ln\left(\frac{R_{CH_4}}{R_{COD}}\right) = a\ln(\tau f) + b \tag{11.140}$$

where a,b = empirical constants, possibly depending on the disc Reynold's number (dimensionless)
d = the disc diameter (m)
f = the disc rotational speed (rev/sec, Hz)
R_{CH_4} = the rate of production of methane (kg/s)
R_{COD} = the rate of feed of COD (kg/s)
τ = the HRT (s)

Combination Fixed-Growth Suspended-Growth Processes

A number of combined fixed-growth suspended-growth processes are available, most of which are patented.

CAPTOR™ and LINPOR™

The CAPTOR™ processes use polyether foam pads about $30 \times 25 \times 12.5$ mm in size, and the LINPOR™ process uses 10×13 mm cubes. The pads and cubes are suspended in the aeration tank and retained by effluent screens. They retain a substantial amount of the biomass and allow high biomass concentration up to 9000 mg/L without overloading the secondary clarifier. The CAPTOR™ system uses about 25 pads/1000 m^3 of mixed liquor.

Moving Bed Biofilm Reactor (MBBR)

The moving bed biofilm reactor marketed by the Kaldnes Miljøteknologi Corporation consists of polyethylene cylinders 10 mm in diameter and 7 mm long suspended in the aeration tank. The packed aeration tank has a specific surface area on the cylinder of 500 m^2/m^3. Again, the packing allows high biomass concentrations. Perforated plates retain the cylinders. The secondary clarifier captures any lost biofilm. All the clarifier underflow is wasted; no sludge recirculation is attempted.

PACT™

DuPont markets the powdered activated carbon treatment (PACT™) process in which powdered activated carbon is added to the aeration basin. The usual application is to industrial wastewaters containing toxic or recalcitrant compounds that are sorbable to activated carbon. The PAC forms a matrix with the biomass, and the biomass may degrade the sorbed matter as well as suspended and soluble organic matter. The chief advantages are improvement in the following (Joint Task Force, 1992):

- Settling rates
- Dewaterability
- Biorefractory compound removal
- Odor removal
- Color removal

The PACT™ process can be sized to nitrify, if desired. Many industrial facilities practice single-pass use of the carbon with disposal, but carbon regeneration is feasible in larger plants.

Contact Aeration

In contact aeration units, narrowly spaced, vertically oriented, flat-plate media fill the upper portion of the aeration tank and are completely and continuously submerged by the mixed liquor. Aeration is provided by diffused air on the tank bottom, and the bubbles rise between the plates, providing oxygen, enhancing mass transfer to the plates, and scouring excess biomass from them. Some of the early designs used wooden laths, granular media, wire screens, brushwood, and even corncobs. Synonyms are *nidus racks*, *tank filters*, *Imhoff filters,* and *Emscher filters*.

A variety of early and recent designs are described by Black and Phelps (1911), Clark and Gage (1913), Bach (1937a, 1937b), Buswell (Anonymous, 1923), Imhoff (1926a, 1926b), Buswell and Pearson (1929), Kato and Sekikawa (1968), and Rusten (1984). The first German plant was used to treat phenolic coke oven wastes at the Helene coalmines near Essen in the mid 1920s. The first American installation was built at Jacksonville, TX, in 1927.

Configuration

Contact aeration systems include preliminary treatment to remove grit and debris, primary settling and scum removal, two-stage contact aeration with intermediate and final settling, disinfection, and sludge stabilization.

The final development in the U.S. was the Hays process ca. 1930 (Griffith, 1943). A Hays plant generally incorporates two aeration basins separated by an intermediate clarifier as well as primary and final clarifiers. Sludges are collected from each clarifier and aeration tank and are wasted without any recycle to the process. The aeration tanks were filled with vertical asbestos plates and have hopper bottoms to collect scoured biomass. The first municipality to adopt the Hays process was Elgin, TX, in about 1938.

Design Criteria

The design load is taken to be the maximum 3-hr load and flow, and is estimated to be 150% of the annual average (Griffith, 1943). The contact plates are flat or corrugated and 8 ft high × 4 ft wide × ¼ in. thick and spaced 2 in. center-to-center normal to the flow direction. The plates are evenly distributed between the two equal-size aeration tanks, and each aeration tank is divided into halves by baffles. There is normally 6 in. of clearance above the air diffusers on the bottom and 4 in. clearance below the water surface.

The design criteria for U.S. Army plants built in the 1940s were as listed below (Mohlman et al., 1946; Fair et al., 1948):

- The first-stage BOD loading was set at an average rate of 6.4 lb BOD/1000 ft^2/day.
- The second-stage BOD loading should be the same, 6.4 lb BOD/1000 ft^2/day.
- The aeration tanks have equal HRTs of about 1.5 to 2.5 hr each.
- The primary settling HRT is 2.5 hr.
- The intermediate clarifier HRT is 1.5 hr.
- The final clarifier HRT is 2.5 hr (Fair et al., 1948).
- The required air supply is at least 1.5 ft^3 air/gal sewage split 60/40 between the first and second aeration tanks.

The total system volume is not much less than that of an activated sludge plant.

The BOD removal efficiency can be estimated by (Mohlman et al., 1946; Fair et al., 1948),

$$E = \frac{100}{1 + 0.248 w_a^{0.746}} \tag{11.141}$$

where E = the annual average BOD_5 removal efficiency, settled influent sewage to settled effluent (%)
w_a = the annual average mass loading rate of BOD_5 (lb/1000 ft^2/hr). Equation (11.141) applies to each stage separately and to both stages combined. The scatter is significant, and only five plants were used to develop the correlation.

The principal problems of the contact-aeration process are as follows (Mohlman et al., 1946):

- Inadequate oxygen transfer with the resulting development of anaerobic conditions in the biofilm and odor production, especially hydrogen sulfide
- Excessive biofilm buildup requiring frequent plate cleaning

Modern Submerged Fixed-Growth Processes

The Joint Task Force (1992) reviewed a large number of fixed submerged packing systems, consisting of high-density media that rest on the tank floor (BIOCARBON™, BIOFOR™, DENITE™, DYNASAND™, FITRAZUR™, FLOPAC™, NITRAZUR™, and OXYAZUR™); low-density media that float and require some sort of retaining system (BIOFILTER™, BIOSTYR™, and DENIPOR™); media suspended in the aeration tank (RINGLACE™ and BIO-2™); and fully submerged rotating biological contactors (SURFACT™).

Some of these processes operate downflow (BIOCARBONE™), and others operate upflow (BIOFOR™). Some packings retain the biomass so that settling of the effluent is unnecessary. However, all packings must be periodically backwashed to remove excess growth. The empty bed HRTs are generally about 1 to 1.5 hr, so the units are small compared to equivalent activated sludge processes. Control systems and instrumentation are relatively complex (Metcalf & Eddy, Inc., 2002).

Trickling Filter-Solids Contacting and Trickling Filter-Activated Sludge

Tricking filters and suspended growth processes have been combined in two ways: the trickling filter-activated sludge (TFAS) process and the trickling filter-solids contact (TFSC) process. In either case, the trickling filter usually discharges directly (without clarification) to an activated sludge plant.

In the TFAS, the activated sludge process may be nitrifying or nonnitrifying, but nonnitrifying is more common. Soluble BOD removal occurs in the trickling filter, and influent particulate BOD and lost trickling filter biomass are decomposed (at least partially) in the activated sludge unit. For a nonnitrification design, the roughing trickling filter is loaded at about 1.2 to 4.8 kg BOD/m^3/day, and the activated sludge process has a HRT of 10 to 60 min and an SRT of 2 to 7 days. The overflow rate on the secondary clarifier is usually 2.0 to 3.5 m/h at peak flow (Metcalf & Eddy, Inc., 2002).

If the influent wastewater contains a significant amount of toxic substances, and if nitrification is to be guaranteed, a secondary clarifier may be installed between the trickling filter and the aeration tank. In this arrangement, the underflow of the intermediate clarifier is wasted and not recycled in order to remove any sorbed poisons. The process loadings are the same as for the TFAS scheme (Metcalf & Eddy, Inc., 2002).

In the TFSC, more of the BOD removal is transferred to the trickling filter, and the solids contacting process serves more as a flocculation step. Nitrification may occur in the trickling filter at the lower loadings. The trickling filter is loaded at about 0.3 to 1.2 kg BOD m^3/day, and the solids contacting tank has an HRT of 10 to 60 min and an SRT of 0.3 to 2 days. The peak clarifier overflow rate is between 2 and 3 m/h (Parker and Bratby, 2001). TFSC plants also incorporate a flocculator/clarifier for the secondary settling step and may include sludge reaeration. Both of these processes are intended to improve solids flocculation and capture. The return sludge from the flocculator/clarifier or reaeration tank is pumped to the inlet end of the solids contact tank.

11.4 Ponds

General Considerations

Classification

Ponds (lagoons) are artificial bodies of surface water designed and constructed to provide wastewater treatment and storage. The most common designs are as follows:

- **Mechanically aerated** — Oxygen supplied by surface aerators, diffused air, etc.
- **Facultative** — Surface layers aerobic by atmospheric reaeration and photosynthesis, bottom layers anaerobic
- **Maturation (polishing, tertiary)** — A long detention time pond that receives the effluent of a secondary treatment system
- **Anaerobic** — Fully anaerobic, treating concentrated wastes and producing methane

Depending on the NPDES permit, the discharge from a pond may be as follows:

- **Continuous** — Continuous, unregulated discharge to a receiving water
- **Intermittent, controlled, or hydrograph controlled** — Discharge only during specified periods and in specified amounts
- **Total containment, nonoverflow, or evaporation/infiltration** — Discharge only via evaporation and/or infiltration (if permitted)

Configuration

A pond system will consist of the following:

- Preliminary screening and grit removal to protect pumps and surface aerators against clogging by debris and to minimize grit accumulation
- The ponds
- Final clarifiers and/or filters to remove suspended biomass
- Disinfection
- Ancillary equipment and storage sheds
- All-weather access roads and parking
- Groundwater monitoring wells
- Fencing and buffer strips

Pond sites should be graded to divert storm water away from the dikes to prevent toe erosion (Wastewater Committee, 1997). In order to prevent liner rupture by bouyant uplift or differential settling, the pond bottom should be at least 4 ft above the top of the groundwater table and 10 ft above any bedrock.

The pond should be subdivided into at least three cells-in-series (Wastewater Committee, 1997). To prevent short-circuiting, no cell may be larger than 40 ac in plan area. Piping should permit isolation and bypassing of each cell for maintenance. The cells are generally rectangular with length-to-width ratios of 3:1 to 4:1. The minimum depth for any pond is 2 ft. Specific types of ponds may have other minimum depths.

Gloyna (1971) provides many recommendations on the design of pond appurtenances.

Dikes and Liners

Cells may share common-wall dikes (Wastewater Committee, 1997). The dikes should be at least 8 ft wide on top for vehicular traffic and have both inner and outer side slopes no steeper than 1 vertical on 3 horizontal. Inner side slopes should be no flatter than 1 vertical on 4 horizontal. The minimum freeboard is 3 ft. The dikes shall be constructed of impervious soil and compacted to 90% standard proctor density. The dikes may not contain or rest on vegetation, peat, roots, or other unstable material. Prior to filling, dikes shall be covered with 4 in. topsoil and seeded with perennial, low-growing, spreading grasses from the outside toe to 2 ft above the pond bottom on the interior slope. Additional riprap may be required on the inner slope to prevent wave erosion and on the outer slope to prevent flood damage from nearby streams or lakes. Riprap on the inner slope should extend from 1 ft above the high water level to 2 ft below the low water level.

Dikes should be inspected regularly for erosion damage by wind, waves, and runoff and for damage by burrowing animals and long-rooted plants (Gloyna, 1971).

Pond bottoms should be flat, impervious, and compacted to at least 90% standard proctor density. Unless the pond is permitted for groundwater recharge, most jurisdictions will require an impermeable pond liner. Typically, the water permeation through the bottom should be less than 500 gal/ac/day.

Piping

Inlet, outlet, and transfer piping should be noncorroding, provided with adequate access for cleaning and maintenance, and valved to permit flow control. Ductile iron is preferred by some jurisdictions, but the usual materials of sanitary sewerage construction (concrete and fired clay) are acceptable. Antiseepage collars should be provided wherever the piping pierces a liner. All piping must be protected from settlement, erosion, and ice.

Influent piping should discharge below the lowest operating level of the pond to avoid nuisance. If the inlet pipe is horizontal, it may lie on the top of the pond bottom, but it should be supported, especially at the discharge end, and provided with a discharge apron at least 2 ft square to protect the liner. A vertical upwards discharge is preferred. This may be a simple bend or discharge bell, but it needs a supporting structure to avoid damage to the liner. Although traditional designs favor single inlet pipes, multiple discharge ports or manifolds give better distribution of the flow across the pond and are preferred. This is less of an issue in mixed, mechanically aerated ponds, but it is a serious problem in anaerobic ponds, which normally treat sludges that accumulate around the inlet pipe's exit. The point of discharge should be located about one-third of the way from the upstream end of the point to the outlet.

Transfer piping should be located so as to minimize short-circuiting. This is usually accomplished by placing a given cell's inlets and outlets catercorner. The discharge should be horizontally or vertically upward, and discharge aprons should be provided to avoid bottom erosion. The pipe should be supported.

Outlet piping is usually submerged and located at least 10 ft horizontally from the toe of the dike and at least 2 ft above the pond bottom. Ponds that stratify may be equipped with multilevel takeoffs. For constant discharge and/or shallow warm ponds, floating surface overflow takeoffs may be installed. All outlet piping should be equipped with scum baffles and should be valved to prevent the receiving water from entering the pond at flood.

Ponds should be equipped with emergency spillways to prevent dike failure by overtopping during extreme inflow events, diversion (bypass) valves and pipes, drainage valves and pipes, and provisions for water level control.

Pond Loadings and Effluent Quality

The areal BOD loading rate largely determines the performance of all waste stabilization ponds naturally aerated by photosynthesis and oxygen uptake from the atmosphere. The effluent BOD_5 data from a large number of ponds fall below the following envelope (Aguirre and Gloyna, 1970):

$$C_{\mathrm{BOD}e} = 55 + 0.21 w_a - 45 e^{-0.038 w_a} \tag{11.142}$$

where $C_{\mathrm{BOD}e}$ = the total effluent BOD_5 (mg/L)
w_a = the areal BOD_5 loading rate (lb BOD_5/ac/day).

The data were collected from tertiary (maturation), facultative, and anaerobic ponds. Performance data on specific processes are given below.

Kinetic Models

Ponds are sometimes modeled assuming first-order decay of BOD and coliform. Common flow models are (a) for *each cell* in mixed-cells-in-series,

$$\frac{C_e}{C_o} = \left(\frac{1}{1 + k\tau_1} \right) \tag{11.143}$$

and (b) for *each cell* in plug-flow-with-dispersion,

$$\frac{C_e}{C_o} = \frac{4a \cdot \exp\left[\frac{1}{2}(1+a)\boldsymbol{Pe}\right]}{(1+a)^2 \cdot \exp[a\boldsymbol{Pe}] - (1-a)^2} \tag{11.144}$$

where $a = \sqrt{1 + \left(4kD_a / u^2\right)}$, (dimensionless)
C_e = the effluent concentration (mg/L or cells per 100 mL)
C_o = the influent concentration (mg/L or cells per 100 mL)
D_a = the axial dispersion coefficient (m^2/s)

k = the first-order decay rate (per s)
L = the length of the cell (m)
Pe = the turbulent Peclet number (dimensionless)
$= uL/D_a$
Q = the total flow through the cell (m^3/s)
u = the horizontal velocity (m/s)
V_1 = the volume of one cell (m^3)
τ_1 = the detention time of one cell (s)
$= V_1/Q$

Axial dispersion is strongly influenced by wind and should be determined *in situ* by tracer studies.

BOD Decay Rate

The Wastewater Committee (1997) recommends a BOD_5 decay rate of 0.28 per day at 20°C and 0.14 per day at 1°C. Other authorities make similar recommendations (Reed et al., 1995). The Streeter–Phelps theta value for BOD decay is about 1.036.

Coliform Decay Rate

Pathogen decay is believed to be the result of predation, starvation, settling, and ultraviolet light irradiation during the daytime. The decay rates of bacteria in ponds is not well established, but it seems clear that highly loaded ponds are less effective than lightly loaded ponds (Gloyna, 1971). Oakley et al. (2000) recommend the following coliform decay rates:

Heavily loaded facultative ponds:

$$k = 0.48 \times 1.18^{T-20} \tag{11.145}$$

Facultative ponds:

$$k = 0.90 \times 1.04^{T-20} \tag{11.146}$$

Maturation ponds:

$$k = 0.81 \times 1.09^{T-20} \tag{11.147}$$

where k = the coliform decay rate (per day)
T = the pond temperature (°C).

Effluent Solids Removal

The effluent BOD of any pond consists almost entirely of suspended heterotrophic bacteria and algae. If required, effluent suspended solids removal can be achieved by intermittent sand filtration or land application.

Mechanically Aerated Ponds

Mechanically aerated ponds are extended aeration plants. There is no sludge recycle, although secondary clarification to capture the net solids production is usual. Detention times are on the order of 1 month, and oxygen is supplied by surface aeration or by submerged air diffusers. Aerated ponds are widely used in the treatment of wastewaters at isolated industrial facilities.

Configuration

Mechanically aerated ponds systems generally consist of the following:

- Preliminary treatment to remove grit, debris and rags to prevent nuisance and clogging of aerators, pumps, and weirs
- The aerated pond
- Secondary clarification without solids recycle
- Disinfection

The pond must consist of at least two aerated cells-in-series followed by a final polishing cell with volume equal to at least 30% of the combined volume of the aerated cells. The depth should be 10 to 15 ft.

Aerators

Aerators must provide oxygen and mixing. The minimum mixing energy for low-speed mechanical aerators may be estimated by Rich's equation (Metcalf & Eddy, Inc., 2002):

$$P_v = 0.004X + 5; \quad X \le 2{,}000 \text{ mg/L} \tag{11.148}$$

where P_v = the required mixing power (kW per 1000 m^3)
X = the MLSS (mg/L).

Equation (11.148) includes a safety factor of 1.25 to 1.5. The threshold mixing power for solids suspension is about 1.5 to 1.45 kW per 1000 m^3.

Closely spaced aerators interact, reducing oxygen transfer and bottom scour. Widely spaced aerators produce unmixed, unaerated dead zones. The maximum spacing should be 0.8 m per kW of installed power but not more than 75 m (Metcalf & Eddy, Inc., 2002). For 75 kW aerators, a minimum spacing of 70 ft and a maximum water depth of 15 ft are recommended (Price, Conway, and Cheely, 1973). Surface aerators in deep basins should be equipped with bottom impellers or draft shrouds and downward-mixing surface impellers should be installed between the aerators, or both.

Kinetics

Equation (11.143) should be applied separately to each of the aerated cells (Wastewater Committee, 1997).

Facultative Ponds

Because of their simplicity, facultative ponds are the most common municipal pond systems. Facultative ponds depend upon natural surface aeration and photosynthesis for oxygen. The sediments and the water layer adjacent to them are usually anaerobic.

Facultative ponds are classified as *controlled-discharge*, in which the rate of discharge is a fixed, constant rate, or *flow-through*, in which there is no control of the discharge rate.

Configuration

In all cases, the system configuration includes at least the following:

- Preliminary treatment to remove grit, debris and rags to prevent nuisance and clogging of piping, pumps, and weirs
- The pond
- Disinfection

Both controlled-discharge and flow-through facultative ponds should consist of two equal-volume *primary* cells-in-series followed by a *secondary* cell of equal or greater (preferred) volume (Wastewater Committee, 1997). The maximum depth in the primary cells should be 6 ft, and the minimum operating depth should be 2 ft. The secondary cells should be at least 8 ft deep to promote suspended solids settling.

Gloyna (1976) recommends a depth of 1 m for tropical and subtropical ponds and 1.5 m for temperate ponds with significant seasonal variations in temperature. In either case, the design surface area is for the operating depth of 1 m.

Areal BOD Loading Rate

In controlled-discharge systems and flow-through systems, the annual average areal BOD_5 loading rate on the primary cells should be limited to 15 to 35 lb BOD_5/ac/day at the mean operating depth (Wastewater Committee, 1997). Detention time in controlled-discharge systems should be 180 days for the volume between the minimum and maximum operating depths. In flow-through systems, the detention time must be at least 90 to 120 days. Longer detention times are needed in cold climates.

In flow-through systems, the primary cells should be designed to maximize BOD removal at peak flow.

Empirical Models

An empirical adjustment of the Gloyna–Espino (1969) formula for facultative ponds yields the following (Reed et al., 1995):

$$V = 0.035QC_{\mathrm{BOD}o} \cdot 1.099^{I(35-T)/250} \tag{11.149}$$

where $C_{\mathrm{BOD}o}$ = the influent BOD_5 (mg/L)
I = the mean solar radiation (Langley's)
Q = the influent sewage flow rate (m^3/d)
T = the average pond temperature for the coldest month (°C)
V = pond volume (m^3)

About 85 to 95% BOD removal can be expected for facultative ponds having this volume. In the case of domestic wastewaters, temperature is the most important factor in pond design, and the design temperature should be for the coldest month of the year.

Sulfides

Anaerobic bacteria in the pond sediments reduce sulfate to sulfide, which is toxic to algae at concentrations above about 6 mg/L. This reduces the oxygen supply to the heterotrophic population, which in turn, reduces BOD removal efficiency and produces nuisance odors. This usually becomes a problem when the influent sulfate concentration exceeds 500 mg/L. The sulfide concentration can be estimated by the following (Gloyna and Espino, 1969):

$$S_{S^{2-}} = \left(0.000118w_a + 0.00166\tau + 0.0553\right)S_{SO_4^{2-}} \tag{11.150}$$

where $S_{S^{2-}}$ = the pond sulfide concentration (mg/L)
$S_{SO_4^{2-}}$ = the influent sulfate concentration (mg/L)
w_a = the ultimate BOD areal load (lb BOD_u/ac/day)
τ = the pond detention time (days)

The sulfide concentration can be reduced by reducing the areal BOD_u loading rate, which has the effect of increasing the pond area.

Bottom Sludge

Sludge and grit accumulate on the bottom of facultative ponds. The amount of sludge at any time can be estimated from the following:

$$m_s = \frac{R_{SSo}}{k_s}\left(1 - e^{-k_s t}\right) \tag{11.151}$$

where k_s = the first-order organic sludge decay rate (per day)
$\approx 0.002 \times 1.35^{T-20}$ (Gloyna, 1971)
m_s = the mass of organic sludge in the primary cells (kg)
R_{SSo} = the settleable solids input rate in the influent wastewater (kg/day)
t = the age of the sludge deposit since the last cleaning (days)

Municipal sewage transports about 95 g VSS/cap/day (Table 8.14). Perhaps two-thirds is settleable. A significant portion of the inorganic fraction of the sewage sludges is intracellular matter and is solubilized during decay and exits in the pond discharge. The grit content of municipal sewage is highly variable between cities, ranging from 0.4 to 10.5 ft^3/mil gal. (Joint Task Force, 1992). Grit does not decay but merely accumulates.

Insects

Mosquitoes are a potential seasonal problem and disease vector in facultative ponds (Gloyna, 1971). They may be controlled by the removal of any emergent vegetation from the pond, as such vegetation provides breeding sites.

Maturation Ponds

The principle purpose of maturation (tertiary, polishing) ponds is the elimination of pathogens and parasites. They are placed last in the process train, and they treat the stable effluents of activated sludge plants, trickling filters, and other ponds. The maturation pond effluent may be disinfected.

Gloyna (1971) recommends maturation pond detention times of 7 to 10 days and depths of 1 m. Leffel et al. (1977) recommend that maturation ponds be constructed as three equal-volume cells-in-series, each cell having a detention time of 5 days. They also observe that the effluent will contain substantial algal concentrations unless the depths are 3 to 8 ft and the detention times are reduced to 48 hr/cell.

Coliform Decay Rate

An apparent first-order decay rate for fecal coliform that incorporates ultraviolet sunlight irradiation may be approximated by the following (Mayo, 1989):

$$k = k_d + \frac{k_s I_o \left(1 - e^{-k_e H}\right)}{k_e H}$$
$$\approx 0.108 + 0.579 \times 10^{-3} \times \frac{I_o}{H};\ \text{at 26 to 34 °C;}\ r = 0.68 \qquad (11.152)$$

where H = the mean depth of the pond (m)
I_o = the average daily solar irradiation at the pond surface (cal/cm^2)
k = the overall bacterial die-off coefficient (per day)
k_d = the dark bacterial die-off coefficient (per day)
k_e = the light extinction coefficient in the pond (per m)
k_s = the specific solar die-off coefficient (cm^2/day/cal)

Some additional data on coliform decay in ponds are given above in the "Coliform Decay Rate" section.

Insects

Mosquitoes are a potential seasonal problem and disease vector in maturation ponds (Gloyna, 1971). They may be controlled by the removal of any emergent vegetation from the pond, as such vegetation provides breeding sites. Maturation ponds also may be stocked with top feeding minnows to prey on the larvae. Midges may also develop in lightly loaded ponds.

Anaerobic Ponds

Anaerobic ponds are designed to treat high-strength wastes and function as anaerobic digesters. Methane production is the key objective, as it minimizes odors and yields a useful by-product. At larger installations, it may be practicable to collect the methane produced. The usual expectation is about 12 ft^3 of total gas (1 atm, 32°F) per day per population equivalent, of which 65% by vol will be methane. The liquid effluent from anaerobic ponds generally contains about 100 to 250 mg/L of BOD_5, and the overall BOD_5 removal efficiency is about 50 to 60% (Aguirre and Gloyna, 1970; Dinges, 1982).

Configuration

Anaerobic ponds are almost always constructed as the first stage of a two-stage anaerobic/facultative (or aerated) pond system.

Most anaerobic ponds are uncovered, and areal loading rates need to be high enough to minimize oxygen penetration. A loading of about 90 lb BOD_5/ac/day will limit oxygen penetration to the top 2 ft of the pond, and a loading of 130 lb BOD_5/ac/day will limit it to the top foot (Oswald, 1968). The usual loading is 150 to 1000 lb BOD_5/ac/day (Aguirre and Gloyna, 1970).

The liquid detention time in the supernatant should be kept relatively short, say 2 to 4 days, to minimize the top surface area. Liquid detention times longer than 4 days result in lower BOD removal (Dinges, 1982).

Pond depths should be 4.5 to 6.0 m (Dinges, 1982). An allowance should be made for sludge solids storage. Domestic wastewaters produce about 0.04 ft^3 of raw wet primary sewage sludge per cap per day and 0.07 ft^3 of raw wet waste activated sludge per cap per day (Fair and Geyer, 1954).

The active sludge digestion volume in an unmixed tank can be approximated as follows (Fair and Geyer, 1954):

$$V = \left[Q_f - \tfrac{2}{3}\left(Q_f - Q_d\right)\right] t_d \tag{11.153}$$

where Q_d = the volumetric flow rate of digested sludge (m^3/s)
Q_f = the volumetric flow rate of fresh sludge (m^3/s)
t_d = the required digestion time (s)
V = the active sludge digestion volume in the digester (m^3)

Additional volume must be allowed for digested sludge storage and for supernatant formation. In general, the volume of digested wet primary sewage sludge is about one-fourth the volume of fresh primary sewage sludge, and the volume of a mixture of digested primary and waste activated sludge is about 40% of that of the raw mixture (Fair and Geyer, 1954). The solids' retention time required for substantially complete digestion, assuming adequate seeding, is about 75 days at 50°F, 56 days at 60°F, and 42 days at 70°F.

Some meatpacking wastes are relatively warm because of hot water use in cleanup operations, and the decay of high-strength wastes releases significant metabolic energy. Pond designers attempt to conserve this heat by minimizing total surface area, top, sides, and bottom. Small top areas also minimize oxygen transfer into the pond, which permits the accumulation of methanogenic organisms.

Below 15°C, and for a pond loading of 425 lb BOD_5/ac/day, the gas production rate in anaerobic ponds is about 500 ft^3 (1 atm, 32°F) per ac per day (Oswald, 1968). Above 15°C, the gas production rate increases nearly linearly up to a rate of 6600 ft^3 (1 atm, 32°F) at 23°C at the same loading.

Kinetics

The required detention time of anaerobic ponds may be correlated with the input and output BOD concentrations by the following (Gloyna, 1971):

$$\tau = \frac{\dfrac{C_{\mathrm{BOD}o}}{C_{\mathrm{BOD}e}} - 1}{k\left(\dfrac{C_{\mathrm{BOD}e}}{C_{\mathrm{BOD}o}}\right)^n} \tag{11.154}$$

where k = an empirical rate constant (per s)
n = an empirical exponent (dimensionless).

In tropical countries, a rate constant of about 6 per day and an exponent of about 4.8 have been reported.

Insects and Odors

Floating scum and manure may support houseflies and stable flies, which are both nuisances and disease vectors. Scum and manure should be broken up and submerged by hosing, the pond should be covered to permit gas collection, or both (Gloyna, 1971).

11.5 Land Application

A wide variety of land application schemes and objectives have evolved, including the following:

- Irrigation of food and fiber crops, sod farms, tree farms, pasture, and golf courses for tertiary wastewater treatment, commercial crop and animal production and recreation
- Wetlands for tertiary wastewater treatment and wildlife conservation
- Rapid infiltration of tertiary effluents for groundwater recharge and storage
- Bioretention facilities for storm water runoff interception and treatment
- Overland flow for secondary wastewater treatment

Crop irrigation, wetlands, and overland flow are described below.

All land treatment schemes require at least the following:

- Preliminary treatment to remove debris, rags and grit to prevent nuisance and clogging of piping and pumps
- Primary settling and skimming to remove settleable solids and scum

- A storage/treatment pond
- A wastewater distribution system
- The wastewater application area
- A drainage collection system
- Disinfection
- Ancillary equipment and storage sheds, influent/effluent monitoring facilities, all-weather roads, fencing, and buffer strips

Most land application systems also incorporate secondary pretreatment for organic matter removal and stabilization. A commonly used secondary treatment process is the facultative pond, which also serves as a flow-storage device when wastewater cannot be applied to land.

Most jurisdictions also enforce one or more of the following restrictions:

- A flat prohibition on site runoff, which requires water storage during freezing or wet weather and the determination of allowable infiltration and percolation rates
- Limitations on the scheduling of wastewater applications and the kinds of crops and animals raised to protect consumers, workers, and animals from infection
- Limitations on the kinds of crops irrigated and pretreatment schemes tailored to meet the needs of specific crops, especially regarding salts
- Limits on the nitrogen fluxes into the underlying groundwater, which may control crop types and usually requires drainage systems for the interception of the percolating, treated wastewater
- Buffer strips and restrictions on application methods to minimize odor nuisance and pathogen and parasite spread by aerosols

The *stabilized*, *disinfected* sludges produced by modern wastewater treatment plants also are often (if not usually) disposed of on land. The sludges are first treated to stabilize them and destroy pathogens and parasites, and they must be monitored for a variety of metals and other contaminants. The 503 Rule for sludge disposal on land is described below.

Crop Irrigation (Slow-Rate Infiltration)

Crop irrigation is most widespread in arid areas, where the water is of major economic value. In these applications, the water requirement is usually seasonal, during summer drought, and the nutrient benefit of the wastewater is negligible. The health of consumers, plant workers, and animals, which have direct contact with the crop and/or irrigated area, is a major concern. Designers also must consider crop management as well as the quality of the drainage water produced.

There are two general types of crop irrigation (Pettygrove et al., 1984; Reed, Crites, and Middlebrooks, 1995). In Type I Slow-Rate Infiltration, the focus is on crop production, and crop yield (and land utilization) is maximized. Salinity control is a major concern. In Type II Slow-Rate Infiltration, cropping is necessary but secondary. Land use is limited to the minimum required for the allowable water flux or nitrate flux.

Treatment Mechanisms

Soils filter and flocculate particulate organics, which the soil flora and faunae then consume or decompose. The flora and faunae include a wide variety of bacteria, fungi, insects, insect larvae, "bugs," and "worms." Bacteria and fungi directly absorb and metabolize soluble organics. These decomposition processes produce the slowly degrading humus that increases the soil's water retention, air and water permeability, resistance to compaction, nutrient availability, and anion and cation exchange capacity (Taylor and Ashcroft, 1972). Some of the particulate organics are pathogens and parasites, and soil microbes prey upon and destroy them.

Nitrifying bacteria oxidize ammonia nearly completely to nitrate. Some of the nitrate enters the groundwater, some of it is denitrified and lost as nitrogen gas, and the crop consumes some of it.

Phosphates and many metal ions are adsorbed or ion-exchanged by soil clay minerals and humus.

Drainage Water Quality

Crop irrigation systems are capable of high levels of wastewater treatment, and the typical drainage water composition is as follows (Sopper and Kardos, 1973):

- BOD_5 = 1 mg/L
- COD = 10 mg/L
- NO^{3-} = TKN – crop uptake
- PO_4^{3-} = 0.5 mg/L
- Coliform count = very low, but not potable

Inorganic Contaminants

Wastewaters containing substantial concentrations of metals and metalloids are not suitable for land irrigation treatment (Table 8.5). Cadmium, copper, molybdenum, selenium, and zinc are accumulated by many crops, making them toxic to consumers (Wright, 1973). Boron, copper, nickel, and zinc are also toxic to many crops and may cause process failure. Metals entering conventional wastewater treatment plants tend to concentrate in the waste sludges, and EPA regulations prohibit the application of metal-enriched sludges to irrigation plots.

Pathogens and Parasites

There is a significant health hazard to using sewage on crops and pasture, and all states require that sewage be disinfected prior to use. A common requirement is a fecal coliform count less than 1000/100 ml (Table 8.5).

In general, wastewaters should not be used to irrigate crops eaten raw, like lettuce, celery, and tomatoes or on root crops, like carrots and potatoes, even if they are cooked. Treated wastewater may be used to irrigate grasses like alfafa, corn, oats, rye, and wheat. In these permissible cases, the edible portion of the plant is exposed to sunlight, which is germicidal, and it is usually cooked.

Nutrients

If the crop needs additional nitrogen and phosphorus beyond that in the soil and wastewater, commercial fertilizers and stabilized or composted sewage sludge solids should be used. Dried primary solids typically are 1 to 1.5% by wt phosphorus as P_2O_5 and 1 to 3.5% by wt nitrogen as NH_4NO_3; secondary solids are typically 3 to 5% by wt P_2O_5 and 4 to 7% by wt NH_4NO_3; and digested solids are 0.5 to 0.7% by wt P_2O_5 and 1 to 4% by wt NH_4NO_3 (Babbitt and Baumann, 1958). Sludges also release nutrients more slowly, which makes nutrient capture by the crop more likely.

Salinity

Deflocculation often occurs when the sodium/calcium ratio becomes large, and clays disperse. The usual design criterion is the sodium adsorption ratio (SAR):

$$SAR = \frac{\{Na^+\}}{\sqrt{\frac{1}{2}\left(\{Ca^{2+}\} + \{Mg^{2+}\}\right)}} \tag{11.155}$$

where SAR = the sodium adsorption ratio (dimensionless)
$\{Ca^{2+}\}$ = the calcium ion concentration (meq/L)
$\{Mg^{2+}\}$ = the magnesium ion concentration (meq/L)
$\{Na^+\}$ = the sodium ion concentration (meq/L)

An SAR less than 3 indicates a low risk of permeability loss, and an SAR of 8 or more indicates a high risk (Table 8.5; Taylor and Aschcroft, 1972).

High total salt concentrations also inhibit many crops. An electrical conductivity less than 0.75 mmhos per cm (25°C) minimizes the deleterious effects on most crops (Table 8.6; Taylor and Aschcroft, 1972).

Hard, alkaline wastewaters also exhibit large increases in pH upon evapotranspiration, which also injures some crops. This is usually explained by a carbonate/bicarbonate equilibrium shift (Stumm and Morgan, 1996):

$$\frac{m_{CO_3^{2-}}}{\left(m_{HCO_3^-}\right)^2} = \frac{K_1}{K_2 K_H p_{CO_2} V} \tag{11.156}$$

where K_1 = the first acid dissociation constant of carbonic acid (mol/L)
K_2 = the second acid dissociation constant of carbonic acid (mol/L)
K_H = the Henry's law constant for carbon dioxide and water (mol/L Pa)
$m_{CO_3^{2-}}$ = the mass of carbonate in solution (mol)
$m_{HCO_3^-}$ = the mass of bicarbonate in solution (mol)
p_{CO_2} = the partial pressure of carbon dioxide in contact with the wastewater (Pa)
V = the volume of wastewater (m^3)

As the solution volume evaporates, the dissolved carbonate-to-bicarbonate ratio rises, and so does pH.

Besides the pH effect, evaporation of hard, alkaline waters precipitates calcium carbonate, which may reduce soil permeability and cement it, and increases the SAR.

Most of these effects can be offset by proper management of irrigation water, providing excess water so that the various concentration limits are not exceeded due to evapotranspiration and so that salts may be flushed from the soil.

Storage Requirements

Public health, crop management, and weather determine the wastewater application schedule and, consequently, the required storage volume. In general, irrigation should cease about 1 month before harvest or grazing and when workers are in field so that pathogens and parasites might die away. Usually, there is no irrigation before cultivating, planting, and harvest, because the ground must be dry and firm for equipment. Irrigation also ceases when the ground is frozen or saturated by rainfall in order to prevent runoff.

The computer programs EPA-1, Cold Climates, and EPA-3, Moderate Climates, estimate the storage days required by cold weather (Whiting, 1976). Cold climates have an average January air temperature less than 40°F. This includes all states along the Canadian border and Alaska except for Ohio, Pennsylvania, and southern New York. Given climate data, EPA-1 classifies all the days in each annual cold period from November in 1 year through April of the next as favorable for irrigation or unfavorable. An unfavorable day has a mean daily air temperature of less than 32°F plus a snow depth on the ground of 1 in. or more plus a precipitation of more than ½ in. Favorable days are otherwise. During an unfavorable day, all the wastewater flow must be stored. On a favorable day, all of that day's wastewater flow plus a volume equal to ½ day's flow in storage (if any) may be applied. EPA-1 applies the procedure to each cold season of record, and assigns the annual storage requirements a return period using the log Pearson Type III method. Figure 11.10 is a map of the isochrones with a 10-year return period.

EPA-3 is a modification of EPA-1 that applies roughly between 35 and 42 °N latitude. In general, the sewage application rate and storage requirement are determined by the crop's consumption water use, which can be obtained from agricultural extension services.

The EPA-2, Wet Climate Model, estimates storage days due to wet weather (Whiting, 1976). In this case, storage is required when the soil is saturated down to plow depth. Any excess of precipitation or irrigation over the amount of evapotranspiration will produce runoff. This model typically applies to the coastal regions of Washington, Oregon, and northern California, southern North Carolina, South Carolina, Florida, the Gulf Coast states, and southeast Texas.

Water climate storage volumes are best estimated using a water budget for each month of a wet year with a return period of 10 to 25 years (Crites et al., 1977):

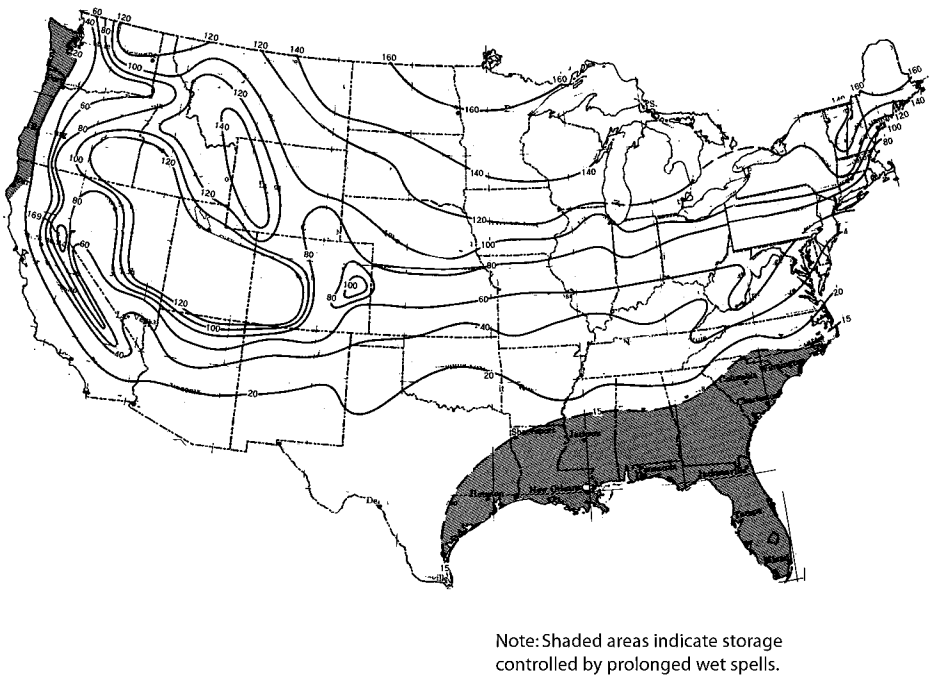

FIGURE 11.10 Storage days due to frozen ground and snow cover.

$$\text{precipitation} + \text{wastewater} = \text{evapotranspiration} + \text{percolation to ground water} + \text{runoff} \tag{11.157}$$

Any runoff would go to storage. The usual units are cm or in. of water over the application area.

Irrigation

Irrigation imitates natural precipitation. Operators apply wastewater to a selected field for several hours to a day, and then the field is rested for a few days to a couple of weeks. Intermittent flooding and draining of the soil pushes out old air ahead of the water wave and draws in new air behind it. While one field is resting, the operators shift the wastewater to another. The duration of the resting period is determined by the field's infiltration capacity, the current weather, the crop's drought tolerance, and the rate of biodegradation of the applied organic and inorganic matter. All of these vary significantly throughout the growing season and even from one field to the next at the same site. Consequently, engineers must design storage volumes, distribution networks, and control structures that give operators the greatest possible flexibility in irrigation quantity and timing.

In the case of Type I Slow-Rate Infiltration systems (crop production), the volume of wastewater applied during a single irrigation is the difference between the available water capacity (AWC) and the management-allowed deficit (MAD) (Pettygrove et al., 1984). The available water capacity is the difference between the soil's field capacity and the crop's wilting point (usually about 15 bar tension). For a clay-loam or a silty-clay-loam, the AWC may be 2 to 2.5 in. of water per ft of soil depth, whereas for a sand or fine sand, it may be as little as 0.5 to 1.0 in./ft. The MAD is usually 30 to 50% of the AWC of the whole root zone. It varies by stage of crop growth. The Department of Agriculture's Soil Conservation Service and Cooperative Extension can provide details for local sites.

The depth of water needed to replenish the AWC is as follows (Pettygrove et al., 1984):

$$d_{irr} = \frac{f_{mad} d_{awc} \left(1 + f_{lch}\right)}{E_u} \tag{11.158}$$

where d_{awc} = the depth of available water in the crop's root zone (cm)
d_{irr} = the depth of wastewater applied during one irrigation (cm)
E_u = the unit application efficiency (decimal)
f_{lch} = the fractional leaching requirement (decimal)
f_{mad} = the fractional management-allowed deficit (decimal)

The unit application efficiency accounts for the fact that the application is not perfectly uniform and that some water is lost to mist and evaporation. The efficiency depends on the kind of distribution system and ensures that all parts of the field get the desired minimum amount of water. The leaching fraction is the amount of water required to control salt buildup. The leaching volume becomes the drainage water that must be captured. The timing of the irrigation is by soil moisture measurements. Pettygrove et al. (1984) provide details.

In the case of Type II Slow-Rate Infiltration systems (wastewater treatment), the depth applied is the net of evapotranspiration plus percolation less precipitation (Pettygrove et al., 1984):

$$d_{irr} = \left(d_{et} - d_{ppt} + d_{prc}\right) \frac{t_{\max}}{30} \tag{11.159}$$

where d_{et} = the month's total evapotranspiration rate (cm)
d_{prc} = the month's total percolation out of the root zone (cm)
d_{ppt} = the month's total precipitation (cm)
$t_{\max}$ = the maximum time between irrigations (days)

The analysis is done month by month throughout the year. The net difference between evapotranspiration and precipitation should be the 90% exceedance value, i.e., a relatively wet month. The allowable monthly percolation is a soil property.

Scheduling

For design purposes, the maximum time between irrigations can be estimated from the following (Pettygrove et al., 1984):

$$t_{\max} \approx \frac{f_{mad} d_{awc}}{r_{et\,\max}} \tag{11.160}$$

where $r_{et\,\max}$ = the 10-year return maximum evapotranspiration rate for the month (cm/d). The actual duration of any irrigation must be less than $t_{\max}$, and Pettygrove et al. (1984) recommend that the irrigation rate be high enough for it to be completed in less than 75% of $t_{\max}$.

Irrigation Methods

Wastewater distribution types include sprinkler, drip pipe, surface flooding (border strip), and ridge-and-furrow distribution. Design recommendations and details are given by Booher (1974), Crites et al., 1977; Dillon, Hiler, and Vittetoe (1972), Fry and Gray (1971), Hart (1975), Jensen (1980), Pair (1975), Pettygrove et al. (1984), Schulbach and Meyer (1979), and the Soil Conservation Service (1974 to date).

Sprinkler systems (spray irrigation) are subdivided into fixed-in-place, hand-moveable, end-pull tractor-mobile, side-wheel self-mobile, center pivot self-mobile, and traveling gun self-mobile. The sprinklers usually have impact nozzles mounted on risers or horizontal, elevated pipes, but some orchard systems use perforated pipes laid on the ground. Fixed-in-place systems are not restricted as to ground slope or crop, and the minimum application rate needed to activate the impact-nozzles is only about 0.12 cm/h (Reed, Crites, and Middlebrooks, 1995). Hand-moveable systems can be placed on grades up to 20%

and require minimum application rates of 0.25 cm/hr to operate the nozzles. Side-wheel, center pivot, and traveling gun self-mobile systems are hydraulically self-mobile and require maximum ground slopes of 10 to 15% and minimum application rates of 0.25 to 0.75 cm/hr to operate. Side-wheel and center pivot self-mobile systems also have maximum crop height limitations. Sprinklers generate aerosols that contain wastewater contaminants. Most jurisdictions require and specify buffer zones and/or mist barriers to prevent contamination of surrounding properties. A common requirement is at least 400 ft of buffer or 200 ft of buffer with a mist barrier of trees (Powell, 1976).

Drip pipe systems generally have no slope restrictions and very low minimum application rates (0.05 cm/hr). The orifices are subject to clogging and require prescreening. They may not be suitable where salinity control is an issue.

Surface flooding (border strip) requires relatively flat fields with grades from 0.5 to 7% and low to moderate infiltration rates for even distribution. The crops must be able to withstand inundation. The minimum widths are set by farm equipment requirements. The maximum widths depend on the uniformity of distribution and are usually less than 100 ft. Clay soil strips are generally longer, up to 1200 ft, and sandy soil strips are generally shorter, up to 300 ft. Unit wastewater flows range from 0.01 to 0.04 ft^3 per ft width per sec for clay-loam soils to 0.03 to 0.11 ft^3 per ft width per sec for sandy-loam soils. Application depths range from 7 to 8 in. for clayey-loam and clay soils to 4 to 5 in. for sandy-loam and sandy soils.

Straight ridge-and-furrow systems are restricted to relatively flat fields (less than 0.25% grade), but furrows that follow contours can be laid across slopes up to 8%. Furrow length and spacing for uniform distribution depend on local soil conditions and may require annual adjustment. Sandy soils (with high infiltration rates) require closely spaced, short furrows, whereas clay soils (with low infiltration rates) need widely spaced, long furrows.

Drainage and Tailwater Collection Systems

Subsoil drains are necessary to intercept percolating water to minimize contamination of the groundwater resource and, especially in arid areas, to prevent salinization of the root zone by the upward migration of the groundwater. The top of the groundwater table should be at least 1 to 1.5 m deep (Pettygrove et al., 1984). In the San Joaquin valley, the pipe spacing is estimated from the following:

$$L = \sqrt{\frac{4k\left(H^2 - d^2\right)}{q}} \tag{11.161}$$

where d = the diameter of the drainpipe (m)
H = the height of the groundwater table above the drainpipe invert (m)
k = Darcy's permeability coefficient (m/s)
L = the distance between pipe center lines (m)
q_{perc} = the rate of percolation water flow (m^3/m^2 s)

The design of the subsurface drains depends on the hydraulic conductivity of the soil (down to at least 10 ft) and the rate of irrigation. The conductivity is measured *in situ* using prescribed borehole techniques. Drains are normally placed below the groundwater table.

Surface flooding, graded border, and ridge-and-furrow distribution systems also require tailwater capture and recycling systems. In arid areas, the tailwater may require treatment prior to reuse.

Area Requirement for Water

In the long run, Eqs. (11.156) and (11.158) apply to all systems. Setting runoff to zero and rewriting to make the area explicit, one gets,

$$A_{ro} = \frac{V_{irr}}{d_{et} + d_{perc} - d_{ppt}} \tag{11.162}$$

where A_{ro} = the total irrigation area required to prevent runoff (m^2)
V_{irr} = the total irrigation volume for some specified period (m^3). The area required to prevent runoff should be compared to the area required for nitrogen control; the larger is the required field area.

For the whole year, V_{irr} is the total annual volume of wastewater less any storage/treatment pond evaporation. However, because of shutdowns for weather, public health protection, cultivation, harvest, etc., this volume must be applied in less than 1 year, perhaps in as little as a few months in severe northern climates. Once the schedule of nonapplication periods is determined, each application period should be analyzed using Eq. (11.162). During such a period, all the wastewater that arrives on-site during the period plus any wastewater taken out of storage should be considered. The analysis should be done for a relatively wet year, say a 10-year rainfall.

Area Requirement for Nitrogen

Because many rural areas depend on untreated groundwater for domestic use, nitrate contamination of the groundwater under the irrigation area is an issue. The required land area for nitrogen removal depends upon the wastewater nitrogen inputs, crop uptake, denitrification, ammonia volatization, and removal by percolation:

$$\frac{V_{irr}C_{No}}{A_N} = m_{crp} + m_{den} + m_{vol} + \frac{f_{prc}V_{irr}S_{NO_3prc}}{A_N} \tag{11.163}$$

where A_N = the area required for nitrogen control (m^2)
C_{No} = the total nitrogen content of the applied wastewater including TKN and nitrate/nitrite, if any (g N/m^3)
f_{prc} = the fraction of the applied wastewater becoming drainage (decimal fraction)
m_{crp} = the crop nitrogen uptake (g N/m^2)
m_{den} = the amount of nitrate/nitrite lost to denitrification (g N/m^2)
m_{vol} = the amount of ammonia lost to volatization (g N/m^2)
S_{NO_3} = the allowable nitrate concentration in the drainage water (g N/m^3)
= 10 mg N/L, for public health reasons
V_{irr} = the volume of wastewater applied during the growing season (m^3)

The area required for nitrogen control should be compared to the area required to prevent runoff; the larger is the required field area. The fraction of the applied wastewater that becomes drainage depends on the irrigated area, so an iterative calculation is needed. The losses due to crop uptake can be determined from the agricultural literature. Some values are given in Table 11.15. Denitrification and volatization are usually taken to be some fraction (roughly 20%) of the applied nitrogen load.

Area Requirement for Organic Matter

Organic loading is not usually a consideration in municipal wastewater treatment, because the applied wastewater is stable pond effluent and because the amounts are small compared to the soil humus (Loehr et al., 1979). Manure application rates are typically on the order of 10 to 20 tons/acre/year, and food processing, winery, brewery, and dairy wastewaters have been applied at rates up to 300 lb BOD_5/ac/day without nuisance as long as the fields were allowed to dry between applications and the soil remained permeable (Loehr et al., 1979; Reed, Crites, and Middlebrooks, 1995).

Oils, grease, and fats need special consideration. Industrial oils are toxic to soil microorganisms at levels around 2 to 4% by wt and to sugar beet, rape, lawn grasses, yams, carrots, turnips, and radishes at soil levels of 0.5% by wt (Overcash and Pal, 1979). Fats, oils, and greases also greatly reduce soil permeability and may accumulate in the soil and form surface mats in severe northern climates.

The usual remedy for soil clogging is rest plus cultivation to break up the surface mats and soil clogs and to redistribute the oils. Sometimes application areas benefit by seeding with soil from established fields that have been receiving oily and fatty wastes.

TABLE 11.15 Crop Nutrient Requirements per Growing Season[a,b]

Crop	lb N/ac	lb P/ac
	Forage	
Alfalfa (legume)	155–220	—
Bermuda grass	480–600	—
Canary grass	226–359	40
Red clover (legume)	77–126	—
Sweet clover (legume)	158	—
Fescue	275	29
Hay	130	—
	Field Crops	
Barley	63	—
Corn	155	31
Cotton	66–100	17
Oats	53	—
Soybeans	94–113	22
Wheat	50–76	20
	Forest	
Deciduous <5 yr	100	—
Deciduous >5 yr	30–50	—
Evergreen <5 yr	60	—
Evergreen >5 yr	20–30	—

Overland Flow

Configuration

Overland flow systems may be regarded as trickling filters that use grass as the biomass support packing. They are alternatives to nonnitrifying activated sludge, trickling filters, and ponds on sloping ground, where excavation costs are excessive, or on relatively impermeable soils with infiltration rates less than 2 in./hr. An overland flow system consists of the following (Crites et al., 1977):

- Preliminary treatment to remove grit, rags and debris to prevent nuisance and clogging of pumps, piping, and weirs
- Primary settling and scum removal or fine screening
- A distribution box to control which slope is in use
- A top-of-slope side-overflow distribution channel or, more usually, a sprinkler system
- A grassy slope
- A toe-of-slope collection channel
- Disinfection
- Ancillary equipment and storage sheds, influent/effluent monitoring facilities, all-weather roads, fencing, and buffer strips

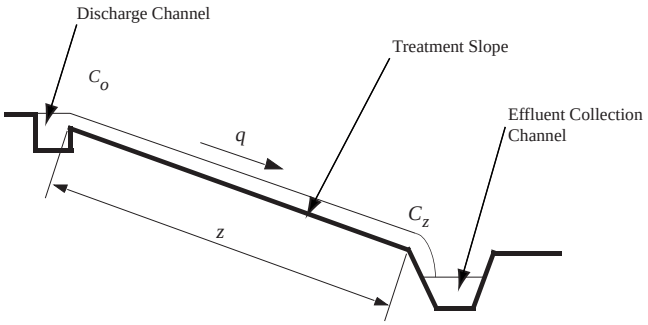

FIGURE 11.11 Overland flow definition sketch.

Overland flow systems sometimes are used to treat pond effluents, but they are poor at algae removal. The crop, almost always grass, must be harvested regularly, and the slopes must permit the safe use of the usual kinds of agricultural equipment.

Wastewater is usually applied using permanent (buried distribution piping) solid-set sprinklers, but perforated pipes and side-overflow weirs are acceptable if energy dissipaters are used to prevent erosion of the slope. If a side-overflow weir is used, wastewater should enter the distribution channel via some sort of manifold system. The momentum of the influent wastewater entering one end of a cross-flow, side-overflow channel makes uniform distribution nearly impossible unless the influent flow is controlled to be constant, which allows a single adjustment of the side-overflow weir. If the influent flow varies, low discharges concentrate near the inlet end of the distribution channel, and high flow discharges concentrate near the dead end of the channel.

In order to get good wastewater distribution, the slopes must be planar. The dip should be between 2 and 6% (to prevent slope erosion) and perpendicular to the top-of-slope distribution system. The strike should be parallel to the distribution system. Slopes are typically 45 to 60 m long if sprinklers are used, and 30 to 45 m long if perforated pipes or side-overflow weirs are used (Reed, Crites, and Middlebrooks, 1995). The minimum slope length is 20 m.

Operation

Wastewater application is intermittent for 5 to 7 days per week and 6 to 12 hr (typically 8 hr) per day (Crites et al., 1977; Reed, Crites, and Middlebrooks, 1995). During the summer growing season, as much as 8 in. pond effluent per week may be applied, but the application rate should be reduced by half during the spring and fall, and applications should cease during the winter. In the case of screened sewage or primary effluent, and if "crop" is not used for food or pasture, a typical hydraulic loading is 2.5 to 8 in./week. The lower rate should be used if the slope is greater than 6% and in cold weather. Lagoon effluents may be loaded at 6 to 16 in./week. Algal removal may be inadequate.

Kinetic Model

BOD_5 removal along the slope is approximately exponential (Fig. 11.11; Reed et al., 1984):

$$\frac{C_{BOD}(z) - C_{BODmin}}{C_{BODo}} = a \cdot \exp\left(-kz/q^n\right) \tag{11.164}$$

where a = an empirical coefficient dependent on q (dimensionless)
C_{BODmin} = the minimum achievable BOD_5 (mg/L)
≈ 5 mg/L
C_{BODo} = the BOD_5 of the applied wastewater (mg/L)
$C_{BOD}(z)$ = the BOD_5 of the wastewater a distance z from the distribution channel (mg/L)
k = an empirical rate constant [$(m^3/m\ h)^n/m$]

q = the hydraulic load (m^3 of flow per m of width per hr)
n = an empirical exponent dependent on q (dimensionless)
z = the distance from the distribution weir *along the slope* (not its horizontal projection) (m)

The values of a, k, and n are not well known, and they are reported for experimental sites during the summer and fall with air temperatures ranging from 48 to 95°F. For screened sewage, the semilogarithmic intercept a declines from about 0.65 to 0.5, and the slope k/q^n increases from 0.018 to 0.033 as the hydraulic load declines from 0.45 to 0.10 m^3/m h. In the case of primary effluent, the intercept a falls from about 0.7 to about 0.35, and the slope k/q^n varies between 0.02 and 0.025, as the hydraulic load declines from 0.37 to 0.1 m^3/m h. There is no data for slope lengths beyond 40 m.

Slope Area and Drainage

The slope area (true, not projected horizontally) is as follows:

$$A_s = \frac{V_{app} z}{q t_{app}} \tag{11.165}$$

where A_s = the true, not projected, slope area (m^2)
q = the hydraulic load (m^3 wastewater per m strip width per hr)
t_{app} = the duration of the application (hr)
V_{app} = the applied wastewater volume, including the daily flow and any wastewater taken from storage (m^3)
z = the true, not projected, length of the strip (m)

The collection channel should be designed for the maximum 24-hr storm with a 25-year return period plus the design maximum week sewage flow. If the channels are earthen or grassy, the channel velocities should be less than 1.5 ft/sec to avoid scour. The collection channel should have a freeboard at maximum flow of 8 in.

The treated effluents of high-strength industrial wastewaters may be recycled to dilute the contaminant concentrations in the applied flow.

Performance

The probable best effluents in the southern U.S. at an application rate of 4 in./week are as follows:

- $BOD_5 \approx 8$ mg/L
- SS ≈ 8 to 16 mg/L
- P removal ≈ 30 to 40 lb/ac yr, if cropped
- N ≈ 3 mg/L total (no nitrification, cropped)
- Coliform ≈ 90 to 95% removal

Rainfall does not impair BOD_5 removal efficiency, because the increased flow increases the water depth on the slope, which limits the decrease in hydraulic detention time; raindrops increase water film turbulence and mass transfer to the biofilm; and rain dilutes the effluent. Consequently, cessation of operation is not required during rainy periods.

Organic loads ought to be limited to less than 100 kg BOD_5/ha/day to avoid anaerobic conditions in the wastewater film and soil (Reed, Crites, and Middlebrooks, 1995).

Constructed Treatment Wetlands

A wetland is a community of hydrophytic plants growing in a hydric soil. Kadlec and Knight (1996) summarize the various kinds of wetlands. At least seasonally, hydric soils are saturated with water, often submerged and anaerobic. Anaerobiosis may proceed even when the soils dry out, if the organic matter content is high enough. Hydric soils may contain little or much organic matter, be acidic to neutral in

pH, have a wide variety of hydraulic conductivities and water-holding capacities, have variable nutrient content, and have variable cation exchange capacity. Typical hydrophytic plants include floating and rooted mosses (*Fontinalis, Sphagnum*), rooted ferns (*Belchnum, Osmunda, Salvinia*), conifers (*Pinus*), floating, submerged, and emergent herbs (*Lemna, Elodea, Sagittaria*), shrubs (*Lyonia*), and deciduous trees (*Acer, Quercus, Populus*) (Kadlec and Knight, 1996). An initial planting of reeds (*Phragmites*), bulrushes (*Scirpus*), cattails (*Typha*), or sedges is sometimes recommended (Crites et al., 1988; Reed, Crites, and Middlebrooks, 1995).

Although constructed treatment wetlands are intended primarily for wastewater treatment, they are also valued and often justified by their roles in wildlife conservation and flood mitigation. Design and operation must preserve these values, too, which limit the kinds of wastewaters that may be applied.

Leachate contamination of groundwater is a concern in some areas, and constructed wetlands are often lined.

Constructed treatment wetlands require a minimum pretreatment of screening, grit removal, settling, scum removal, and disinfection. It is especially important to remove settleable solids that may form noisome sludge deposits near the inlets. Many wetlands receive secondary effluents and function as effluent polishing processes. Other wetlands are used to treat acid mine drainage.

Wetlands may be classified as free water surface (FWS), in which water flows over the top of the soil, or subsurface flow (SSF), in which water flows through the soil. They are usually riparian and subject to flooding, so embankments must be protected from erosion. In either case, the principal agent of wastewater stabilization is the microbial biofilm attached to various surfaces. SSF systems generally have more surface area for biofilm attachment than do FWS systems and can accept higher organic and nitrogen loadings. In general, SSF wetlands are preferred for the treatment of domestic wastewaters because of the following:

- They are somewhat more efficient than FWS systems due to their larger biofilm attachments areas.
- They suppress insect vectors.
- They exclude human and animal contact with the wastewater.

Free Water Surface (FWS) Wetlands

FWS wetlands consist of three to four squarish cells-in-series (Watson, 1989). Tracer studies show that the flow regime is complex and not adequately described as plug-flow-with-dispersion; the actual flow regime strongly affects the apparent reaction rate values (Kadlec et al., 1993). FWS bottoms are generally on impermeable soils, but a liner system may be required to prevent groundwater contamination.

Oxygen is available to the nitrifying bacteria from atmospheric exchange and algal photosynthesis. Many aquatic macrophytes also have a tubular airway system that directly connects their (aerobic) roots to the atmosphere. These airways may also transport a small amount of oxygen to the otherwise anaerobic soil.

The depth of flow is typically 6 to 24 in., and the areal requirement for the hydraulic load is typically 20 to 75 ac/mgd for secondary treatment and 10 to 50 ac/mgd for secondary effluent polishing. The hydraulic detention times range from a few to several days (Watson, 1989).

Organic loading is not normally considered a major factor in FWS wetland design. Observed organic loads range from 18 to 116 kg BOD_5/ha/day, with a recommended maximum of 110 kg/ha/day (Watson, 1989).

The correlation between inlet and outlet BOD_5s is as follows (Kadlec and Knight, 1996):

$$C_{BODe} = 0.173C_{BODo} + 4.7; \quad \left(r^2 = 62;\ n = 440\right) \tag{11.166}$$

where C_{BODe} = the total effluent BOD_5 (mg/L)
C_{BODo} = the total inlet BOD_5 (mg/L).

The data are highly scattered, and the standard error of the outlet BOD is 13.6 mg/L. Inlet BODs ranged from 10 to 680 mg/L, and outlet BODs ranged from 0.5 to 227 mg/L. The effluent BODs appear to be independent of hydraulic loading between 0.27 and 25.4 cm/day.

Nitrogen removal in FWS wetlands proceeds by ammonia volatization, biomass incorporation and burial, and nitrification/denitrification. The first-order mass transfer coefficients for the areal reaction rates at 20°C and their theta values are as follows (Kadlec and Knight, 1996):

Mineralization of organic nitrogen:

$$k_{\min} = 17 \times 1.05^{T-20} \tag{11.167}$$

Nitrification of ammonia:

$$k_{nit} = 18 \times 1.04^{T-20} \tag{11.168}$$

Denitrification of nitrite/nitrate:

$$k_{dn} = 35 \times 1.09^{T-20} \tag{11.169}$$

where k_{dn} = the areal denitrification rate coefficient (m/yr)
$k_{\min}$ = the areal mineralization rate coefficient (m/yr)
k_{nit} = the areal nitrification rate coefficient (m/yr)

The minimum effluent organic nitrogen concentration for a FWS wetland is about 1.5 mg N/L. The effluent ammonia nitrogen concentration is generally less than 0.1 mg N/L. The Water Environment Federation recommends the following concentration estimators (Reed, Crites, and Middlebrooks, 1995):

$$\ln\left(S_{\mathrm{NH}e}\right) = 0.688\ln\left(S_{\mathrm{NH}o}\right) + 0.655\ln\left(q\right) - 1.107 \tag{11.170}$$

$$C_{\mathrm{N}e} = 0.193C_{\mathrm{N}o} + 1.55q - 1.75 \tag{11.171}$$

where $C_{\mathrm{N}e}$ = the effluent total nitrogen concentration, ammonia plus nitrate (mg N/L)
$C_{\mathrm{N}o}$ = the influent total nitrogen concentration, ammonia plus nitrate (mg N/L)
q = the areal hydraulic load (cm/d)
$S_{\mathrm{NH}e}$ = the effluent ammonia nitrogen concentration (mg N/L)
$S_{\mathrm{NH}o}$ = the influent ammonia nitrogen concentration (mg N/L)

Initially, in a new wetland, phosphorus removal occurs by adsorption to minerals on the surface of the soil. Later, removal is by incorporation into biomass and settling. The settling material is liable to scour and discharge during storm events. In the long run, phosphorus removals average 30 to 60%, and the first-order mass transfer rate coefficient for the areal P removal rate is about 10 m/yr (Reed, Crites, and Middlebrooks, 1995).

Suspended solids removal declines as the hydraulic load increases. At loads between 0.4 and 75 cm/d, the effluent SS concentration of a FWS wetland may be approximated as follows (Reed, Crites, and Middlebrooks, 1995):

$$X_{\mathrm{SS}e} = \left(0.1139 + 0.00213q\right)X_{\mathrm{SS}o} \tag{11.172}$$

where q = the hydraulic load (cm/d)
$X_{\mathrm{SS}e}$ = the effluent SS concentration (mg/L)
$X_{\mathrm{SS}o}$ = the influent SS concentration (mg/L)

Subsurface Flow (SSF) Wetlands

SSF wetlands consist of a constructed permeable bottom, often crushed limestone or gravel, through which the wastewater flows. Under the assumption that the root zone is less than 30 cm deep, the usual

bed depth is 45 to 60 cm (Kadlec and Knight, 1996). The bed must be able to transmit the expected maximum wastewater flow and the design precipitation in the face of degradation of the bed's hydraulic conductivity without surface flooding. Hydraulic conductivities for the selected bed material must be measured to ensure adequate hydraulic capacity. A liner system is needed to keep the wastewater flow out of the groundwater.

The principal source of oxygen in SSF beds is the atmosphere. Under average design conditions, the beds are not completely saturated and contain a vadose zone open to the atmosphere. Aeration is improved by intermittent or varying hydraulic loading, which flushes air out of and into the vadose zone. The effluents of SSF wetlands contain very little oxygen, generally less than 1 mg/L. In some jurisdictions, the effluents must be reaerated before discharge.

The areal requirement for the hydraulic load is 5 to 20 ac/mgd for secondary and polishing wetlands (Watson, 1989).

For SSF wetlands, the correlation between inlet and outlet BOD_5s is as follows (Kadlec and Knight, 1996):

Soil beds with reeds (Phragmites):

$$C_{BODe} = 0.11C_{BODo} + 1.87; \quad (r = 0.74; n = 73) \tag{11.173}$$

Gravel beds:

$$C_{BODe} = 0.33C_{BODo} + 1.4; \quad (r^2 = 0.48; n = 100) \tag{11.174}$$

where C_{BODe} = the total effluent BOD_5 (mg/L)
C_{BODo} = the total influent BOD_5 (mg/L).

Again, the data are highly scattered. For the soil/reed systems, the inlet BODs ranged from 1 to 330 mg/L, and outlet BODs ranged from 1 to 50 mg/L. For the gravel systems, the influent BODs ranged from 1 to 57 mg/L, and the effluent BODs ranged from 1 to 36 mg/L. The effluent BODs appear to be independent of hydraulic loading between 0.27 and 25.4 cm/d.

Nitrogen removal in SSF wetlands proceeds by ammonia volatization, biomass incorporation and burial, and nitrification/denitrification.

The first-order reaction coefficients for the mass transfer rate coefficients at 20°C and their theta values are as follows (Kadlec and Knight, 1996):

Mineralization of organic nitrogen:

$$k_{\min} = 35 \times 1.05^{T-20} \tag{11.175}$$

Nitrification of ammonia:

$$k_{nit} = 34 \times 1.04^{T-20} \tag{11.176}$$

Denitrification of nitrite/nitrate:

$$k_{dn} = 50 \times 1.09^{T-20} \tag{11.177}$$

where k_{dn} = the areal denitrification rate coefficient (m/yr)
$k_{\min}$ = the areal mineralization rate coefficient (m/yr)
k_{nit} = the areal nitrification rate coefficient (m/yr)

These rates are about twice those of FWS systems because of the greater biomass in SSF.

Suspended solids removal declines as the hydraulic load increases. Between 0.4 and 75 cm/day, the effluent SS concentration of a SSF wetland may be approximated as follows (Reed, Crites, and Middlebrooks, 1995):

$$X_{SSe} = (0.1058 + 0.0011q)X_{SSi} \tag{11.178}$$

where q = the hydraulic load (cm/d)
X_{SSe} = the effluent SS concentration (mg/L)
X_{SSi} = the influent SS concentration (mg/L)

11.6 Bioremediation and Composting

Gas treatment processes and compost piles consist of permeable, moist solid packings that support aerobic biodegradation on their surfaces. In the case of gas treatment, the substrate is contained in the contaminated gas stream passing through the packing voids. Contaminated soils have a thin layer of adsorbed material on their surfaces. In the case of composting, the substrate is the pile itself.

Treatment of Gases and Soils

A *biopile*, *biofilter*, *bioscrubber*, *biosparger*, *biovent*, *biologically activated foam*, or *soil filter* is an aerobic packed-bed bioreactor used for the biological treatment of contaminated gases and/or soils. They may be regarded as a subclass of trickling filter. Bioventing, biosparging, or soil venting typically refers to the *in situ* treatment of contaminated soils. Biopiles are piles of contaminated soils that are excavated and transported to a nearby treatment facility. The other terms refer to systems used to remove odors and biodegradable volatile organic carbon (VOC) compounds from process off-gases.

Water

The ideal water content for soil systems is between 10 and 20% by wt or 70 to 95% of field capacity, and the extreme limits are 5 to 30% by wt (von Fahnestock et al., 1996). It is necessary that the packing be unsaturated to permit air permeation. In the case of biopile for contaminated soil remediation, the water is added as the soil is being prepared for placement on the pad or liner. In the case of biofilters and bioscrubbers, the raw gas is humidified.

In some applications, the gas flow may dry the packing, and provision for water addition is needed. This can be done by placing drip pipes on top of the packing. However, the packing should not be flooded or wetted to the point where gas flow is impeded. Off-gases from liquid and/or sludge processing may be saturated with water vapor and may deposit water in the packing. In these cases, predrying the gas stream may be necessary.

Nutrients

It is generally necessary to seed the packing with a suite of acclimated microbes and to provide nutrients and trace minerals. Nutrients may be available from compost and soils used as packing in bioscrubbers. Tables 11.2 and 11.3 can be used as guides to the quantities needed. The usual rules of C:N less than 20:1 and C:P less than 100:1 apply. The carbon content is that of the contaminated gas. In the case of biopile for contaminated soil remediation, the nutrients are added as the soil is being prepared for placement on the pad or liner.

pH

The pH of the sorbed and capillary water should be somewhat above 7. The maximum range for biodegradation is 6 to 9.

Poisons

Tables 11.4 and 11.5 may be used as guides.

Bioventing and Biosparging

Bioventing is the aeration of vadose and capillary zone subsurface soils *in situ* (Leeson and Hinchee, 1995). In biosparging, the air is injected into the contaminated saturated zone, and biodegradation occurs in the overlying vadose and capillary zones (O'Brien and Gere, 1995). In either case, the purpose is to stimulate the biodegradation of soil contaminants by the indigenous microbes. Soil venting is usually intended merely to strip VOCs from the vadose or capillary zone with the expectation that gas treatment will be provided at the ground surface.

The system generally consists of a system of air injection and extraction wells and soil gas monitoring wells. An extracted gas treatment process will be required if the extracted gas contains high concentrations of VOC. The details of the installation depend critically on the three-dimensional position of the spilled contaminants, the local distribution of soil types, and the location of the vadose, capillary, and saturated zones, all of which must be determined by borehole studies. It may be necessary to model the pattern of gas flows through the soils in order to optimize well placement.

Groundwaters with high iron and manganese concentrations may plug the soil around the air injection diffusers.

If the organic contaminant is stripped into the flowing air rather than degraded *in situ*, it will be necessary to collect and treat the off-gas (Leeson and Hinchee, 1995). In general, substances with vapor pressures near atmospheric are stripped rather than degraded *in situ*. These substances are typically the lighter fractions of gasoline like butanes and propylene. If the organic contaminant does not volatize, it may not become available to the microbes. In general, this includes alkanes larger than undecane, polynuclear aromatic hydrocarbons, phenols, and long-chain alcohols and organic acids. Typically, these are found in diesel fuel. The ideal subjects of bioventing and biosparging have vapor pressures on the order of 10^{-3} to 10^{-1} atm. These substances are commonly found in jet fuels.

Some soils have very low water contents, and bioventing may further dry them. Although biodegradation has been observed at moisture contents as low as 5%, it is very slow, and optimal decay rates occur at moisture contents of 15 to 25% (Leeson and Hinchee, 1995). Water can be added to shallow soils by surface irrigation, but deeper soils require trenches, infiltration galleries, or dry wells (O'Brien and Gere, 1995).

If needed, nutrients can be added to soils by the same techniques used to add water, however, most soils do not require nutrient addition.

Biodegradation half-lives range from days for metabolic intermediates, to months for polynuclear aromatic hydrocarbons, to years for chlorinated hydrocarbons (Leeson and Hinchee, 1995).

Biopiles

In the case of bioremediation of VOC-contaminated soils, the soil becomes the biopile, and the biopile is a temporary construct. The complete system will include the following (von Fahnestock et al., 1996):

- The biopile treatment unit
- A contaminated soil storage pad
- A processing area to grind and screen the soil and to add microbial seed (soil from previous biopiles), bulking agents (if needed), nutrients, and water
- Access roads, equipment maneuvering areas, equipment and monitoring sheds, and fencing

Typical biopile dimensions for contaminated soil are 50 ft wide × 60 ft long × 4.5 ft high. They contain about 500 yd^3 of soil. Storage piles are somewhat larger. The fenced site area will be about 1 ac. Soil is moved by front-end loader and mixed. Typically, contaminated soil requires about 4 months of aeration for complete removal of the VOCs.

The biopile sits on a concrete pad or on compacted clayey soil plus an impermeable liner (40 to 60 mil HDPE). If necessary, pile leachate can be collected by sloping the pad/liner toward one end and installing a perforated PVC drain and sump. In any case, the surrounding soil should be graded and bermed to

collect any leachate and to prevent surface runoff from entering the pile. Leachate and runoff may require collection and treatment.

Directly on top of the pad or liner is a layer of clean graded sand about 1 ft deep. A manifold of perforated PVC pipe rests on the clean sand layer and is covered by a protective 8 in. of pea gravel. The manifold legs are 2 to 4 in. in diameter and about 30 ft long. They are valved to permit air distribution control. Each leg is capped at one end and connected to an unperforated header at the other. The manifold extracts soil air by vacuum or pumps atmospheric air into it.

In vacuum extraction systems, the off-gases are collected for further treatment or recycling. Also, because the soil gas is water-saturated at the pile temperature, vacuum extraction systems generally require water knockout systems and knockout water collection and treatment.

In dry climates, additional water can be supplied by a drip pipe on top of the soil.

At the top of the biopile, a 20 mil HDPE cover excludes precipitation. The upper liner requires a tie-down system. The biopile also contains a soil gas sampling system so the extent of treatment can be monitored.

Biofilters and Bioscrubbers

Biofilters and bioscrubbers are used to treat the off-gases from other processes. The earliest proposal of biofilters for odor control was made by Bach in 1923, and applications of the concept began in the 1950s (Leson and Winer, 1991).

A biofilter or bioscrubber consists of the following (Leson and Winer, 1991):

- A raw gas collection system
- A raw gas heat exchanger to cool or heat the gas
- A raw gas humidifier
- A filter box that contains a packing supported over an air diffusion system and a supplementary water addition system
- An off-gas monitoring system

If the foul gas contains a mixture of hydrogen sulfide and VOCs, a two-stage system is recommended (Joyce and Sorensen, 1999). The first stage contains the autotrophic, sulfide-oxidizing *Thiobacillus* spp., and the second stage contains a mixed heterotrophic biofilm that oxidizes the VOCs. *Thiobacillus* produces sulfuric acid, and the stages are biologically separated by biofilm pH.

The removal rates for different classes of substances decline along the series alcohols > esters > ketones > aromatics > alkanes (Deshusses and Johnson, 2000). In general, substances with high dimensionless Henry's law coefficients or high octanol-water partition coefficients resist removal. Biofilters are not recommended if the following obtain (Nash and Siebert, 1996):

- There are economical, simple alternatives.
- Contaminant recovery and recycling are practicable.
- The contaminants are not fully known.
- The contaminants are insoluble in water.
- The contaminants have sterically hindered structures that resist biodegradation.
- Halogenated organics are present.

The best results to date have been obtained with sulfides. However, sulfuric acid is produced which lowers the biofilm pH unless it is flushed with water.

Biofilters should be sized using the data obtained from pilot studies. Packing depths are typically 1 to 2 m with gas detention times of 1 to 2 min and pressure drops of 15 to 30 cm or more of water (Nash and Siebert, 1996). Typical contaminant unit degradation rates range from 10 to 100 $g/m^3/hr$, and gas application rates up to 300 $m^3/m^2/hr$ are feasible (Leson and Winer, 1991).

The packing may be any permeable material, including plastic trickling filter media, granular activated carbon, diatomaceous earth, graded sands, soil, composting material, artificial foams (Hun, 1998), etc. A number of proprietary systems are available. Some packings, like compost, are able to hold sorbed and capillary water. Nonabsorbent media like those used in trickling filters require intermittent water application to keep the biofilm wet.

The pores of the wet packing must be large enough to permit gas flow. A d_{60} greater than 4 mm and an organic matter content of at least 55% are recommended (Leson and Winer, 1991). A porosity of at least 25% or higher is recommended, and 80% is preferred (Leson and Winer, 1991). Bulking agents may be required to maintain the porosity, especially where compost materials are employed. Soils should be free of clay and silt (von Fahnestock et al., 1996).

Raw gases should contain about 95% relative humidity in order to avoid drying of the packing and/or microbes. The raw gas may be humidified by spray humidifiers. The filter may produce leachate. This must be collected for treatment.

Waste gas temperatures should be between 20 and 40°C for optimal results. High temperatures will pasteurize the biofilter.

Some biodegradable contaminants exhibit substrate toxicity, and dilution of the waste gas with ambient air may be needed. VOC concentrations should be less than 3 to 5 g/m^3.

Composting

Composting is the aerobic conversion of waste solids to commercially viable humus for soil conditioning. The preferred starting material is yard waste, but properly prepared municipal solid wastes and POTW sludges are acceptable. In normal household and commercial use, individuals will come into close, unprotected contact with the compost. Consequently, it is mandatory that the compost be free of pathogens and parasites, hard sharp objects like broken glass and metals, and nuisances like odors and plastics.

Composting is normally done in open-air windrows on slabs, but enclosed in-tank processing is also practiced. In either case, the composting material may produce odors if aeration is inadequate and may combust spontaneously if water is inadequate. Storage piles of raw materials attract insects, rodents, and larger scavengers, which are nuisances and which may be disease vectors. The composting piles contain large numbers of fungi that are allergens to many people. The finished product should be free of such problems.

Municipal Solid Waste

The processing of municipal solid waste (MSW) entails the following (Haug, 1993; Hickman, 1999; Skitt, 1972):

- Collection
- Bag breaking
- Hand sorting
- Trommel screening
- Magnetic separation
- Shredding
- Addition as needed of water, wood chips (bulking agent), energy amendment (sawdust), nutrients, pH adjustment, and seed
- Composting pile
- Product screening to recover bulking agent
- Curing pile
- Fine screening and packaging

The collection of MSW is normally done by others and delivered to the site during normal business hours. A storage bin will be needed to facilitate processing.

The MSW is first put through low power flails to break open plastic trash bags and permit further separation. The flailed material is then spread on a picking floor to a depth of less than 1 ft, and pickers pass through the MSW and collect salvage, hazardous material, and noncompostible or inappropriate material. Bag removal can be done at this stage.

The sorted material is then transported by conveyor belt to trommel screens for the removal of dirt, stones, bricks, cans, bottles, and other small dense debris. For MSW, the usual trommel opening is 4 in. Because of MSW variability, trommels must have adjustable speeds and inclines. Very long trommels with multiple cascades are required. About 50 to 60% removal of dirt, etc., can be expected.

Screening is followed by magnetic separation of ferrous metals. The metal is usually recycled to mini steel mills and must be nearly free of paper. Generally, two to three stages of magnetic separation are needed, perhaps with intermediate air classification.

The remaining MSW is then shredded by hammer mill. Generally, 1.5 to 3 in. pieces are preferred for windrows, and 0.5 to 1.5 in. sizes are preferred for in-tank processing. Shredding must be done after screening and magnetic separation, because shredders typically imbed broken glass, dirt, and metal into the paper, which makes their subsequent separation impossible and degrades the scrap value.

A number of additives are mixed into the shredded waste as needed. These may include fresh compost for seeding (1 to 5% by wt), water (up to 50 to 60% by wt), a bulking agent (for pile permeability), sawdust (for pile temperature maintenance to >50°C), nutrients (C:N ≈ 30 to 35 by wt; C:P ≈ 75 to 150 by wt) and pH adjustment (7 to 8). If shredded tires are used for bulking, the metal content of the rubber is a concern. The usual bulking agent is 1 to 2 in. wood chips.

The mixture is then placed in windrows on slabs or in tanks. Transfer is done by front-end loader or conveyor belt. Slabs and tanks must have leachate collection systems. Windrows are mixed and turned twice a week by machine, and tanks are mixed by augers. Windrows are aerated by vacuum piping placed on the slab, and tanks have air diffusers. The off-gas should be collected and treated for odor and fungus spore control. The off-gas from windrow vacuum systems also requires water knockouts.

The composting temperature is controlled by the aeration system. The usual air requirement is 10 to 30 scf per lb compost per day. The optimum temperature range for newsprint and other cellulosic wastes is 45 to 50°C; for freshly prepared MSW mixtures it is 55 to 60°C; and for stabilized MSW it is around 40°C (Haug, 1993).

Composting requires about 5 weeks and converts about 40 to 50% of the volatile solids in MSW to humus. The fresh compost is screened to remove bulking agent and transferred to an unaerated, unmixed curing pile, where it is held for about 1 month to cure. A portion of the fresh compost is used to seed the raw MSW. Finally, the cured compost is finely screened to remove all objectionable material and packaged for sale to vendors. The product must be free of pathogens, parasites, metal, glass, ceramics, plastics, and bulking agent.

Sewage Sludges and Garbage

The system configuration for POTW sludges and garbage is nearly the same as for MSW composting (Hay and Kuchenrither, 1990). The initial steps of bag breaking, sorting, screening, magnetic separation, and shredding are not needed. Water, nutrients, and pH adjustments are also not normally needed. However, a bulking agent is always required, and sawdust is often needed to offset excessive moisture in the raw material. Holding times and conversions are the same as for MSW.

Material, Heat, and Air Balances

The wet weight of the raw compost mixture, which is needed to size material handling equipment, slabs, and tanks, is as follows (Haug, 1993):

$$W_m = W_s + W_r + W_b + W_a + W_w \tag{11.179}$$

where W_a = the wet weight of the energy amendment, usually sawdust (kg)
W_b = the wet weight of the bulking agent, usually wood chips (kg)

W_m = the wet weight of the raw compost mixture (kg)
W_r = the wet weight of the recycled fresh compost seed (kg)
W_s = the wet weight of the raw waste material (substrate) to be composted, e.g., sewage sludge, garbage, or MSW substrate (kg)
W_w = the weight of any water added to the mixture (kg)

The weight of the waste material (substrate) is known, and the weight of the recycled seed compost is proportional to it. The other material weights are determined by considerations of permeability, average moisture content, and pile temperature. The sawdust amendment and the added water are mutually incompatible additions. Water is added only to dry wastes, and sawdust is added only to wet wastes.

In terms of dry weights (total solids, TS), this becomes as follows:

$$f_{sm}W_m = f_{ss}W_s + f_{sr}W_r + f_{sb}W_b + f_{sa}W_a$$
$$X_m = X_s + X_r + X_b + X_a \tag{11.180}$$

where f_{sa} = the weight fraction of dry solids in the energy amendment (dry wt/wet wt, dimensionless)
f_{sb} = the weight fraction of dry solids in the bulking agent (dry wt/wet wt, dimensionless)
f_{sm} = the weight fraction of dry solids in the raw compost mixture (dry wt/wet wt, dimensionless)
f_{sr} = the weight fraction of dry solids in the recycled compost seed (dry wt/wet wt, dimensionless)
f_{ss} = the weight fraction of dry solids in the waste material (substrate) to be composted (dry wt/wet wt, dimensionless)
X_a = the dry weight of the energy amendment (kg TS)
X_b = the dry weight of the bulking agent (kg TS)
X_m = the dry weight of the raw compost mixture (kg TS)
X_r = the dry weight of the recycled compost seed (kg TS)
X_s = the dry weight of the substrate (kg TS)

The organic matter in the pile is usually reported as volatile solids:

$$f_{vm}f_{sm}W_m = f_{vs}f_{ss}W_s + f_{vr}f_{sr}W_r + f_{vb}f_{sb}W_b + f_{va}f_{sa}W_a$$
$$X_{vm} = X_{vs} + X_{vr} + X_{vb} + X_{va} \tag{11.181}$$

where f_{va} = the weight fraction of volatile solids in the dry energy amendment (VS/TS, dimensionless)
f_{vb} = the weight fraction of volatile solids in the dry bulking agent (VS/TS, dimensionless)
f_{vm} = the weight fraction of volatile solids in the dry raw compost mixture (VS/TS, dimensionless)
f_{vr} = the weight fraction of volatile solids in the dry recycled compost seed (VS/TS, dimensionless)
f_{vs} = the weight fraction of volatile solids in the dry raw waste (VS/TS, dimensionless)
X_{va} = the weight of dry volatile solids in the energy amendment (kg VS)
X_{vb} = the weight of dry volatile solids in the bulking agent (kg VS)
X_{vm} = the weight of dry volatile solids in the raw compost mixture (kg VS)
X_{vr} = the weight of dry volatile solids in the recycled compost seed (kg VS)
X_{vs} = the weight of dry volatile solids in the raw waste (kg VS)

A portion of the volatile solids is biodegradable:

$$f_{bm}f_{vm}f_{sm}W_m = f_{bs}f_{vs}f_{ss}W_s + f_{br}f_{vr}f_{sr}W_r + f_{bb}f_{vb}f_{sb}W_b + f_{ba}f_{va}f_{sa}W_a$$
$$X_{bm} = X_{bs} + X_{br} + X_{bb} + X_{ba} \tag{11.182}$$

where f_{ba} = the weight fraction of biodegradable volatile solids in the energy amendment (kg biod VS/kg VS)
f_{bb} = the weight fraction of biodegradable volatile solids in the dry bulking agent (kg biod VS/kg VS)
f_{bm} = the weight fraction of biodegradable volatile solids in the dry raw compost mixture (kg biod VS/kg VS)
f_{br} = the weight fraction of biodegradable volatile solids in the dry recycled compost seed (kg biod VS/kg VS)
f_{bs} = the weight fraction of biodegradable volatile solids in the dry waste (kg biod VS/kg VS)
X_{ba} = the weight of dry biodegradable volatile solids in the energy amendment (kg VS)
X_{bb} = the weight of dry biodegradable volatile solids in the bulking agent (kg VS)
X_{bm} = the weight of dry biodegradable volatile solids in the raw compost mixture (kg VS)
X_{br} = the weight of dry biodegradable volatile solids in the recycled compost seed (kg VS)
X_{bs} = the weight of dry biodegradable volatile solids in the raw waste (kg VS)

The decay of the biodegradable material consumes oxygen and produces heat and determines the airflow rate.

The biodegradable fraction on any component is closely related to its lignin content and may be approximated by the following (Haug, 1993):

$$f_{bi} = 0.83 - 0.028 f_{li} \tag{11.183}$$

where f_{bi} = the fraction of component i that is biodegradable (kg biod VS/kg VS)
f_{li} = the fraction of component i that is lignin (kg lignin/kg VS).

The fraction of the recycled seed that is biodegradable may be assumed to be zero, and any sawdust amendment may be assumed to be 100% biodegradable. Raw wastes are commonly 40 to 50% biodegradable. About 15 to 30% of wood chips are lost due to mechanical breakage in the screening process. The small wood fibers become part of the compost product. The bulking agent also slowly degrades and becomes part of the compost product. At least 5% of a wood-chip bulking agent degrades in each pass through the composting pile.

The air requirement depends on the composition of the waste and any biodegradable additions. Some of the stoichiometric oxidation reactions of typical compost components are as follows (Haug, 1993):

Combined POTW sludges:

$$C_{10}H_{19}O_3N + 12.5\ O_2 \rightarrow 10\ CO_2 + 8\ H_2O + NH_3 \tag{11.184}$$

1.99 g O per g biodegradable solids

MSW:

$$C_{64}H_{104}O_{37}N + 70.75\ O_2 \rightarrow 64\ CO_2 + 50.5\ H_2O + NH_3 \tag{11.185}$$

1.53 g O per g biodegradable solids

Mixed paper:

$$C_{266}H_{434}O_{210}N + 268.75\ O_2 \rightarrow 266\ CO_2 + 215.5\ H_2O + NH_3 \tag{11.186}$$

1.23 g O per g biodegradable solids

Wood:

$$C_{295}H_{420}O_{186}N + 306.25\ O_2 \rightarrow 295\ CO_2 + 208.5\ H_2O + NH_3 \tag{11.187}$$

1.41 g O per g biodegradable solids

Yard waste:

$$C_{27}H_{38}O_{16}N + 27.75\ O_2 \rightarrow 27\ CO_2 + 17.5\ H_2O + NH_3 \qquad (11.188)$$

1.40 g O per g biodegradable solids

The airflow strips water from the compost pile. It may be assumed that exit air is saturated with water vapor at the pile temperature (Haug, 1993):

$$\log_{10} p_{vsat} = -\frac{2238}{T} + 8.896 \qquad (11.189)$$

$$\omega_{sat} = \frac{0.6221 p_{vsat}}{p_{atm} - p_{vsat}} \qquad (11.190)$$

where p_{atm} = the total atmospheric pressure, dry air plus water vapor (mm Hg)
p_{vsat} = the vapor pressure of water in saturated air at the specified temperature (mm Hg)
T = the absolute temperature (K)
ω_{sat} = the saturated specific humidity (kg H_2O/kg air)

The required airflow for water removal is, therefore, as follows:

water in air = water in raw compost mixture − water in final compost product

$$(\omega_{sat} - \omega)\rho_a Q_a = (1 - f_{sm})W_m - \frac{(1 - f_{sr})(X_m - X_{bm})}{f_{sr}} \qquad (11.191)$$

where Q_a = the volumetric airflow rate (m^3/s)
ρ_a = the air density (kg/m^3)
ω = the specific humidity of the ambient air (kg H_2O/kg air)

At 77°F (25°C) and 70% relative humidity, which are typical summer conditions, air holds 0.014 lb water per lb dry air (23.8 mm Hg). At 131°F (55°C), which is a typical compost pile temperature, saturated air holds 0.115 lb water per lb dry air (118 mm Hg).

The airflow rate also affects the pile temperature. The heat balance for a compost pile is as follows:

$$h_{lhv} = \left[C_{pa}(T_p - T_a) + \omega_{sat} C_{pv}(T_p - T_a) + \lambda(\omega_{sat} - \omega)\right]\rho_a Q_a \qquad (11.192)$$

where C_{pa} = the constant pressure-specific heat of dry air (kJ/kg K)
≈ 1 kJ/kg K (0.24 Btu/lbm °F)
C_{pv} = the constant pressure specific heat of water vapor (kJ/kg K)
≈ 1.93 kJ/kg K (0.46 Btu/lbm °F)
h_{lhv} = the lower heating value of the raw waste plus sawdust amendment (kJ/kg)
T_a = the ambient air temperature (K)
T_p = the compost pile temperature (K)
λ = the latent heat of evaporation of water (kJ/kg)
≈ 2371 kJ/kg at 55°C (1019 Btu/lbm)

The lower heating value is required, because water exits the pile as vapor.

The higher heating value of the dry raw compost mixture can be estimated from the modified Dulong formula (Tchobanoglous, Theisen, and Vigil, 1993):

$$h_{hhv} = 145P_C + 610\left(P_H - \frac{P_O}{8}\right) + 40P_S + 10P_N \qquad (11.193)$$

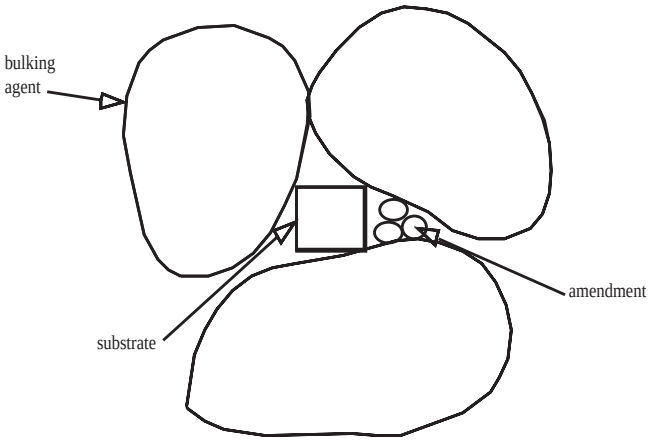

FIGURE 11.12 Free air space in solid waste mixtures.

where h_{hhv} = the higher heating value of the dry, ash-free biodegradable material in the mixture (Btu/lbm VS)
P_C = the percent weight of carbon in the dry, ash-free mixture (%)
P_H = the percent weight of hydrogen in the dry, ash-free mixture (%)
P_N = the percent weight of nitrogen in the dry, ash-free mixture (%)
P_O = the percent weight of oxygen in the dry, ash-free mixture (%)
P_S = the percent weight of sulfur in the dry, ash-free mixture (%)

The lower heating value is simply the higher heating value less the latent heat of evaporation of the water formed:

$$h_{lhv} = h_{hhv} - 18\lambda f_H \tag{11.194}$$

where f_H = the weight fraction of hydrogen in the dry, ash-free biodegradable solids (lbm H/lbm VS).

Airflow cools the pile and dries it. Which factor controls depends on the starting condition of the mixture, the desired moisture content of the composted waste, and the maximum pile temperature.

Free Airspace

Following agricultural practice, the void volume includes substrate water (which the bulking agent may absorb) and free airspace. The volume of the raw mixture is equal to the free airspace volume plus the volume of the individual component particles (Fig. 11.12):

$$\text{mix vol} = \text{free air vol} + \text{waste particle vol} + \text{bulking agent particle vol} + \text{amendment particle vol} \tag{11.195}$$

$$\frac{W_m}{\gamma_m} = \varepsilon_{fa}\frac{W_m}{\gamma_m} + \frac{W_s}{\gamma_s} + (1-\varepsilon_b)\frac{W_b}{\gamma_b} + (1-\varepsilon_a)\frac{W_a}{\gamma_a}$$

where ε_a = the void fraction of the amendment (dimensionless)
ε_b = the void fraction of the bulking agent (dimensionless)
ε_{fa} = the free airspace fraction of the raw mixture (dimensionless)
ε_s = the void fraction of the raw waste (substrate) (dimensionless)
= 0, by assumption for wet wastes like sludges
γ_a = the wet, bulk density of the amendment, including voids (kg/m^3)
γ_b = the wet bulk density of the bulking agent, including voids (kg/m^3)

γ_m = the wet bulk density of the raw mixture, including voids (kg/m^3)
γ_s = the wet bulk density of the raw waste, including voids (kg/m^3)

Raw wastes like POTW sludges are mostly water, even after dewatering. Therefore, the void volume of sludges is zero. Bulking agents are added to the wet solids to maintain voids for airflow. The free airspace fraction of the mixture, ε_{fa}, should be at least 20%, and the optimum is 30 to 35%. Absorption of water from the wet raw waste by the bulking agent shrinks the volume of the raw waste in the mix and creates additional free airspace.

The amount of water adsorbed is limited by the absorptive capacity of the bulking agent or the amount of water in the substrate. Ignoring the amendment volume, which is small, this leads to two formulas for the volume of the raw mixture without free water films (Haug, 1993):

Bulking agent absorptive capacity limited:

$$\text{absorbed water} = \text{final bulking agent water} - \text{initial bulking agent water}$$

$$W_{wabs} = \left(\frac{f_{sb}}{f_{sb}^{\min}} - f_{sb} \right) W_b - (1 - f_{sb}) W_b \tag{11.196}$$

$$W_{wabs} = \left(\frac{f_{sb}}{f_{sb}^{\min}} - 1 \right) W_b$$

$$\frac{W_m}{\gamma_m} = \varepsilon_m \frac{W_m}{\gamma_m} + \left[\frac{W_s}{\gamma_s} - \left(\frac{f_{sb}}{f_{sb}^{\min}} - 1 \right) \frac{W_b}{\rho} \right] + (1 - \varepsilon_b) \frac{W_b}{\gamma_b} \tag{11.197}$$

Substrate surface water limited:

$$\text{water absorbed} = \text{initial substrate water} - \text{final substrate water}$$

$$W_{wabs} = (1 - f_{ss}) W_s - \left(\frac{f_{ss}}{f_{ss}^{\max}} - f_{ss} \right) W_s \tag{11.198}$$

$$W_{wabs} = \left(1 - \frac{f_{ss}}{f_{ss}^{\max}} \right) W_s$$

$$\frac{W_m}{\gamma_m} = \varepsilon_m \frac{W_m}{\gamma_m} + \left[\frac{W_s}{\gamma_s} - \left(1 - \frac{f_{ss}}{f_{ss}^{\max}} \right) \frac{W_s}{\rho} \right] + (1 - \varepsilon_b) \frac{W_b}{\gamma_b} \tag{11.199}$$

where $f_{sb}^{\min}$ = the minimum fraction of dry solids in the bulking agent when it is saturated with water (kg dry solid/kg wet solid)
$f_{ss}^{\max}$ = the maximum fraction of dry solids in the waste (kg dry solid/kg wet solid)
W_{wabs} = the water absorbed by the bulking agent (kg)
ρ = the mass density of water (kg/m^3)

Both formulas are more conveniently written in terms of bulk volume mixing ratios (Haug, 1993):

$$r_{bs} = \frac{\text{bulking agent volume}}{\text{substrate volume}} = \frac{W_b / \gamma_b}{W_s / \gamma_s} \tag{11.200}$$

$$r_{mb} = \frac{\text{mixture volume}}{\text{bulking agent volume}} = \frac{W_m / \gamma_m}{W_b / \gamma_b} \tag{11.201}$$

$$r_{ms} = \frac{\text{mixture volume}}{\text{waste volume}} = \frac{W_m/\gamma_m}{W_s/\gamma_s} \tag{11.202}$$

Bulking agent absorptive capacity limited:

$$1 = (1-\varepsilon_m) r_{ms} + \frac{\gamma_b}{\rho}\left(\frac{f_b}{f_b^{\min}} - 1\right) r_{bs} - (1-\varepsilon_b) r_{bs} \tag{11.203}$$

Substrate water limited:

$$1 = (1-\varepsilon_m) r_{ms} - (1-\varepsilon_b) r_{bs} + \frac{\gamma_s}{\rho}\left(1 - \frac{f_{ss}}{f_{ss}^{\max}}\right) \tag{11.204}$$

For wet substrates like POTW sludges, the mixture is mostly bulking agent; a typical mixture to bulking agent ratio, r_{mb}, is 1.1 (Haug, 1993).

The design unknown is the bulking agent to waste substrate ratio, r_{bs}. Both values produced by Eqs. (11.196) and (11.197) are used to calculate the weight of bulking agent required. Then, the amount of water absorbed by the bulking agent is computed for both cases. The smaller amount of absorbed water controls. The volume of the mixture is then estimated using r_{mb}.

Kinetics

For garbage and raw POTW sludges, the peak oxygen consumption rates are on the order of 4 to 14 mg O_2/g VS/hr (14 to 50 scm/ton/hr) (Haug, 1993). Newsprint and MSW absorb oxygen at much lower rates, on the order of 0.5 mg O_2/g VS/hr. These rates control the capacity of the aeration system.

The decay of many waste materials (substrates) can be represented as a pseudo first-order reaction if the wastes are subdivided into fast and slow reacting portions (Haug, 1993):

$$\frac{dX_{bs}}{dt} = k_{df} X_{bsf} + k_{ds} X_{bss} \tag{11.205}$$

where k_{df} = the decay rate of the fast-reacting biodegradable waste material (substrate) (per day)
k_{ds} = the decay rate of the slow-reacting biodegradable waste material (substrate) (per day)
X_{bsf} = the dry weight of the fast-reacting biodegradable waste material (substrate) (kg VS)
X_{bss} = the dry weight of the slow-reacting biodegradable waste material (substrate) (kg VS)

The fast-reacting fractions are poorly known. Reported values for POTW sludges range from about one-fifth to two-fifths (Haug, 1993). The fast rates are often five to ten times the slow rates.

11.7 Sludge Stabilization

The treatment goal is the production of a stabilized sludge that will not produce offensive odors or attract disease vectors. The stabilization of wastewater sludges can occur aerobically or anaerobically. Stabilization means that the bulk of the organic solids is converted to metabolic end-products that resist further degradation and that do not produce nuisance odors or attract vectors. In aerobic digestion, these products are carbon dioxide, water, various inorganic salts, and humic/fulvic materials. In anaerobic digestion, the products are methane, carbon dioxide, various inorganic salts, and humic/fulvic materials.

Vector attraction is considered to be reduced if the following occurs (EPA, 1993; Stein et al., 1995):

- The VS content of the sludge is reduced by at least 38% by aerobic or anaerobic digestion.
- An anaerobically digested sludge loses less than 17% of its VS content upon further anaerobic batch-digestion at 30 to 37°C for 40 additional days.
- An aerobically digested sludge containing less than 2% solids loses less than 15% of its VS content upon further aerobic batch-digestion at 20°C or 30 additional days; sewage sludges containing more than 2% solids should be diluted to 2% solids prior to testing.
- The specific oxygen uptake rate of an aerobically digested sewage sludge is reduced to 1.5 mg O_2/g TS/hr at 20°C.
- A sludge is digested aerobically at an average temperature of 45°C (minimum 40°C) for at least 14 days.
- The sludge is lime-stabilized (see below).
- The moisture content of the stabilized sewage sludge is less than 25%.
- The moisture content of an unstabilized sewage sludge is less than 10%.
- The sewage sludge is injected below the ground surface; no sludge may be on the surface within 1 hr of injection; Class A sludges must be injected within 8 hr of its discharge from a pathogen reduction process.
- The sewage sludge is incorporated into the soil by plowing and disking within 8 hr of land application.

Aerobic digestion consumes energy because of the aeration requirement. Anaerobic digestion is a net energy producer because of the methane formed, but often, the only economic use of the methane is

digester and space heating. Aerobic digestion seldom produces offensive odors (the usual smell being mustiness), but failed anaerobic digesters can produce foul odors.

Sludge digestion substantially reduces the numbers of pathogens and parasites, but it does not qualify as a sludge disinfection process. If digested sludges are to be applied to land, disinfection by heat treatment and/or lime stabilization is required.

Anaerobic Digestion

Anaerobic digestion stabilizes organic sludges by converting them to gas and humus. The principal interest is the methane content of the gas, which is usable as a fuel. It is, however, a dirty gas, containing carbon dioxide, greasy aerosols, hydrogen sulfide, water vapor, and nitrogen, and it requires cleanup before use. Also, its fuel value is low compared to natural gas (pure methane). The upshot is that many facilities that have access to cheap commercial fuels burn off the methane to control its fire and explosion hazards. Some of the digester gas may be used for space heating, as this requires only sulfide removal. Iron sponge scrubbers usually remove hydrogen sulfide, which is relatively cheap.

The humus is suitable as a soil conditioner as long as its heavy metal and pathogen/parasite content is low. These must be monitored regularly. Most of the municipally produced humus is spread on farmland, either as a wet sludge or a dewatered solid. Some of it is incinerated, although it makes better sense to incinerate the raw sludge and capture its fuel value for the burning process.

Facilities Arrangement

According to the ASCE survey of POTWs, about three-fourths of the plants employing anaerobic digestion have single-stage, heated (95°F), mixed tanks (Leininger, Sailor, and Apple, 1983). About one-fourth of the plants have two-stage systems with heated, mixed primary tanks followed by unheated, unmixed secondary tanks. The secondary tanks are intended to capture and thicken digested solids. However, the suspended solids produced by the primary tanks settle poorly because of gas flotation, particle size reduction due to digestion, and particle size reduction due to mixing (Brown and Caldwell, Consulting Engineers, Inc., 1979). In full-scale field units, only about one-third of the suspended solids entering the secondary digester will settle out (Fan, 1983). The construction of secondary digesters does not appear to be warranted.

Plants that attempt to concentrate digested sludges by gravity thickening (in secondary digesters or otherwise) frequently recycle the supernatant liquor to the primary settlers. This practice results in digester feed sludges that contain substantial portions of previously digested, inert organic solids, perhaps 25 to 50% of the VS in the feed. Consequently, the observed volatile solids destructions are significantly reduced, frequently to as little as 30%. Such low destructions merely indicate the presence of recirculated inert volatile solids and do not imply that incomplete digestion is occurring. However, if substantial fractions of inert organics are being recirculated, then the digesters are oversized or their hydraulic retention time and treatment capacity are reduced.

Typical digestion tanks are circular in plan with conical floors for drainage. Typical tank diameters are 24 m, and typical sidewall depths are 8 m (Leininger, Sailor, and Apple, 1983). Almost half of the digesters are mixed by recirculated digester gas, nearly one-fourth by injection from the roof via gas lances. About two-fifths of the digesters are mixed by external pumps, which generally incorporate external heat exchangers. So-called egg-shaped digesters permit more efficient mixing and are gradually replacing the old-fashioned cylindrical digesters in new facilities.

Digesters are almost always heated by some kind of external heat exchanger fueled with digester gas. In cold climates, gas storage is usually practiced, usually in floating gasholder covers or flexible membrane covers.

Microbiology and Pattern of Digestion

Many of the bacteria responsible for anaerobic digestion are common intestinal microbes (Kirsch and Sykes, 1971). They are fastidious anaerobes; molecular oxygen kills them. The preferred temperature is

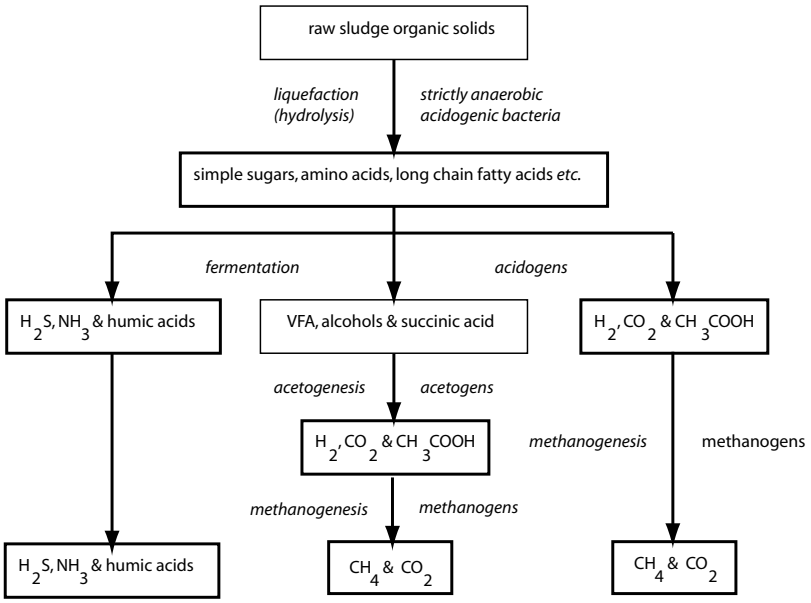

FIGURE 11.13 Pattern of organic solids decomposition in anaerobic digestion.

37°C (human body temperature), and the preferred pH range is about 6.5 to 7.5. Facultatively anaerobic bacteria like the coliforms comprise only a few percent of the population or less.

The pattern of anaerobic decomposition of wastewater sludges is indicated in Fig. 11.13. The primary ecological division among the bacteria in digesters is between acidogens and methanogens. The acidogen population (as a whole) hydrolyzes the cellulose and other complex carbohydrates, proteins, nucleotides, and lipids to simple organic molecules and ferments them to hydrogen gas, carbon dioxide, acetic acid, and other volatile fatty acids (VFA), other organic acids, alcohols, ammonia, hydrogen sulfide, and humic and fulvic acids. Three carbon and larger VFA, other organic acids, and alcohols are converted to acetic acid, possibly hydrogen gas and carbon dioxide, by a subgroup of the acidogenic population called the acetogens.

The methanogenic population (as a whole) converts acetic acid, carbon dioxide, and hydrogen, formic acid, methanol and tri-, di-, and monomethylamine to methane (Whitman, Bowen, and Boone, 1992).

$$CH_3COOH \rightarrow CH_4 + CO_2 \tag{11.206}$$

$$CO_2 + 4H_2 \rightarrow CH_4 + 2H_2O \tag{11.207}$$

$$4HCOOH \rightarrow CH_4 + 3CO_2 + 2H_2O \tag{11.208}$$

$$4CH_3OH \rightarrow 3CH_4 + CO_2 + H_2O \tag{11.209}$$

$$4CH_3NH_2 + 3H_2O \rightarrow 3CH_4 + CO_2 + 4NH_3 \tag{11.210}$$

No other substrates are known to support growth of the methanogens. Nearly all the known methanogens (except for *Methanothrix soehngenii*, which grows only on acetic acid) grow by reducing carbon dioxide with hydrogen, but the largest source of methane in digesters, about 70%, is derived from the lysis of acetic acid (McCarty, 1964). The methanogens are autotrophs and derive their cell carbon from carbon dioxide.

The composition of typical digested municipal sludge is given in Table 11.16, and the fate of various wastewater sludge components during digestion is indicated in Table 11.17 (Woods and Malina, 1965).

TABLE 11.16 Approximate Composition of Digested Sludge

Item	Primary Digester Sludge		Secondary Digester Settled Sludge Solids with Associated Interstitial Water		Secondary Digester Decanted Supernatant Liquor	
	Median	Range	Median	Range	Median	Range

[a] Experimental error.

Source: Woods, C.E. and Malina, J.F., Jr. 1965. "Stage Digestion of Wastewater Sludge," *Journal of the Water Pollution Control Federation*, 37(11): 1495.

Overall, about 60% of the sludge organic matter is converted to gas, about 30% ends up as soluble organic matter, and 10% ends up in the residual humus solids. Over 80% of the influent carbohydrates and lipids are gasified, and most of the remainder ends up as soluble products. Only about half the proteins and other nitrogenous organics are gasified, and nearly one-third is converted to soluble products.

Gas Stoichiometry

The principal benefit of anaerobic digestion is the methane gas produced, which can be used as a fuel. Typical municipal digesters produce a gas that is approximately 65% by vol. methane, 30% carbon dioxide, 2.6% nitrogen, 0.7% hydrogen, 0.4% carbon monoxide, 0.3% hydrogen sulfide, and about 0.2% other illuminants (Pohland, 1962). The fuel value of the raw gas is about 620 Btu/scf (1 atm, 32°F). Digester

gas is saturated with water vapor at the digestion temperature (42 mm Hg at 35°C) and contains an aerosol of small grease and sludge particles that is formed as gas bubbles burst at the liquid surface. The aerosols and hydrogen sulfide must be removed prior to transmission and burning.

The fuel value of the gas resides in the methane content. At 25°C (77°F), methane has a lower heating value (product water remains a vapor) of 21,500 Btu/lb (959 Btu/ft^3) and a higher heating value (product water condenses) of 23,900 Btu/lb (1,064 Btu/ft^3) (Van Wylen, 1963). Methane has an autoignition temperature of 650°C and lower and upper explosion limits in air of 5.3 and 15% by vol., respectively (Dean, 1992).

The quality and quantity of this gas is determined by the chemical composition of the volatile solids that are destroyed. This can be estimated using the following modification of Buswell's (1965) stoichiometry:

$$\begin{aligned} &C_v H_w O_x N_y S_z + \left(v - \frac{w}{4} - \frac{x}{2} + \frac{3y}{4} + \frac{z}{2}\right) H_2O \rightarrow \\ &\left(\frac{v}{2} + \frac{w}{8} - \frac{x}{4} - \frac{3y}{8} - \frac{z}{4}\right) CH_4 + \left(\frac{v}{2} - \frac{w}{8} + \frac{x}{4} + \frac{3y}{8} + \frac{z}{4}\right) CO_2 + y\,NH_3 + z\,H_2S \end{aligned} \tag{11.211}$$

Organic nitrogen is released as ammonia, which reacts with water to form ammonium hydroxide and to trap some of the carbon dioxide produced:

$$NH_3 + CO_2 + H_2O \rightarrow NH_4^+ + HCO_3^- \tag{11.212}$$

The net result is that each mole of ammonia traps one mole of carbon dioxide. Accounting for this effect, the expected mole fractions of methane, carbon dioxide, and hydrogen sulfide are as follows:

$$f_{CH_4} = \frac{4v + w - 2x - 3y - 2z}{8(v - y + z)} \tag{11.213}$$

$$f_{CO_2} = \frac{4v - w + 2x - 5y + 2z}{8(v - y + z)} \tag{11.214}$$

$$f_{H_2S} = \frac{z}{v - y + z} \tag{11.215}$$

The estimate for hydrogen sulfide given in Eq. (11.215) is a maximum. The usual hydrogen sulfide concentration in digester gas is about 1% by vol., but it is variable (Joint Task Force, 1992). There are three general processes that reduce its gas phase concentration. First, hydrogen sulfide is a fairly soluble gas, about 100 times as soluble as oxygen, and much of it remains in solution. Second, hydrogen sulfide is also a weak acid, and the two-step ionization, which liberates bisulfide and sulfide, is pH dependent:

$$H_2S \leftrightarrow HS^- + H^+ \tag{11.216}$$

$$HS^- \leftrightarrow S^{2-} + H^+ \tag{11.217}$$

At 35°C and pH 7, most of the hydrogen sulfide exists as bisulfide, which further increases the amount of sulfide that remains in the sludge. Third, sulfide forms highly insoluble precipitates with many metals and can be trapped in the digested sludge as a metallic sulfide. The most common form is ferrous sulfide.

Carbohydrates and acetic acid produce gases that are 50/50 methane and carbon dioxide by vol. Proteins and long-chain fatty acids produce gases that are closer to 75/25 methane and carbon dioxide by vol.

Equation (11.211) indicates that anaerobic digestion is a pseudohydrolysis reaction, and that the weight of the gases produced may exceed the weight of the solids destroyed because of the incorporation of water. However, in the case of carbohydrates and acetic acid, there is no water incorporation, and the weight of the gases equals the weight of the carbohydrate/acetic acid destroyed. There is significant water incorporation in the destruction of long-chain fatty acids, and the weight of the gases formed may be 50% greater than the weight of the fatty acid destroyed. In the case of protein fermentation, there is significant water incorporation, but the trapping of carbon dioxide by ammonia yields a gas weight that is lower than the protein weight.

Primary sludges tend to contain more fats and protein and less carbohydrate than secondary sludges. Consequently, secondary sludges produce less gas but with a somewhat higher methane content. On the basis of volatile solids destroyed, the gas yields are as follows:

- Primary Sewage Solids (Buswell and Boruff, 1932):
  - 1.25 g total gas per g VS destroyed
  - 1.16 L total gas (SC) per g VS destroyed
  - CH_4:CO_2::67:33, by vol.
- Waste Activated Sludge and Trickling Filter Humus (Fair and Moore, 1932c):
  - 0.71 g total gas per g VS destroyed
  - 0.66 L total gas (SC) per g VS destroyed
  - CH_4:CO_2::71:29, by vol.

It is easier to estimate the methane production from a COD balance on a digester. Because it is an anaerobic process, all the COD removed from the sludge ends up in the methane produced. The COD:CH_4 ratio can be estimated from,

$$CH_4 + 2O_2 \rightarrow CO_2 + 2H_2O \tag{11.218}$$

Consequently, the COD of 1 mole of methane is 64 g or 4 g COD/g CH_4. Because 1 mole of any gas occupies 22.414 L at standard conditions (0°C, 1 atm), the ratio of gas volume to COD is 0.350 L CH_4 (SC) per g COD removed.

Kinetics

Sludge digesters are usually designed to be completely mixed, single-pass reactors without recycle. This is due to the fact that digested sludges are only partially settleable, and solids capture by sedimentation is impractical. Consequently, the hydraulic retention time of the system is also the solids' retention time:

$$\Theta_X = \frac{VX}{QX} = \frac{V}{Q} = \tau \tag{11.219}$$

where Q = the raw sludge flow rate (m^3/s)
V = the digester's volume (m^3)
X = the suspended solids' concentration in the digester (kg/m^3)
Θ_X = the solids' retention time (s)
τ = the hydraulic retention time (s)

Stewart (1958) first demonstrated and Agardy, Cole, and Pearson (1963) confirmed the applicability of Gram's (1956) model for the activated sludge process to anaerobic digestion. The important relationships are as follows:

$$\mu = Yq \tag{11.220}$$

$$q = \frac{q_{max} S}{K_s + S} \tag{11.221}$$

$$\mu = \frac{\mu_{max} S}{K_s + S} \tag{11.222}$$

$$\frac{1}{\Theta_X} = \mu - k_d \tag{11.223}$$

where K_s = Monod's affinity constant (kg COD/m^3)
k_d = the "decay" rate (per s)
q = the specific uptake (or utilization) rate (kg COD/kg VSS·s)
q_{max} = the maximum specific uptake (or utilization) rate (kg COD/kg VSS·s)
S = the kinetically limiting substrate's concentration (kg COD/m^3)
μ = the specific growth rate (per s)
μ_{max} = the maximum specific growth rate (per s)
Θ_X = the solids' retention time (s)

The rate-limiting step in the conversion of organic solids to methane is the fermentation of saturated long-chain fatty acids to acetic acid (Fan, 1983; Novak and Carlson, 1970; O'Rourke, 1968). Kinetic constants for growth on selected volatile fatty acids, long-chain fatty acids, and hydrogen are given in Table 11.18. The minimum solids' retention time for satisfactory digestion is determined by using the kinetic parameters for long-chain fatty acid fermentation.

The kinetic parameters apply to the "biodegradable" fraction of the lipids in municipal wastewater sludges. This really means the fraction converted to gas; the remaining lipid is conserved in other soluble and particulate microbial products. O'Rourke (1968) estimates that 72% of the lipids in municipal sludges can be gasified at 35°C. The gasifiable fraction falls to 66% at 25°C and to 59% at 20°C. Lipids are not gasified below 15°C.

TABLE 11.18 Gram Model Kinetic Parameters for Anaerobic Digestion at 35°C (Preferred Design Values Shown Boldface)

	Substrate				
Gram Model Parameter	H_2	Acetic Acid	Propionic Acid	Butyric Acid	Long-Chain Fatty Acids
μ_{max} (per day)	1.06	0.324	0.318	0.389	0.267 **(0.267)**
q_{max} (kg COD/kg VSS· d)	24.7	6.1	9.6	15.6	6.67 **(6.67)**
K_s (mg COD/L)	569 (mm Hg)	164	71	16	2000 **(1800)**
k_d (per day)	–0.009	0.019	0.01	0.027	0.038 **(0.030)**
Y (kg VS/kg COD)	0.043	0.041	0.042	0.047	0.054 **(0.040)**

The Wastewater Committee (1997) limits the solids loading to primary anaerobic digesters to a maximum of 80 lb VS per 1000 ft^3 per day (1.3 $kg/m^3 \cdot d$), providing the units are completely mixed and heated to 85 to 95°F. The volume of secondary digesters used for solids capture and storage may not be included in the loading calculation. If the feed sludges have a VS content of 2%, the resulting hydraulic retention time of the primary digester is 16 days.

The median HRT employed for mixed, heated primary digesters treating primary sludge only is 20 to 25 days (Joint Task Force, 1992). The implied safety factor for 90% conversion of volatile solids to gas is about 2 to 2.5. Excluding HRTs less than 10 days, the median HRT for mixed, heated digesters fed a blend of primary and waste activated sludges is about 30 to 35 days. For either sludge, the modal HRT is 20 to 25 days.

Temperature

Nearly all municipal digesters are heated to about 35°C (or 95°F), which is in the mesothermal range to which the intestinal microbes that dominate the process are adapted. Anaerobic ponds used to treat packinghouse wastes may not be heated directly, but much of the process wastewater is hot, and the metabolic heat contributes to maintaining a temperature above ambient.

Psycrophilic digesters operate below 30°C. Psycrophilic digestion is quite common in anaerobic ponds, septic tanks, and wetlands. Psycrophilic digestion is slower than mesophilic or thermophilic digestion. Also, below about 30°C, the fraction of the sludge solids converted to gas is reduced (Maly and Fadrus, 1971). The reduction is roughly linear, and at 10°C, the fraction of solids converted to gas is only about 60% of the conversion at 30°C. Long-chain fatty acids accumulate below about 18°C, which causes foaming (Fan, 1983).

Thermophilic digesters operate above 40°C, usually at 50°C or somewhat higher. The chief advantages of thermophilic digestion are as follows (Buhr and Andrews, 1977):

- More rapid completion of the digestion process, as indicated by the cumulative gas production
- Better dewatering characteristics
- Disinfection of pathogens and parasites, if operated above 50°C

There are, however, several reports of disadvantages (Pohland, 1962; Kirsch and Sykes, 1971):

- Accumulation of volatile fatty acids and reduction of pH
- Accumulation of long-chain fatty acids
- Reduced gas production per unit volatile solids fed
- Reduced methane content of the gas
- Offensive odors
- Reduced volatile solids destruction
- Impaired dewatering characteristics
- Increased heating loss rates (although the tanks are smaller, and the smaller surface area somewhat offsets the higher heat flux)

The systems reporting impaired digestion were not operating stably, and there is a general opinion that thermophilic digestion is difficult to establish and maintain. Part of the problem may lie in the reduced suite of microbes that are able to grow thermophilically. Naturally occurring thermophilic environments are rare, and there are few thermophiles among the acidogens and methanogens in primary sewage sludge, which is derived entirely from psycrophilic and mesophilic environments. In any particular plant, the conversion from mesophily to thermophily may require some time for proper seeding by the few thermophiles in the influent sludge. If the digester goes sour in the interim, the seeding may fail to take. It should be noted that many of the failed thermophilic digestion experiments were conducted using laboratory-scale units. The seeding problem here is compounded by the Poisson nature of the sludge sampling process; it is likely that none of the small samples needed for laboratory work will contain any

thermophiles. It should be noted that the full-scale thermophilic plant at Los Angeles was a stable process (Garber, 1954).

The effect of temperature on digestion can be represented in terms of Gram's model. For digestion temperatures in the range 20 to 35°C, Parkin and Owen (1986) recommend the following:

$$q_{\max} = 6.67 \times 1.035^{T-35} \quad \left(\text{kg COD/kg VSS} \cdot \text{d}\right) \tag{11.224}$$

$$K_s = 1.8 \times 0.8993^{T-35} \quad \left(\text{g COD/L}\right) \tag{11.225}$$

$$k_d = 0.030 \times 1.035^{T-35} \quad \left(\text{per day}\right) \tag{11.226}$$

$$Y = 0.040 \quad \left(\text{g VSS/g COD}\right) \tag{11.227}$$

The base values are referenced to 35°C and are derived from O'Rourke's (1968) work. True growth yields do not vary significantly with temperature. The microbial decay rate is so poorly known that temperature adjustments may not be warranted. Note that the effective θ for the combined temperature effect on the maximum uptake rate and the affinity constant is about 1.15, which is much larger than the values reported for gasification rates.

pH

Methane production only occurs between pH 5 and 9; the optimum pH is near 7 and falls rapidly as the pH increases or decreases. Price's (1963) data may be summarized as follows:

- Peak rate of methane formation at pH 7
- 90% of peak rate at pH 6.5 and 7.5
- 75% of peak rate at pH 6 and 8
- 50% of peak rate at pH 5.8 and 8.4
- 25% of peak rate at pH 5.4 and 8.8

Inhibitors

Digestion inhibitors are listed in Table 11.19. Some of the metals listed are also nutrients. The optimum concentration for Na^+, K^+, or NH_4^+ is 0.01 mol/L; the optimum concentration for Ca^{2+} or Mg^{2+} is 0.005 mol/L (Kugelman and McCarty, 1965).

Poisons must be in soluble form to be effective. Cobalt, copper, iron, lead, nickel, zinc, and other heavy metals form highly insoluble sulfides ranging in solubility from 10^{-5} to 10^{-11} mg/L, which eliminates the metal toxicity (Lawrence and McCarty, 1965). Heavy metals may comprise as much as 10% of the volatile solids without impairing digestion if they are precipitated as sulfides. The requisite sulfide may be fed as sodium sulfide or as various sulfate salts, which are reduced to sulfide.

It should be noted that methanogens reduce mercury to mono- and dimethylmercury, which are volatile and insoluble and may be present in the digester gas. Alkyl mercurials are toxic.

Halogenated methane analogs like chloroform, carbon tetrachloride, and Freon are toxic to methanogens at concentrations on the order of several mg/L (Kirsch and Sykes, 1971).

Moisture Limitation

The stoichiometry of anaerobic digestion indicates that water is consumed and may be limiting in low moisture environments. Anaerobic digestion proceeds normally at total solids concentrations up to 20 to 25% by wt (Wujcik, 1980). Above about 30% TS, the rate of methane production is progressively reduced and ceases at 55% TS. In this range, the methanogens appear to be water-limited rather than salt-, ammonia-, or VFA-limited. Above 55% TS, acid production is inhibited.

TABLE 11.19 Anaerobic Digestion Inhibitors

Substance	Effect	Concentration Units	Concentration
Inorganic			
Ammonia-nitrogen	Moderate	mg/L	1500–3000
	Strong	mg/L	3000
Calcium	Moderate	mg/L	2500–4500
	Strong	mg/L	8000
Chromium (III)	Strong	mg/L	180–420 (total)
Chromium (VI)	Strong	mg/L	3.0 (soluble)
	Strong	mg/L	200–260 (total)
Copper	Strong	mg/L	0.5 (soluble)
	Strong	mg/L	50–70 (total)
Magnesium	Moderate	mg/L	1000–1500
	Strong	mg/L	3000
Nickel	Strong	mg/L	1.0 (soluble)
	Strong	mg/L	30 (total)
Potassium	Moderate	mg/L	2500–4500
	Strong	mg/L	12,000
Sodium	Moderate	mg/L	3500–5500
	Strong	mg/L	8000
Zinc	Strong	mg/L	1.0 (soluble)
Organic			
Acetaldehyde	50% activity	mmol/L	10
Acrylic acid	50% activity	mmol/L	12
Acrylonitrile	50% activity	mmol/L	4
Acrolein	50% activity	mmol/L	0.2
Aniline	50% activity	mmol/L	26
Catechol	50% activity	mmol/L	24
Chloroform	"inhibitory"	mg/L	0.5
3-Chloro-1,3-propandiol	50% activity	mmol/L	6
1-Chloropropane	50% activity	mmol/L	1.9
1-Chloropropene	50% activity	mmol/L	0.1
2-Chloropropionic acid	50% activity	mmol/L	8.0
Crotonaldehyde	50% activity	mmol/L	6.5
Ethyl acetate	50% activity	mmol/L	11.0
Ethyl benzene	50% activity	mmol/L	3.2
Ethylene dichloride	"inhibitory"	mg/L	5
Formaldehyde	50% activity	mmol/L	2.4
Kerosene	"inhibitory"	mg/L	500
Lauric acid	50% activity	mmol/L	2.6
Linear alkylbenzene sulfonate	"inhibitory"	mg/L	1% of dry solids
Nitrobenzene	50% activity	mmol/L	0.1
Phenol	50% activity	mmol/L	26
Propanol	50% activity	mmol/L	90
Resorcinol	50% activity	mmol/L	29
Vinyl acetate	50% activity	mmol/L	8

Mixing

For high-rate digesters fed unthickened sludges, the required mixing power is about 0.2 to 0.3 hp per 1000 cu ft (Joint Task Force, 1992). Alternatively, the required rms velocity gradient is 50 to 80 per sec, and the turnover time is 30 to 45 min.

In conventional digesters, mixing becomes impaired at VS loading rates above 0.3 lb per cu ft per day (4 kg/m^3·d) (Metcalf & Eddy, Inc., 1991). Ammonia toxicity limits VS loadings to about 0.2 lb per cu ft per day (3.2 kg/m^3·d) (Joint Task Force, 1992).

Sludge pumping becomes a problem at about 8 to 12% TS (Brisbin, 1957). In this range, the Hazen–Williams C coefficient should be reduced by 60 to 75%.

Heat Balance

The higher heating value of raw or digested sludge solids is as follows (Fair and Moore, 1932):

Primary sludge:

$$\Delta H = 29P^{4/3} \quad \left(\text{Btu/lb TS}\right) \tag{11.228}$$

Waste activated sludge:

$$\Delta H = 25P^{4/3} \quad \left(\text{Btu/lb TS}\right) \tag{11.229}$$

where P = the percentage of volatile solids in the total solids (%).

Note that the heating value does not vary linearly with the volatile solids content of the sludge solids. For primary sludges, the higher heating value extrapolated to 100% VS is 13,500 Btu per lb; for waste activated sludges, the higher heating value extrapolated to 100% VS is 11,600 Btu per lb.

The principal use of digester gas is digester heating. The steady state heat transfer due to conduction through material is directly proportional to the temperature difference and the area normal to the heat flow, and it is inversely proportional to the thickness of the material. A heat transfer coefficient, k, may be defined for any pure substance by,

$$Q_h = \frac{kA\Delta T}{L} \tag{11.230}$$

where A = the area normal to the heat flux (m^2)
k = the heat transfer coefficient (J/m·s·K)
L = the thickness of the medium conducting the heat (m)
Q_h = the heat flow (J/s)
ΔT = the temperature difference across the conducting medium (K)

Heat transfer coefficients for some materials are given in Table 11.20.

If a wall or roof is made up of several layers of different substances, then an overall heat transfer coefficient, K, can be calculated by summing the temperature drops across each component and by noting that each component transmits the same heat flux and has the same area:

$$\frac{1}{K} = \frac{L_1}{k_1} + \frac{L_2}{k_2} + \cdots \frac{L_{n-2}}{k_{n-2}} + \frac{L_{n-1}}{k_{n-1}} \tag{11.231}$$

where K = the overall heat transfer coefficient (J/m^2·s·K). As a matter of convenience, the thickness of the composite is adsorbed into the definition of the overall transfer coefficient.

TABLE 11.20 Heat Transfer Coefficients for Various Materials

Material	Transfer Coefficient, k (Btu·in./ft²·hr°F)
Air	0.17
Brick	3.0–6.0
Concrete	2.0–3.0
Earth, dry	10
Earth, wet	30
Mineral wool insulation	0.26–0.29
Steel	5.2–6.0

Chapters 13–20*, WEF Manual of Practice No. 8, ASCE Manual and Report on Engineering Practice No. 76. Water Environment Federation, Alexandria, VA; American Society of Civil Engineers, New York.

A complete heat balance on an anaerobic digester is as follows:

$$\underbrace{\Delta H_{req}}_{\text{heat required}} = \underbrace{C_p \rho Q\left(T_{dig} - T_{slu}\right)}_{\text{raw sludge heating}} + \underbrace{K_r A_r\left(T_{dig} - T_{air}\right)}_{\text{heat through roof}} + \underbrace{K_w A_w\left(T_{dig} - T_{grd}\right)}_{\text{heat through wall}} + \underbrace{K_f A_f\left(T_{dig} - T_{grd}\right)}_{\text{heat through floor}} - \underbrace{H_{met} Q\left(X_{vo} - X_{ve}\right)}_{\text{metabolic heat}} \tag{11.232}$$

where A = area normal to heat flux (m²)
C_p = constant pressure specific heat of water (J/kg)
H_{met} = metabolic heat release (J/kg·VS)
ΔH_{req} = heat requirement (J/s)
K = overall heat transfer coefficient (J/m²·s·K)
Q = sludge flow rate (m³/s)
T_{air} = air temperature (K)
T_{dig} = digester temperature (K)
T_{grd} = ground temperature (K)
T_{slu} = sludge temperature (K)
X_{ve} = effluent VSS (kg/m³)
X_{vo} = influent VSS (kg/m³)
ρ = mass density of water (kg/m³)

When VS are destroyed, approximately 80% of their fuel value is retained in the methane formed, and 20% is liberated to the digesting sludge as metabolic heat (Fan, 1983). A somewhat conservative estimate of the metabolic heat release is 2000 Btu/lb VS destroyed (1100 cal/g VS destroyed). This raises the possibility of autothermal anaerobic digestion. Ignoring the heat losses by conduction and setting the heat requirement to zero, one gets,

$$X_{vo} - X_{ve} = \frac{C_p \rho\left(T_{dig} - T_{slu}\right)}{H_{met}} \tag{11.233}$$

Assuming 60% VS destruction and a sludge temperature increase of 40°F, the influent VS concentration for autothermal mesophilic digestion is about 5% by wt. This is equivalent to about 8% by wt TS, which is near the pumping limit.

Aerobic Digestion

Configuration

Aerobic digestion is usually restricted to smaller facilities where the cost of aeration is offset by the simplicity of the operation and facilities (Joint Task Force, 1992).

The digesters are constructed as open, unheated tanks. A variety of plan geometries have been built, including rectangular, circular, and annular tanks (Joint Task Force, 1992). Side water depths range from 10 to 25 ft. Aerobic digesters are liable to foam, and freeboard heights of 1.5 to 4 ft are required to retain the foam. Aeration and mixing are usually provided by diffused air systems, either coarse or fine bubble. Airflow rates of 20 to 40 scfm per 1000 cu ft are needed for mixing. Diffused air permits better control of dissolved oxygen and reduces heat losses, which is important in cold climates. Mechanical surface aerators have lower maintenance costs, but they produce greater heat losses, increase foam production, and are more liable to reduce oxygen transfer efficiency due to foam.

Typical process loadings are 24 to 140 lb VS per 1000 ft^3/day, and reactor volume allowances are 3 to 4 ft^3 per cap (Schwinn and Gassett, 1974). Many small facilities store digested sludge in the digester for substantial time periods prior to disposal (e.g., because of seasonal land application), and allowances must be made for this additional storage.

Federal regulations require minimum solids' retention times of 40 days at 20°C and 60 days at 15°C and a minimum volatile solids destruction of 38% (Environmental Protection Agency, 1993).

Typical compositions of aerobic digester supernatants are summarized in Table 11.21.

Microbiology

The process of aerobic sludge digestion is a continuation of phenomena occurring in the activated sludge process. In some installations, soluble substrate levels are low, and heterotrophic growth of bacteria is small. Initially, there may also be some endogenous respiration by bacteria starved for substrate. The principal digestion process is the predation and scavenging by "worms," rotifers, and protozoa of the bacteria and other sludge solids and cell lysis by viruses. Some bacteria may hydrolyze particulate matter, and the digestion processes of the predators and scavengers may release soluble substrates that support some heterotrophic growth and the growth of their phages. Additional soluble substrate may be released when the phages lyse the cells of their bacterial hosts.

TABLE 11.21 Properties of Aerobic Digester Supernatants

Parameter (Units)	Mean Value	Range
BOD (mg/L)	500	9–1700
Soluble BOD (mg/L)	51	4–183
COD (mg/L)	2600	228–8140
Suspended solids (mg/L)	3400	46–11,500
Alkalinity (mg/L, as $CaCO_3$)	—	473–514
pH	7	5.9–7.7
TKN (mg/L)	170	10–400
Total P (mg/L)	98	19–241
Soluble P (mg/L)	26	2.5–64

Sources: Schwinn, D.E. and Gassett, R.B., eds. 1974. *Process Design Manual for Upgrading Existing Wastewater Treatment Plants*. Environmental Protection Agency, Technology Transfer, Washington, DC.

Kinetics

The usual assumptions are that the volatile solids may be divided into an inert fraction and a biodegradable fraction with destruction that obeys first-order kinetics (Adams, Eckenfelder, and Stein, 1974). For a completely mixed digester, the volatile solids destruction may be modeled as follows:

$$\frac{X_{vd} - X_{vi}}{X_{vo} - X_{vi}} = \frac{1}{1 + k_d \Theta_X} \tag{11.234}$$

where k_d = the decay rate (per sec)
X_{vd} = the VSS in the digester (kg/m^3)
X_{vi} = the inert or unbiodegradable VSS (kg/m^3)
X_{vo} = influent VSS (kg/m^3)
Θ_X = the solid's retention time (sec)

A typical decay rate at 20°C is 0.08 to 0.12 per day (Brown and Caldwell, 1979). The decay may decline with increasing suspended solids concentrations. For bench-scale units, Reynolds (no date) reported a decline from 0.72 per d at a TSS of 8400 mg/L to 0.34 per d at a TSS of 22,700 mg/L. The sludge was digested at room temperature. Reynolds decay rates are substantially higher than other reported rates; his sludges were obtained from a contact-stabilization plant.

At very long HRTs, the digester VSS concentration, X_{vd}, approaches the inert or unbiodegradable VSS concentration, X_{vi}. Typically, about 50 to 60% of the volatile solids in waste activated sludge are biodegradable (Reynolds, no date).

It should be noted that the suspended ash (TSS minus VSS) is solubilized during digestion, and its concentration declines in parallel with the decline in VSS (Eckenfelder, 1956; Reynolds, no date). However, the solubilized solids remain in the liquid as part of the sludge and are not removed unless a dewatering process is applied to the sludge.

For temperatures above 15°C, SRTs range from 10 to 15 days for waste activated sludge and 15 to 20 days for primary sludge and for mixtures of waste activated and primary sludges (Schwinn and Gassett, 1974).

Temperature

The variation of the decay rate with temperature is given approximately by the following:

$$k_d = 0.332\left\{1 - \exp\left[-0.0403\left(T - 8\right)\right]\right\}; \qquad R^2 = 0.53 \tag{11.235}$$

where k_d = the decay rate (per day)
T = the digestion temperature (°C)

Equation (11.235) was derived from the data summarized by Brown and Caldwell (1979) using the Thomas graphical method for fitting the BOD_5 curve. All the data were used, and the data span the temperature range 10 to 64°C. The derived curve lies somewhat above the hand-drawn curve presented in the report. The scatter about either line is very large, and digestion rates should be based upon pilot studies.

An examination of the plotted data suggests that the digestion rate reaches a maximum of 0.23 per day at a digestion temperature of 40°C. There is no clear thermophilic digestion range, which may reflect the limited number of thermophilic eukaryotes. There are no thermophilic rotifers or worms, which are the dominant predators affecting aerobic digestion.

pH

The comments on the activated sludge process apply here as well. Organic solids destruction is not appreciably affected between pH 6 and 9. However, as long as the dissolved oxygen concentration is above 2 mg/L, aerobic digesters will nitrify, and the pH will fall in poorly buffered waters.

Inhibitors

See Tables 11.4 and 11.5. If nitrification is desired, the special requirements of the nitrifying bacteria will control.

Oxygen Requirements

The general oxygen balance for activated sludge also applies to aerobic digestion. For nonnitrifying digesters,

$$R = 1.42Q\left(X_{vo} - X_{ve}\right) \tag{11.236}$$

and for nitrifying digesters,

$$R = 1.98Q\left(X_{vo} - X_{ve}\right) \tag{11.237}$$

See the comments about oxygen requirements in the activated sludge process, especially the requirements of the nitrifying bacteria.

Mixing Requirements

The power required to mix thickened sludges may be estimated from the following (Zwietering, 1958; Reynolds, no date):

$$P = 0.00475\mu^{0.3} X_{TSS}^{0.298} V \tag{11.238}$$

where $P_{\min}$ = minimum required mixing power (hp)
V = digester volume (1000 gal)
X_{TSS} = the TSS concentration (mg/L)
μ = the liquid viscosity (centipoise)

Autothermal Thermophilic Digestion

The heat balance given above for anaerobic digesters also applies to aerobic digesters. However, in aerobic digestion, all the higher heating values of the destroyed volatile solids are released as metabolic heat, so the break-even point for autothermal digestion is a feed sludge containing between 1 and 2% VS. This is equivalent to about 2 to 3% TS, which is well within the limits for good mixing.

In European practice, waste activated sludges are first thickened to at least 2.5% by wt VSS (Joint Task Force, 1992). The digesters are cylindrical with a height-to-diameter ratio of 0.5 to 1.0. They are operated in the fill-and-draw mode with two temperature phases per cycle. The first temperature phase is 35 to 50°C and is intended to stabilize the sludge. The second phase is 50 to 65°C and is intended to reduce pathogens. The HRT for the digester is 5 to 6 days, with a minimum HRT of 20 hr in either temperature phase. Aeration is generally by diffused air. Substantial foaming occurs; foam cutters are needed to control foam accumulation. Nitrification does not occur at thermophilic temperatures, which reduces the oxygen requirement.

Land Disposal of Sludges

The general requirements for pathogens in sewage sludges applied to land are given in Table 11.22 (EPA, 1993, 1994). The Class A requirements apply to sewage sludges used on home gardens and lawns. Class A specifications also may be used for sludges applied to agricultural land, forest, public contract sites, or reclamation sites. Class B specification may be used for sludges applied to agricultural land, forests, public contract sites, and reclamation sites if certain site usage, cropping, and pasturing restrictions are met.

TABLE 11.22 General Pathogen Restrictions for the Disposal of Sewage Sludges

Pathogen	Class A Requirements (Lawn and Garden)	Class B Requirements (Agricultural Land)
Fecal coliform	All alternatives: <1000 MPN per g total solids	$<2 \times 10^6$ per g total solids
Salmonella	All alternatives: <3 MPN per 4 g total solids	—
Enteric viruses	Alternatives 3 through 6: <1 PFU per 4 g total solids	—
Helminth ova	Alternatives 3 through 6: <1 ova per 4 g total solids	—

Sources: Environmental Protection Agency. 1993. "Standards for the Use or Disposal of Sewage Sludge," *Federal Register*, 58(32): 9248.

Environmental Protection Agency. 1994. "Standards for the Use or Disposal of Sewage Sludge," *Federal Register*, 59(38): 9095.

Class A Sludges

Sewage sludges can be graded Class A if they are subjected to certain pathogen reduction treatments. There are six alternative treatments.

Alternative 1

This alternative requires heat inactivation of pathogens. Specific testing for enteric viruses and helminth ova is not required.

The minimum temperature for heat inactivation regardless of contacting time is 50°C (EPA, 1993). The contacting time required depends on the solids content of the sludge, the temperature, and the mode of heating. Required contacting times for disinfection temperatures of 50°C and above are given by equations that follow. Note that each method of heating and sludge concentration has an absolute minimum contacting time regardless of temperature.

- If the sludge solids concentration is 7% by weight or higher, heating of the bulk sludge is by heat exchanger, use Eq. (11.239) below. The minimum contacting time regardless of disinfection temperature is 20 min.

$$t_c = \frac{131\,700\,000}{10^{0.1440T}} \tag{11.239}$$

where t_c = the contacting time in days
≥ 20 min regardless of temperature
T = the inactivation temperature in °C
≥ 50°C

- If the sludge solids concentration is 7% by weight or higher, sludge heating is by diffused hot gas or hot immiscible liquid use Eq. (11.239) above, with the proviso that the minimum contacting time is 15 min, regardless of disinfection temperature.
- If the sludge concentration is less than 7% solids by weight, use Eq. 11.240 below to determine contacting times, with the proviso that the minimum contacting time regardless of inactivation temperature is 30 min.

$$t_c = \frac{50\,070\,000}{10^{0.1440T}} \tag{11.240}$$

where t_c = the contacting time in days
≥ 30 min regardless of temperature
T = the inactivation temperature in °C
≥ 50°C

Alternative 2
This method combines pH and heat inactivation:

- The pH of the sludge shall be kept above 12 for 72 hr.
- During the period of elevated pH, the sludge temperature shall be kept at 52°C or higher for at least 12 hr.
- After heat/pH treatment, the sludge shall be air-dried to a solids content of at least 50% by weight.

Alternative 3
No treatment method is specified; rather the sludge quality is further constrained. The sewage sludge shall be tested periodically for enteric viruses and viable helminth ova as well as fecal coliform and *Salmonella*, and it will be graded Class A as long as the conditions of Table 11.22 are met. Failure to meet the tabulated requirements requires pathogen treatment and retesting of the treated sludge.

Alternative 4
No pathogen reduction treatment is required. However, the sludge must meet the conditions in Table 11.22 at the time of sale or usage.

Alternative 5
The sludges must meet the fecal coliform and *Salmonella* standards in Table 11.22 at the time of sale and usage and must be subjected to pathogen reduction treatments specified in Appendix B of the Rule.

Alternative 6
The sludges must meet the fecal coliform and *Salmonella* standards in Table 11.22 at the time of sale and usage and must be subjected to pathogen reduction treatments approved by the permitting authority.

Class B Sludges

Alternative 1
The sludge must meet the fecal coliform standard in Table 11.22 at the time of usage.

Alternative 2
The sludge must be subjected to a pathogen reduction treatment specified in Appendix B of the rule.

Alternative 3
Sludges graded Class B must be subjected to pathogen reduction processes approved by the permitting authority. Also, there are site usage restrictions:

- Food crops that touch the sludge/soil mixture and are not entirely above ground may not be harvested for 14 months after sludge application.
- Food crops with harvested parts below the ground may not be harvested for 20 months after sludge application, if the sludge remains on the land surface for 4 months or longer prior to incorporation into the soil.
- Food crops with harvested parts below the ground may not be harvested for 38 months after sludge application when the sludge lies on the land surface for less than 4 months before incorporation into the soil.
- Food crops, feed crops, and fiber crops shall not be harvested for 30 days after sludge application.
- Animals may not be pastured on the land for 30 days after sludge application.
- Turf may not be harvested for 1 year after sludge application if the turf will be used as a lawn or if there is a high potential for public contact with the turf.
- Public access to land with a high potential to public exposure shall be restricted for 1 year after sludge application.
- Public access to land with a low potential for public exposure shall be restricted for 30 days after sludge application.

Lime Stabilization

Lime stabilization requires that the sludge pH be raised above 12 and preferably above 12.5. The pH of 12 or more must be held for at least 2 hr without additional lime, and a pH of at least 11.5 must be held without additional lime for another 2 hr (Stein et al., 1995). At these pHs, there is substantial hydrolysis of organic molecules, and the lime dosage is controlled by the amount of solids to be treated. Following are some guidelines as to hydrated lime dosages (Joint Task Force, 1992):

Primary sludge — 0.1 to 0.15 kg $Ca(OH)_2$ per kg suspended solids
Activated sludge — 0.3 to 0.5 kg $Ca(OH)_2$ per kg suspended solids
Septage — 0.1 to 0.3 kg $Ca(OH)_2$ per kg suspended solids

At pH 12, a minimum contacting time of at least 72 hr is required for stabilization (Class A, Alternative 2). The hydrolysis reactions consume lime, so additional dosages of lime may be required during the contacting period.

Fecal streptococci are not inactivated unless the contacting time is at least 1 hr, and high pH does not affect nematodes, protozoa, or mites.

Lime stabilization releases organic nitrogen as ammonia, and some means of controlling the emitted ammonia gas is required.

Concentration and Loading Limits for Sewage Sludge

Concentration and loading limits for various contaminants are given in Table 11.23 (EPA, 1993, 1994). Bulk or packaged sewage sludges may not be land applied if any pollutant exceeds its *ceiling* concentration. Furthermore, packaged sewage sludge may not be land applied if any pollutant exceeds the *monthly average concentration* or *annual loading limit.* Sludges may not be applied to agricultural land, forest, public contact sites, or land reclamation sites if any pollutant exceeds either the *monthly average* or *cumulative limits*. If sludge is applied to a home garden or lawn, the pollutants may not exceed the *monthly average limits*.

Sewage sludges cannot be land applied if the ground is flooded, frozen, covered with snow, if it drains to a wetland or surface water, or is within 10 m of a surface water. Sewage sludge may not be land applied if it would adversely affect a threatened or endangered species.

Sewage sludge may be applied to agricultural land, forest, public contact sites, or land reclamation sites at or below the usual agronomic limits. For agricultural land, the agronomic rate is typically 10 tonne per ha per yr; for forest and public contact sites, it is 18 tonne per ha per yr; for reclamation sites, a single application of 112 tonne per ha is typical (Stein et al., 1995). Sewage sludges are applied annually to agricultural land between harvest and planting. It is applied to forest annually to once every few years.

TABLE 11.23 Limits on Pollutants Applied to Land

Pollutant	Ceiling Concentration (mg/kg)	Monthly Average Concentration (mg/kg)	Annual Loading Rate (kg/ha/365 days)	Cumulative Loading Limit (kg/ha)
Arsenic	75	41	2.0	41
Cadmium	85	39	1.9	39
Chromium	3000	1200	150	3000
Copper	4300	1500	75	1500
Lead	840	300	15	300

12.1 Introduction

The quality of the ambient air is an issue that is a common denominator among all people throughout the world. This statement is based on the simple fact that to live everyone must breathe. Despite this fact, air quality is an issue that has been historically ignored until it deteriorates to a point where breathing is uncomfortable or even to where life itself is threatened. However, this approach to air quality is changing rapidly as no aspect of the environment has recently received greater attention than that of air pollution and its effects on our health and well-being.

In the U.S., this attention is illustrated by the Clean Air Act Amendments of 1990. This legislation is one of the most comprehensive pieces of environmental legislation ever enacted. The scope of this legislation's effects can be illustrated by the cost of compliance with its provisions. The estimated cost of compliance in the year 2000 was $25.6 billion (year 2000 dollars). The expected cost of compliance in the year 2010 will be $35.6 billion (year 2000 dollars). The estimated monetary benefit from enhanced health and welfare was $93.5 and $144.9 billion, respectively. This was based on a review of both the costs and benefits of the Clean Air Act Amendments required under section 812 of the CAAA. The level of attention the issue of air quality management is receiving is indeed significant, but the field is often misunderstood.

The focus of this chapter is to provide a synopsis of the various aspects involved in air quality engineering and management. The chapter will begin by presenting an overview of the major air quality regulations and pollutants of concern. This discussion will be followed by descriptions of methods used in estimating and quantifying emissions, methods of controlling typical emission sources, a discussion of the meteorology affecting dispersion of emitted pollutants, and conclude with a discussion of the models used to estimate the effects of emission of pollutants on the ambient atmosphere.

12.2 Regulations

Historical Perspective

The regulation of air pollution has evolved from a level of local ordinances in the late 1800s to the federally driven regulatory efforts of today. In 1881, Cincinnati and Chicago became the first American cities to pass smoke control ordinances. This type of local ordinance was the primary means of air quality regulation until the federal government began addressing the issue with the passage of the Air Pollution Control–Research and Technical Assistance Act in 1955. However, this act was not a means of federal regulation, but only a means of providing funds for federal research and technical assistance for an issue that, at the time, was felt to be a state and local problem.

In 1963, the president of the U.S. pushed for the passage of the first Clean Air Act. At that time Congress recognized that air pollution "resulted in mounting dangers to the public health and welfare, including injury to agricultural crops and livestock, damage to and deterioration of property, and hazards to air and ground transportation" [Cooper and Alley, 1990]. This act was the first to address interstate air pollution problems. Further regulations on air pollution were introduced in 1965 with the first set of amendments to the Clean Air Act. These amendments were divided into two provisions addressing air pollution prevention and air pollution resulting from motor vehicles. This act set a national standard for emissions from automobiles to prevent automobile manufacturers from having to comply with 50 different sets of emission standards.

Regulation of ambient air quality was first addressed with the Air Quality Act of 1967. This act was also significant in that for the first time the federal government was granted enforcement authority and was required to develop and promulgate air quality criteria based on scientific studies.

The foundations of the air quality regulations that are in effect today were laid in 1970 with the second set of amendments to the Clean Air Act. These amendments grouped areas of the country into two classes based on the quality of their ambient air in relation to established standards. Separate regulations were developed to apply to the areas based on the air quality in that particular area. This set of amendments also set a time frame in which the areas of the country not in compliance with established ambient air standards would come into compliance with these standards. The authority of the federal government over air quality issues took a giant step forward with this act, and a giant leap forward when this act was coupled with the National Environmental Policy Act that established the Environmental Protection Agency (U.S. EPA) in 1970. This provided for air quality regulation that could be developed and managed at the federal level but implemented by the individual states.

Despite the new level of federal enforcement over the Clean Air Act, the deadlines for compliance with the ambient air standards were not met and in 1977, the Clean Air Act was amended for the third time. The Amendments of 1977 took a proactive stance toward ambient air quality with provisions to prevent areas currently meeting ambient air standards from deteriorating, while at the same time requiring those areas not in compliance with ambient air standards to come into compliance. The amendments of 1977 further required review of air quality and regulations every five years by the U.S. EPA.

Again, despite the new regulations, air quality did not improve. However, federal regulatory efforts plateaued until 15 November 1990 when the Clean Air Act was revised for the fourth time and created the air quality regulations in effect today.

The Clean Air Act Amendments of 1990 are a comprehensive set of regulations that address air pollution from many sources and include systems to measure progress and assure compliance of affected entities. The seven titles of the Clean Air Act are:

- Title I: Air Pollution Prevention and Control (Includes Section 112 Hazardous Air Pollutants)
- Title II: Emissions Standards for Moving Sources
- Title III: General (includes citizen suits, emergency powers, and administrative details)
- Title IV: Acid Deposition Control

- Title V: Permits
- Title VI: Stratospheric Ozone Protection
- Title VII: Enforcement

Regulatory Overview

Air Pollution Sources

Air pollution is defined as the intentional or unintentional release of various compounds into the atmosphere. These compounds consist of both gases (vapors and fumes) and solids (particulates and aerosols) which can be emitted from natural and/or human sources. Typically, pollution arising from human sources, such as manufacturing and automobiles, far outweighs the contribution of compounds arising from natural sources, such as volcanoes, forest fires, and decay of natural compounds [Environmental Resources Management, 1992].

When evaluating the regulatory effects of the emission of various pollutants, the source of the pollutant is always considered. However, the term *source* takes on several meanings when used in different situations. In this chapter, it will be used to relate to human sources that are stationary in nature.

There are two types of stationary sources that must be considered when addressing emissions: point and nonpoint sources. Point sources include such things as stacks, vents, and other specific points where gas streams are designed to be emitted. Nonpoint sources, or fugitive or secondary sources, include releases of compounds from leaking valves, flanges, and pumps, or release of compounds from wastewater treatment plants [Environmental Resources Management, 1992].

Regulation of Ambient Air Quality

National Ambient Air Quality Standards

National Ambient Air Quality Standards (NAAQS) have been established for criteria pollutants. These consist of six primary pollutants and one secondary pollutant. The six primary criteria pollutants, or pollutants that are emitted directly to the atmosphere, are carbon monoxide (CO), nitrogen oxides (NO_x), particulates PM_{10} and $PM_{2.5}$, sulfur oxides (SO_x), volatile organic compounds (VOCs), and lead. The secondary criteria pollutant is ground-level ozone, and is called a secondary pollutant because it is formed through photochemical reactions between VOCs, NO_x, and sunlight. Therefore, ground-level ozone is not emitted directly to the atmosphere, but formed only after its precursors have been emitted and photochemically react.

NAAQS were set by the U.S. EPA based on two criteria: primary standards for the protection of human health and secondary standards for the protection of the public well-being (such as vegetation, livestock, and other items that can be related to nonhealth effects). These standards differ in that the primary standards are designed to directly protect human health, while the secondary standards are designed to protect the quality of life. Table 12.1 lists the NAAQS for each of the criteria pollutants and the time frame over which the standard is applied. For further definitions of a regulated air pollutant the reader is advised to contact a state environmental regulatory office for the most current definitions from the U.S. EPA.

Attainment and Nonattainment

The U.S. EPA monitors concentrations of the criteria pollutants through a national monitoring network. If the monitoring data show that the NAAQS levels have been exceeded then that area of the country is in nonattainment. If the monitoring shows that NAAQS levels have not been exceeded then the area is in attainment.

The attainment/nonattainment designation applies to each criteria pollutant. As a result an area may have exceeded the NAAQS for SO_2 and is therefore still an attainment area for SO_2.

With the implementation of the Clean Air Act Amendments of 1990, the nonattainment provisions were amended to expand nonattainment designations based on the air quality in the area. While the previous regulations only considered areas to be attainment or nonattainment, the new regulations have

TABLE 12.1 National Ambient Air Quality Standards

Criteria Pollutant	Averaging Period	Primary NAAQS ($\mu g/m^3$)	Secondary NAAQS ($\mu g/m^3$)
PM_{10}	Annual	50	150
	24 hours	150	150
$PM_{2.5}$	Annual[a]	15	15
	24 hours[a]	65	65
Sulfur dioxide (SO_2)	Annual	80	
	24 hours	365	
	3 hours		1300
Nitrogen dioxide (NO_2)	Annual	100	100
Ozone	1 hour	235	235
	8 hours[a]	157	157
Carbon monoxide (CO)	8 hours	10,000	10,000
	1 hour	40,000	40,000
Lead	Quarterly	1.5	1.5

[a] The 1997 Revised $PM_{2.5}$ and 8-hour ozone were challenged in court and were the subject of a significant question regarding the constitutionality of EPA's power to make policy without legislative review and EPA's responsibility to consider economic implications of policymaking. A February 27, 2001 ruling by the Supreme Court found the EPA could move forward with the $PM_{2.5}$ standard but must review the proposed ozone standard. The revised standards were cleared of remaining legal hurdles in March 2002.

TABLE 12.2 Ozone Nonattainment Area Classifications

Ozone Concentration (ppm)	Nonattainment Classification
0.120–0.138	Marginal
0.139–0.160	Moderate
0.161–0.180	Serious
0.181–0.280	Severe
Above 0.280	Extreme

established classes of nonattainment that range from marginal to extreme. Table 12.2 lists the new definitions of nonattainment for ground-level ozone. The new regulations also include differing requirements for areas in various classes of nonattainment in an effort to bring these areas into compliance with the NAAQS.

Regulation of Emission Rates

The NAAQS set acceptable concentrations for pollutants in the ambient atmosphere but do not enforce emission rates for sources such that these levels are met. Regulation of emission rates from stationary sources to control ambient concentrations arise from four programs: Prevention of Significant Deterioration (PSD), New Source Review (NSR), New Source Performance Standards (NSPS), and Hazardous Air Pollutants (HAPs). Each is described below.

Prevention of Significant Deterioration

When the Clean Air Act was amended in 1977, provisions were included to prevent areas in attainment with the NAAQS from being polluted up to the level of the NAAQS. These provisions are the major regulatory program for attainment areas and are known as the PSD provisions. PSD regulates new major sources and major modifications to existing sources.

Under PSD, a major source is defined as a source that has the potential to emit more than 100 tons per year (tpy) if the source is one of the 28 listed sources in the program, or has the potential to emit 250 tpy if the source is not among the listed sources. A major modification is the expansion of an existing source that increases emissions beyond a specific de-minimis amount.

Any new source that is regulated by PSD must apply for a PSD permit prior to beginning construction. A PSD permit application requires the preparation of an extensive amount of information on not only the process but also the impacts of the project [Environmental Resources Management, 1992]. To comply with the PSD provisions, an applicant must demonstrate the use of Best Available Control Technology (BACT) and demonstrate that the project will have no adverse effects on ambient air quality through ambient monitoring and/or dispersion modeling.

BACT specifies a level of emissions control a process must have. BACT can be a piece of add-on control equipment such as a catalytic incinerator or baghouse, or can involve process modifications or work-practice standards such as the use of water-based paints as opposed to solvent-based paints, or ensuring solvent storage tanks are covered when not in use. A control technology review is done in the preparation of a PSD permit to determine what other, similar sources have used as a BACT level of control. This ensures that suggested BACT is at least as effective as what has been previously used.

New Source Review

The NSR provisions were established at the same time as the PSD provisions and regulate new major sources and major modifications in nonattainment areas. The NSR provisions are more stringent than the PSD provisions. The goal of the NSR program is to improve the ambient air quality in areas that do not meet the NAAQS.

NSR requires that each new major source or major modification install a Lowest Achievable Emission Rate (LAER) level of emissions control, obtain emissions offsets equal to the source's emission rate plus a penalty for cleaner air, and investigate alternate sites for the proposed expansion. Unlike the PSD provisions, a major source under NSR depends on the classification of the nonattainment area the source is to be constructed in. For example, a major source in an extreme ozone nonattainment area is any source emitting more than 10 tpy of VOCs. However, in a moderate nonattainment area a major source is any source emitting more than 100 tpy of VOCs.

Under NSR, a LAER level of control is required to be installed. This level of control is similar to BACT in that it is at least as stringent, but often is more stringent and is related to process modification. The LAER level of control is determined on a case-by-case basis as is BACT emissions control.

Emissions offsets are also required under the NSR provisions. Emissions offsets are a method of lowering total emissions in a nonattainment area by requiring new sources to first reduce emissions from an existing operating source. This is done by a ratio such that for the total new emissions a greater amount of existing emissions will be offset or eliminated. This reduction in existing emissions can result from adding new controls on existing sources, shutting existing sources down, or purchasing "banked" offsets from another company that has previously shut a source down and has documented these emissions.

New Source Performance Standards

NSPS are based on the premise that new sources should be able to operate with lesser amounts of emissions than older sources. As a result, the NSPS establish emission rates for specific pollutants for specific sources that have been constructed since 1971. NSPS standards have been established for more than 60 different types of sources.

Hazardous Air Pollutants

The emission of HAPs was originally regulated in 1970 when Congress authorized the U.S. EPA to establish standards for HAPs not regulated under the NAAQS. The National Emission Standards for Hazardous Air Pollutants (HESHAP) program was developed for this purpose. However, this program was ineffective and managed to regulate only seven hazardous compounds by 1990: asbestos, benzene, mercury, beryllium, vinyl chloride, arsenic, and radionuclides.

In 1990, a new HAPs program was established to regulate a new list of 189 hazardous compounds. The U.S. EPA has the authority to modify the list and issue a clarification regarding listed chemicals such as has been done with the "certain glycol-ether" category. Industry may also petition to have substances deleted from the list as a group successfully did in 1996 to have caprolactam removed from the list. Table 12.3 lists the 188 regulated HAPs. This program regulates major sources of HAPs by requiring the installation of Maximum Achievable Control Technology (MACT) and assessment of residual risk after the application of MACT.

A major HAPs emission is any source with the potential to emit 10 tpy of any single HAP or 25 tpy of any combination of three or more HAPs. Federal EPA has developed MACT standards for many but not all industrial categories. Many industries are still awaiting final rulings. This has resulted in states implementing case-by-case MACT to prevent significant increases in HAP emissions prior to the federal promulgation of MACT standards for an industry category. This requires the state departments of environmental quality to demand the installation or incorporation of control technologies at least as stringent as any other control device being used in or on a similar process on newly constructed and reconstructed facilities.

Title V Permits

Title V of the Clean Air Act established a national air permit program. States and Regions must develop permitting programs as stringent as or more so than those set forth by the U.S. EPA. Title V requires major sources of criteria pollutants, sources subject to NSPS, municipal waste incinerators, PSD & NSR sources, and major air toxics sources to obtain a Title V operating permit. Facilities may avoid the Title V permit process by formally agreeing to restrict emissions below thresholds via the use of a synthetic minor permit or Federally Enforceable State Operating Permit (FESOP). These are filed and negotiated with the state permitting agency or local air board.

Preparation of the Title V permit application is not a trivial task. The paperwork associated with applications for a moderate size facility is often measured in feet. Consistency, attention to detail, and clear communication with the permit granting authority will speed the application process. In general a Title V permit requires the following:

- Identification: Including each process with its feed stocks and emission points.
- Emissions: Must be estimated from each process.
- Applicable Regulations: Must be identified for each process and the facility as a whole.
- Compliance Demonstration: Show how the facility is in compliance with applicable regulations for each process.
- Compliance Dedication: Show how the facility and each process will remain in compliance with applicable regulations for each process.
- Certification: A responsible company representative must verify the information provided is truthful and accurate.

Source: Air Quality Permitting, R. Leon Leonard

The permit preparer should refer to the specific state application forms and presiding authority where the facility is located for further guidance in permit preparation.

Compliance Assurance Monitoring

Title VI of the Clean Air Act Amendments includes Compliance Assurance Monitoring (CAM) provisions. The CAM rule, issued in 1997, requires operators of emissions control equipment to monitor the operation and maintenance of their control equipment. Performance tests and design parameters are used to determine a normal range or "indicator range" of operation. If the control device is later found to be out of this "indicator range" steps must be taken to investigate the aberration and correct it if the control device is found to be faulty. State and local authorities must be informed of any non-compliance status that occurred or is occurring due to problems associated with the control device. Extended operation of a control device outside of its prescribed normal condition can result in state mandated intensive evaluation and improvement of control practices.

TABLE 12.3 Hazardous Air Pollutants

Chemical Abstract Service #	Chemical Name
75-07-0	Acetaldehyde
60-35-5	Acetamide
75-05-8	Acetonitrile

Chemical Abstract Service #	Chemical Name
	Antimony Compounds
	Arsenic Compounds (inorganic including arsine)
	Beryllium Compounds
	Cadmium Compounds
	Chromium Compounds
	Cobalt Compounds
	Coke Oven Emissions
	Cyanide Compounds[1]
	Glycol ethers[2]
	Lead Compounds
	Manganese Compounds
	Mercury Compounds
	Fine mineral fibers[3]
	Nickel Compounds
	Polycyclic Organic Matter[4]
	Radionuclides (including radon)[5]
	Selenium Compounds

Note: For all listings above which contain the word "compounds" and for glycol ethers, the following applies: Unless otherwise specified, these listings are defined as including any unique chemical substance that contains the named chemical (i.e., antimony, arsenic, etc.) as part of that chemical's infrastructure.

[1] X′CN where X = H′ or any other group where a formal dissociation may occur. For example, KCN or $Ca(CN)_2$.

[2] On January 12, 1999 (64FR1780), the EPA proposed to modify the definition of glycol ethers to exclude surfactant alcohol ethoxylates and their derivatives (SAED). On August 2, 2000 (65FR47342), the EPA published the final action. This action deletes individual compounds in a group called the surfactant alcohol ethoxylates and their derivatives (SAED) from the glycol ethers category in the list of hazardous air pollutants (HAP) established by section 112(b)(1) of the Clean Air Act (CAA). EPA also made conforming changes in the definition of glycol ethers with respect to the designation of hazardous substances under the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA).

The following definition of the glycol ethers category of hazardous air pollutants applies instead of the definition set forth in 42 U.S.C. 7412(b)(1), footnote 2: Glycol ethers include mono- and di-ethers of ethylene glycol, diethylene glycol, and triethylene glycol R-(OCH2CH2)n-OR′

Where:

n = 1, 2, or 3

R = alkyl C7 or less, or phenyl or alkyl substituted phenyl

R′ = H, or alkyl C7 or less, or carboxylic acid ester, sulfate, phosphate, nitrate, or sulfonate

The U.S. EPA maintains a summary of modifications to the list of air toxics at (http://www.epa.gov/ttn/atw/atwsmod.html). On this page is an extensive (200+ pages) list of many of the chemicals within the glycol ethers category.

[3] (Under Review) Includes mineral fiber emissions from facilities manufacturing or processing glass, rock, or slag fibers (or other mineral derived fibers) of average diameter 1 micrometer or less.

[4] (Under Review) Includes organic compounds with more than one benzene ring, and which have a boiling point greater than or equal to 100°C. Limited to, or refers to, products from incomplete combustion or organic compounds (or material) and pyrolysis processes having more than one benzene ring, and which have a boiling point greater than or equal to 100°C.

[5] A type of atom which spontaneously undergoes radioactive decay.

State and Local Air Quality Programs

In addition to the federal air quality programs described above, many state and local governments have their own air quality regulations. These regulations are required to be at least as stringent as the federal programs; many are far more stringent.

One of the most common requirements at the state and local levels of regulation is the requirement for all new sources, regardless of size, to obtain an air pollution construction permit prior to beginning construction of the source. In many cases, small sources are determined to be exempt from the permitting requirements, or are merely given registration status as opposed to a full construction and operating permit. Nonetheless, even small sources are required to give notification prior to beginning construction or face serious penalties for not doing so.

12.3 Emissions Estimation

Estimation of emissions from a source is a process which involves the qualification and quantification of pollutants that are generated by the source. This process is of paramount importance as the emission estimates will be used to describe the applicability of various regulations, and thus influence how the source is constructed and operated.

To begin the process of estimation, the source must be reviewed to determine its size and nature. This includes the quantification of all raw material inputs (existing or planned), production steps, and release points to qualify what types of emissions might possibly exist. In this step, review of similar sources is imperative as this information can provide a vast array of information that is easily overlooked. The reader is referred to the Air and Waste Management Association's *Air Pollution Engineering Manual* or the U.S. EPA's AP-40 as references for the review of similar sources. These texts provide an overview of a variety of industrial processes and the types and quantities of emissions they generate and emissions controls they employ.

After the source has been reviewed and the potential emissions qualified, the process of assessing the quantities of pollutants that are or can be emitted can begin.

Typically, emissions estimates are generated in two ways: by mass balance or by the use of emission factors. A mass balance is a process based on the fact that because mass is neither created nor destroyed, the mass of raw material into an operation can be quantified and proportioned as to their amounts in either the finished product or in a waste stream. As a result, the portion of the raw materials released into the air can be quantified. However, an appropriate mass balance is a difficult task as there are typically many different raw material inputs into a facility, making the process very complex. Further, many types of raw material inputs result in emissions that are not readily apparent. Because of these factors, the mass balance approach to estimating emissions is not recommended.

The second method of quantifying emissions is the use of an emission factor. An emission factor is a relation between a common operation and the average emissions it generates. For example, the combustion of 1,000,000 standard cubic feet of natural gas in a small industrial boiler results in the emission of 35 pounds of CO. Therefore, the emission factor would be 35 lb CO/10^6 scf or natural gas combusted. Emission factors are generated simply by relating emissions to a representative operating variable, and are often a single number that is the weight of pollutant divided by a unit weight of the activity that generates the pollutant [U.S. EPA, 1993]. Further, when operating variables become complex or contain a number of variables, the emission factor might consist of a series of equations encompassing the variables to determine emissions.

The use of emission factors is common, and the U.S. EPA compiles emission factors for almost every conceivable process. These factors are published in a manual entitled the *Compilation of Air Pollutant Emission Factors,* or AP-42, available from the National Technical Information Service (NTIS) Wide Web at (www.epa.gov/ttn/chief). Recent revisions have reduced the number of subcategories within general process emission groups, for example: particulate emission factors for natural gas combustion were previously divided into utility/large boilers, small industrial boilers, commercial boilers, and residential furnaces. Recent revisions of the natural gas emission factors present only a single PM emission factor without regard to the size of the source. This reflects recent analysis that demonstrated boiler emission factors were generally dependant on operating practices and not so dependant on the physical characteristics and capacity of the boiler. Examples of typical emission factors are given in Tables 12.4, 12.5, and 12.6.

TABLE 12.4 Emission Factors for Criteria Pollutants and Greenhouse Gases from Natural Gas Combustion[a]

Pollutant	Emission Factor ($lb/10^6$ scf)	Emission Factor Rating
CO_2[b]	120,000	A
Lead	0.0005	D
N_2O (Uncontrolled)	2.2	E
N_2O (Controlled-low-NO_x burner)	0.64	E
PM (Total)[c]	7.6	D
PM (Condensable)[c]	5.7	D
PM (Filterable)[c]	1.9	B
SO_2[d]	0.6	A
TOC	11	B
Methane	2.3	B
VOC	5.5	C

[a] Units are in pounds of pollutant per million standard cubic feet of natural gas fired. Data are for all natural gas combustion sources. To convert from $lb/10^6$ scf to $kg/10^6$ m^3, multiply by 16. To convert from $lb/10^6$ scf to lb/MMBtu, divide by 1020. The emission factors in this table may be converted to other natural gas heating values by multiplying the given emission factor by the ratio of the specified heating value to the average natural gas heating value of 1020 BTU/scf. TOC = Total Organic Compounds. VOC = Volatile Organic Compounds.

[b] Based on approximately 100% conversion of fuel carbon to CO_2. $CO_2[lb/10^6\ scf] = (3.67)\ (CON)(C)(D)$, where CON = fractional conversion of fuel carbon to CO_2, C = carbon content of fuel by weight (0.76), and D = density of fuel, 4.2×10^4 $lb/10^6$ scf.

[c] All PM (total, condensible, and filterable) is assumed to be less than 1.0 μm in diameter. Therefore, the PM emission factors presented here may be used to estimate PM_{10}, $PM_{2.5}$, or PM_1 emissions. Total PM is the sum of the filterable PM and condensible PM. Condensible PM is the particulate matter collected using EPA Method 202 (or equivalent). Filterable PM is the particulate matter collected on, or prior to, the filter of an EPA Method 5 (or equivalent) sampling train.

[d] Based on 100% conversion of fuel sulfur to SO_2. Assumes sulfur content in natural gas of 2000 grains/10^6 scf. The SO_2 emission factor in this table can be converted to other natural gas sulfur contents by multiplying the SO_2 emission factor by the ratio of the site-specific sulfur content (grains/10^6 scf) to 2000 grains/10^6 scf.

Source: U.S. EPA. 1998. AP-42 Section 1.4 Natural Gas Combustion

The use of emissions factors is relatively simple and typically consists of the process of unit cancellation once the quantity of operational variable has been determined. For example, the determination of annual emissions from a 20 MMBtu/hr (MMBtu denotes a million British thermal units) natural-gas-fired boiler consists of the following process.

Example 12.1

Natural gas higher heating value (HHV) = 1,020 Btu/scf. Therefore, the boiler uses

$$\left(\frac{20{,}000{,}000\ \text{Btu/hr}}{1020\ \text{Btu/ft}^3}\right) = 19{,}608\ \text{ft}^3/\text{hr} \tag{12.1}$$

or for operation over 8760 hours/year, annual use is

$$19{,}608\frac{\text{ft}^3}{\text{hr}} \times 8760\frac{\text{hr}}{\text{year}} = 1.718 \times 10^8\ \frac{\text{ft}^3}{\text{year}} \tag{12.2}$$

TABLE 12.5 Emission Factors for Nitrogen Oxide (NO_x) and Carbon Monoxide (CO) from Natural Gas Combustion[a]

Combustor Type (MMBtu/hr Heat Input) [SCC]	NO_x[b] Emission Factor (lb/10^6 scf)	NO_x[b] Emission Factor Rating	CO Emission Factor (lb/10^6 scf)	CO Emission Factor Rating
Large Wall Fired Boilers (>100) [1-01-006-1, 1-02-006-01, 1-03-006-01]				
Uncontrolled (Pre-NSPS)[c]	280	A	84	B
Uncontrolled (Post-NSPS)[c]	190	A	84	B
Controlled-Low NO_x burners	140	A	84	B
Controlled-Flue gas recirculation	100	D	84	B
Small Boilers (<100) [1-01-006-02, 1-02-006-02, 1-03-006-02, 1-03-006-03]				
Uncontrolled	100	B	84	B
Controlled-Low NO_x burners	50	D	84	B
Controlled-Flue gas recirculation	32	C	84	B
Tangential-Fired Boilers (All Sizes) [1-01-006-04]				
Uncontrolled	170	A	24	C
Controlled-Flue gas recirculation	76	D	98	D
Residential Furnaces (<0.3) [No SCC]				
Uncontrolled	94	B	40	B

[a] Units are in pounds of pollutant per million standard cubic feet of natural gas fired. To convert from lb/10^6 m^3, multiply by 16. Emission factors are based on an average natural gas higher heating value of 1020 Btu/scf. To convert from lb/10^6 scf to lb/MMBtu, divide by 1020. The emission factors in this table may be converted to other natural gas heating values by multiplying the given emission factor by the ratio of the specified heating value to this average heating value. SCC - Source Classification Code.

[b] Expressed as NO_2. For large and small wall fired boilers with SNCR control, apply a 24 percent reduction to the appropriate NO_x emission factor. For tangential-fired boilers with SNCR control, apply a 13% reduction to the appropriate NO_x emission factor.

[c] NSPS = New Source Performance Standard as defined in 40 CFR 60 Subparts D and Db. Post-NSPS units are boilers with greater than 250 MMBtu/hr of heat input that commenced construction modification, or reconstruction after August 17, 1971, and units with heat input capacities between 100 and 250 MMBtu/hr that commenced construction modification, or reconstruction after June 19, 1984.

thus, the operational variable for the emission factor has been quantified for annual use. Now, turning to Tables 12.4 through 12.6, the emissions factors are used for a small, uncontrolled industrial boiler. Emissions are determined in the following manner. For filterable particulate matter, the emission factor = 1.9 lb/10^6 ft^3 (Table 12.4):

$$\frac{1.9\ \text{lb}}{10^6\ \text{ft}^3} \times 1.718 \times 10^8 \frac{\text{ft}^3}{\text{year}} = 326\ \text{lb part/year} \tag{12.3}$$

For condensible particulate matter, the emission factor = 5.7 lb/10^6 ft^3 (Table 12.4):

$$\frac{5.7\ \text{lb}}{10^6\ \text{ft}^3} \times 1.718 \times 10^8 \frac{\text{ft}^3}{\text{year}} = 979\ \text{lb part/year} \tag{12.4}$$

For sulfur dioxide, the emission factor = 0.6 lb/10^6 ft^3 (Table 12.5):

$$\frac{0.6\ \text{lb}}{10^6\ \text{ft}^3} \times 1.718 \times 10^8 \frac{\text{ft}^3}{\text{year}} = 103\ \text{lb SO}_2\text{/year} \tag{12.5}$$

TABLE 12.6 Selected Hazardous Air Pollutant Emission Factors from Natural Gas Combustion[a,b,c]

CAS No.	Pollutant	Emission Factor (lb/10^6 scf)	Emission Factor Rating
71-43-2	Benzene	2.1 E-03	B
25321-22-6	Dichlorobenzene	1.2 E-03	E
206-44-0	Fluoranthene	3.0 E-06	E
86-73-7	Fluorene	2.8 E-06	E
50-00-0	Formaldehyde	7.5 E-02	B
110-54-3	Hexane	1.8 E+00	E
91-20-3	Napthalene	6.1 E-4	E
108-88-3	Toluene	3.4 E-3	C
7440-50-8	Copper	8.5 E-04	C
7440-02-0	Nickel	2.1 E-03	C

[a] Units are in pounds of pollutant per million standard cubic feet of natural gas fired. To convert from lb/10^6 scf to kg/10^6 m^3, multiply by 16. Data are for all natural gas combustion sources. Emission factors are based on an average natural gas higher heating value of 1020 Btu/scf. To convert from lb/10^6 scf to lb/MMBtu, divide by 1020. The emission factors in this table may be converted to other natural gas heating values by multiplying the given emission factor by the ratio of the specified heating value to this average heating value.

[b] Hazardous Air Pollutant as defined by Section 112(b) of the Clean Air Act.

[c] This table does not contain all metal or speciated organic compound emission factors for natural gas combustion. Selected emission factors were chosen. Refer to AP-42 for the complete compilation of emission factors.

For nitrogen oxides (NO_x), the emission factor = 100 lb/10^6 ft^3 (Table 12.5):

$$\frac{100\ \text{lb}}{10^6\ \text{ft}^3} \times 1.718 \times 10^8 \frac{\text{ft}^3}{\text{year}} = 17{,}200\ \text{lb NO}_x/\text{year} \tag{12.6}$$

For carbon monoxide, the emission factor = 84 lb/10^6 ft^3 (Table 12.5):

$$\frac{84\ \text{lb}}{10^6\ \text{ft}^3} \times 1.718 \times 10^8 \frac{\text{ft}^3}{\text{year}} = 14{,}400\ \text{lb CO}/\text{year} \tag{12.7}$$

For VOC, the emission factor = 5.5 lb/10^6 ft^3 (Table 12.4):

$$\frac{5.5\ \text{lb}}{10^6\ \text{ft}^3} \times 1.718 \times 10^8 \frac{\text{ft}^3}{\text{year}} = 945\ \text{lb VOC}/\text{year} \tag{12.8}$$

For Toluene, a hazardous air pollutant, the emission factor = 3.4E-03/10^6 ft^3 (Table 12.6):

$$\frac{3.4\ \text{E-03 lb}}{10^6\ \text{ft}^3} \times 1.718 \times 10^8 \frac{\text{ft}^3}{\text{year}} = 0.584\ \text{lb Toluene}/\text{year} \tag{12.9}$$

12.4 Stack Sampling

In the field of air pollution, the process of quantifying emissions is often referred to as air or stack sampling. This process consists of examining a sample of gas from the emission stream to determine both the physical characteristics of the stream and the concentrations of pollutants contained therein. While this seems relatively easy, the process is somewhat more complicated because of the nature of the medium being sampled.

As opposed to a liquid sample that can be contained, transported, and examined in a remote location with relative ease, a gas sample obtained on-site must either be quantified directly or be altered such that the constituents contained within the sample are immobilized. Immobilization is necessary because it is impractical to transport an actual quantity of the gas sample for later analysis. However, even though the sample has been transformed for evaluation at a separate location, the sample must still provide an accurate depiction of the pollutants in the gas stream being emitted. As the pollutants of concern consist of both the solid and gaseous states, sampling methods consist of a wide variety of procedures that are specific to the pollutant of concern. These methods vary from sampling for entrained particulate to the detection of multitudes of different organics and inorganics.

As a wide variety of procedures exist, the U.S. EPA has standardized these procedures and codified them such that the data resulting from their application are precise and accurate if appropriate methods are used in specific sampling scenarios. These procedures or methods refer directly to the analysis of one or more pollutants. Table 12.7 is a listing of the currently approved U.S. EPA methods with their title and appropriate *Code of Federal Regulations* reference. It should be noted that the references for the technical corrections should be reviewed in addition to the original citation for a complete description of the relevant sampling methodology.

All of the methods listed in Table 12.7 employ similar initial methods to measure the basic characteristics of the gas stream. For instance, sampling methods 1 through 3 consist of the measurement of the physical dimensions of the duct or stack, velocity, and CO_2 and O_2 concentrations, respectively. These methods are used to reflect on the appropriate locations and sample volumes that must be withdrawn to provide a representative sample of the gas stream. As a result, many other sampling methods employ these basic methods during their trials.

Of all the sampling methods, the first five are typically employed in most sampling scenarios. As a result of the great number and variation between all of the individual methods, this discussion will focus on the basic procedures and hardware of method 5, as this is the most common sampling method. The reader is referred to 40 CFR Part 60 for the specific sampling procedures for method 5 and other methods. Additionally, the reader is referred to *Methods of Air Sampling and Analysis* for further information on the analysis of specific compounds.

The U.S. EPA method 5 sampling train is used in the determination of particulate in gas streams. The method 5 sampling train is composed of a heated sampling probe, a sample case, and a control case. A schematic of the assembly is illustrated in Fig. 12.1.

In Fig. 12.1, the heated sampling probe is attached to the sample case. The probe consists of a nozzle of known inner diameter, a thermistor to determine stack temperature, another thermistor to determine probe temperature, and a pitot tube. Ending in a stainless steel or glass ball joint depending on the probe liner material, the probe is joined to the filter housing in the sample case by a ground glass joint. The pitot tube and thermistors are connected to the control case through the "umbilical cord" running from the sample case to the control case. The umbilical cord houses both a section of tubing the gas stream is drawn through and a wire harness connecting the control case and the sample case. This configuration results in the sample being drawn from the gas stream through the probe, the sample case, and finally the control case.

Inside the sample case, the gas stream is passed through a heated filter housing to remove particulate. The housing is heated to prevent the gas stream from falling below the dew point, and fouling the filter with moisture and most importantly to control the particulate formation temperature at 250°F. After the filter housing, the gas stream is passed through a set of four impingers immersed in an ice bath. The first two impingers are filled with a liquid-absorbing reagent (dependent on the pollutant being sampled) to remove a pollutant from the gas stream. These are followed by an empty third impinger serving as a moisture trap, and a fourth impinger filled with silica gel to adsorb any remaining moisture. As a result of passing through the sample case, the gas stream being sampled has had the particulate filtered from it, and the moisture and pollutant removed. To sample other pollutants, the contents of the first two impingers are altered to remove the specific pollutant of concern.

After being drawn through the sample case, the gas stream passes through the umbilical cord to the control case. In Fig. 12.1, the control case flow path is shown, while Fig. 12.2 is a photograph of a typical control case. A vacuum gauge indicates negative pressure in the line downstream of the filter. To control flow to the pump, two valves are used. The first valve is the coarse control valve, and is plumbed immediately upstream in line with the pump. A second valve, or the fine control valve, controls a recycle stream around the pump. These valves serve to control the amount of gas sample being drawn by the system. After the pump, the gas stream passes through a dry gas meter and then through an orifice plate.

The system described above allows a known volume of gas to be drawn with known velocities in the nozzle. This is important because the velocity of the gas in the ductwork and the velocity of the sample being drawn by the system can be matched. As a result, particulate in the gas stream can be sampled in the gas stream or isokinetically. If the sample is collected such that the velocity in the nozzle is greater than in the duct, the sample is said to be superisokinetic and provides a particulate sample biased on the low side with regard to mass. A nozzle velocity below the duct velocity is said to be subisokinetic and

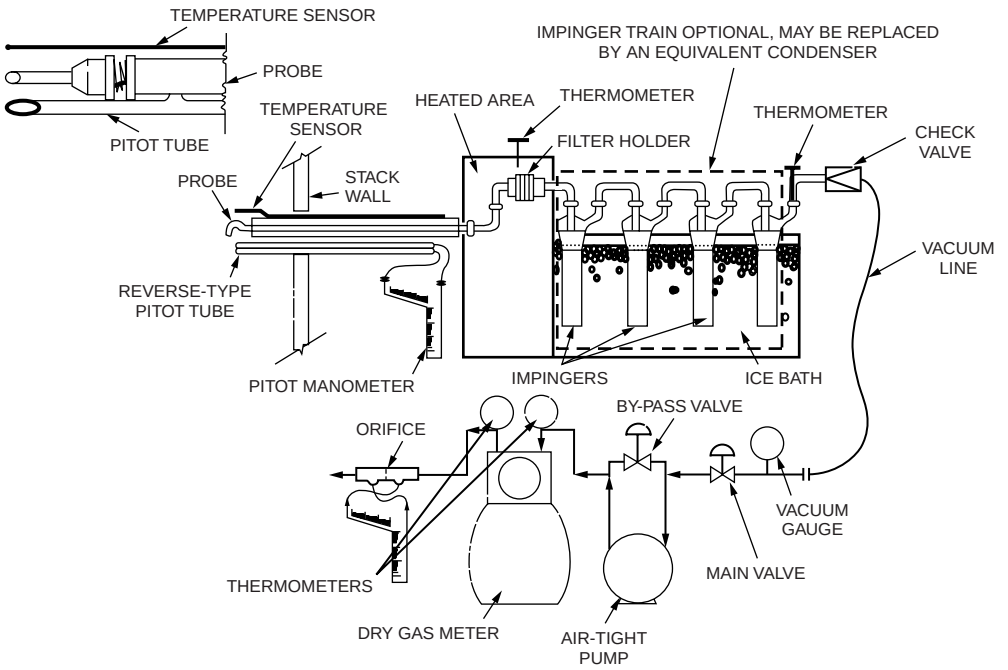

FIGURE 12.1 Method 5 sampling hardware schematic.

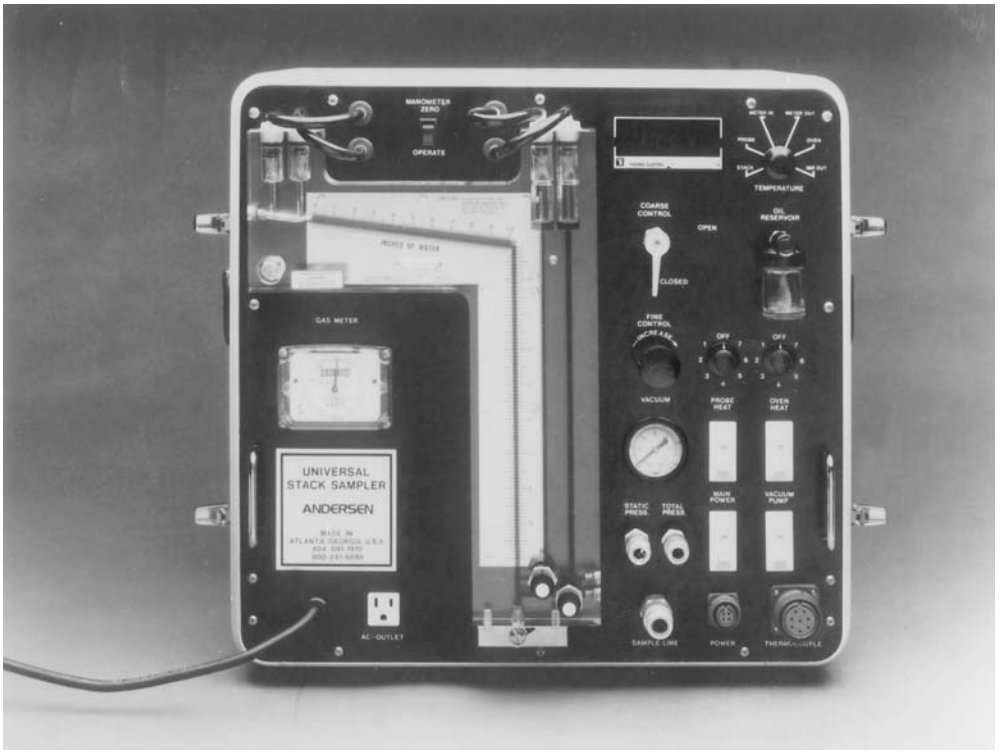

FIGURE 12.2. Typical control case.

provides a particulate sample biased on the high side with regard to mass. Thus, to provide an accurate depiction of the particulate emissions the sample needs to be isokinetic. To this end, the EPA specifies that the sample be between 90 and 110% isokinetic.

With known stack gas parameters of temperature, pressure, composition, and moisture content, values for the pressure drop across the orifice in the control case under a different temperature and pressure can be determined. Thus, with changing duct velocities, different standard flows in the system necessary to maintain appropriate nozzle velocities can be determined from the calibration graphs for the control case. As mentioned previously, standard flows are then used to determine the appropriate ΔH (pressure drop across the orifice meter) value for a specific velocity pressure. The method 5 sampling train is unique in that both a rate meter (orifice plate) and totalizing meter (dry gas meter) allow for a post-test check of the isokinetic percentage.

12.5 Emissions Control

Particulates

Aerodynamic Diameter

Engineers who are concerned with the removal of solid particles from gas streams are less concerned with the physical shape of the particle and more interested in the particles' aerodynamic behavior in the gas stream. As such, the term *aerodynamic diameter* is widely used in the design and selection of air pollution control hardware for particulate control. Aerodynamic diameter can be defined as an equivalent diameter of a nonspherical particle whose actual shape can be spherical but is usually nonspherical and whose aerodynamic behavior is identical to a unit density sphere in stokes flow.

The measurement of aerodynamic diameter is best performed using isokinetic sampling procedures directly in the gas stream with a multistage impactor which has been calibrated with unit density spheres. One such impactor is the Anderson® Impactor seen in Fig. 12.3. As the particles proceed through the multistage impactor, their velocities are stepwise increased at each impaction stage. Immediately following this acceleration, the conveying gas stream is routed through 90 degree turns at each stage of the impactor. Since the particles have much greater inertia than the gas molecules, the particles cannot negotiate the 90 degree turns; that is, they deviate from the streamlines of gas flow and impact a collection surface or stage.

Each collection stage is gravimetrically analyzed and the data is presented graphically on a log-probability plot seen in Fig. 12.4. Most particulates generated by abrasion, fracturing, or condensation phenomena have aerodynamic diameters that are log-normally distributed as is reflected by the straight line shown in Fig. 12.4. This plot is very useful to the engineer either designing or selecting the appropriate control hardware. For example, particles with an extremely wide aerodynamic diameter distribution would be represented by an almost vertical line or an infinite slope in Fig. 12.4. On the other hand, particles which did not vary widely in their aerodynamic diameters would be represented by an almost horizontal line or a line with near-zero slope. Therefore, a quick glance at the slope immediately tells the engineer whether he or she is dealing with an almost infinite variability in particle sizes or a near mono-dispersion of particles.

Additionally, the intersection of the line in Fig. 12.4 with the 50% probability value on the abscissa is the mass median diameter of the particle distribution. This mass median diameter immediately tells the engineer what type of particulate control hardware probably will be needed. For example, particle diameter distributions having submicron mass median diameters require relatively high-energy devices for removal while super-micron-diameter particles require lesser amounts of energy.

Typically, for particles larger than 40 microns in aerodynamic diameter, gravity force is utilized for removal. Obviously this force is very cost-effective and if properly combined with low transport velocities and subsequently high residence times respectable removal efficiencies can result.

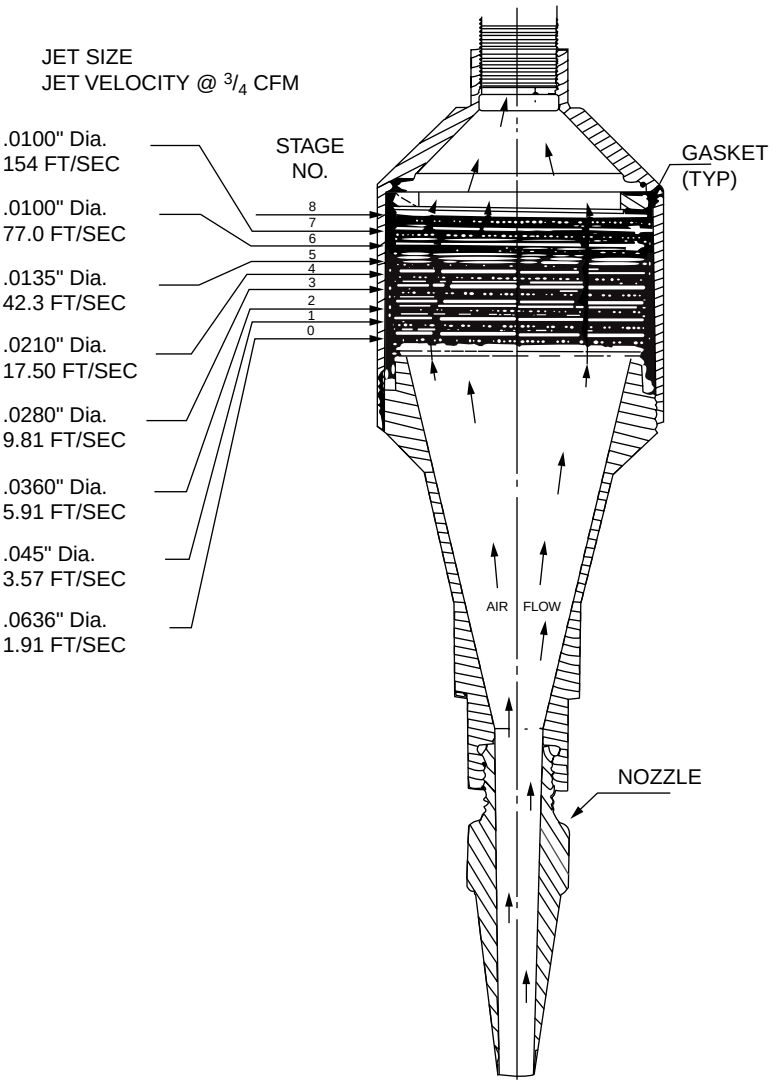

FIGURE 12.3 Anderson® impactor.

As the particles become smaller, greater forces must be brought into play for their removal. For particles between 10 to 40 microns in aerodynamic diameter, centrifugal forces are brought into play through the use of cyclones. For the removal of particles smaller than 10 microns in aerodynamic diameter, fabric filtration, electrostatic precipitators, and high-energy wet scrubbing are employed.

Settling Chambers

Particles larger than 40 microns in aerodynamic diameter settle readily under the influence of gravity. If the particulate matter is being carried in an exhaust gas stream as opposed to fugitive dust in the atmosphere, a settling chamber is a very cost-effective device for their removal. A settling chamber is essentially a wide spot in a duct which significantly reduces the gas velocity and, therefore, the particulate transport velocity, allowing enough residence time for gravity to act on the particle and separate it from the gas stream.

A side view of a settling chamber is seen in Fig. 12.5. As the entering particle decelerates due to the increased cross-sectional area for flow, gravity force accelerates the particle to its terminal settling velocity.

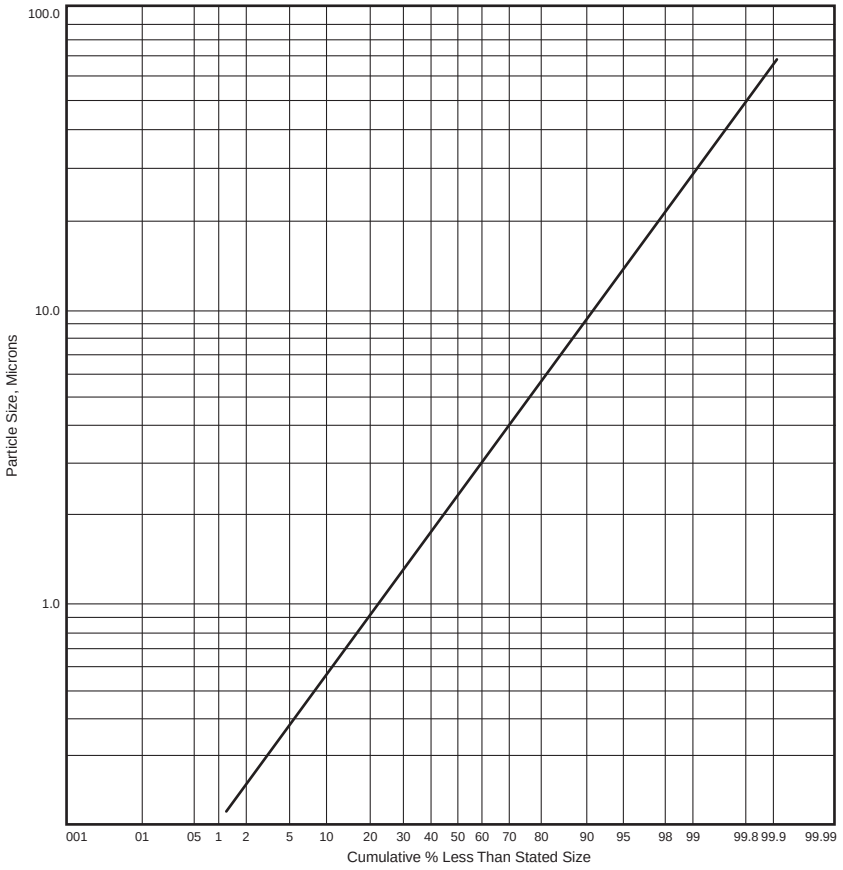

FIGURE 12.4 Log probability plot.

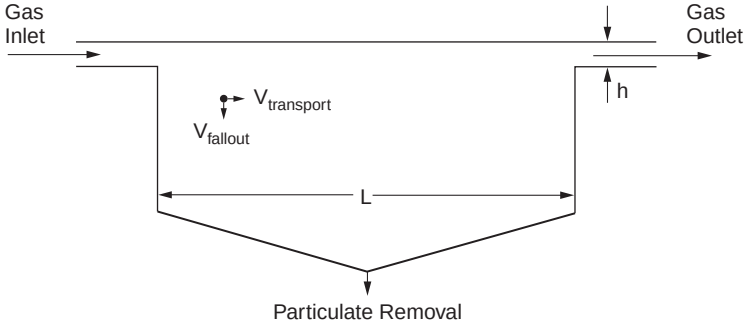

FIGURE 12.5 Settling chamber.

If the residence time in the chamber is sufficient such that the particle falls at least a distance *h*, the particle will be captured in the chamber. In other words, for 100% capture, a particle's fallout time must be at least be equal to or less than its transport time (residence time):

$$T_f = T_t \tag{12.10}$$

If particle fallout time is expressed as

$$T_f = \frac{h}{V_t} \tag{12.11}$$

and the particle transport time is expressed as

$$T_t = \frac{L}{V} \tag{12.12}$$

the relationship for 100% particle capture efficiency is

$$\frac{h}{V_t} = \frac{L}{V} \tag{12.13}$$

where T_f is particle fallout time, T_t is particle transport time, h is vertical distance the particle must fall in order to be captured or the distance from the chamber ceiling to the lower lip of the outlet duct, L is chamber length, and V is the particle's horizontal transport velocity, which can be assumed to be the same as the gas velocity.

Therefore, geometric combinations which satisfy the relationship $h/V_t = L/V$ will successfully capture particles greater than 40 microns in diameter provided chamber turbulence is small. A reasonable rule of thumb assumes the terminal settling velocity is one-half of the calculated value and thereby a conservative design is achieved.

Particle Settling Velocity

The terminal settling velocity can be approximated from the following equations according to the particle diameter and expected flow regime. For particles with aerodynamic diameters less than 100 microns whose Reynolds numbers are less than about 2.0, the terminal settling velocity, V_t, is given by the following:

$$V_t = \frac{d_p^2 g\left(\rho_p - \rho_f\right)}{18\mu_f} \tag{12.14}$$

Equation (12.14) is the terminal settling velocity of a spherical particle in stokes or laminar flow.

For larger particles between 100 and 1000 microns which are in the transition region between laminar and turbulent flow and whose Reynolds numbers are between about 2.0 and 500, V_t is given by the following relationship:

$$V_t = \frac{0.2\rho_p^{2/3} g^{2/3} d_p}{\rho f^{1/3} \mu_f^{1/3}} \tag{12.15}$$

For particles larger than 1000 microns which are in turbulent flow regime and whose Reynolds numbers are between 500 and 10^5, V_t is given by the following:

$$V_t = 1.74\left(\frac{\rho_p g d_p}{\rho_f}\right)^{1/2} \tag{12.16}$$

where V_t is particle settling velocity, cm/s; ρ_p is particle density, g/m^3; g is acceleration due to gravity, cm/s^2; d_p is particle diameter, cm; and μ_f is fluid viscosity, g/cm-s.

TABLE 12.8 Flow Regime K Values

Flow Regime	K Range
Stokes	$K \leq 3.3$
Intermediate	$3.3 \leq K \leq 43.6$
Turbulent	$43.6 \leq K \leq 2360$

Selecting which particle terminal settling velocity equation to use is more easily and accurately done by forming the following K criterion:

$$K = d_p \left(\frac{\rho_p g \rho_f}{\mu_f^2} \right)^{1/3} \tag{12.17}$$

and selecting the flow regime according to the value of K in Table 12.8.

Cyclones

Particle aerodynamic diameters from 40 down to 10 microns are usually removed from a gas stream by cyclonic separation. In this smaller particle diameter range, an additional force, namely centrifugal force, must be applied to effect their removal. In the case of the settling chamber for larger particles, one g force was utilized. With the cyclone, many equivalent g forces are utilized via centrifugal force. A ratio of the centrifugal to gravitational force is called the separation factor of the cyclone:

$$\begin{aligned} \text{Separation force} &= \frac{\text{Centrifugal force}}{\text{Gravity force}} \\ &= \frac{mV^2/r}{mg} \\ &= \frac{v^2}{rg} \end{aligned} \tag{12.18}$$

For cyclones this separation factor can be as high as 2500, which means 2500 gs of force are applied to the particles as compared to 1 g in a settling chamber. A cyclonic separator can be thought of as a settling chamber of revolution. In other words, the cyclone is also a wide spot in the exhaust gas duct which provides sufficient residence time for the centrifugal forces to act and remove the particles from the gas stream.

A conventional cyclone consists of a tangential entry, a main cylinder section, a conical lower section with provision for particle removal, and a gas outlet tube, as shown in Fig. 12.6. The gas enters the main cylinder tangentially and spirals downward (forming the primary vortex) into the conical section, thus imposing a centrifugal force on the entrained particles which move radially outward, impacting the side walls and falling to the bottom of the cyclone. Since there is no gas exit at the bottom of the cyclone, the primary vortex downward movement stops, the spiral tightens (now called the secondary vortex) and moves vertically up and out of the top of the cyclone through the outlet tube. The size of these cyclones can vary from 2 feet in diameter up to 12 to 15 feet in diameter. Figure 12.7 shows the dimensional labeling for a typical tangential entry cyclone. The conventional cyclone design geometry dimensional relationships as given by Lapple are shown in Table 12.9. Note that each of the lengths are proportional to the main body diameter of the cyclone. Once the main body diameter is chosen, the remaining lengths are set.

Since Lapple's original work on the conventional cyclone, other researchers have suggested geometry ratios slightly different from that of Lapple. These geometries are shown in Table 12.9, and have been identified as "high efficiency" and "high throughput."

Conventional Cyclone Design Approach

In the 1950s, Lapple correlated the collection efficiency data from many sizes of conventional cyclones using a "cut-diameter" variable. This correlation, seen in Fig. 12.8, is the classic approach to designing

TABLE 12.9 Lapple Design Values for Cyclones

	Cyclone Type		
	High Efficiency	Conventional	High Throughput
Body diameter, D/D	1.0	1.0	1.0
Height of inlet, H/D	0.5	0.5	0.75
Width of inlet, W/D	0.2	0.25	0.375
Diameter of gas exit, D_e/D	0.5	0.5	0.75
Length of vortex finder, S/D	0.5	0.625	0.875
Length of body, L_b/D	1.5	2.0	1.5
Length of cone, L_c/D	2.5	2.0	2.5
Diameter of dust outlet, D_d/D	0.375	0.25	0.375

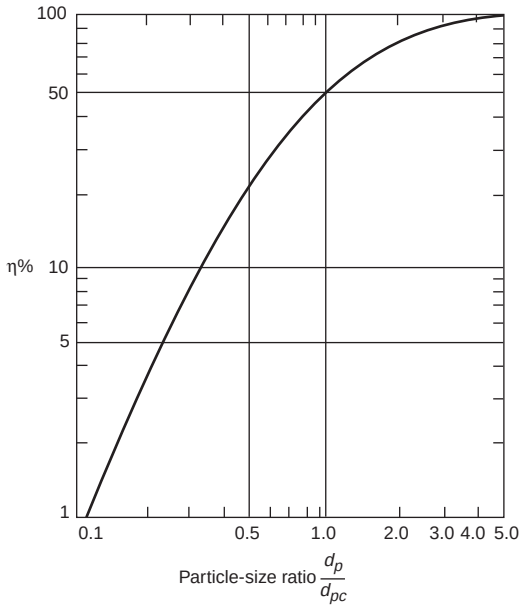

FIGURE 12.8 Cut diameter (*Source:* Cooper, C. D. and Alley, F. C. 1990. *Air Pollution Control: A Design Approach.* Waveland Press, Prospect Heights, IL. Reprinted by permission of Waveland Press, Inc. All rights reserved.)

and sizing a conventional cyclone. The cut-diameter is that diameter of particle captured at a 50% efficiency in the cyclone. It is calculated from the following equation:

$$d_p = \left(\frac{9\mu W_i}{2\pi N v_i (\rho_p - \rho_g)} \right)^{1/2} \tag{12.19}$$

where d_{pc} is the cyclone cut-diameter, μ is the gas velocity, W_i is the inlet width of the cyclone, v_i is the inlet gas velocity, ρ_p and ρ_g are the particle and gas densities, respectively, and N is the number of primary vortex revolutions. N can be estimated by the ratio of L_b/H (refer to Fig. 12.6).

Once the cut-diameter d_{pc} is calculated, the Lapple nondimensional ratio, D_p/D_{pc} can be formed and Fig. 12.8 used to determine the specific collection efficiency of the particles of interest. The overall

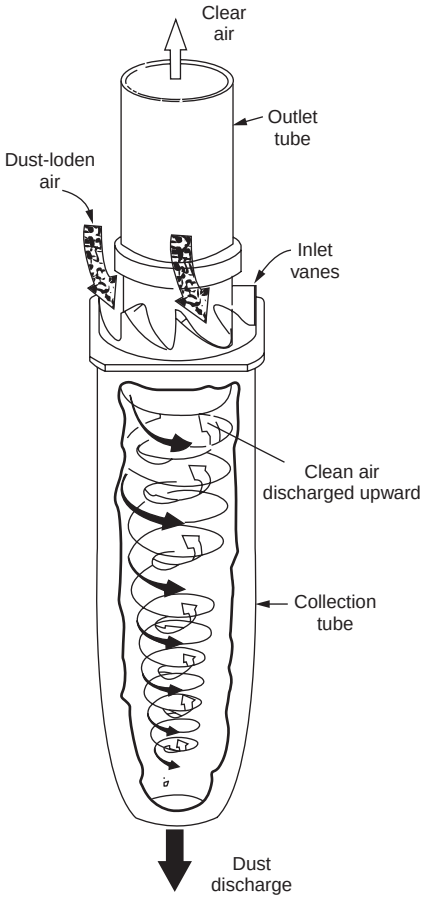

FIGURE 12.9 Axial flow cyclone.

collection efficiency of the cyclone is the summation of the specific efficiency from each size range chosen weighted according to the mass of particles in each size range.

Another version of a cyclonic separator is the axial flow cyclone shown in Fig. 12.9. These units are usually much smaller than the conventional unit and are usually ganged together in parallel to increase the amount of gas they process. These units vary in size from a few inches to 18 inches in diameter.

Wet Scrubbers

Where gravity or centrifugal forces fail to remove smaller particles, wet scrubbers can be employed. However, keep in mind that the wet scrubber merely converts an air pollution problem into a water pollution problem. The wet scrubber presents a liquid, usually water, into a particulate-laden gas stream where the liquid droplets and particles are brought together. Upon contact, the particle is surrounded by liquid and the apparent mass of the original particle is increased. The particles, now with a greater apparent mass, can be removed from the gas stream using straightforward impaction or cyclonic mechanisms.

Generally, the smaller the particle to be removed, the greater the energy input into the scrubber for effective particulate removal. The water- and particulate-laden gas stream can be brought together in a number of different ways. One common way is to inject the water through spray nozzles into the relatively low-velocity gas stream. These low-energy wet scrubbers are referred to as *spray chamber scrubbers* and are usually effective only for relatively large particles greater than 5 microns. The spray nozzles relative to the gas stream are usually arranged cocurrent, countercurrent, or crosscurrent using a cone-type spray

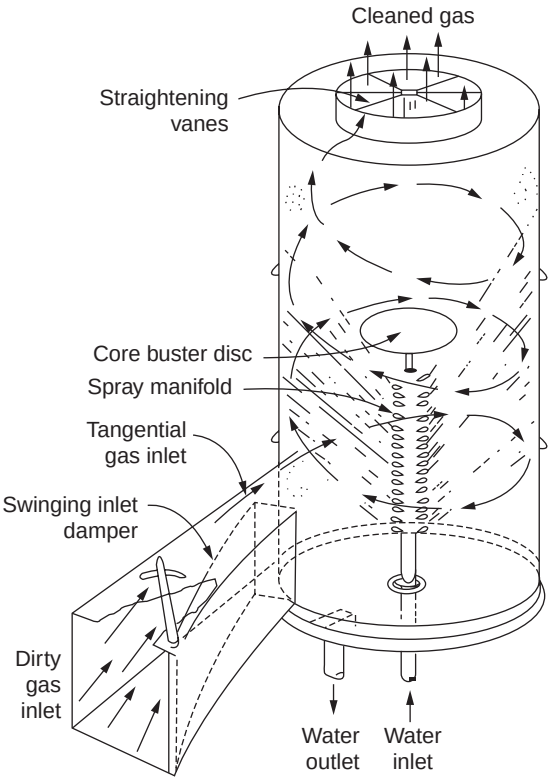

FIGURE 12.10 Wet scrubber. (*Source:* Cooper, C. D. and Alley, F. C. 1990. *Air Pollution Control: A Design Approach.* Waveland Press, Prospect Heights, IL. Reprinted by permission of Waveland Press, Inc. All rights reserved.)

pattern with liquid requirements from 15 to 25 gallons/1000 ft^3 at a liquid delivery pressure of about 40 psi. There are literally hundreds of spray chamber scrubber configurations on the market. Figure 12.10 shows a typical configuration.

Other methods of bringing the water and particulate matter together involve impaction of a liquid droplet–gas mixture on a solid surface. In orifice scrubbers, the gas impinges on a liquid surface and then the droplet–gas mixture must negotiate a series of tortuous turns through a baffle arrangement. In impingement scrubbers the liquid droplet–gas mixture flows upward through perforated trays containing liquid and froth and then impacts on plates above the trays.

High-efficiency scrubbers for submicron particulate matter accelerate the gas stream in a venturi and present the liquid to the gas near the throat of the venturi. These venturi scrubbers are very effective for submicron particulate removal and operate with relatively high gas–side pressure drops from approximately 20 to 120 inches–water column. As a result they are energy intensive and have high operational costs. However, they can achieve collection efficiencies of 93% or greater on particles larger than 0.3 microns [Cooper and Alley, 1990].

The general equation for overall wet scrubber particulate removal efficiency is given by

$$N = 1 - e^{-f_{(system)}} \tag{12.20}$$

where $f_{(system)}$ is a term representing some function of the particular scrubber system variables. The form of this equation predicts an exponentially increasing collection efficiency with particle diameter and asymptotically approaches 100%.

Wet Scrubber Design Approach

Calvert suggests a design approach based on a single droplet target efficiency, impaction parameter and the concept of particle penetration [Calvert, 1972]. Penetration is defined as the converse of collection efficiency:

$$P = 1 - N \tag{12.21}$$

where N is the particle collection efficiency fraction and P is the fraction of particles that escape (or penetrate) the collection device.

Combining the general efficiency and penetration equations yields

$$P = 1 - \left(1 - e^{-f_{(system)}}\right) \tag{12.22}$$

or $P = e^{-f_{(system)}}$. Calvert defines $f_{(system)}$ as an empirical function dependent on the particle aerodynamic diameter, d_p. Now:

$$f_{(system)} = A_{cut} d_p^{B_{cut}} \tag{12.23}$$

where A_{cut} is a parameter which characterizes the particulate aerodynamic size distribution and B_{cut} is an empirical constant of 2.0 for plate towers and venturi scrubbers and 0.7 for centrifugal scrubbers. The penetration is now:

$$P = e^{-A_{cut} d_p^{Bcut}} \tag{12.24}$$

which yields the penetration for one particle size distribution. The overall penetration is the summation of the penetration from each chosen size range weighted according to the mass of particles in each size range.

By integrating the penetration, P, over a lognormal size distribution of particles and various geometric standard deviations and mass median diameters, Calvert developed the curves in Fig. 12.11. Knowing

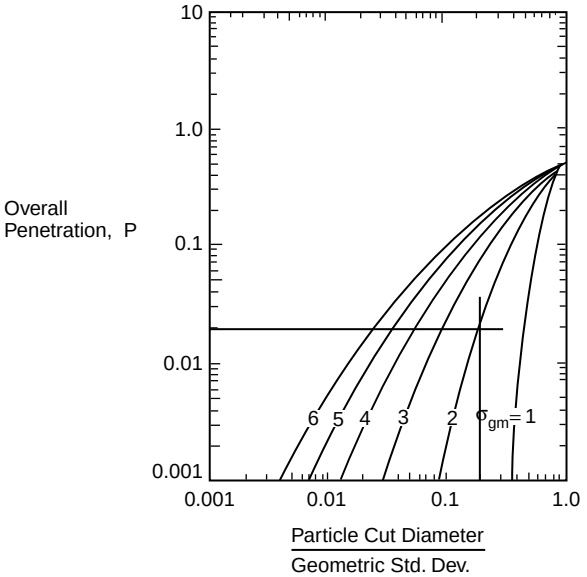

FIGURE 12.11 Calvert design curves ($B_{cut} = 2$).

the required overall collection efficiency of the scrubber and the mass median diameter of the particle size distribution challenging the scrubber, the cut size of the scrubber can be determined.

Consider this example: an *in situ* aerodynamic particle size sample and subsequent gravimetric analysis indicated that the mass median diameter of the distribution was 10 microns and the geometric standard deviation of the distribution was 2.0. If a collection efficiency of 98% is required to meet the emission standards what must the cut diameter of a venturi ($B_{cut} = 2$) scrubber be?

$$\begin{aligned} P &= 1 - N \\ &= 1 - 0.98 \\ &= 0.02 \end{aligned} \tag{12.25}$$

Now from Fig. 12.11, for $P = 0.02$ and SD = 2.0 microns, $dp_{50}/dp_{gm} = 0.185$ and, therefore, $dp_{50} = dp_{gm} \times 0.185 = 10 \times 0.185 = 1.85$ microns. In this example, the scrubber must collect the 1.85-micron particles with an efficiency of at least 50% to meet the overall scrubber efficiency of 98%.

Fabric Filters

Where it is not desired to create a water pollution problem from an air pollution problem, dry collection of fine particulate matter in gas streams can be very effectively accomplished using baghouse filtration. Baghouses have been around for quite some time and their usefulness is continually being extended due to advances in the media or substrate material onto which the particles are being collected. The "heart" of a baghouse filtration system is the media which acts as a substrate for collection of a filter "cake" which ultimately does the "filtering."

Baghouses are typically grouped into three classes based on the method employed to clean the filtration media: reverse air, shaker, and pulse jet. The reverse air baghouse is cleaned by taking the baghouse compartment to be cleaned out of operation and reversing the air flow through the filter, thus removing the cake from the filtration bags. A shaker baghouse also has a compartment taken out of service and mechanically shakes the bags to dislodge the filter cake physically. The most recent innovation in baghouse cleaning consists of the pulse-jet baghouse. This type of baghouse is cleaned by pulsing high pressure blasts of air through the interior of the bag while the bag is in service.

Filtration Media

Many different types of fabrics are used in baghouse filters. Fiberglass and even ceramic fibers are used in high-temperature applications. More commonly used are cotton, polyesters, and teflon coatings. Matching the proper bag material with the gas stream characteristics is extremely important for long bag life. Table 12.10 is an example of some of the more popular fabric materials with their temperature limitations and acid, alkali, and flexure/abrasion resistance.

As can be seen from Table 12.10, most conventional fibers are limited to operating temperatures less than 260°C (500°F). Nextel® is a relatively new high-temperature fiber developed by 3M which has an upper temperature limit of 760°C (1400°F). The fiber is made of continuous individual ceramic filaments. The technology is based on a "sol-gel" process whereby a chemical sol is extruded through a spinneret and then fired. The resulting metal oxide fibers are polycrystalline woven fiberglass [Hansen, 1994].

Sintamatic™, a filter matrix consisting of Teflon (PTFE)-coated polyethylene beads sintered into a rigid matrix, is a newer technology in baghouse filter media. As opposed to flexible fabric material, this media is configured in rectangular, hollow, fan-fold rigid panels affixed to an air manifold. The vertically oriented, fan-fold, rigid panels are ganged together in parallel units. Filtration takes place across the outside of the fan-fold panel with the cleaned gas proceeding into the hollow interior space in each panel and up into the clean air manifold.

Since the media is composed of polyethylene and PTFE it is very resistant to acids and bases. However, the major hindrance is temperature; it has an upper limit of about 140°F. A scanning electron microscope was used to examine a cross section of the media [Pedersen, 1993]. Figure 12.12 shows the media magnified 72 times with the horizontal white bar in the lower right of the photo representing 100 microns.

TABLE 12.10 Properties of Filter Fabrics

Material	Maximum Temperature		Acid Resistance	Alkaline Resistance	Flex Abrasion	Relative Cost
	Continuous (°C)	Surge (°C)				
Cotton	82	107	P	VG	VG	2

P — poor, F — fair, G — good, VG — very good, EX — excellent.

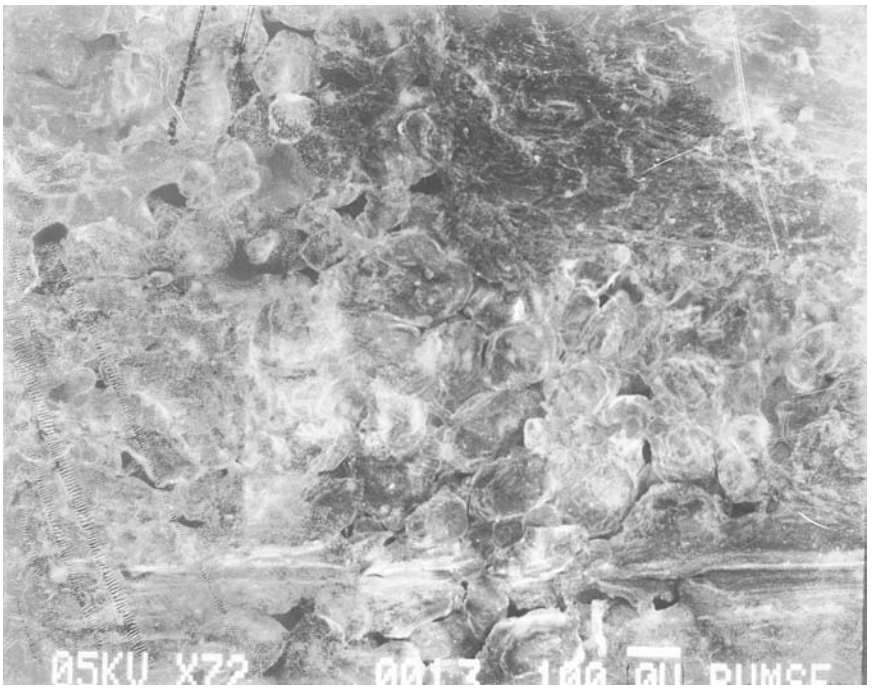

FIGURE 12.12 Sintamatic filter media.

Most of the polyethylene beads are between approximately 50 and 200 microns, with the average being 100 microns. Most of the visible pores appear to be smaller than 100 microns. An analysis of the pore structure indicated the media porosity to be about 0.054 [Pedersen, 1993]. This author has sampled a Sintamatic baghouse handling toxic metal dusts in an ambient air stream and found the unit to perform extremely well.

Air-to-Cloth Ratio

The primary design variable for a baghouse filter is the air-to-cloth ratio (A/C) which is the actual air flow rate through the baghouse divided by the filtration or cloth area. The A/C has units of meters/min

and ranges from 1.0 to 7.7 cm/s (2.0 to 15.0 ft/min). A very conservative design has A/C ratios around 1.0 cm/s (2.0 ft/min) while most industrial applications are in the 2.5 to 3.0 cm/s (5 to 6 ft/min) A/C range. Applications in aggregate crushing, sand reclaiming operations, and other applications where the particulate matter is relatively large in diameter and easily cleaned off the surface of the filter media can use A/C ratios between 3.0 to 7.7 cm/s (6 to 15 ft/min).

The selection of an optimum A/C ratio depends on the cleaning method, type of filter media, temperature, and the characteristics of the particles. Also involved are the trade-offs between initial cost and future operation and maintenance costs. A lower A/C means lower power cost, less maintenance, and higher dust collection efficiency. However, a low A/C also means more filter area and higher initial cost. Assuming no short-circuiting of inlet gas is occurring around the bags within the baghouse, poor collection efficiencies usually result from too high an air-to-cloth ratio for the application. Returning to conservative A/C ratios in the range of 2.0 or even 1.0 solves most former baghouse failure problems.

Baghouses typically have overall collection efficiencies greater than 98% for particles less than 10 microns in aerodynamic diameter. Therefore, they are widely used when high collection efficiencies for relatively small particulate matter are required. Their high collection efficiency is due to three mechanisms of impaction, interception, and diffusion acting simultaneously to remove particles down into the submicron size range.

For the environmental engineer, the challenge is to properly match one of the various types of baghouses available with the gas stream and the particulate matter to be collected.

Gas Conditioning

Since most baghouses are not very tolerant of high temperatures and moisture condensation, conditioning of the challenge gas streams is an extremely important consideration. High temperatures can cause bag media failure and even fires. Gas-entrained sparks or static electricity buildup can also cause fires and explosions. If water vapor within the gas stream is allowed to condense on the filter cake, the cake turns to mud, the pressure drop rises rapidly and the filter media becomes impervious to airflow or "blinds." High gas temperatures and moisture condensation must be avoided in baghouse systems. Three methods of reducing baghouse inlet gas temperatures are ambient air dilution, radiation and free convection, and water injection. A starting point common to the selection or design of any cooling method is the calculation of the heat energy that must be removed from the gas stream prior to baghouse entry.

Gas Stream Cooling Requirements

The following heat transfer rate equation is used to calculate the heat energy that must be removed from the gas stream:

$$q = mc_p\left(T_p - T_{bi}\right) \tag{12.26}$$

where q is the heat removed in Btu/hr; m is the mass flow rate of gas in lb/hr; c_p is the specific heat of the gas at constant pressure in Btu/lb, °F; T_p is the process gas temperature; and T_{bi} is the baghouse gas inlet temperature in degrees Fahrenheit. Regardless of the method of gas cooling that is employed prior to baghouse entry, the amount of heat to be removed from the gas stream is the same for the three methods.

Ambient Air Dilution

Mixing ambient air with the hot process gas prior to baghouse entry is an effective method of cooling. Even in some systems employing other methods of cooling, emergency cooling is usually affected by dilution with ambient air. Usually, a simple tee employing a butterfly valve in the ambient air leg is inserted in the duct just upstream of the baghouse. A temperature-controlled modulating valve driver can be used to position the butterfly valve and maintain the desired inlet baghouse gas temperature.

The following heat transfer rate equation can be solved for the desired mass flow rate of dilution air to maintain the inlet baghouse gas temperature below desired limits:

$$m_{\text{air}} = \frac{q}{c_{p_{\text{air}}}\left(T_{bi} - T_{\text{amb}}\right)} \tag{12.27}$$

where q is the heat energy to be removed from the process gas stream, Btu/hr; c_p is the specific heat of the ambient air, 0.24 Btu/lb, °F; T_{bi} is the baghouse inlet gas temperature; and T_{amb} is the ambient dilution air temperature, °F.

Now the dilution air volume flow rate, Q, is calculated from

$$Q = \frac{m_{\text{air}}}{\rho_{bi_{\text{air}}}} \tag{12.28}$$

where $\rho_{bi_{\text{air}}}$ is the density of the gas entering the baghouse, lb/ft^3.

While this method is effective for cooling, it must be pointed out that the dilution air volume flow rate is a significant portion of the total gas the baghouse must now handle. In some situations, depending on the original process gas temperature, the dilution air flow rate will exceed the process gas flow rate. Therefore, the main disadvantage with this method of cooling is the added gas that the baghouse must now process.

Radiation and Free Convection

This cooling method employs a long duct for radiation and free convection gas cooling between the process and the baghouse. With this method, the heat energy needed to be removed from the gas stream can be calculated from the following equation:

$$q = q_{\text{free convection}} + q_{\text{radiation}} \tag{12.29}$$

or

$$q = U_{\text{combined}} A\left(\text{LMTD}\right) \tag{12.30}$$

where U_{combined} is the overall heat transfer coefficient of the cooling duct, Btu/(hr ft^2 °F); A is the exterior duct area for heat transfer; and LMTD is the log mean temperature difference between the cooling duct and the ambient air. Since we are interested in the diameter and length required for the cooling duct, the above equation is solved for the heat transfer area, A, as

$$A = \pi DL = \frac{q}{U_{\text{combined}}\text{LMTD}} \tag{12.31}$$

and for a chosen diameter,

$$L = \frac{q}{U_{\text{combined}}\text{LMTD}\pi D} \tag{12.32}$$

Radiation and free convection cooling has the distinct advantage over the dilution cooling scheme in that the gas handled by the baghouse contains no added dilution air and, therefore, is significantly less in volume flow. There is the added expense of the ductwork, but this is usually more than offset by the reduction in the amount of gas passing through the baghouse. Since the controlling thermal resistance in this cooling method is the internal duct wall convective heat transfer coefficient, schemes to spray water on the external surface of the pipe to significantly reduce the required pipe length are usually not successful.

This cooling method can require up to a few hundred feet of cooling duct, so there must be ample room available at the site for successful implementation. Where space is available, long horizontal duct runs have worked successfully; where space is at a premium, serpentine configurations can be used effectively.

Evaporative Cooling

Utilization of the latent heat of vaporization of water of about 1000 Btu/(lb water) is an extremely effective method of cooling process gas prior to baghouse entry. This method requires a contact chamber, spray nozzles, and a dew point sensing and feedback control system to modulate the water flow to the spray nozzles. This method has the advantages of small space requirement and lower capital cost, but it does require a reasonably sophisticated water flow control system to prevent dew point problems (liquid drops forming in the baghouse).

The total heat energy to be removed by the injected water is the sum of the sensible and latent heat absorbed by the water. This includes the sensible heat raising the liquid water from its injection temperature up to its vaporization point, the latent heat during vaporization, and the sensible heating of the water vapor up to the desired baghouse inlet gas temperature. In equation form:

$$q_{\text{total}} = q_{\text{sensible}} + q_{\text{latent}} \tag{12.33}$$

where

$$\begin{aligned} q_{\text{sensible}} &= mc_p\Delta T_{\text{liquid}} + mc_p\Delta T_{\text{vapor}} \\ q_{\text{latent}} &= mh_{fg} \end{aligned} \tag{12.34}$$

c_p is the specific heat at constant pressure of liquid water or vapor and h_{fg} is the latent heat of vaporization of water changing phase from a liquid to a vapor, 1000 Btu/lb.

Example 12.2

It is desired to cool 50,000 acfm of process gas at 1500°F down to 500°F prior to baghouse entry using water injection. Compute the amount of heat needed to be removed from the gas stream and the needed water injection rate as well as the rise in dew point temperature after injection. Heat to be removed from gas stream:

$$\begin{aligned} q &= mc_p\left(T_{\text{process gas}} - T_{\text{baghouse inlet}}\right) \\ q &= (50{,}000)(0.02)(0.25)(1500-400) \\ q &= 275{,}000\ \frac{\text{Btu}}{\text{min}} \end{aligned} \tag{12.35}$$

Mass flow rate of water assuming initial water temperature is 70°F and the vaporization point of water occurs at 212°F:

$$q = mc_p\Delta T_{\text{liquid}} + mc_p\Delta T_{\text{vapor}} + mh_{fg} \tag{12.36}$$

substituting:

$$275{,}000\ \frac{\text{Btu}}{\text{min}} = m\left[(1.0)(212-70) + (0.46)(400-212) + \left(1000\ \frac{\text{Btu}}{\text{lb}}\right)\right] \tag{12.37}$$

solving for m:

$$m = 224\ \frac{\text{lb water}}{\text{min}} \quad \text{or} \quad 27\ \frac{\text{gal}}{\text{min}} \tag{12.38}$$

Therefore, 27 gpm of water must be injected directly into the gas stream to cool it from 1500°F down to 400°F. This injection of liquid adds 7800 acfm of vapor to the process gas stream at 400°F which must be considered as part of the baghouse air to cloth ratio.

The vapor equivalent of the 27 gpm liquid water injected is calculated as follows:

$$\text{Vapor volume}\left(\text{ft}^3\right) = 10.1\left(\frac{T}{P}\right)L \tag{12.39}$$

where L is in gallons, T is temperature in Rankine (i.e., 400 + 460), and P is pressure in Hg. Substituting:

$$\begin{aligned}\text{Vapor volume}\left(\text{ft}^3\right) &= 10.1\left(\frac{860}{29.92}\right)27 \\ &= 7838 \text{ acfm at } 400°\text{F}\end{aligned} \tag{12.40}$$

This is a 36% increase in gas flow that the baghouse will have to handle (over that of the cooled process gas of 21,938 acfm at 400°F).

Effect on Dew Point

The added water vapor to the process gas stream will increase the specific humidity of the mixture. The specific humidity (SH) of the mixture is

$$\begin{aligned}\text{SH} &= 224\,\frac{\text{lb water/min}}{(21{,}938 \text{ acfm})}\left(0.046\,\frac{\text{lb}}{\text{ft}^3}\right) \\ &= 0.22\,\frac{\text{lb water}}{\text{lb dry air}}\end{aligned} \tag{12.41}$$

This specific humidity corresponds to a dew point of 151°F and compares to 42°F prior to water injection. Therefore, water injection of 27 gpm elevates the dew point of the baghouse inlet gas from 42°F to 151°F. Caution must be exercised so that the 151°F dew point temperature of the inlet gas is never approached or liquid droplets will blind the baghouse.

Sulfur Dioxide

The emission of sulfur dioxide (SO_2) is a common occurrence from the combustion of fossil fuels for power generation and from other industrial processes that involve the use of sulfur. Combustion process, however, generates up to 75% of all SO_2 emissions with the fuel itself being the source of sulfur. As a result, this discussion will focus on the control of SO_2 from combustion sources.

SO_2 is formed when fuel-bound sulfur is combusted, and in the process converted to SO_2 by combining with the combustion air at a molecular weight ratio of 2:1. As a result, one gram of fuel-bound sulfur results in 2 grams of SO_2 and necessitates substantial control measures for flue gas treatment.

The nature of formation of SO_2 leaves two options in its emissions control: one, control emissions by eliminating the formation of SO_2, or two, remove SO_2 from the combustion flue gas after its formation. The first process is referred to as fuel conversion and the second as flue gas desulfurization (FGD).

Fuel Conversion

The process of fuel conversion seems relatively simple as it consists of the removal of sulfur from the fuel to be combusted or the use of a different, lower-sulfur fuel. This can involve the use of natural gas, distillate oils with low sulfur contents, or low-sulfur coals in place of higher-sulfur counterparts.

These alternatives pose simple answers to a more complex issue, in that many combustion units are designed to burn a specific fuel type, making switching to a different fuel cost-prohibitive. Additionally,

the use of low-sulfur coal is often cost-prohibitive as the transportation costs are often extreme. Further, fuel conversion involving the removal of sulfur from crude oils that can be distilled is far simpler than the removal of sulfur from coals.

As a result of the cost issues and the complexity of the removal of sulfur from fuel sources, controlling emissions by fuel conversion is typically a good method of reducing SO_2 emissions from sources burning distillate oils or sources that have exposure to a supply of low-sulfur coal. Often fuel conversion is used to lower total control costs or to reduce SO_2 emissions below regulated levels.

Flue Gas Desulfurization

Flue gas desulfurization (FGD), in this discussion, is a process that focuses on the removal of SO_2 from a combustion gas stream. On a broader scale, flue gas desulfurization can be applied to control sulfurous compounds in many different types of industrial emissions. FGD systems consist of two different types — throwaway and regenerative — that operate on either a wet or dry basis. Throwaway and regenerative systems differ in that throwaway systems convert the sulfur compounds into a form that is disposed of as a solid waste, while regenerative systems convert the sulfur into either an elemental sulfur or sulfuric acid form that can be reused or sold.

Throwaway Systems

Throwaway systems operate by the scrubbing of the gas stream where the scrubber water contains a reactant, typically lime or limestone, such that the SO_2 present reacts and is removed in a solid form in the scrubber blowdown. Often a simple scrubber configuration is used and is followed by some sort of gravity thickener to remove the solids from the effluent scrubber water. The overall stoichiometry for the reaction can be represented by the following [Cooper and Alley, 1990]:

$$\begin{aligned} CaO + H_2O &\rightarrow Ca(OH)_2 \\ SO_2 + H_2O &\rightarrow H_2SO_3 \\ H_2SO_3 + Ca(OH)2 &\rightarrow CaSO_3 \cdot 2H_2O \\ CaSO_3 \cdot 2H_2O + \tfrac{1}{2}O_2 &\rightarrow CaSO_4 \cdot 2H_2O \end{aligned} \tag{12.42}$$

Limestone and lime systems operated in this manner are capable of 90 and 95% removal efficiencies, respectively.

A variation of the scrubbing method is the spray injection of a lime slurry into the hot gas stream. As the slurry is injected into the hot gas stream the SO_2 reacts with the lime in the aqueous phase, dries, and is removed in the solid phase by filtration in a baghouse. This type of operation results in lower maintenance, energy use, and operating costs [Cooper and Alley, 1990].

Dry lime or limestone injection systems operate by injecting the lime or limestone into the flue gas, causing the SO_2 present to adsorb and react. Final reaction products are then removed by filtration. These systems are limited by the fact that the site of reaction is only on the surface of the reactant, and is thus hindered in a manner that spray injection is not.

Regenerative Systems

Regenerative FGD systems operate in a manner that is similar to throwaway systems with the exception of an additional step that either transforms or reclaims the reaction products. An example of this is magnesium oxide scrubbing. This process employs the use of MgO as the scrubbing agent, wherein SO_2 is absorbed and forms magnesium sulfite (or sulfate). This reaction by-product is then recalcined, forming MgO and SO_2, with the MgO being returned to the scrubber and the SO_2 being captured in a concentrated form that can be utilized as a feedstock in sulfuric acid production. Disadvantages to the system lie in the heat required to recalcine the magnesium sulfite [Wark and Warner, 1981]. Other examples of regenerative FGD systems are single alkali scrubbing, double alkali scrubbing, citric acid scrubbing, the Sulf-X process, and the Wellman-Lord process.

Nitrogen Oxides

The formation of nitrogen oxides (NO_x) is similar to SO_2 in that NO_x is formed as the result of combustion processes. NO_x is composed of several different forms of nitrogenous compounds. Included among these are nitrous oxide (N_2O), nitric oxide (NO), nitrogen dioxide (NO_2), nitrogen trioxide (N_2O_3), nitrogen tetroxide (N_2O_4), and nitrogen pentoxide (N_2O_5). While all of these components can exist in a combustion gas stream at some point, NO_x typically refers to NO and NO_2.

The formation of NO_x begins with the formation of NO in the flame zone of a combustion process where fuel-bound nitrogen combines with the oxygen present in combustion air to form NO and is termed fuel NO_x. Additionally, atmospheric nitrogen in the combustion air also combines with oxygen to form NO and is known as thermally generated NO_x. After formation, the NO generated rapidly cools with the gas stream where a majority (approximately 95%) converts to NO_2. As a result, NO_2 is the principal component of NO_x that is emitted to the atmosphere. For a more complete discussion of combustion by-product formation, the reader is referred to the chapter on incineration.

NO_x can be controlled by a variety of methods. These control methods can be grouped in three forms: fuel conversion, combustion modifications, and flue gas treatment. Fuel conversion is the process of changing fuels to take advantage of lower-nitrogen fuels. This consists primarily of the use of natural gas over fuel oils or coals, and suffers from the same type of limitations as fuel conversion to control SO_2, described above. Therefore, fuel conversion will be omitted from this discussion. The second form is combustion modifications that lower the potential for formation of NO_x during combustion processes. The third form is the use of downstream controls to remove NO_x from the flue gas.

Combustion Modifications

Combustion modifications take advantage of the characteristics of NO_x formation in an effort to minimize it. These efforts focus on the combination of nitrogen and oxygen in the region of combustion (flame zone) at a high enough temperature to form NO. Modifications employed for this include air variations, low NO_x burners (LNB), and fuel reburning [Makansi, 1988].

Combustion Air Variations

One of the most simple combustion modifications is to alter the manner in which the combustion air is supplied to the flame. This is done in an effort to lower both the peak flame temperature and oxygen concentrations in the regions of highest temperature. Typical methods consist of the following [Makansi, 1988]:

1. Placing burners out of service (BOOS) and fuel biasing that provide combustion regions that are fuel rich followed by regions that are fuel lean to stretch the combustion zone, lowering peak temperatures and oxygen concentrations. NO_x reductions of up to 20% are possible with these methods.
2. Low excess air firing (LEAF) to reduce the excess combustion air from typical levels of 10–20% to 2–5%. This reduces oxygen concentrations in the flame zone and results in decreased NO_x formation, up to 20%, and a more efficient flame.
3. Overfire air is a means of air staging, or elongating the combustion zone by forcing a portion, 10–20%, of the combustion air to a set of ports above the burners. This in essence creates fuel-rich and fuel-lean zones and results in NO_x emission reductions of 15–30%.
4. Flue gas recirculation (FGR) is a process that recycles a portion of the combustion gases back into the virgin combustion air to reduce combustion temperatures and thereby reduces thermally generated NO_x up to 20–30%.

Low NO_x Burners

Low NO_x burners are a technology that has developed in order to retrofit existing, NO_x intensive, combustion units with a burner that will allow the combustion unit to operate at its design level, but with substantially lower NO_x emissions. This is done within the burner itself by combining the combustion air and fuel in different manners (this varies from vendor to vendor) such that oxygen levels are

reduced in the critical NO_x formation zones. Low NO_x burners themselves are capable of NO_x reductions of up to 20–30%, and when coupled with overfire air systems NO_x reduction of up to 50% are possible [Smith, 1993]. Installation of these types of burners is limited by the design of the combustion unit, and in some cases will require modification of existing fuel- and air-handling equipment.

Fuel Reburning

Fuel reburning is a method of fuel staging wherein a portion of the fuel for the combustion unit is fed into the unit downstream of the initial combustion zone. This action creates a second combustion zone which is operated substoichiometrically. In the second zone, the NO created in the first zone is kept at temperature for longer periods of time and thereby allowed to convert back to elemental N_2. The fuel added for reburning must be of high enough volatility to allow continued combustion and therefore this method favors oil- and gas-fired units. NO_x reductions of 75–90% are possible with this type of configuration [Makansi, 1988].

Downstream Processes

Downstream controls for the removal of NO_x from combustion gas streams consists of two types. The first type is the addition of urea or ammonia to the hot combustion stream, causing the NO_x in the gas stream to be converted into water and nitrogen. This first type includes both selective catalytic and noncatalytic reduction. The second type of downstream control is the removal of NO_x from a gas stream by scrubbing.

Selective Catalytic Reduction

Selective catalytic reduction (SCR) of NO_x utilizes a catalytic transition metal grid in combination with ammonia at temperatures of 600–700°F to convert the NO_x present in the gas stream back to elemental N_2 and water. This process is governed by the NO_x concentration in the flue gas with the injection of ammonia being a function of this concentration. Removal efficiencies for this type of operation range from 80–90% [Makansi, 1988].

However, drawbacks to this type of removal system include a poor catalyst life of only one to five years and emission of unreacted ammonia. The portion of ammonia passing through the system is referred to as ammonia slip.

Selective Noncatalytic Reduction

Selective noncatalytic reduction (SNCR) is similar to SCR in that the injection of ammonia or urea is utilized to convert NO_x emissions into elemental N_2 and water. However, this system does not utilize a catalyst for this reaction; instead, the ammonia is injected in a higher-temperature region of the gas stream taking advantage of the heat as a catalyst. The temperature required, typically 1600–2000°F, necessitates that the injection location be either physically in the combustion unit or immediately downstream in the ductwork. Removal efficiencies of up to 80% are possible with SNCR.

Flue Gas Denitrification

Flue gas denitrification (FGDN) is the process of scrubbing NO_x from a gas stream. However, while the principles of operation for the scrubbing system are the same for its particulate removal and FGD counterparts, the scrubbing liquid is substantially different. This is due to the fact that many of the NO_x constituents vary in their degree of water solubility. As a result, scrubbing systems for the removal of NO_x typically employ a series of individual scrubbers whose makeup liquid varies with intended removal. Operation of the scrubbers is relatively maintenance free with the requirement of continued chemical addition for the makeup water. Removal efficiencies can approach 90% with FGDN.

Volatile Organic Compounds

The control of VOCs is a complex issue as there are a great number of organic compounds being emitted, either directly or indirectly, with all compounds having various structures and properties. The issue is further complicated by the fact that a majority of the air toxics list, provided earlier in the chapter, is

composed of VOCs and requires a MACT level of control as opposed to the nontoxic VOCs RACT level of control requirement for most cases of VOC emission. As a result, there are a great number of VOC emissions controls that are in place or are being recommended for various situations.

However, the description of all methods of VOC control is beyond the scope of this chapter. The reader is referred to the Air and Waste Management Association's *Air Pollution Engineering Manual* and the chapter in this handbook on incineration for further information on the subject of VOC emissions control for those points not covered in this discussion. Emissions control focused on in this discussion will consist of the standard methods of adsorption and incineration that are capable of high removal efficiencies and are most likely to be considered in control technology reviews.

Carbon Absorption

Carbon absorption is the use of the physicochemical process of adsorption to remove dilute organics from a gas stream. Adsorption itself is the interphase accumulation or concentration of substances at a surface or interface of the adsorbent, in this case activated carbon [Weber, 1972]. Accumulation or concentration of molecules at the surface of the adsorbent is the result of the molecule being attached to the surface by van der Waals forces, physical adsorption, chemical interaction with the adsorbent, or chemical adsorption. Both types of adsorption are reversible, although chemical adsorption requires a greater driving force to desorb the molecules.

The adsorption process itself consists of the use of an adsorbent medium, typically activated carbon, that is placed in the gas stream such that the gas has to pass through the medium. As the gas passes through the carbon, the constituents of the gas stream make contact with it and adsorb. After a period of time, the carbon can no longer adsorb organics and is removed from service. This carbon can then be reactivated by steam stripping or incineration to remove the organics, or disposed of as a solid or hazardous waste. Steam stripping of the carbon provides the option of reclaiming the organics previously lost to the atmosphere. Activated carbon is composed of nutshell or coal that has been charred in the absence of oxygen and activated by steam stripping or various other methods.

In operation, a carbon adsorber consists of a bed of carbon whose dimensions are a function of the VOCs being removed. The bed usually operates in a passive mode, as described earlier, with the carbon that is first exposed being the first expended. As the carbon is expended or spent, a front develops that demarks spent carbon from carbon that is still active. Through the life of the carbon bed, the front progresses from one end of the bed to the other. The end of the operational life of the bed is realized when the front "breaks through" the opposite end of the bed and the bed has lost its ability to remove organics. In operation, the bed is removed from service and replaced prior to breakthrough such that continued emissions control is ensured.

Carbon absorption is employed for a wide variety of uses due to its versatility and the potential to reclaim organics. Operation of carbon beds is a relatively simple process that is maintenance nonintensive. Typically, maintenance of the beds involves only the servicing of the air-handling equipment and exchange or recharge of the bed once the carbon is spent. In many cases, exchange of the carbon is handled by the vendor. Lifetimes of the carbon bed and the removal efficiency it will provide are functions of the design of the bed. However, in most cases carbon adsorbers are designed for removal efficiencies of 99% or greater.

A significant drawback to adsorption is the fact that it is not a means of ultimate disposal. Adsorption provides only the ability to concentrate and transfer a pollutant from a gas stream to a medium where ultimate disposal or reuse is possible. Some facilities employ carbon adsorption in series with incineration. The concentrated gas from the carbon desorption process is ducted to an incinerator for final treatment. This arrangement is attractive to facilities with high volume, low concentration gas streams. Without the concentration provided by the carbon absorption system, a much larger incinerator would have to be selected.

Incineration

The second type of control commonly employed for the emission of VOCs is incineration. This control oxidizes the organics to CO_2 and water by combustion or through the use of a catalyst. Incineration for

the control of VOCs is a means of ultimate disposal and is typically employed for more concentrated gas streams where the composition of organics in the gas stream is known and reasonably constant. Destruction efficiencies in excess of 99% are possible with incineration. However, large variations in the organic feed stream result in inefficiencies during combustion and can produce products of incomplete combustion (PICs) and result in poor destruction efficiencies. The degree to which this is possible is dependent on the type of incinerator employed. Again, the reader is referred to the chapter on incineration for a more complete discussion of combustion and operation of incinerators in general.

There are three types of incinerators: direct, thermal, and catalytic. These vary by the manner in which the oxidation of the organics takes place, or by the manner in which the organics are combusted.

Direct Incineration

Direct incineration is the combustion of the gas stream of organics itself. This is done by igniting the gas stream and allowing the organics to combust instantaneously on their own and requires concentrations of organics in the gas stream that will support this type of combustion. As a result, this type of incineration is used on gas streams with concentrated organics. Flaring is a form of direct incineration.

Thermal Oxidation

Thermal oxidation is a process that oxidizes organics by introducing the organics around a flame such that oxidation of the organics is the result of the elevated temperature in the chamber. Unlike direct incineration, the organics themselves are never the primary fuel for combustion; they are a secondary combustion process. In fact the concentrations of organics must be below that required for combustion on their own. Oxidation in this case is a function of the temperature, 1200–2000°F, and residence time, 0.2–2.0 seconds, of the organics in the combustion chamber.

Catalytic Oxidation

Catalytic oxidation is the third type of oxidation process commonly used in the control of VOCs. This process utilizes the ability of a transition metal catalyst to oxidize organic compounds to CO_2 and water at relatively low temperatures. For this type of oxidation, organic concentrations below those that require thermal or direct incineration are used. Operation of this type of incinerator consists of the introduction of the organic-laden gas stream into a bed of catalyst at temperatures of 650–800°F. As the gas stream passes through the bed, the organics react in the presence of the catalyst and are oxidized.

Condensation

While not as frequently employed as adsorption or incineration, condensation of waste gases can be an attractive and even profitable alternative in certain cases. A refrigerated condensation system reduces gas emissions by lowering the gas stream temperature to below its dew point and providing extensive condensing surface area in the gas flow path thus accelerating the conversion of the waste back to liquid form. The condensed liquid can be returned to the process and reused or salvaged. Equipment costs can vary widely for similar flow capacity units depending on the character of the gas stream. The units are best suited for gas streams with relatively high solvent loads, low water content, and low solvent volatility. Dilute, highly volatile gas streams saturated with water generally require multistage refrigeration systems, even cryogenic systems, with provisions to avoid icing and in most cases will not be economically viable as an emission control alternative. While the capital cost is generally the highest for condensation, over time the salvaged solvent can reduce the annualized costs significantly even, in some cases, to the point of generating a net financial gain.

12.6 Odor

Odor is defined as the characteristic of a substance that makes it perceptible to the sense of smell. This definition includes all odors regardless of their hedonic tone. In the field of air pollution, concern over odors is limited to those compounds or mixtures thereof that result in the annoyance of an individual.

In human terms, compounds producing displeasure due to their odor are typically not threatening to human health but do produce a great deal of physiological stress. In fact, in Metcalf and Eddy's text on wastewater engineering, one of the principal characteristics of wastewater considered is the odor. This is due to the fact that offensive odors can cause decreased appetites, lowered water consumption, impaired respiration, nausea, and mental perturbation. The Metcalf and Eddy text further reports that in extreme situations offensive odors from wastewater treatment facilities can have substantial health impacts on a communitywide basis [Tchobanoglous, 1979].

Sense of Smell

The sense of smell is a sensation that is produced when a stimulant comes into contact with the olfactory membranes located high in the nasal passages. As the stimulants contact the olfactory membranes they are absorbed and excite the membranes. There are thought to be seven primary classes of stimulants that affect the olfactory membranes. These seven stimulants are as follows:

1. Camphoraceous
2. Musky
3. Floral
4. Peppermint
5. Ethereal
6. Pungent
7. Putrid

The seven stimulants are felt to be the primary sensations; however, this is a topic of debate as others feel that there are perhaps 50 or more classes or primary stimulants. The primary stimulants illustrate the complexity of the sense of smell in relation to the other senses in that there are only three primary color sensations of the eye and four primary sensations associated with taste.

While there are seven stimulants of the olfactory membranes, reaction to a stimulant varies from person to person: a rose may not smell as sweet to one person as it does to another. This results in great difficulty in assessing the magnitude of an odor.

Characteristics of Odor

Human response to odor depends on the characteristics of the property being assessed. The odor intensity, detectability, character, and hedonic tone all influence the response to a particular compound [Prokop, 1992].

The odor intensity is the strength of the perceived sensation. Intensity of the odor is a function of the concentration of the odiferous compound coupled with a human response. Intensities of odors can be the same for different compounds at different concentrations.

Detectability is the minimum concentration of an odiferous compound that produces an olfactory response. The detectable limit for odors is referred to as the odor threshold. Measurement of this characteristic of odor is difficult as the threshold varies from person to person and is further complicated as the detectable concentration varies with previous exposure. Odor threshold limits are often reported as the concentration that produces an olfactory response in 50% of the test population.

The character of an odor refers to the associations of the person sensing the odor. This is the characteristic that separates the odors of different compounds that are presented in similar intensities. Table 12.11 presents a list of several different compounds with their odor thresholds and associated characteristics.

Similar to the character of an odor is the hedonic tone of the odor. The hedonic tone is a reflection on the degree of pleasantness or unpleasantness associated with an odor. Hedonic tone is assessed by the response of different individuals.

TABLE 12.11 Odor Descriptions of Various Compounds

Compound	Formula	Molecular Weight	50 Percent Detection Thresholds ($\mu g/m^3$)	Odor Description
Acetaldehyde	CH_3CHO	44	90	Pungent, fruity
Ammonia	NH_3	17	3700	Pungent, irritating
Dimethyl sulfide	$(CH_3)_2S$	62	51	Decayed cabbage
Hydrogen sulfide	H_2S	34	5.5	Rotten eggs
Methyl mercaptan	CH_3SH	48	2.4	Rotten cabbage
Pyridine	C_5H_5N	79	1500	Pungent, irritating
Trimethylamine	$(CH_3)_3N$	59	5.9	Pungent, fishy

Sources: Adapted from Prokop, W. H. 1992. *Air Pollution Engineering Manual — Odors.* Air and Waste Management Association. Van Nostrand Reinhold, New York; and Nagy, G. Z. 1991. The odor impact model. *J. Air Waste Manage. Assoc.* 41(10):1360–1362.

Odorous Compounds

Odorous compounds are emitted from a variety of sources and consist of both organic and inorganic compounds that exist primarily in the gas phase, but can also exist as solids. Table 12.11 lists examples of both organic (such as acetaldehyde) and inorganic (such as ammonia) compounds. Typically odorous compounds are emitted from processes which involve anaerobic decomposition of organic matter [Prokop, 1992].

Most odorous compounds are significantly volatile compounds with molecular weights from 30 to 150. Typically the lower molecular weight compounds have higher vapor pressures and thus are more volatile [Prokop, 1992]. A positive example of the use of an odiferous compound is the addition of mercaptans to nonodiferous natural gas supplies. This process is done in order to provide a method of detection for leaks of natural gas, and thus, hopefully, prevent catastrophes.

Measurement

The measurement of odor is subjective as the process necessitates the assessment of odor characteristics by noninstrumental means. Intensity, detectability, character, and hedonic tone are typically assessed by sensory methods involving the use of an odor panel. An odor panel is a group of people that are presented a series of gas streams and asked to qualify and quantify what is presented.

The particulars of the measurement of odor are beyond the scope of this chapter. For further information, the reader is referred to the chapter on odors in the Air and Waste Management Association's *Air Pollution Engineering Manual* for a synopsis of odor measurement involving odor panels.

Odor Control Techniques

Odor control techniques involve essentially the same elements as the methods employed in the control of VOCs. Controls that are typically used consist of the following:

1. Process modification
2. Masking agents or odor modification
3. Carbon adsorption
4. Absorption/chemical oxidation
5. Incineration

The first control to be considered is prevention of odor formation. This is an attempt to reduce the generation of odors through changes in process equipment design and/or operating procedures. This process would typically involve the identification and elimination of the area in the process that creates the compound of concern. In some instances, this can simply involve ensuring that a waste stream receives proper aeration. However, another situation would be one in which the compound in question is an

TABLE 12.12 Process Modification

Advantages	Disadvantages
Process changes alone may reduce odors enough to minimize odor complaints	The effect of modifications is difficult to predict without extensive testing
Changes can be made relatively quickly	Process modifications may not be able to provide a suitable reduction
Costs should be lower than the installation of downstream controls	Modifications could result in decreased production capacity

TABLE 12.13 Carbon Adsorption

Advantages	Disadvantages
Control efficiencies can range from 95 to 98%	Extensive preconditioning of the gas stream may be required
A relatively small amount of auxiliary fuel is required since carbon beds are typically regenerated every 8 to 24 hours	Adsorption beds typically require large amounts of space
	Specialized maintenance may be required
	Even with regenerating systems, periodic replacement of carbon is needed every three to five years
	Regeneration of gas may be another source of odor

TABLE 12.14 Absorption

Advantages	Disadvantages
Respectable odor control efficiencies are possible	Control efficiencies may not meet required levels for odor control
No auxiliary fuel is needed	Particulate control is needed upstream of the scrubber
	Corrosion of the scrubber is a problem
	Creates a wastewater disposal problem

integral part of the process and as a result necessitates the use of a downstream control. Advantages and disadvantages of process modification are listed in Table 12.12.

A second consideration in the reduction of an emissions odor is odor masking or modification. This type of control method attempts to modify the hedonic tone of the odor or the emissions stream such that the offending odor is less unpleasant. Odor masking does not result in a reduction of the offending compound; it merely attempts to alter the intensity or character of the offending compound. Usually these types of controls are not very effective and are expensive in relation to other methods of control.

Carbon adsorption involves the removal of the odiferous compounds by passing the emission stream through a carbon bed. The carbon is stationary in the bed, and as the gas stream passes through, the organics adsorb onto the carbon through a physicochemical process. As the carbon reaches a maximum capacity it is either exchanged with new carbon or regenerated. Regeneration of the carbon is typically done by passing a steam through the bed to desorb the organics. A few of the advantages and disadvantages are listed in Table 12.13.

Absorption is the removal of organics by wet scrubbing with various oxidizing agents to remove odors from emission streams. A typical scrubbing system would consist of a venturi scrubber followed by a packed-tower scrubber. The venturi scrubber serves to remove particulate and presaturate the gas stream. After the venturi, the gas stream is passed through a packed-tower scrubber where the odiferous organics are removed. Sodium hypochlorite and potassium permanganate are two of the more commonly used oxidants in packed-tower scrubbers. Table 12.14 lists a few of the advantages and disadvantages of absorption for odor control.

The final control option generally used for odors is incineration. Thermal and catalytic incinerators are employed in controlling odors; however, thermal incineration is more common. Temperatures and residence times for thermal incineration vary depending on the nature of the gas stream. Catalytic

incineration is a method to lower operating temperatures and thus lower operating costs; however, catalyst poisoning is a significant problem. Both types of incineration offer the most effective means of odor control, but do so at the highest capital and operating costs.

12.7 Air Pollution Meteorology

After an emission source has been characterized as to type and size, the question arises as to how the source and the resulting emissions will affect the quality of the downwind ambient air. This determination requires that the source further be described by modeling, or the estimation of the atmospheric dispersion of the various components of the gas stream. The modeling step is often what determines an appropriate emission rate.

Once the gas stream is emitted into the atmosphere, a complex series of events begins to unfold. The components (or pollutants) in the gas stream join the environment and are transported, dispersed, and eventually removed from the atmosphere according to the physical nature of the component. However, before examining the dispersion of the gas stream, a basic understanding of the environment which governs the dispersion is required.

Wind (Advection)

The atmosphere is an ocean of air that is in continual motion primarily as a result of solar heating and the rotation of the earth. As the sun heats different parcels of air in different areas, the heated air responds by expanding and increasing in pressure. Subsequently, differential pressure areas arise and result in large-scale air motions, or winds. This is illustrated on a global basis by the large-scale winds created as a result of differential heating between the equator and the poles. Figure 12.13 illustrates the various winds that

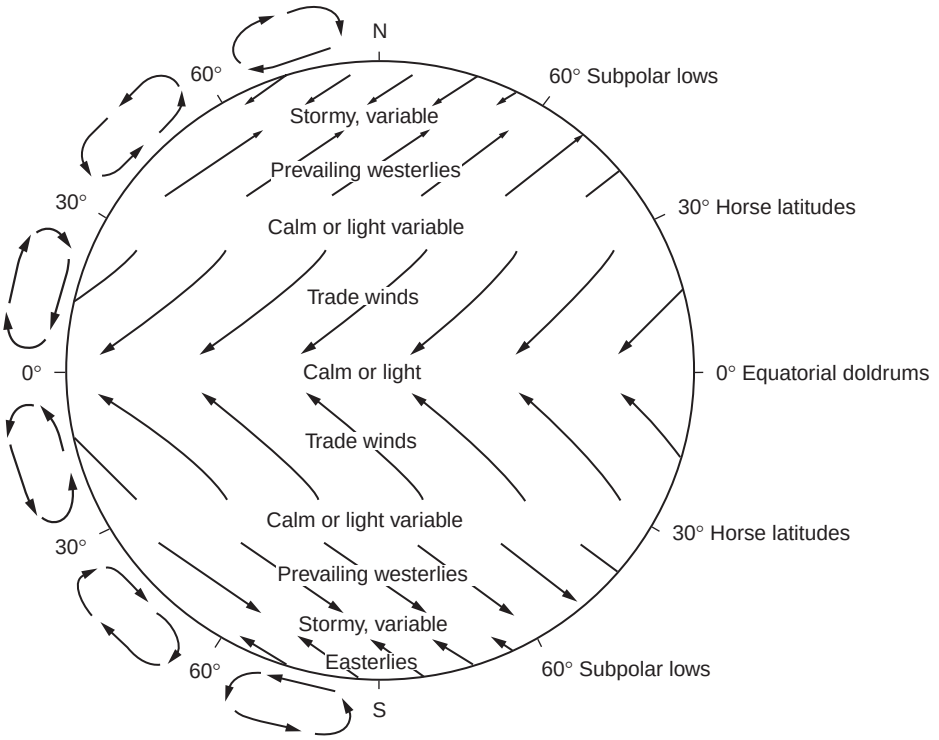

FIGURE 12.13 General global air circulation. (*Source:* Cooper, C. D. and Alley, F. C. 1990. *Air Pollution Control: A Design Approach.* Waveland Press, Prospect Heights, IL. Reprinted by permission of Waveland Press, Inc. All rights reserved.)

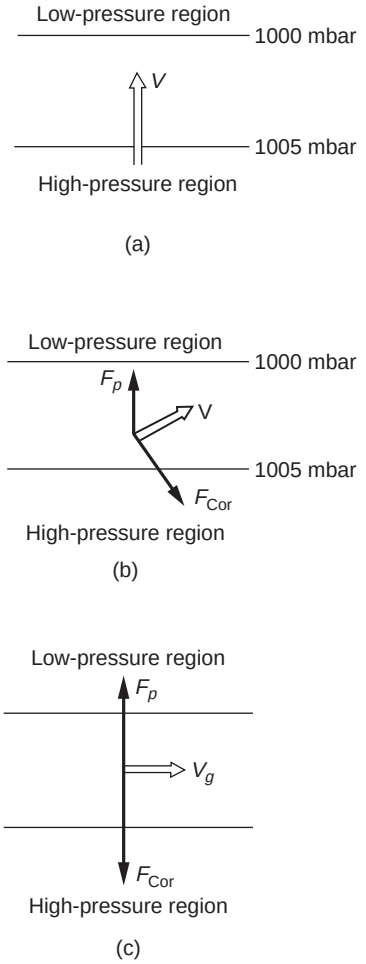

FIGURE 12.14 Effects of various forces on wind direction relative to pressure isobars. (a) Pressure gradient force only. (b) Pressure gradient force with Coriolis force. would be created by differential heating on a global scale if the earth were smooth and of homogenous composition [Cooper and Alley, 1990].

Wind Variations

As described previously, movement of air (or wind) is a result of the pressure gradient created by high- and low-pressure regions interacting. This pressure gradient results in a force, F_p, that creates a velocity vector from the high-pressure region to the low-pressure region and, ideally, is perpendicular to both pressure regions or isobars. This is shown in Fig. 12.14(a), where V is the velocity vector or wind created by the pressure gradient force.

However, as the earth is rotating the effects of the Coriolis force, F_{Cor}, are realized on the movement of air as well. These forces result in the deflection of the wind from the ideal perpendicular gradient. In the northern hemisphere, these forces deflect the wind to the right, relative to the surface, while in the southern hemisphere the force deflects the wind to the left. The magnitude of the Coriolis force is a function of the velocity of the air, latitude, and the earth's rotational speed. These forces are at a maximum at the poles and zero at the equator [Wark and Warner, 1981]. When the pressure gradient and Coriolis forces are combined, the result, depicted in Fig. 12.14(b), is a velocity vector whose angle is a function

of the relative magnitude of the two forces to each other. In the ideal case, the pressure gradient and Coriolis forces are balanced such that the resultant velocity vector is parallel to the isobars. This is depicted in Fig. 12.14(c). The resulting wind always moves such that the pressure gradient force is in the direction of the low-pressure region and is balanced by the Coriolis force in the direction of the high-pressure region. The corresponding velocity vector is at a right angle to both. Movement of the wind is to the right of the Coriolis force and is therefore moving such that the low-pressure region is to the left of the vector. This idealized wind is referred to as the geostrophic wind and approximates conditions a few hundred meters above the earth's surface [Wark and Warner, 1981].

While the geostrophic wind is associated with parallel isobars, the gradient wind is associated with curved isobars. The gradient wind differs from the geostrophic wind by the centripetal acceleration, a_c, associated with the movement of a parcel of air in a curvilinear motion. The gradient wind is evident around centers of high and low pressure [Wark and Warner, 1981].

Winds at the earth's surface are further complicated by the fact that the earth is not smooth and homogenous. As a result several other factors need to be considered when discussing the magnitude and direction of the wind. Among these are [Cooper and Alley, 1990]:

1. Topography
2. Diurnal and seasonal variation in surface heating.
3. Variation in surface heating from the presence of ground cover and large bodies of water

Principal among these factors is the frictional force, F_f, arising from surface roughness or the effect of the earth's topography. Additionally, variation in heating arises from daily and seasonal changes that affect the movement of air on a local basis. Both of the factors are combined as surface heating is a function of incoming solar radiation and the local surface characteristics.

The region of the atmosphere between the earth's surface and the upper reaches of the atmosphere is referred to as the planetary boundary layer [Wark and Warner, 1981]. In this layer, all of the factors mentioned above result in this frictional force that combines with the pressure and Coriolis force to alter the direction and magnitude of the wind at a slight angle toward the low-pressure region. This is illustrated in Fig. 12.15. The frictional force acts opposite to the direction of the velocity vector, which in turn acts at a right angle to the Coriolis force. The resulting magnitude of the wind velocity is the sum of the components of the individual force vectors, with the direction being at a slight angle toward the low-pressure region. This surface wind is of a magnitude less than the geostrophic wind.

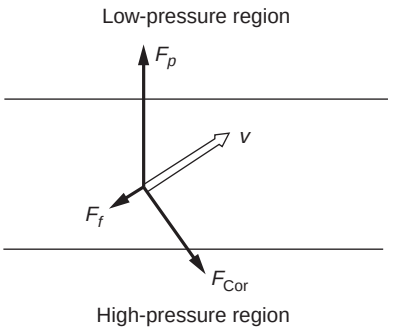

FIGURE 12.15 Frictional force effect on the magnitude and direction of the wind. (*Source:* Wark, K. and Warner, C. F. 1981. *Air Pollution, Its Origin and Control.* Harper & Row, New York. Used by permission.)

The combination of the pressure gradient, Coriolis, centripetal acceleration, and frictional forces is determined in the clockwise and counterclockwise flow around high- and low-pressure systems, respectively. This pattern of flow is shown in Fig. 12.16.

Wind Rose

The wind in a specific location varies with the movement of pressure systems and heating patterns and produces characteristic patterns that can be represented by a statistical diagram called a *wind rose* [Turner, 1979]. A wind rose is a polar diagram that plots the frequency of the observed direction of a wind as a spoke. Additionally, the magnitude of the wind from a particular direction is included in the diagram as the length of the individual segments of the spoke. The observed direction of the wind is the direction from which the wind is blowing. Figure 12.17 is a wind rose generated from AIRS data for 1992 in Chicago, Illinois.

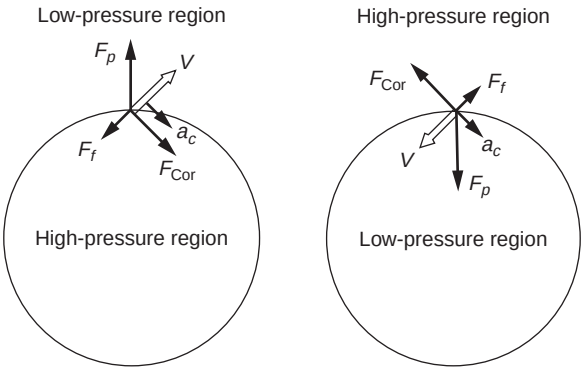

FIGURE 12.16 Force balances around (a) a high-pressure region, and (b) a low-pressure region. (*Source:* Wark, K. and Warner, C. F. 1981. *Air Pollution, Its Origin and Control.* Harper & Row, New York. Used by permission.)

In *Recommended Guide for the Prediction of the Dispersion of Airborne Effluents,* ed. J. R. Martin. The American Society of Mechanical Engineers, New York. Used by permission.)

Vertical Velocity Profile

When all of the factors influencing the magnitude and direction combine, the resulting wind is found to vary in magnitude with elevation above the earth's surface. In the lower reaches of the atmosphere the magnitude of the wind is retarded by the frictional forces, but as elevation increases the frictional forces diminish and the magnitude of the wind increases. This relationship is described as the vertical velocity profile of the wind, and can be approximated numerically by

$$\frac{u}{u_1} = \left(\frac{z}{z_1}\right)^p \tag{12.43}$$

where u is the wind velocity at an elevation of z, u_1 is the wind velocity at an altitude of z_1, and p is a constant based on the stability of the atmosphere. The constant p ranges from 0 to 1. Figures 12.18 and 12.19 demonstrate the effects of the local surface characteristics and atmospheric stability on the vertical velocity profile of the wind.

Stability

As the wind varies with differential heating, elevation, and surface characteristics, the stability of the atmosphere, or its ability to enhance or impede vertical motion, also varies [Turner, 1979]. The turbulence of the lower atmosphere is a function of the vertical temperature gradient, wind speed and direction, and surface characteristics. Stability can be classified into six categories based on general atmospheric conditions. These categories, included in Table 12.15, decrease in dispersional ability as the letter designation increases. Further, actual atmospheric conditions are assigned a stability class by several different methods, with each method varying in degree of complexity. A general description of the atmospheric stability, letter designation, and associated vertical velocity profile constant are given in Table 12.16.

Perhaps the method most often used is based on reference to a given vertical temperature gradient a parcel of air should encounter. The reference gradient is the dry adiabatic lapse rate.

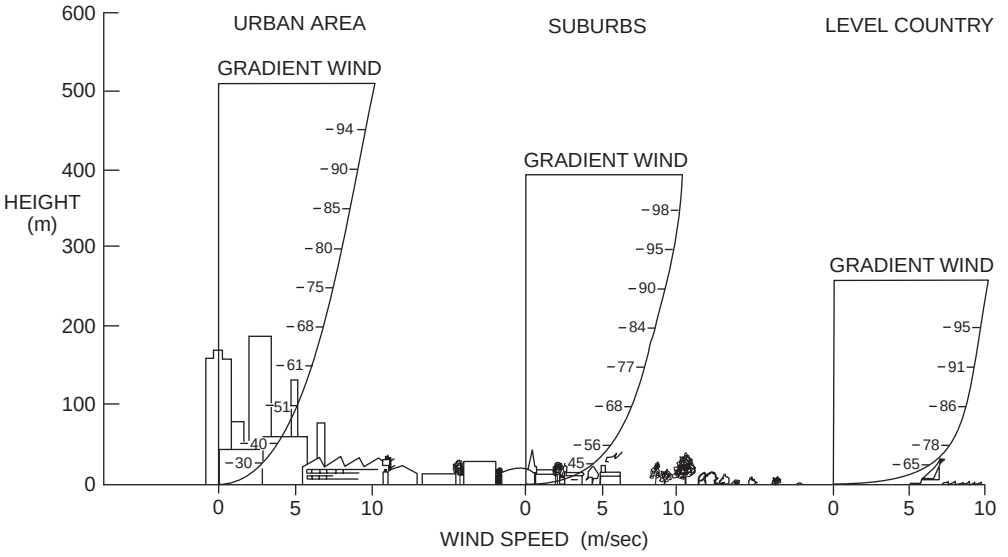

FIGURE 12.19 Vertical velocity profile variations as a function of surface characteristics. (*Source:* Turner, D. B. 1979. Meteorological fundamentals. TABLE 12.15 Key to Stability Categories

Surface Wind at 10 meters (m/s)	Day			Night	
	Incoming Solar Radiation[c]			Thinly Overcast or Low Cloud Cover (≥ 1/2)	Cloud (≤ 3.8)
	Strong[a]	Moderate	Slight[b]		
<2	A	A-B	B		
2-3	A-B	B	C	E	F
3-5	B	B-C	C	D	E
5-6	C	C-D[d]	D	D	D
>6	C	D	D	D	D

[a] Strong incoming solar radiation corresponds to a solar altitude greater than 60° with clear skies.

[b] Slight insolation corresponds to a solar altitude from 15° to 35° with clear skies.

[c] Incoming radiation that would be strong with clear skies can be expected to be reduced to moderate with broken (5/8 to 7/8 cloud cover) middle clouds and to slight with broken low clouds.

[d] The neutral class, D, should be assumed for overcast conditions during both the night and day.

Lapse Rates

The dry adiabatic lapse rate is the theoretical rate of cooling that should predict the temperature of a parcel of air as it rises in the atmosphere. This rate is derived by the situation that when a parcel of air rises in the atmosphere it expands and cools as the surrounding pressure decreases. If the parcel is assumed to expand and cool under adiabatic conditions (that is, assuming there is no heat exchange with its surroundings) the parcel of air should cool at a rate of –5.4°F per 1000 feet (–1°C/100 meters) increase in elevation.

TABLE 12.16 Stability Category Descriptions

Stability Descriptions[a]	Letter Designations[a]	Velocity Profile Constants (*P* Values)
Very unstable	A	0.12
Moderately unstable	B	0.16
Slightly unstable	C	0.20
Neutral	D	0.25
Moderately stable	E	0.30
Very stable	F	0.40

[a]*Source:* Turner, D. B. 1979. Meteorological fundamentals. In *Recommended Guide for the Prediction of the Dispersion of Airborne Effluents,* ed. J. R. Martin, pp. 1–15. The American Society of Mechanical Engineers, New York. Used by permission.

Stability Classes

Actual lapse rates in the atmosphere can be determined readily and correspond to atmospheric conditions at that particular time. There are five general lapse rates found in the atmosphere.

1. *Superadiabatic.* Shown in Fig. 12.20(a), this condition occurs on days when strong solar heating is present, and results in a lapse rate greater than –1°C/100 meters. Superadiabatic conditions are typically found only in the lower 200 meters of the atmosphere and are associated with a stability class of A, or very unstable conditions.
2. *Neutral.* This condition is associated with overcast days and strong to moderate wind speeds. The lapse rate approximates the dry adiabatic lapse rate very closely, as shown in Fig. 12.20(b). Stability classes associated with neutral conditions are B, C, or D indicating moderately unstable to neutral conditions.
3. *Subadiabatic.* This condition is associated with relatively calm days without strong solar heating. The lapse rate is below the –1°C/100 meters rate, as shown in Fig. 12.20(c). Subadiabatic conditions correspond to stability classes of D or E for neutral to moderately stable.
4. *Isothermal.* Shown in Fig. 12.20(d), the temperature in the atmosphere is constant with height, and as a result, there is no lapse rate. Isothermal conditions coincide with a stability class of D.
5. *Inversion.* When the temperature gradient increases with height, often found in the evenings on days with strong solar heating, the condition is referred to as a thermal inversion. This condition demonstrates extremely stable conditions, with a stability class of F, and results in a positive lapse rate. This is shown in Fig. 12.20(e).

Plume Characteristics

For each of the atmospheric stability classes listed above, there is a plume type that is characteristic in both plume shape and downwind concentration. That is, as the gas stream is emitted from the source, the gas stream (or plume) initially rises and then begins to dissipate in the atmosphere.

Atmospheric stability governs the general characteristics of any plume because the maximum height the plume rises to, the degree of dissipation, and the downwind distances where the plume constituents first come into contact with the surface and the distance that the constituents interact with the surface are all functions of the atmospheric conditions when the plume is emitted. Five general types of plumes can be visually identified, each generally corresponding to an atmospheric stability class.

The first type of plume is the *looping plume* associated with great instability in the atmosphere, or a stability class of A. The name of the plume arises from its shape when viewed from a horizontal perspective. A looping plume, shown in Fig. 12.21, is characterized by a tortuous shape that finds the plume rising and falling. This type of plume has a very short downwind initial contact distance with plume constituents resulting in a gradual concentration profile over a long downwind distance. Strong

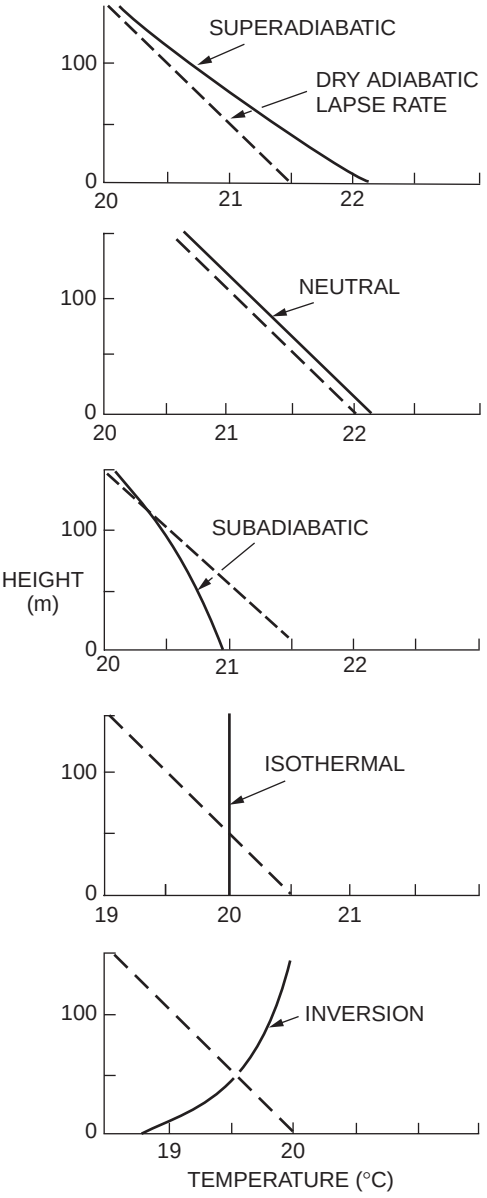

FIGURE 12.20 Atmospheric lapse rates in comparison to the dry, adiabatic lapse rate for (a) superadiabatic, (b) neutral, (c) subadiabatic, (d) isothermal, and (e) inversion conditions. (*Source:* Turner, D. B. 1979. Meteorological fundamentals. In *Recommended Guide for the Prediction of the Dispersion of Airborne Effluents,* ed. J. R. Martin. The American Society of Mechanical Engineers, New York. Used by permission.)

instability in the atmosphere creates this situation as the plume is influenced only by great mixing and no forces preventing surface contact. Additionally, when viewed vertically, the plume meanders a great distance from its original centerline, and thus has the potential for the plume constituents to affect a large surface area.

The second type of plume is the *coning plume,* shown in Fig. 12.22, and corresponds to the near-neutral conditions or atmospheric conditions in classes B, C, or D. Initially, the plume follows the same pattern as the looping plume when viewed vertically. However, when viewed horizontally the plume has

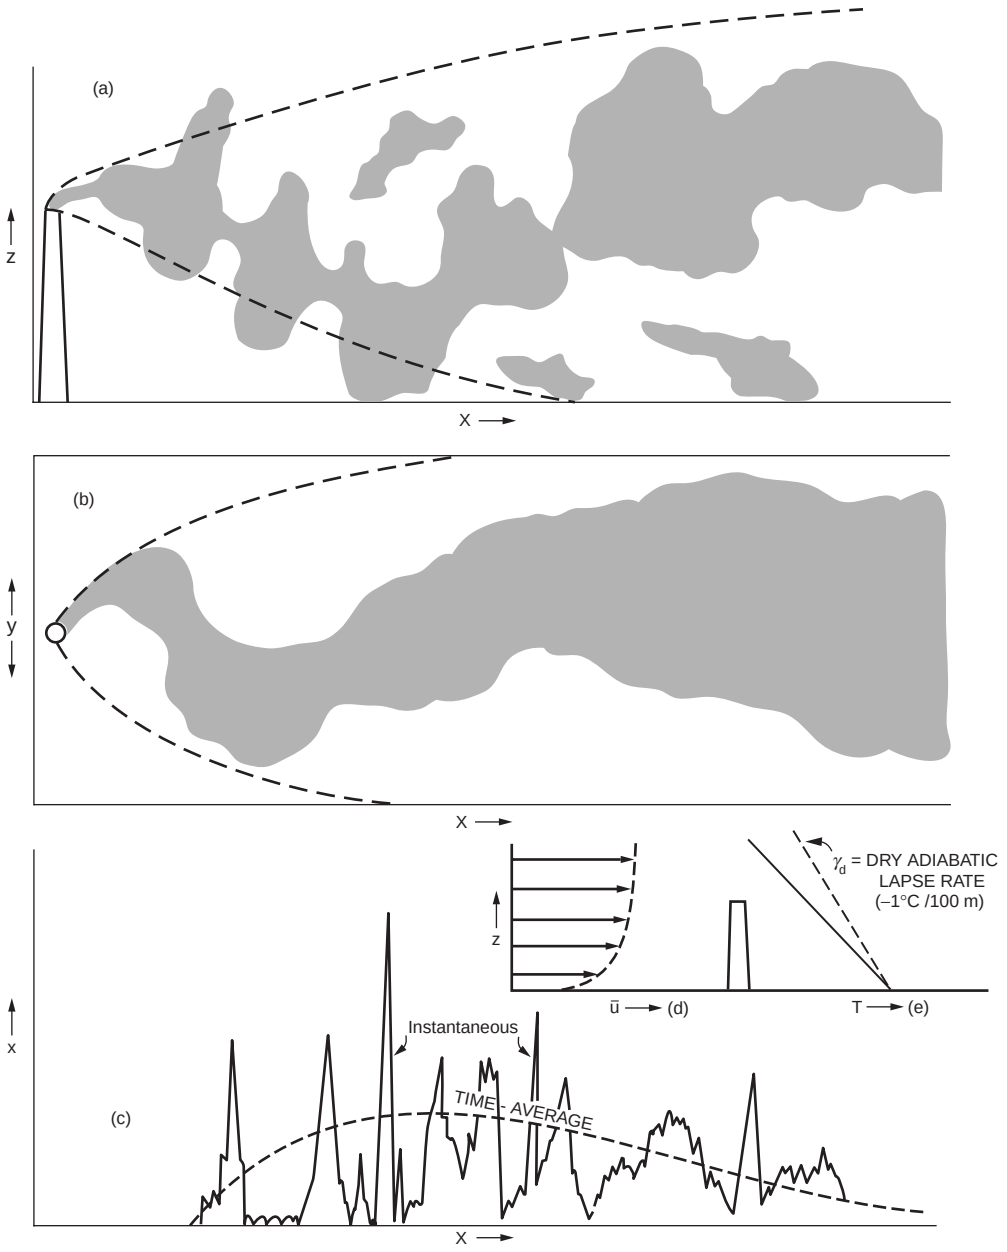

FIGURE 12.21 Looping plume. (*Source:* Pack, D. H. and Halitsky, J. 1979. Behaviour of airborne effluents. In *Recommended Guide for the Prediction of the Dispersion of Airborne Effluents,* ed. J. R. Martin. The American Society of Mechanical Engineers, New York. Used by permission.)

a much more gradual pattern of dissipation. This is due to the decreased mixing ability of the atmosphere. As a result of the decreased mixing, the plume is carried over a much greater distance before its initial surface contact. Downwind distances these constituents are deposited over are less than the looping plume, and result in higher surface concentrations of the constituents.

The third type of plume is the *fanning plume,* the plume type associated with inversion conditions. These conditions, with a stability class of F, result in the plume being held in a vertical plane by the cooler air below the stack and the warmer air above it, as is illustrated in Fig. 12.23. As a result, the downwind

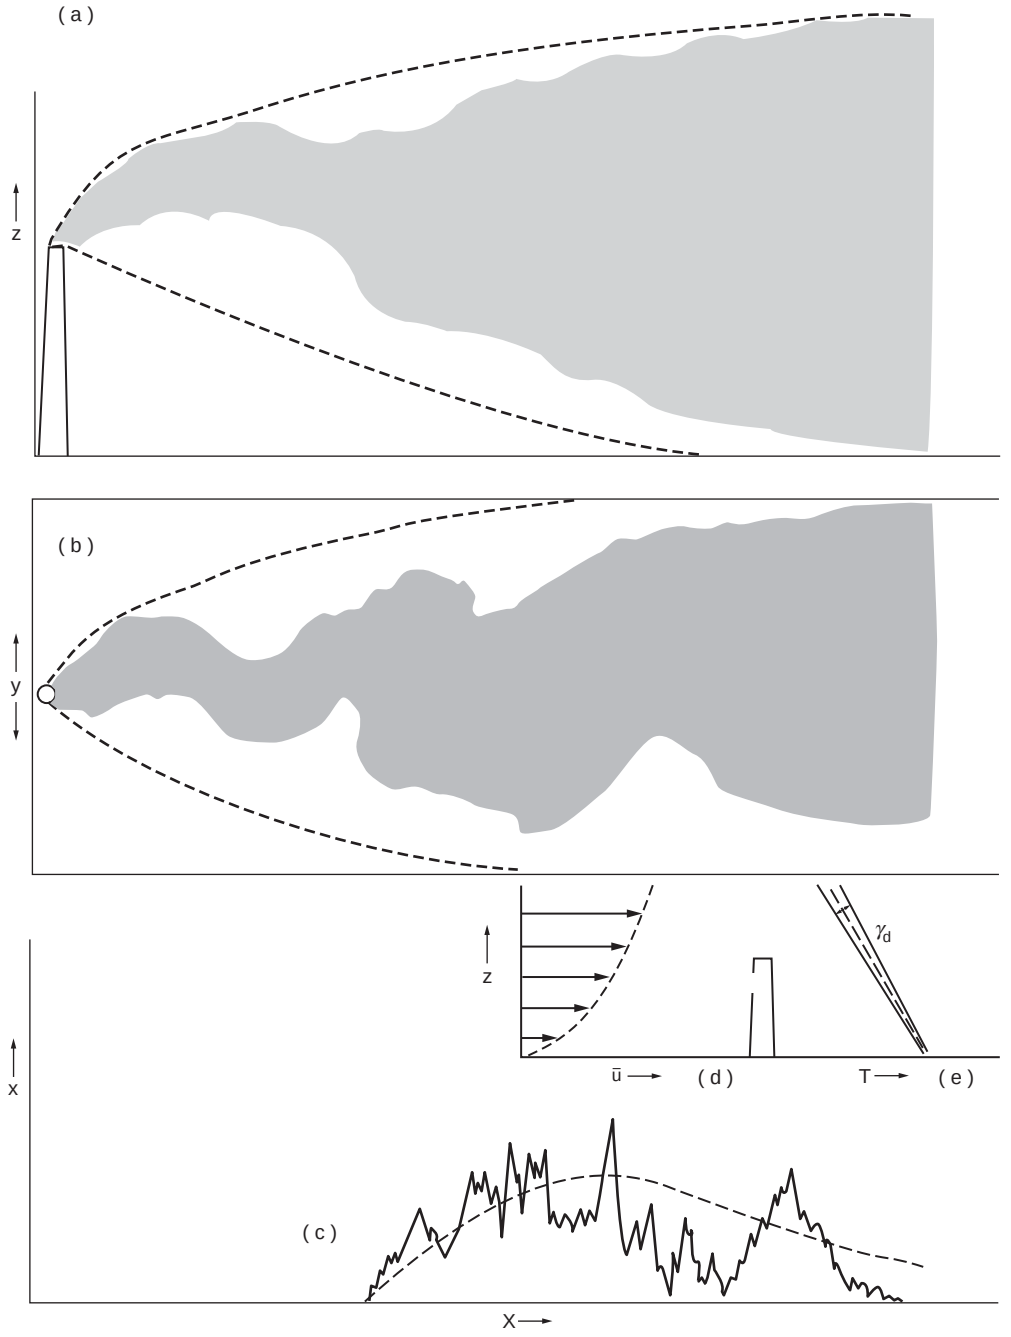

FIGURE 12.22 Coning plume. (*Source:* Pack, D. H. and Halitsky, J. 1979. Behaviour of airborne effluents. In *Recommended Guide for the Prediction of the Dispersion of Airborne Effluents,* ed. J. R. Martin. The American Society of Mechanical Engineers, New York. Used by permission.)

concentrations are virtually nonexistent as the plume constituents have a much greater time to dissipate before contacting the earth's surface.

The *fumigation plume* is the fourth type of plume and is the result of an elevated inversion. The warmer air above the stack holds the plume rise to a maximum elevation at the lower limit of the inversion. This

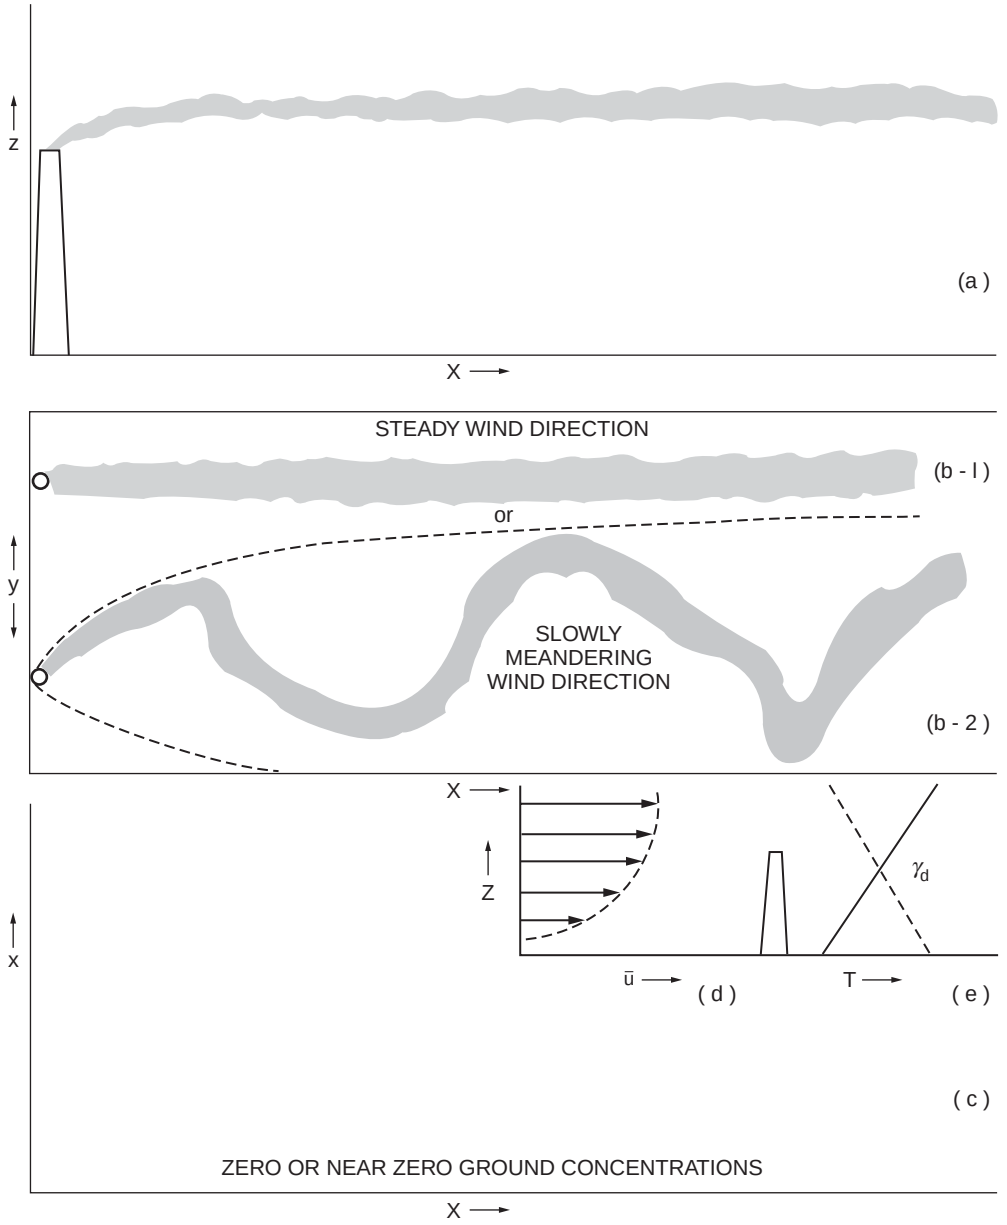

FIGURE 12.23 Fanning plume. (*Source:* Pack, D. H. and Halitsky, J. 1979. Behaviour of airborne effluents. In *Recommended Guide for the Prediction of the Dispersion of Airborne Effluents,* ed. J. R. Martin. The American Society of Mechanical Engineers, New York. Used by permission.)

type of plume, shown in Fig. 12.24, is similar to a coning with the exception that surface concentrations tend to be higher as a result of the limited upper mixing boundary.

The final type of plume is the *lofting plume,* shown in Fig. 12.25. This plume is the result of a surface inversion that restricts the plume's ability to reach the surface. Concentration profiles for this plume are identical to the fanning plume; none of the plume's constituents are detectable until the plume has traveled through the surface inversion.

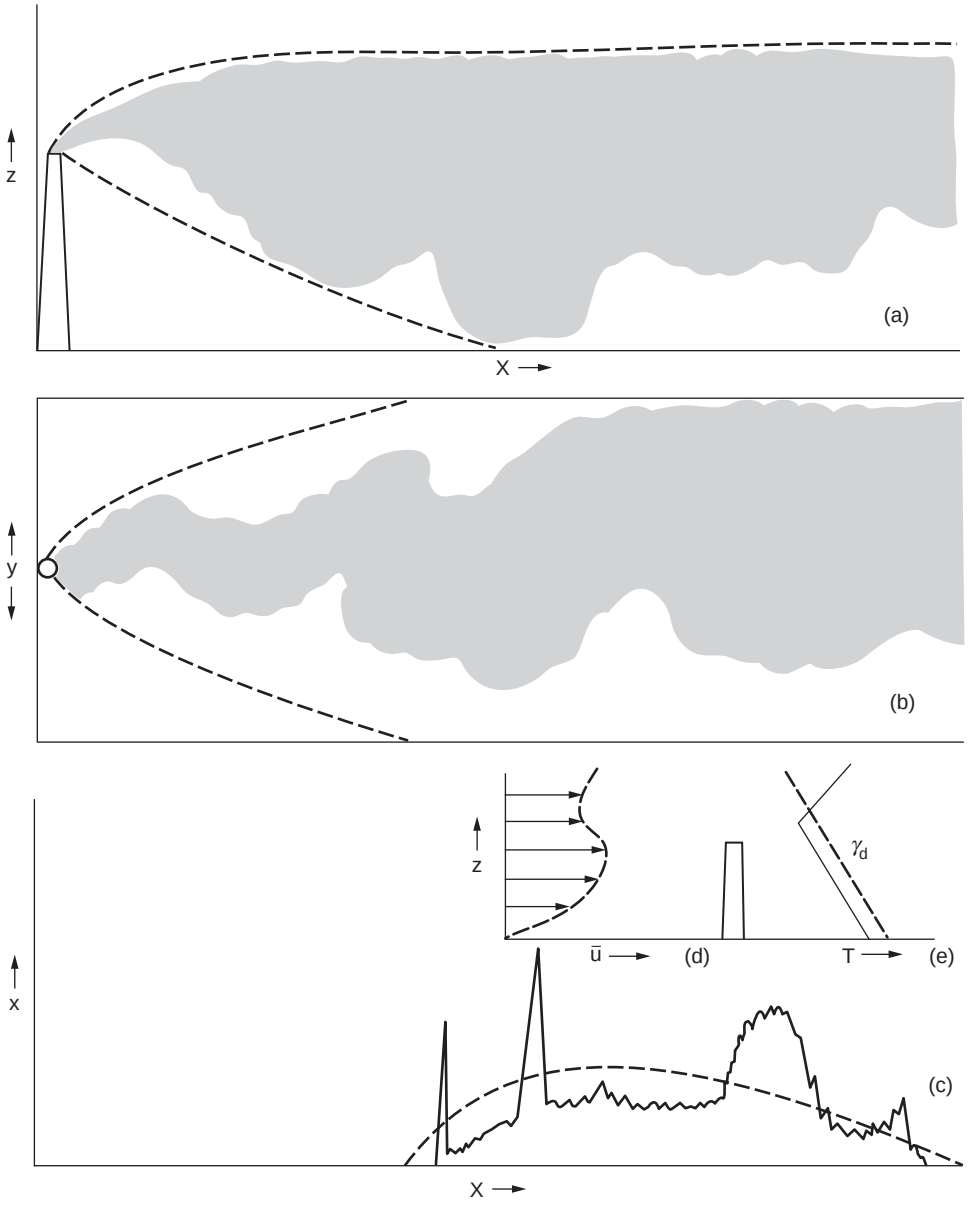

FIGURE 12.24 Fumigation plume. (*Source:* Pack, D. H. and Halitsky, J. 1979. Behaviour of airborne effluents. In *Recommended Guide for the Prediction of the Dispersion of Airborne Effluents,* ed. J. R. Martin. The American Society of Mechanical Engineers, New York. Used by permission.)

12.8 Dispersion Modeling

The estimation of downwind concentrations of pollutants emitted from a source involves approximating the cumulative effect of many atmospheric and emission variables. This modeling effort is done mainly to determine the effects the source presently has, or will have in the future, on its surrounding environ-

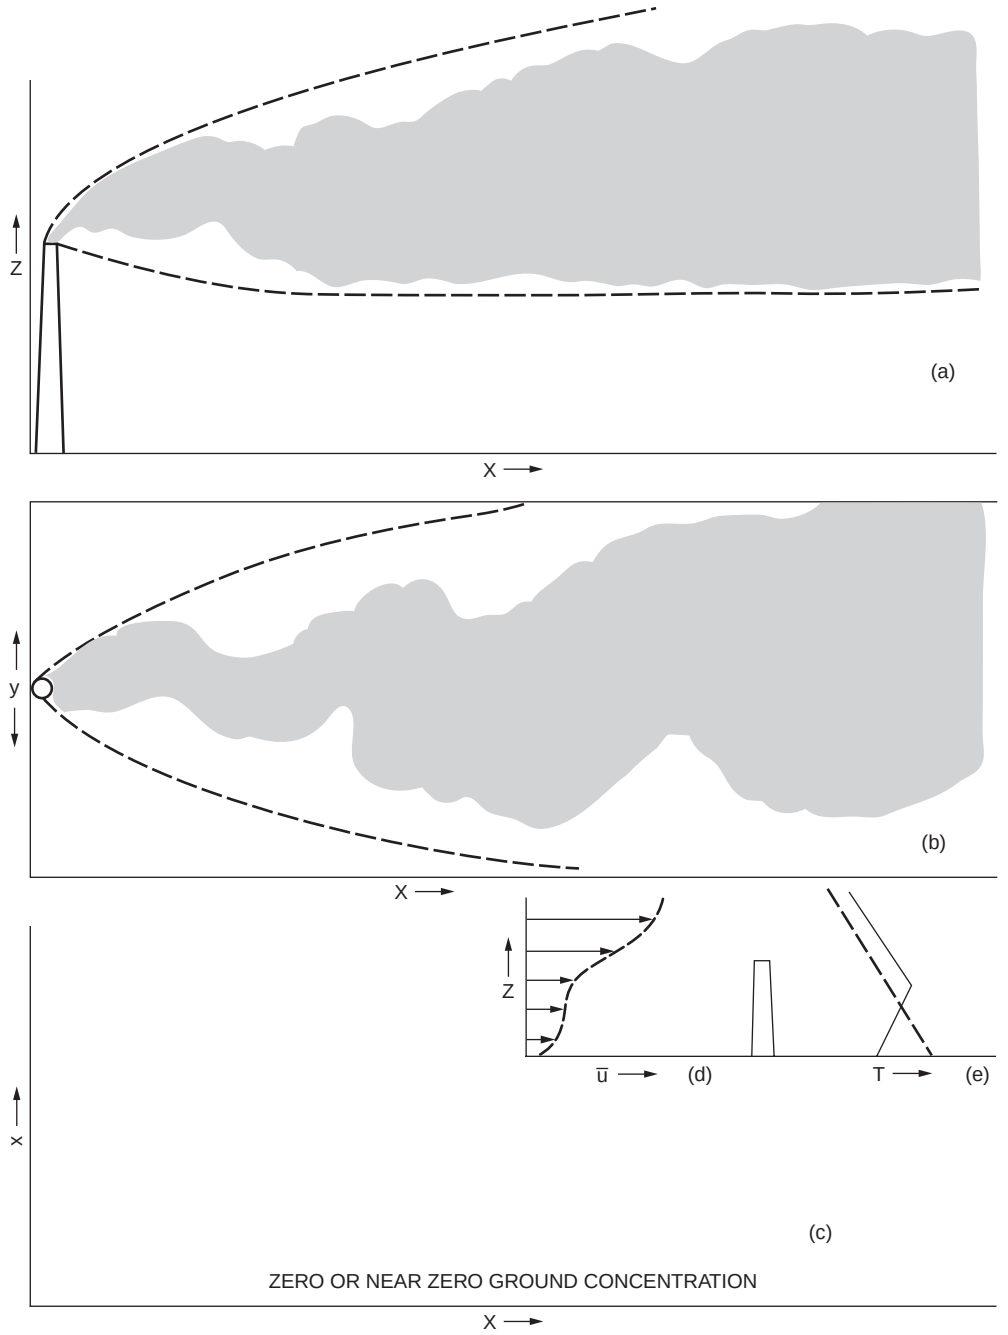

FIGURE 12.25 Lofting plume. (*Source:* Pack, D. H. and Halitsky, J. 1979. Behaviour of airborne effluents. In *Recommended Guide for the Prediction of the Dispersion of Airborne Effluents,* ed. J. R. Martin. The American Society of Mechanical Engineers, New York. Used by permission.)

ment. Types of air pollution models vary from very basic models describing a single source to regional airshed models that describe multitudes of sources over large metropolitan areas.

All of the models employed for air quality analysis are derived from four basic types of models. These are the Gaussian, numerical, statistical or empirical, and physical. Gaussian models are the most widely

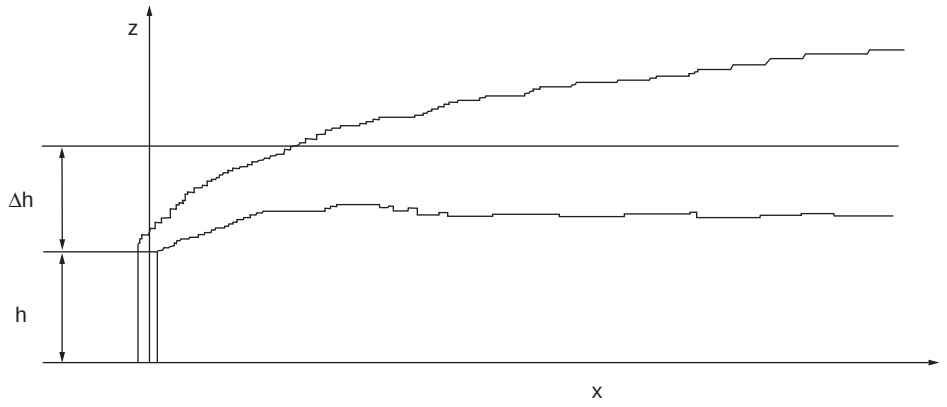

FIGURE 12.26 Plume rise.

used models for the estimation of nonreactive pollutants. Numerical models are favored in the analysis of urban areas with reactive pollutants, but are a great deal more complex. Statistical or empirical models are typically used in situations where data is lacking, and physical models are actual simulations in wind tunnels or other fluid-modeling facilities [U.S. EPA, 1993].

Because of the wide range of models, the description of the fundamentals of each individual model is beyond the scope of this chapter. As a result, this discussion will focus on the basics of the most common, the double Gaussian or normal dispersion model. This model will be described in an effort to cover the basic approaches to modeling a single source in noncomplex terrain for both gaseous and particulate pollutants.

Plume Rise

Coordinate System

The first step in describing the plume rise, or effective stack height, is the development of a system of coordinates to describe the dispersion of the plume in three dimensions. The system employed assumes the origin to be at the base of the source. From the origin the x axis extends in the direction of the mean wind, the y axis extends perpendicular to the x axis, and the z axis extends vertically (along the stack) from the origin, perpendicular to both the x and y axes.

Effective Stack Height

Plume height (H), or effective stack height, is the elevation in the z axis the plum rises to. This is defined by the following equation:

$$H = h + \Delta h \tag{12.44}$$

where the plume height H is the sum of the height of the actual stack h and the additional height Δh the plume rises under the effects of the momentum and buoyancy forces of the gas stream being emitted. Figure 12.26 illustrates the plume rise.

The determination of Δh is done by attributing this variable to the major force affecting it. From this plumes are grouped into two categories: momentum sources and buoyant sources. Momentum sources are small-volume sources having appreciable exit speeds with little temperature excess. These are conditions described by exit speeds of greater than or equal to 10 m/s with temperatures less than 50°C above the ambient temperature. Buoyant sources are larger-volume source with higher temperatures. Typically these sources will have volumetric flow rates greater than 50 m^3/s and temperatures greater than 50°C above ambient temperature [Frizzola et al., 1979]. In describing these situations, only one force is considered in determining the plume rise.

Momentum Sources

Plume rise from a momentum source is described mathematically as a function of the exit conditions and the wind speed at the stack height by the following relationship.

$$\Delta h = D\left(\frac{V_s}{u_s}\right)^{1.4} \tag{12.45}$$

where Δh is the height of the plume above the stack (m)
D is the diameter of the stack (m)
V_s is the emission velocity (m/s)
u_s is the mean wind speed at the stack height (m/s)

Buoyant Plume Sources

Buoyant plume sources, as described previously, can be described mathematically only by inclusion of atmospheric conditions at the time of emission. As plume rise varies accordingly to the atmosphere, three different equations are used to describe this situation. The three equations apply to stable conditions, unstable conditions, and both stable and unstable conditions in the absence of appreciable wind.

Under stable conditions, or stability classes of E or F, the following equations describe the plume rise if there is appreciable wind present.

$$\Delta h = 2.6\left(\frac{F}{u_s S}\right)^{1/3} \quad \text{and} \quad F = g V_s\left(\frac{D}{2}\right)^2\left(\frac{\rho_a - \rho_s}{\rho_a}\right) \tag{12.46}$$

where g is the acceleration due to gravity (9.807 m/s^2)
V_s is the emission velocity (m/s)
D is the diameter of the stack (m)
ρ_a is the density of the ambient air (g/m^3)
ρ_s is the stack gas density (g/m^3)
S is the stability parameter (1/s^2)

The stability parameter is further defined as

$$S = \left(\frac{g}{T}\right)\left(\frac{\partial \Theta}{\partial z}\right) \tag{12.47}$$

where T is the ambient temperature (K) and $\partial\Theta/\partial z$ is the vertical potential temperature gradient. For stability categories E and F, $\partial\Theta/\partial z$ is 0.02 and 0.04 K/m, respectively.

$$\Delta h = \frac{1.6F^{1/3}\left(3.5x\right)^{2/3}}{\overline{u}_s} \tag{12.48}$$

where the downwind distance the plume rises to an elevation of Δh is $3.5x$. x is determined by the following equations.

$$\begin{aligned} x &= 14F^{5/8} \quad \text{when} \quad F \le 55\left(\frac{\text{m}^4}{\text{s}^3}\right) \\ x &= 34F^{2/5} \quad \text{when} \quad f > 55\left(\frac{\text{m}^4}{\text{s}^3}\right) \end{aligned} \tag{12.49}$$

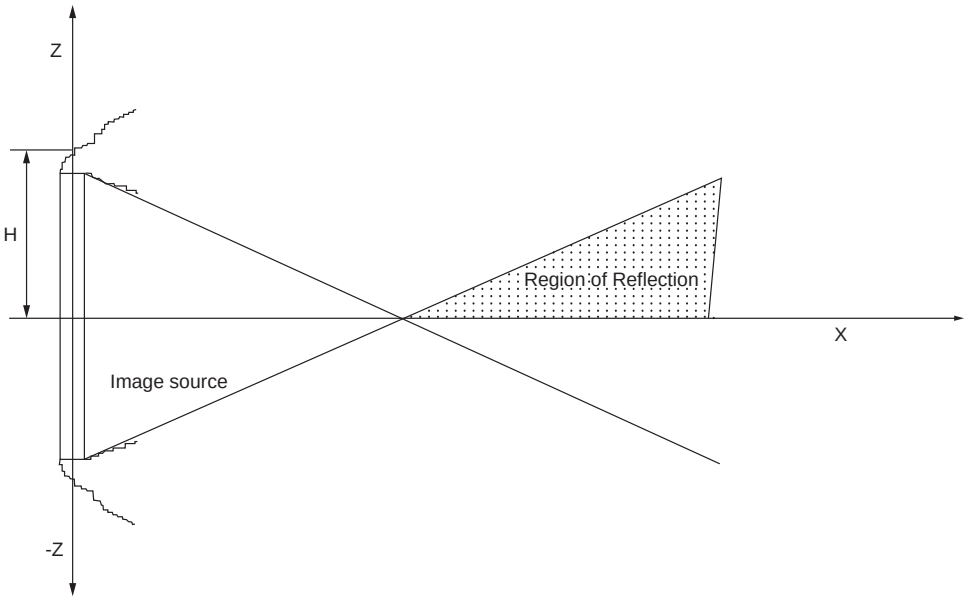

FIGURE 12.27 Region of reflection.

During both stable and unstable conditions, if there is an absence of wind there is an almost vertical rise in the plume. This rise can be described by the following equation.

$$\Delta h = 5.0 \frac{F^{1/4}}{S^{3/8}} \tag{12.50}$$

After the plume type and rise have been determined, the effective stack height should be determined by adding the plume rise to the physical stack height. It should be noted that synonymous units are required in the calculation of effective stack height and that the plume rise equations listed above are all in S.I. units.

Gaseous Dispersion

Currently, worldwide use is being made of the double normal Gaussian mathematical dispersion model for estimating downwind concentrations of pollutants from point, area, and fugitive sources. The Gaussian model is used throughout the U.S. by the Environmental Protection Agency and the respective state and local air pollution control agencies. Its development over the past 25 years has resulted in a rather powerful and cost-effective tool for regulatory planning and implementation purposes.

The model is a combination of empirical and theoretical considerations. It is certainly not a perfect tool but through validations and sometimes calibrations, it is widely accepted. The model uses an exponential decay term (e^{-t}) to account for downwind dilution effects and borrows the Gaussian distribution from statistics to simulate the vertical and crosswind distribution of a pollutant at any point downwind. Furthermore, the model recognizes plume reflection at the earth's surface and provides for a superposition solution or mirror-image stack below the ground plane to account for pollutant reflection at the surface. Figure 12.27 illustrates the plume reflection effect. Elevated sources such as tall stacks are handled by shifting the plume centerline above the surface.

For a surface which absorbs and does not reflect pollutants Eq. (12.51) can be used.

$$C(x, y, z) = \frac{Q}{2\pi u_s \sigma_y \sigma_z} \exp\left[-\frac{1}{2}\left(\frac{y^2}{\sigma_y^2} + \frac{(z-H)^2}{\sigma_z^2}\right)\right] \tag{12.51}$$

TABLE 12.17 σ_y and σ_z Determinations for Open-country Conditions with Downwind Distances between 100 and 10,000 Meters

Stability Class	σ_y (m)	σ_z (m)
A	$0.22x(1 + 0.0001x)^{-1/2}$	$0.20x$
B	$0.16x(1 + 0.0001x)^{-1/2}$	$0.12x$
C	$0.11x(1 + 0.0001x)^{-1/2}$	$0.08x(1 + 0.0001x)^{-1/2}$
D	$0.08x(1 + 0.0001x)^{-1/2}$	$0.06x(1 + 0.0001x)^{-1/2}$
E	$0.06x(1 + 0.0001x)^{-1/2}$	$0.03x(1 + 0.0001x)^{-1}$
F	$0.04x(1 + 0.0001x)^{-1/2}$	$0.016x(1 + 0.0001x)^{-1}$

Source: Smith, M. E., et al. 1979. Calculations of dispersion and deposition. In *Recommended Guide for the Prediction of the Dispersion of Airborne Effluents,* ed. J.R. Martin. The American Society of Mechanical Engineers, New York. Used by permission.

where Q is the mass emission rate of pollutant (g/s)
u_s is the wind speed at stack height at the time of emission (m/s)
σ_y is a stability constant described in Table 12.1 (m)
H is the effective stack height (m)
σ_z is a stability constant described in Table 12.1 (m)

For situations which require the consideration of surface reflection, which occurs for most cases, the double normal Gaussian model of Eq. (12.52) must be used.

$$C(x, y, z) = \frac{Q}{2\pi u_s \sigma_y \sigma_z}\left[\exp\left(-\frac{y^2}{2\sigma_y^2}\right)\right]\left[\exp\left(\frac{-(z-H)^2}{2\sigma_z^2}\right)\right] + \exp\left(\frac{-(z+H)^2}{2\sigma_z^2}\right) \qquad (12.52)$$

The σ_y and σ_z values are borrowed from the Gaussian distribution statistics and are analogized here as pollutant dispersion variables instead of standard deviations as we usually think of them in a statistical sense. σ_y is the pollutant dispersion coefficient in the crosswind direction and σ_z is the dispersion coefficient in the vertical. These dispersion coefficients were originally derived from diffusion experiments on the O'Neill, Nebraska grass flats following World War II. Since then they have been modified significantly with experiments in St. Louis, Missouri and elsewhere giving rise to both an urban and a rural version of the model. The dispersion coefficients can be determined from Table 12.17 for various downwind distances and atmospheric stability classes [Smith et al., 1979].

It is interesting to note that Eq. (12.52) does not contain a σ_x or downwind dispersion coefficient. The reason for this is that this model simulates a continuous point source release as opposed to a "puff" or instantaneous release. The resulting downwind pollutant concentration gradient along a limited segment of the plume centerline is insignificant compared to the crosswind and vertical gradients. Hence, no σ_x or downwind dispersion coefficient is used in the continuous release model.

Note that the exponential term in Eq. (12.52) can never be greater than unity and that all parameters with units must cancel out. The engineering units of concentration are formed from the first term in the equation. The numerator has the units of mass per time and the denominator volume per time, yielding mass per volume or pollutant concentration units. A worst-case scenario for the model would be the situation in which the stack height is zero, as in the case of a burning pile of leaves, and the concentration is desired directly downwind on the ground along the plume centerline. In this situation, note that $y = 0$, $z = 0$, and $H = 0$, resulting in the exponential term going to a unity value (1.0) leaving the final term to be $Q/(\pi u_s \sigma_y \sigma_z)$.

Particulate Dispersion

The double normal Gaussian model just discussed is valid for gases and suspended particulate matter. In addition, the model can be modified to handle settleable particulate matter. This is usually defined as those particles greater than 40 microns in diameter. (A typeset period on this page is about 1000 microns in diameter.) We are interested in having a model consider particulate settling because in some instances surface deposition of a toxic particle from an elevated plume is very important to know. Instead of the model calculating pollutant concentration, we may be more interested in mass of deposition per unit area per unit time.

Examining the dynamics of particles settling out of an elevated plume, we can differentiate the centerline of the gaseous portion of the plume from the centerline of the settleable particulate portion of the plume. Considering only the settleable particulate plume centerline, we note that for each size class of particle there is a distance downwind beyond which no more particles of that size will be found because they have all settled to the ground. In other words, the plume centerline for that particle size has disappeared. We can represent the disappearance of that particle size class with a plume centerline that tilts downward from near the top of the stack and eventually disappears downwind into the surface. This type Gaussian model is referred to as a *tilted plume* model.

The amount of plume tilt is determine from the terminal settling velocities of the various sizes of particles in the plume, the distance downwind where they have settled out, and the mean wind speed. If the terminal settling velocity of the particle is defined as V_t, the downwind distance as x, and the wind speed as u, the ratio $V_t x/u$ can be used to shift the plume centerline downward. Equation (12.53) is the familiar Gaussian model with the plume-shift term incorporated.

$$C(x, y, z) = \frac{Q_p}{2\pi u_s \sigma_y \sigma_z} \exp\left[-\frac{1}{2}\left\{\left(\frac{y}{\sigma_y}\right)^2 + \left(\frac{z - \left[H - \left(V_t x/u_s\right)\right]}{\sigma_z}\right)^2\right\}\right] \tag{12.53}$$

Additionally, the mass deposition rate of particulate in a given area can be determined by multiplying the concentration deposited by the terminal settling velocity. This is given by the following equation.

$$\omega(x, y, z) = \frac{Q_p V_t}{2\pi u_s \sigma_y \sigma_z} \exp\left[-\frac{1}{2}\left\{\left(\frac{y}{\sigma_y}\right)^2 + \left(\frac{z - \left[H - \left(V_t x/u_s\right)\right]}{\sigma_z}\right)^2\right\}\right] \tag{12.54}$$

Regulatory Air Models

From the first basic Gaussian air models, an entire library of models has developed with each new model being employed for new uses or being a refinement of an existing model. As a result of continuous updating and advancement of air models, the use of specific models in regulatory applications changes as new models become available.

In regulatory efforts the use of a specific model is based on the desired result of the modeling. For example, the use of a simple Gaussian model to describe the impact of a major source in complex terrain is beyond the capabilities of the model and is therefore not recommended. However, if only rough estimates are required for a single source on open terrain, the simple Gaussian model would probably suffice. Because of the existence of these types of situations, individual models are recommended for specific applications. Tables 12.18 and 12.19 are a listing of the regulatory air models and their applications currently preferred or recommended as alternatives by the U.S. EPA.

TABLE 12.18 Preferred Air Quality Models

Preferred Models	
Buoyant line and point source dispersion model (BLP)	BLP is a Gaussian plume dispersion model for plume rise and downwash effects from stationary line sources.
CALINE3	CALINE3 is used to estimate the concentrations of nonreactive pollutants emanating from highway traffic.
Climatological dispersion model (CDM 2.0)	CDM is a climatological steady-state Gaussian plume model for seasonal or annual arithmetic average pollutant concentrations in an urban area.
Gaussian-plume multiple source air quality algorithm (RAM)	RAM is a Gaussian plume model for estimating relatively stable pollutants from point and area sources in level terrain.
Industrial source complex model (ISC3)	ISC3 is a Gaussian plume model to describe an industrial source complex in either short- or long-term models with limited terrain adjustment.
Urban airshed model (UAM)	UAM is a three-dimensional urban simulation model for estimating ozone concentrations from short-term conditions.
Offshore and coastal dispersion model (OCD)	OCD is a Gaussian model developed to estimate the effect of offshore sources on coastal regions.
Emissions and dispersion modeling system (EDMS)	EDMS is a combined emissions/dispersion model for assessing pollution at civilian airports and military air bases.
Complex terrain dispersion model plus algorithms for unstable conditions (CTDMPLUS)	CTDMPLUS is a refined point source Gaussian air quality model for use in all stability conditions for complex terrain situations.

TABLE 12.19 Alternative Air Quality Models

Alternative Models	
AVACTA II Model	AVACTA II is a Gaussian model that describes atmospheric dispersion in terms of segment or puff elements. It is particularly suited to simulations of sulfur species but can simulate virtually any pair of primary-secondary pollutants.
Dense Gas Dispersion Model DEGADIS	DEGADIS is used to model the transport of toxic chemical releases in to the atmosphere.
ERT Visibility Model	The ERT visibility model is designed to address visibility impairment for arbitrary lines of sight.
HGSYSTEM	HGSYSTEM is a system of linked models that estimate near and fair-field dispersion from spills of either two-phase, nonreactive multi-compound mixtures or hydrogen fluoride with reactions.
Higher Order Turbulence Model for Atmospheric Circulation/Random Puff Transport and Diffusion HOTMAC/ RAPTAD	HOTMAC/RAPTAD combines an Eulerian mesoscale weather prediction model with a Lagrangian random puff model to forecast transport and diffusion over complex terrain. It is significantly different in its physics and modeling system than most regulatory models presented here.
LONGZ	LONGZ is a steady-state Gaussian plume model for urban and rural areas that estimates annual average concentrations of pollutants from up to 14,000 sources.
Maryland Power Plant Siting Program (PPSP) Model	PPSP is a Gaussian plume model applicable to tall stacks in either rural or urban areas with simple terrain.
Mesoscale Puff Model (MESOPUFF II)	MESOPUFF II is a short-term, regional scale puff model used to estimate concentrations of up to five pollutant species.
Mesoscale Transport Diffusion and Deposition Model for Industrial Sources (MTDDIS)	MTDDIS is a variable trajectory Gaussian puff model for long-range transport of point source emissions over level or rolling terrain.
Multi-Source (SCSTER) Model	SCSTER is a steady state, Gaussian dispersion model for multiple sources in urban or rural terrain. SCSTER is a modified version of the EPA CRSTER model.

TABLE 12.19 (continued) Alternative Air Quality Models

Alternative Models	
PANACHE	PANACHE simulates continuous or short term pollution dispersion via Eulerian or Lagrangian finite volume fluid mechanics code. Complex terrain and source, receptor relationships can be modeled.
Plume Visibility Model (PLUVUE II)	PLUVUE II is used for estimating visual range reduction and atmospheric discoloration from a single emission source.
Point, Area, Line-Source Algorithm (PAL-DS)	PAL-DS is an algorithm for estimating short-term dispersion from line, point, or area sources based on steady state Gaussian plume assumptions.
Reactive Plume Model (RPM-IV)	RPM-IV is used for estimating short-term concentrations of primary and secondary reactive pollutants from point or area sources.
Shoreline Dispersion Model (SDM)	SDM is a multipoint Gaussian model that calculates source impacts from fumigation events.
SHORTZ	SHORTZ uses the steady-state bivariate Gaussian plume model to estimate ground-level concentrations in urban and rural terrain for both simple and complex terrain.
Simple Line-Source Model	The Simple Line-Source Model is used to determine exhaust concentrations within 100 meters of a roadway in relatively flat terrain.
SLAB	SLAB estimates spatial and temporal distributions of short-term ambient concentrations resulting from the release of denser than air gases.
WYNDValley Model	WYNDValley is a multilayer Eularian grid dispersion model that permits flexibility in modeling.

Leo Weitzman
LVW Associates, Inc.

Many types of devices are used for incineration. The most obvious are incinerators, which are furnaces especially designed and built to burn wastes. However, wastes, especially hazardous wastes, are also burned in boilers and industrial furnaces, mainly cement and aggregate kilns. Approximately 50% of the incinerable hazardous wastes produced in the United States in 1993 were burnt in cement kilns. Irrespective of the type of furnace used, as soon as it burns wastes, it becomes subject to all appropriate laws and regulations that govern the handling, storage, and combustion of wastes.

When properly performed, incineration is highly efficient, destroying virtually all organic contaminants, reducing the volume of material to be landfilled, and producing extremely low levels of air emissions. Incineration facilities frequently encounter opposition from neighbors and from political groups, and it can be argued that such opposition represents the greatest barrier to its widespread use. Incineration is also heavily regulated by federal, state, and local statutes and regulations. The regulations govern every facet of the design, construction, testing, and operation of all waste combustion facilities, and a thorough understanding of the legal aspects is essential to successful operation of an incineration facility. The regulatory requirements are briefly discussed below, but because of their complexity and the fact that they are subject to frequent changes, the reader is strongly urged to contact all appropriate regulatory agencies to obtain the latest regulatory standards and requirements before proceeding with any facet of waste management. A convenient development of the last 10 years is the posting of regulations,

guidance documents, test methods, and other information on the World Wide Web. The text includes references to websites containing detailed information. The websites are operated by the various government agencies and are generally kept up-to-date; however, with time, addresses may change.

The following discussion restricts itself to the law currently in the U.S. Virtually every environmental law in effect can apply to an incineration facility. Many facilities are subject to state and local statutes that, in the U.S., are usually similar, and often identical, to the federal laws. Throughout the world, environmental requirements for incinerators set different limits on allowable releases, but the types of contaminants that are regulated are generally similar. As a result, all environmental laws have an inherent similarity that makes an understanding of one set of comprehensive laws applicable to an understanding of any other set. The discussion is to be considered descriptive of the general concepts of the laws.

13.1 Regulations and Regulatory Background

The following four laws in the U.S. are the most important to waste combustion:

1. The Clean Air Act of 1972 and its subsequent amendments and reauthorizations (most recent being 1990) specify ambient concentrations of a variety of air pollutants and limit the emissions of hazardous or toxic air pollutants from all sources, including some nonhazardous waste incinerators.
2. The Toxic Substances Control Act (TSCA) bans the use of polychlorinated biphenyls (PCB) and sets strict regulations for their incineration and disposal by other means. This law only impacts incinerators burning polychlorinated biphenyls, PCBs.
3. The Resource Conservation and Recovery Act (RCRA) of 1976 and its successors, the Hazardous and Solid Waste Amendments (HSWA), are the basis for regulation of all wastes, and specifically, of incineration.
4. The Clean Water Act applies to all effluents to any waterway or wastewater treatment plant.

An incineration facility includes units for receiving, storing, pretreating (if necessary), transferring, and burning of the wastes. It usually also includes laboratory facilities for testing wastes received and samples of discharge streams, and other facilities related to recordkeeping. The laws require that extensive and detailed records be kept. Most of these activities, including incineration of hazardous and medical wastes, are regulated under solid waste (in the U.S. RCRA) laws. The incineration of nonhazardous waste is regulated under the clean air laws as well as under RCRA and, in the U.S., the incineration of PCB wastes is regulated under TSCA. The application of the clean water legislation to incinerators is equivalent to that for any wastewater discharge and is not covered further herein.

Incineration and Clean Air Laws

The first significant environmental regulations for incinerators in the United States were promulgated under the Clean Air Act (CAA) of 1972. The CAA required that states set up regulatory programs to reduce the ambient concentrations of the following five general categories of air pollution, called criteria pollutants:

- Particulate
- Sulfur oxides (SO_2 and SO_3)
- Nonmethane hydrocarbons (HC)
- Nitrogen oxides (NO_x)
- Carbon monoxide (CO)

All sources of air pollution, including incinerators, are required to meet emission standards for particulate. While in theory all sources were also required to meet hydrocarbon and CO standards, the CO limits in many cases were set at levels greater than typically found in most incinerators. Note that more recently, waste combustion laws have set more stringent limits on CO emissions.

The limits on SO_x and NO_x and total hydrocarbons are generally imposed only when the facility is in an area that does not meet the ambient air quality standards specified by the CAA — termed a "nonattainment" area — and when the potential emissions of these contaminants exceeds a specified value. Many large incinerators, boilers, cement kilns, and other industrial furnaces used for hazardous waste destruction can be major sources of contaminants; hence, CAA regulations influence their normal operation. Some of the regulatory restrictions under the CAA and subsequent amendments established that may impact incinerators and BIFs include:

- The Prevention of Significant Deterioration (PSD) requires that any major emission source in an area where the ambient air quality is currently being met must have sufficiently low emissions so that it will not significantly worsen it. The intent was to assure that the facility not degrade the air quality in areas that had better than the minimum specified by the CAA up to the maximum. All new major sources built in nonattainment areas are subject to New Source Reviews (NSR) to assure that they will not contribute to a significant further decrease in ambient air quality.
- National emission standard hazardous air pollutant (NESHAP) regulations regulate the emissions of specific, toxic pollutants.
- State and local governments place restrictions on the emission of specific compounds and substances classified as toxic.
- Restrictions on the emissions of metals, HC1, and toxic organics are made based on risk to health and the environment (as determined by a risk assessment) in addition to the limits specified in regulations.

The Clean Air Act was extensively amended and expanded in its 1990 reauthorization (PL0101–549, 101st Congress, Nov. 15, 1990). These amendments resulted in major changes to the types of contaminants regulated and to the procedures to be followed for their regulation.

Emission standards for municipal waste combustors under the Clean Air Act are published in 40 CFR §60, subpart Ca, 40 CFR §60.30a through §60.39a. These standards place limits on the emissions of particulate and the other criteria pollutants, acid gas (especially hydrogen chloride), chlorodibenzodioxins (CDDs), and chlorodibenzofurans (CDFs). They also specify the procedures for compliance testing, operator training, and reporting and recordkeeping.

Virtually all boilers and industrial furnaces, whether they burn hazardous waste or not, are subject to significant regulation under the Clean Air Act. These regulations still apply even when the units burn wastes or engage in other activities that are subject to RCRA standards. When more than one law applies, the more stringent of the applicable regulations must be obeyed.

Incinerator Regulation Under the Toxic Substances Control Act

The Toxic Substances Control Act (TSCA) governs the incineration of polychlorinated biphenyls (PCBs). PCBs are a class of compounds that was used extensively for many industrial applications, especially as dielectric fluids, and which were banned under TSCA. Such separation of PCB handling from the handling of other wastes is unique to the U.S. The PCB incinerator regulations are codified in 40 CFR §761.70, Annex I, which requires the following:

- For a solids incinerator, PCB emissions are not to exceed 1 mg per kg of PCB fed to the incinerator — this corresponds to a destruction and removal efficiency (DRE) of 99.9999%.
- Particulate emissions must be controlled to a level specified by the EPA Regional Administrator or, for systems to be operated in more than one region, the Director, Exposure Evaluation Division of Office of Pesticides and Toxic Substances (OPTS) of the EPA.
- The HCl must be controlled, and the level of control for each facility must be specified by the EPA Regional Administrator or, for systems to be operated in more than one region, the Director, Exposure Evaluation Division of OPTS.

- The incinerator must satisfy the following combustion conditions 40 CFR §761.70:
  - 1200°C (±100°C) with 3% oxygen and a 2-sec gas residence time in the combustion chamber
  - 1600°C (±100°C) with 2% oxygen and a 1-sec gas residence time in the combustion chamber.
  - A combustion efficiency, CE, greater than 99% as calculated by the following equation:

$$\%CE = 100\% \left[CO_2 / (CO_2 + CO) \right] \tag{13.1}$$

  - where CO_2 is the molar or volume fraction of carbon dioxide in the exit gas from the combustion chamber, and CO is the molar or volume fraction of carbon monoxide in the exit gas from the combustion chamber.
- The incinerator must be tested (trial burn) prior to use, and it must contain sufficient monitors and safety interlocks to automatically shut off the PCB feed if minimum operating conditions are not met.

Incineration is regulated under TSCA for wastes containing more than 500 ppm PCB. Wastes containing more than 500 ppm PCB may only be destroyed in an approved incinerator or equivalent pursuant to 40 CFR §761.60(e). The TSCA Regulations for PCB waste allow the disposal of "mineral oil dielectric fluid" and other liquids contaminated with less than 500 ppm PCB in a "high efficiency boiler" defined as one meeting the following requirements 40 CFR §761.60:

1. The boiler is rated at a minimum of 50 MMBtu/hr (Million Btu/hr).
2. For natural gas and oil-fired boilers, the concentration of CO ≤ 50 ppm and $O_2 \geq 3\%$.
3. For coal-fired boilers, the concentration of CO ≤ 100 ppm and $O_2 \geq 3\%$.
4. The PCB-contaminated fluid does not comprise more than 10% on a volume basis of the fuel feed rate.
5. The boiler must be at operating temperature when the PCB-contaminated material is fed. No waste feed is permitted during startup or shutdown.
6. The owner and operator must comply with monitoring and recordkeeping requirements described in 40 CFR § 760.60(6).

Since, approximately, 1999, the regulation of PCB incinerators has been consolidated under the RCRA hazardous waste combustion program that is discussed in the following section.

Incinerator Regulation Under the Resource Conservation and Recovery Act

The "Resource Conservation and Recovery Act" of 1976 (RCRA) as amended in 1986 under the name "Hazardous and Solid Waste Amendments" (HSWA) requires that the EPA promulgate regulations governing the handling of all wastes. The term RCRA is commonly used to refer to RCRA, HSWA, and subsequent amendments, and it will be similarly used herein.

In the U.S., the RCRA regulations are given in the Code of Federal Regulations, 40 CFR §260 through §280, which set design and performance standards for waste generation, storage, transport, disposal, and treatment. The RCRA regulations set standards for all aspects of waste management, including standards for the following:

- Generators and transporters of hazardous wastes
- Owners and operators of treatment, storage, and disposal facilities
- Waste combustion devices also fall under this heading.

The general requirements for all treatment, storage, and disposal (TSD or TSDF) facilities are described in "Standards for Owners of Hazardous Waste Treatment, Storage, and Disposal Facilities," 40CFR §264, which specify that an owner or operator satisfy requirements such as the following:

- Construct all facilities such as storage tank farms, drum storage areas, waste receiving areas, and landfills in a manner that minimizes the environmental impact of routine operations and upset conditions.
- Develop a contingency plan and emergency procedures to cope with spills, fires, and other accidents.
- Maintain records of waste produced, treated, and disposed, and identify their fate or disposition.
- Develop a closure and postclosure plan, which includes costs, and show that money will be available to implement the plan.
- Meet financial requirements that verify that he has the ability to clean up in case of an accident or close his facility after its useful life is over.
- Manage containers, tanks, surface impoundments, waste piles, and landfills properly.

The general requirements for all treatment, storage, and disposal (TSD or TSDF) facilities are described in "Standards for Owners of Hazardous Waste Treatment, Storage, and Disposal Facilities," 40 CFR §264, which specify that such facilities meet minimum facility-wide standards. All hazardous waste incinerators are subject to the general standards for storage and disposal as well as the specific standards dealing with the incineration process. For more detailed guidance, consult "Permit Applicants' Guidance Manual for the General Facility Standards of 40 CFR §264" SW-968, (EPA, 1983) and "Risk Burn Guidance for Hazardous Waste Combustion Facilities" (EPA, 2001).

The RCRA regulations require owners and operators of all TSD facilities to obtain an operating permit from the appropriate regulatory agency, the EPA Regional Office, or if authority has been so transferred, a state agency. To obtain a permit, the applicant submits the following general information as well as process (e.g., container storage, tank treatment, land disposal, incineration, etc.) information:

- Description of the facility
- Description of the waste
- Security procedures and inspection schedule
- Contingency plan
- Description of preventive maintenance procedures
- Personnel training program
- A closure plan including cost estimates
- Assurance that the operator of the facility is financially able to assume this responsibility

Definition of Solid, Hazardous, and Medical Waste

RCRA classifies a waste as any material that has no value and that is commonly disposed. It further specifically excludes from this definition, any waste material discharged to the air (and regulated under the Clean Air Act) or to a wastewater treatment plant or waterway (and regulated under the Clean Water Act). This is a simplistic definition, but it is reasonably adequate in most circumstances. See 40 CFR §260.10 for the legal definitions of the terms related to waste.

A solid waste can be further classified as a nonhazardous waste, a medical waste, or a hazardous waste. The classification governs the regulations for the waste's incineration and, hence, defines the types and operating conditions for the combustors that may be used. A nonhazardous waste is any solid waste that does not meet the requirements for a medical waste or a hazardous waste. Certain wastes, such as household and commercial refuse, are classified to be nonhazardous by law. Similarly, certain high volume industrial wastes, such as mine tailings and ash from combustion of coal, are classified by law as nonhazardous. Medical wastes are characterized by their potential to contain some form of pathogen. Wastes from a hospital are an example. As can be seen, the classifications are generally made on the basis of exclusions, that is, (1) a waste material is a solid waste if it is not an air pollutant or a wastewater, and (2) a solid waste is a nonhazardous waste if it does not meet the definition of a hazardous or medical

waste. The definition of a hazardous waste thus becomes critical to that of the other types of wastes. A waste is classified as hazardous under RCRA if:

1. It exhibits any of the following characteristics:
   (a) *Ignitability:* It is ignitable, detonates readily, or it is an oxidizing agent, which causes other materials to ignite or burn as defined in 40 CFR §261.21 (Waste Category D001).
   (b) *Corrosivity:* It has a pH of less than 2 or more than 12.5 or is corrosive to steel as defined in 40 CFR §261,22 (Waste Category D002).
   (c) *Reactivity:* It is unstable and readily undergoes change without detonating; it will react with air or water or will spontaneously react under shock or friction as described in 40 CFR §261.23 (Waste Category D003).
   (d) *Toxicity:* It is toxic, it leaches specific contaminants at an excessive rate as shown (formerly by the EP Toxicity 40 CFR §261.24, and Appendix II and now) by the TCLP (40 CFR §261.24 and Appendix II), which has superseded the EP Toxicity test.
2. It is specifically listed in 40 CFR §261.11 Subpart C as a hazardous waste because of any of the following:
   (a) It exhibits any of the hazardous waste characteristics described above.
   (b) It has been found to be fatal to humans in low doses or, in the absence of data on human toxicity, it has been shown to be toxic to animals at specified low doses [40CFR §261.11 (a)2].
   (c) It contains a toxic constituent listed in Appendix VIII to Part 261 (Appendix VIII is a list of compounds and classes of compounds, i.e., lead and compounds not otherwise specified, which have been determined by the EPA Administrator to be toxic, unless the Administrator determines that the waste does not pose a present or potential hazard.) (40 CFR §261.111).

Wastes that are classified as hazardous solely because they are ignitable, reactive, or corrosive (but not toxic) and contain no Appendix VIII constituents are exempt from those hazardous waste incinerator regulations that relate to performance; however, they are still subject to waste analysis and closure requirements of the regulations and must have a permit [40 CFR §264.340(b)].

Regulation of Incinerators

Incinerators burning refuse and other nonhazardous wastes are regulated under RCRA and the Clean Air Act. The two sets of regulations were consolidated under RCRA as codified in 40 CFR §240 and for medical wastes in §259. The regulation of both solid wastes, but especially of medical wastes, requires a substantial amount of recordkeeping to track the wastes' ultimate disposal or destruction.

Emission limits on nonhazardous waste incinerators are set on particulate, hydrogen chloride gas, sulfur dioxide, volatile metals, semivolatile metals, nonvolatile metals, chlorodibenzodioxins, and chlorodibenzofurans. The federal limits on emissions for nonhazardous waste incinerators are now substantially equivalent to those for hazardous waste incinerators and are presented in the discussion of the regulation of hazardous waste incinerators.

Physically, medical wastes are similar to general refuse, but they may be contaminated with pathogens. They often also contain large quantities of polyvinyl chloride (PVC) and other chlorinated materials, which form hydrogen chloride (HCl) on combustion. All of the pertinent environmental laws place limits on the amount of HCl that may be emitted.

A major concern when operating an incinerator for medical wastes is maintenance of a sufficiently high temperature for a sufficiently high solids and gas residence time to assure that the waste is sterilized. Chlorodibenzo-dioxin and -dibenzofuran emissions are regulated to the lesser of the following two limits: 30 ng/m^3 or the amount determined to be safe on the basis of a site-specific risk assessment.

Hazardous wastes compromise the third set of wastes that are commonly incinerated. The treatment, storage, and disposal of hazardous wastes are regulated under Volume 40, Part 264, Subtitle C of the Resource Conservation and Recovery Act (RCRA). RCRA was passed by Congress in 1976 and amended by the Hazardous and Solid Waste Amendments (HSWA) in 1984. Regulations that are new or have not

been finalized can be found in the *Federal Register*, a document that is published daily and contains notification of government agency actions. Daily updates of the *Federal Register* can be obtained through the Government Printing Office and on-line at *http://www.access.gpo.gov/nara/cfr/index.html.*

RCRA allows states the option of developing and administering waste programs in lieu of the federal program the U.S. EPA administers. However, the U.S. EPA must approve a state's program before it can take the place of the U.S. EPA's program. To gain approval, a state program must be consistent with and equivalent to the federal RCRA program, and at least as stringent. In addition, state programs may be more stringent or extensive than the federal program. For example, a state may adopt a broader definition of hazardous waste in its regulations, designating as hazardous a waste that is not hazardous under the federal regulations. Virtually all states now have primary responsibility for administering extensive portions of the waste combustion regulations.

The U.S. EPA developed performance standards for the combustion of wastes based on research on combustion air emissions and risk assessment for the inhalation pathway only. Risk from indirect pathways is not addressed by the current federal standards. In addition to performance standards, owners or operators of hazardous waste combustion units are subject to general standards that apply to all facilities that treat, store, or dispose of waste. General standards cover such aspects of facility operations as personnel training, inspection of equipment, and contingency planning.

Facilities that burn wastes must apply for and receive a RCRA permit. This permit, issued only after a detailed analysis of the data provided in the RCRA Part B permit application, specifies conditions for operations to ensure that hazardous waste combustion is carried out in a safe manner and is protective of the health of people living or working nearby and to the surrounding environment. Permits can be issued by the U.S. EPA or by states with approved RCRA/HSWA programs. The procedures followed for issuing or denying a permit, including provisions for public comment and participation, are similar, whether the U.S. EPA or a state agency is responsible.

The permitting process for an incinerator is lengthy and requires the participation of affected individuals such as neighbors, local governments, surrounding industries, hospitals, and others collectively referred to as "stakeholders." The EPA published guidance on public participation that is available on the website, *http://www.epa.gov/epaoswer/hazwaste/permit/pubpart.htm.*

This, and all other guidance, recommend that the public be informed of the plans for an incinerator early in the planning process and that the stakeholders be apprised of developments on a regular basis.

Once a permit is issued, the owner or operator of the combustion unit is legally bound to operate according to the conditions specified within it. When owners or operators fail to meet permit requirements, they are subject to a broad range of civil and criminal actions, including suspension or revocation of the permit, fines, or imprisonment. One measure of combustion unit performance is destruction and removal efficiency (DRE). Destruction refers to the combustion of the waste, while removal refers to the amount of pollutants cleansed from the combustion gases before they are released from the stack. For example, a 99.99% DRE (commonly called "four nines DRE") means that 10 mg of the specified organic compound is released to the air for every kilogram of that compound entering the combustion unit; a DRE of 99.9999% ("six nines DRE") reduces this amount to one gram released for every kilogram. It is technically infeasible to monitor DRE results for all organic compounds contained in the waste feed. Therefore, selected indicator hazardous compounds, called the principal organic hazardous constituents (POHCs), are designated by the permitting authority to demonstrate DRE.

POHCs are selected based on their high concentration in the waste feed and whether they are more difficult to burn as compared to other organic compounds in the waste feed. If the combustion unit achieves the required DRE for selected POHC, the combustion unit should achieve the same or better DRE for organic compounds that are easier to combust. This issue is discussed in greater detail later in this chapter in the section on performance testing.

RCRA performance standards for hazardous waste combustors require a minimum DRE of 99.99% for hazardous organic compounds designated in the permit as the POHCs; a minimum DRE of 99.9999% for dioxins and furans; for incinerators: removal of 99% of hydrogen chloride gas from the RCRA combustion emissions, unless the quantity of hydrogen chloride emitted is less than 4 pounds per hour

or for boilers and industrial furnaces (BIF): hydrogen chloride/chlorine gas emissions within acceptable risk-based emission limits (known as Tiers I, II, III, or adjusted Tier I); metals emission limits within risk-based limits; products of incomplete combustion (PIC) emissions within risk-based limits; and a limit of 180 mg of particulate matter per dry standard cubic meter (mg/dscm) (0.0015 gr/scf) of gas emitted through the stack.

The metal emission limits are set for three categories of metals: volatile, semivolatile, and nonvolatile metals. The categories are based on whether the particular metal is likely to be a vapor, solid, or both in the incinerator stack. Mercury is the only volatile metal that is regulated. The semivolatile metals, like antimony and lead, partially volatilize in the stack. They can be emitted as a metal vapor and as a particulate. The nonvolatile metals, such as chromium, do not volatilize to a measurable extent in the stack. They are released to the environment as particulates.

These standards were set based on the levels of performance that have been measured for properly operated, well-designed combustion units. Although for most wastes the 99.99 DRE is considered to be protective of human health and the environment, a more stringent standard of 99.9999 DRE was set for wastes containing dioxins or furans because of the U.S. EPA's and the public's concern about these particularly toxic chemicals.

Permits are developed by determining the likely operating conditions for a facility, while meeting all applicable standards and other conditions the permitting authority may feel are necessary to protect human health and the environment. These operating conditions are specified in the permit as the only conditions under which the facility can legally operate. The permit also specifies the maximum rate at which different types of wastes may be combusted, combustion unit operating parameters, control device parameters, maintenance and inspection procedures, training requirements, and other factors that affect the operation of the combustion unit. The permit similarly sets conditions for all other hazardous waste storage, treatment, or disposal units to be operated at the facility.

Recognizing that it would take the U.S. EPA and authorized states many years to process all permit applications, Congress allowed hazardous waste facilities to operate without a permit under what is referred to as interim status. Owners and operators of interim status combustion units must demonstrate that the unit meets all applicable performance standards and emission limits by submitting data collected during a trial burn.

Once the trial burn is completed, the data are submitted to the permitting agency and reviewed as part of the trial burn report. It is within the permitting agency's discretion to reject the trial burn data if they are insufficient or inadequate to evaluate the unit's performance. Once the data are considered acceptable, permit conditions are developed based on the results of the successful trial burn.

Since, approximately 1996, the U.S. EPA has been developing a different permitting approach for new combustion units. As of early 2001, this approach is substantially in place. Under this new approach, a RCRA permit must be obtained before construction of a new hazardous waste combustion unit begins. The RCRA permit for a new combustion unit covers four phases of operation: (1) a "shake- down period," when the newly constructed combustion unit is brought to normal operating conditions in preparation for the trial burn; (2) the trial burn period, when burns are conducted so that performance can be tested over a range of conditions; (3) the period after the trial burn (this period may last several months), when data from the trial burn are evaluated, and the facility may operate under conditions specified by the permitting agency; and (4) the final operating period, which continues throughout the life of the permit.

The permitting agency specifies operating conditions for all four phases based on a technical evaluation of combustion unit design, the information contained in the permit application and trial burn plan, and results for trial burns for other combustion units. These operating conditions are set so that the combustion units theoretically will meet all performance standards at all times. Results from the trial burn are used to verify the adequacy of these conditions. If trial burn results fail to verify that performance standards can be met under some operating conditions, the permit will be modified for the final operating phase so that the combustion unit cannot operate under these conditions.

The process for review of a permit application may vary somewhat depending on the permitting agency. The basic process, however, consists of five steps:

1. Upon receipt of the application, the U.S. EPA or the authorized state agency issues a notice to everyone on the facility's mailing list that the application has been submitted. The agency then reviews the application for completeness. If information is missing, the reviewer issues a Notice of Deficiency to request additional information from the applicant.
2. The permitting agency evaluates the technical aspects of the application and any other information submitted by the applicant (for example, performance data from an interim status combustion unit or a trial burn plan for a new unit).
3. The permitting agency prepares either a draft permit if it judges that the facility operations will meet the regulatory standards and will not result in unacceptable risk, or issues a notice of intent to deny the application. In either case, a notice is sent to the applicant and is published in a local newspaper. Issuance of a draft permit does not constitute final approval of the permit application. The draft permit, however, consists of all the same elements as a final permit, including technical requirements, general operating conditions, and special conditions developed specifically for the individual facility, including the duration of the permit.
4. The permitting agency solicits comments from the public during a formal public comment period. If requested to do so, the permitting agency will provide notice of and hold a public hearing during the public comment period.
5. After considering the technical merits of the comments, the permitting agency makes a final decision on the application, and the permit is either issued or denied. If a permit is issued, the permit conditions are based on a careful examination of the complete administrative record, including all information and data submitted by the applicant and any information received from the public.

The permit, as issued, may differ from the draft permit. It may correct mistakes (for example, typographical errors) or it may contain substantive changes based on technical or other pertinent information received during the public comment period. For new combustion units, the final permit is revised to reflect trial burn results. If the permitting agency intends to make substantive changes in the permit as a result of comments received during the public comment period, an additional public comment period may be held before the permit is issued.

EPA has published numerous guidance documents describing specific procedures to be followed in various aspects of incinerator permitting and operation. The reader is specifically referred to the *Engineering Handbook for Hazardous Waste Incineration* (Bonner, 1981) for discussion of incineration equipment and ancillary systems. This book was updated and published in 1994 under the title *Engineering Handbook for Combustion of Hazardous Waste*. The "Guidance Manual for Hazardous Waste Incinerator Permits (EPA, 1983) and "Handbook, Guidance on Setting Permit Conditions and Reporting Trial Burn Results" (EPA, 1989b) along with the "Implementation Document for the BIF Regulations" (EPA, 1992) provide necessary information for permitting a hazardous waste combustor and operating it in compliance with applicable regulations, "Human Health Risk Assessment Protocol for Hazardous Waste Combustion Units," (EPA, 1998b), *Risk Assessment, Risk Burn Guidance for Hazardous Waste Combustion Facilities* (EPA, 2001), and *Screening Level Ecological Risk Assessment Protocol for Hazardous Waste Combustion Facilities* (EPA, 1999). EPA's regulations and guidance are constantly updated and changed. It is, therefore, strongly recommended that the latest version be obtained from the appropriate regulatory agency. The key guidance documents are available from the EPA's website *http://www.epa.gov/epaoswer/hazwaste/combust.htm*.

Oxygen Correction Factors

RCRA (and some other) regulations require reporting of CO, chlorodibenzodioxin, chlorodibenzofuran, mercurcy, nonvolatile metals, semivolatile metals, and particulate concentrations in the flue gas corrected to 7% oxygen. The equation used to calculate this correction factor is as follows (*Federal Register*/Vol. 55, No. 82/Friday, April 27, 1990, P. 17918):

$$CO_c = CO_m \times 14/(E - Y)$$

Where CO_c is the corrected CO concentration, CO_m is the measured CO concentration, E is the enrichment factor, percentage of oxygen used in the combustion air (21% for no enrichment), and Y is the measured oxygen concentration in the stack by Orsat analysis, oxygen monitor readout, or equivalent method.

Regulatory Requirements for Risk Assessments

In 1993, through a series of memos and policy statements, the U.S. Environmental Protection Agency expanded the review of incinerators to include estimation of risk through a site-specific risk assessment. The details of this estimating procedure are beyond the scope of this manual. Briefly, however, this policy requires that the EPA perform a risk assessment on all waste combustion facilities to determine whether the statutory emission limits are adequate for protecting health and the environment. If the risk assessment indicates that they are not, it requires that the emission limits for the facility be set at a lower value. The risk assessment methodology to be followed by EPA is described in, "Human Health Risk Assessment Protocol for Hazardous Waste Combustion Facilities" (EPA, 1998b), and "Screening Level Ecological Risk Assessment Protocol for Hazardous Waste Combustion Facilities" (EPA, 1999). The latest version of the risk assessment procedure can be obtained from the following EPA website: *http://www.epa.gov/epaoswer/hazwaste/combust.htm*.

13.2 Principles of Combustion and Incineration Thermodynamics

The physical and chemical processes of combustion are the same whether the materials are burned in an open fire, an engine, or a refractory-lined chamber like a boiler or incinerator. Combustion requires the presence of organic matter, oxygen (usually air), and an ignition source. The term "fuel" in the context of combustion is used to designate any organic material that releases heat in the combustion chamber, regardless of whether it is a virgin fuel such as natural gas or fuel oil or a waste material. When organic matter containing the combustible elements carbon, sulfur, and hydrogen, is raised to a high enough temperature (order of 300 to 400°C, 600 to 800°F), the chemical bonds are excited and the compounds break down. If there is insufficient oxygen present for the complete oxidation of the compounds, the process is termed pyrolysis. If sufficient oxygen is present, the process is termed combustion.

Pyrolysis is a necessary first step in the combustion of most solids and many liquids. The rate of pyrolysis is controlled by three mechanisms. The first mechanism is the rate of heat transfer into the fuel particle. Clearly, therefore, the smaller the particle or the higher the temperature, the greater the rate of heating and the faster the pyrolytic process. The second mechanism is the rate of the pyrolytic process. The third mechanism is the diffusion of the combustion gases away from the pyrolyzing particles. Clearly, the last mechanism is likely to be a problem only in combustion systems that pack the waste material into a tight bed and provide very little gas flow.

At temperatures below approximately 500°C (900°F), the pyrolysis reactions appear to be rate controlling for solid particles less than 1 cm in diameter. Above this temperature, heat and mass transfer appear to limit the rate of the pyrolysis reaction. For larger pieces of solid under most incinerator conditions, heat and mass transfer are probably the rate-limiting step in the pyrolysis process (Niessen, 1978). Because pyrolysis is the first step in the combustion of most solids and many liquids, heat and mass transfer is also the rate-limiting step for many combustion processes.

Pyrolysis produces a large number of complex organic molecules that form by two mechanisms, cracking and recombination. In cracking, the constituent molecules of the fuel break down into smaller portions. In recombination, the original molecules or cracked portions of the molecule recombine to form larger, often new, organic compounds such as benzene. Pyrolysis is also termed destructive distillation. The products of pyrolysis are commonly referred to as Products of Incomplete Combustion, PICs. PICs include a large number of different organic molecules.

Pyrolysis is only the first step in combustion. To complete combustion, a properly designed incinerator, boiler, or industrial furnace mixes the pyrolysis off-gases with oxygen, and the mixture is then exposed

to high temperatures. The resulting chemical reactions, those of combustion, destroy the organic materials. Combustion is a spontaneous chemical reaction that takes place between any type of organic compound (and many inorganic materials) and oxygen. Combustion liberates energy in the form of heat and light. The combustion process is so violent and releases so much energy that the exact organic compounds involved become relatively unimportant. The vast majority of the carbon, hydrogen, oxygen, sulfur, and nitrogen will behave, in many ways, like a mixture of the elements. This is a very important concept because, for all but the most detailed calculations, the combustion process can be evaluated on an elemental basis.

The process of combustion can be viewed as taking place in three primary zones: (1) Volatilization or pyrolysis zone — referred to here as the pre-flame zone, (2) the flame zone, and (3) the postflame or burnout zone. In the first zone, the organic material in the gaseous, liquid, or solid fuel, is vaporized and mixes with air or another source of oxygen. Those organic compounds that do not vaporize typically pyrolyze, forming a combustible mixture of organic gases. Volatilization is endothermic (heat absorbing), while pyrolysis is, at best, only slightly exothermic. As a result, this step in the combustion process requires a heat source to get the process started.

The source of the initial heat, called the "ignition source," the match or pilot flame for example, provides the energy to start the combustion reaction. Once started, the reaction will be self-sustaining as long as fuel and oxygen are replenished at a sufficiently high rate to maintain the temperature above that needed to ignite the next quantity of fuel. If this condition is met, the ignition source can be removed. The energy released from the initial reaction will activate new reactions, and the combustion process will continue. A material that can sustain combustion without the use of an external source of ignition is defined to be autogenous.

In order to speed the phase change to the vapor, a liquid is usually atomized by a nozzle that turns it into fine droplets. The high surface-to-volume ratio of the droplets increases the rate at which the liquid absorbs heat, increases its rate at which it vaporizes or decomposes, and produces a flammable gas which then mixes with oxygen in the combustion chamber and burn. Atomization, while usually desirable, is not always necessary. In certain combustion situations, the gas temperatures may be high enough or the gas velocities in the combustion chamber large enough to allow the fuel or waste to become a gas without being atomized.

The phase change is speeded for solids by agitating them to expose fresh surface to the heat source and improve volatilization and pyrolysis of the organic matter. Agitation of solids also increases the rate heat and oxygen transfer into the bed and of combustion gases out of the bed. In practice this is done in many different ways, such as:

- Tumbling the solids in a kiln
- Raking the solids over a hearth
- Agitating it with a hot solid material that has a high heat capacity as in a fluidized bed
- Burning the solids in suspension
- Burning the solids in a fluidized bed
- If the combustion is rapid enough, it can draw some of the air that feeds the flame through a grate holding the solids.

It is important that the amount of fuel charged to the burning bed not exceed the heating capacity of the heat source. If this occurs, the burning mass will require more heat to vaporize or pyrolize than the heat source (the flame zone) can supply, and the combustion reactions will not continue properly. In most cases, such overloading will also result in poor distribution of air to the burning bed and improper flow of combustion gases away from the flame. The combined result will be that the flame will be smothered.

Consider one of the simplest forms of combustion, that of a droplet of liquid or a particle of solid (the fuel) suspended in a hot oxidizing gas as shown in Fig. 13.1. The fuel contains a core of solid or liquid with a temperature below its boiling or pyrolysis point. That temperature is shown as T_b. The

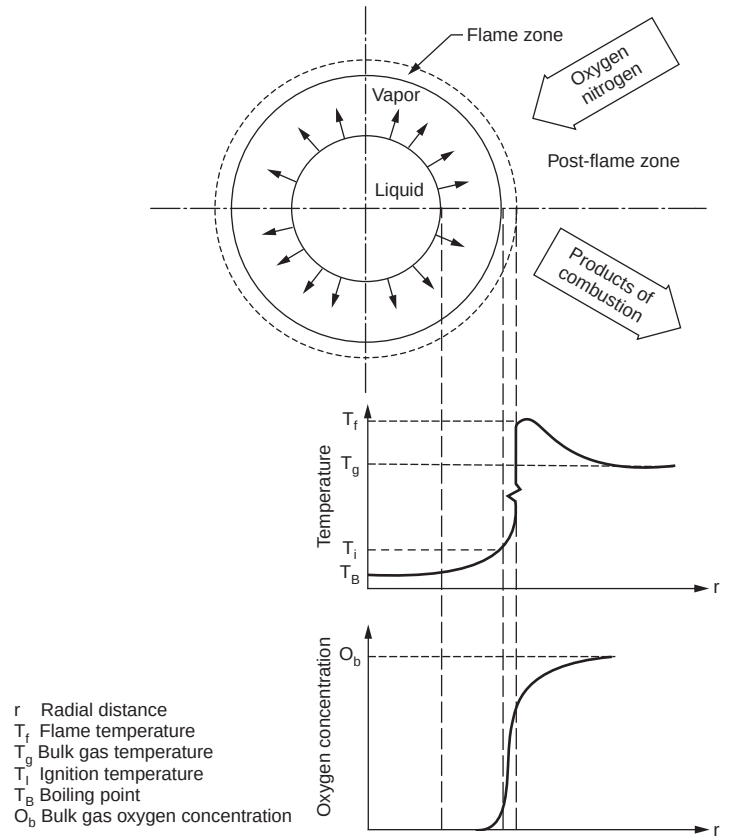

FIGURE 13.1 Combustion around a droplet of fuel. (Reproduced courtesy of LVW Associates, Inc.)

liquid or solid core is surrounded by a vapor shell consisting of the vaporized liquid and the products of pyrolysis of the fuel. The fuel and its surrounding vapor are the first zone of combustion. The vapor cloud surrounding the liquid core is continually expanding or moving away from the core. As a shell of gases around the droplets expands, it heats and mixes with oxygen diffusing inward from the bulk gases. At some distance from the core, the mixture reaches the proper temperature (T_i), and oxygen-fuel mixture ignites. The actual distance from the core where the expanding vapor cloud ignites is a complex function of the following factors:

- The bulk gas temperature
- The vapor pressure of the liquid and latent heat of vaporization
- The temperature at which the material begins to pyrolyze
- The turbulence of the gases around the droplet (which affect the rate of mixing of the out-flowing vapor and the incoming oxygen)
- The amount of oxygen needed to produce a stable flame for the liquid
- The heat released by the combustion reaction

Ignition creates the second zone of the combustion process, the flame zone. The flame zone has a small volume compared to that of the pre- and postflame zones in most combustors, and a molecule of material will only be in it for a very short time, on the order of milliseconds. Here, the organic vapors rapidly react with the air (the chemical reaction is discussed below) to form the products of combustion. The temperature in the flame-zone, T_f, is very high, usually well over 1700°C (3000°F). At these elevated

temperatures, the atoms in the molecule are very reactive, and the chemical reactions are rapid. Reaction rates are on the order of milliseconds.

The very high temperature in the flame zone is the main reason one can consider the major chemical reactions that occur in combustion to be functions of the elements involved and not of the specific compounds. The vast majority (on the order of 99% or more) of the organic constituents released from the waste and fuel are destroyed in the flame zone.

The flame around a droplet can be viewed as a balance between the rate of outward flow of the combustible vapors against the inward flow of heat and oxygen. In a stable flame, these two flows are balanced, and the flame appears to be stationary.

The rapid chemical reactions in the flame zone generate gaseous combustion products that flow outward and mix with additional, cooler, air and combustion gases in the postflame region of the combustion chamber. The gas temperature in the postflame region is in the 600 to 1200°C (1200 to 2200°F) range. The actual temperature is a function of the flame temperature and the amount of additional air (secondary air) introduced to the combustion chamber.

The chemical reactions that lead to the destruction of the organic compounds continue to take place in the postflame zone, but because of the lower temperatures, they are much slower than in the flame zone. Typical reaction rates are on the order of tenths of a second. Because of the longer reaction times, it is necessary to keep the gases in the postflame zone for a relatively long time (on the order of 1 to 2 sec) in order to assure adequate destruction. Successful design of a combustion chamber requires that it maintain the combustion gases at a high enough temperature for a long enough time to complete the destruction of the hazardous organic constituents.

Note that the reaction times and temperature ranges that are given above are intended only to provide a sense of the orders-of-magnitude involved. This discussion should not be interpreted to mean that one or two seconds are adequate or that a lower residence time or temperature is not acceptable. The actual temperature and residence time needed to achieve a given level of destruction is a complex function, which is determined by testing the combustor and verifiying its performance by the trial burn.

The above description of the combustion process illustrates how the following three factors, commonly referred to as the "three Ts": (1) temperature, (2) time, and (3) turbulence, affect the destruction of organics in a combustion chamber. Temperature is critical, because a minimum temperature is required to pyrolyze, vaporize, and ignite the organics and to provide the sensible heat needed to initiate and maintain the combustion process. Time refers to the length of time that the gases spend in the combustion chamber, frequently called the "residence time." Turbulence is the most difficult to measure of the three terms. It describes the ability of the combustion system to mix the gases within the flame and in the postflame zone with oxygen well enough to oxidize the organics released from the fuel.

The following three points illustrate the importance of turbulence:

1. The process of combustion consumes oxygen in the immediate vicinity of pockets of fuel-rich vapor.
2. The destruction of organic compounds occurs far more rapidly and cleanly under oxidizing conditions.
3. In order to achieve good destruction of the organics, it is necessary to mix the combustion gases moving away from the oxygen-poor pockets of gas with the oxygen-rich gases in the bulk of the combustion chamber.

Therefore, turbulence can be considered the ability of the combustor to keep the products of combustion mixed with oxygen at an elevated temperature. The better the furnace's ability to maintain a high level of turbulence (up to a point), the higher the destruction of organic compounds it is likely to achieve.

Complex flames behave in an analogous manner to the simple flame described above. The major difference is that the flame is often shaped by the combustion device to optimize the "three Ts." To illustrate, consider a Bunsen burner flame. The fuel is introduced through the bottom of the burner's tube and accelerated by a nozzle in the tube to increase turbulence. Openings on the side of the tube

permit air to enter and mix with the fuel. This air is called "Primary Air" because it mixes with the fuel prior to ignition. The flow rate of the fuel and air are adjusted so that the mixture is slightly too rich (too much fuel or not enough oxygen) to maintain combustion. When the mixture hits the ambient air at the mouth of the burner, it mixes with additional oxygen and ignites. The flame of a properly adjusted Bunsen burner will be hollow. The core will contain a mixture of fuel and air, which is too rich to burn, the preflame zone. The flame zone is well defined. In it, the rapid flow of primary air and fuel increases turbulence. The postflame zone is virtually nonexistent for an open burner because there is no combustion chamber to maintain the elevated temperature.

The Bunsen burner is designed for gaseous fuels. The fuel is premixed with air to minimize the amount of oxygen that must diffuse into the flame to maintain combustion. Premixing the fuel with air also increases the velocity of the gases exiting the mouth of the burner, increasing turbulence in the flame and producing a flame with a higher temperature than that of a simple gas flame in air. Liquid combustion adds a level of complexity. Liquid burners consist of a nozzle, whose function is to atomize the fuel, mounted into a burner, burner tile, or burner block that shapes the flame so that it radiates heat properly backwards and provides good mixing of the fuel and air. The whole assembly is typically called the burner. The assembly may be combined into a single unit, or the burner and nozzle may be independent devices. The fundamental principles of operation of liquid burners are the same as those of a Bunsen burner, with the added complexity of atomizing the fuel so that it will vaporize readily. In all liquid fuel burners, the fuel is first atomized by a nozzle to form a finely dispersed mist in air. Heat radiating back from the flame vaporizes the mist. The nozzle mixes the vapor with some air, but not enough to allow ignition. The mixture is now equivalent to the gas mixture in the tube of the Bunsen burner; it is a mixture of combustible gases and air at a concentration too rich (too much fuel or not enough oxygen) to ignite.

As the fuel-air mixture moves outward, it mixes with additional air, either by its impact with the oxygen-rich gases in the combustion zone or by the introduction of air through ports in the burner. As the gases mix with air, they form a flame front. The flame radiates heat backwards to the nozzle where it vaporizes the fuel.

Since most nozzles cannot tolerate flame temperatures, the nozzle and burner must be matched so that the cooling effect of the vaporizing fuel prevents radiation from overheating the nozzle. Similarly, if the liquid does not evaporate in the appropriate zone (if, for example, it is too viscous to be atomized properly) then it will not vaporize and mix adequately with air. Proper balance of the various factors results in a stable flame. Clearly, it is important that all liquid burned in a nozzle must have properties within the nozzles design limits. A flame that flutters a lot and has numerous streamers is typically termed "soft." One that has a sharp, clear spearlike (like a bunsen burner flame) or spherical appearance is termed "hard." Hard flames tend to be hotter than soft flames.

Nozzles operate in many ways. Some nozzles operate like garden hoses, the pressure of the liquid fed to them is used to atomize the liquid fuel. Others use compressed air, steam, or nitrogen to atomize the liquid. Nitrogen is used in those cases when the liquid fuel is reactive with steam or air. A third form of nozzle atomizes the liquid by firing the liquid against a rotating plate or cup. The type of nozzle used for any given application is a function of the properties of the liquid.

A great deal of information about the fuel and about the combustion process can be gained by looking at the flame in a furnace. CAUTION — Protective lenses must always be worn when examining the flame. The flame's color is a good indicator of its temperature. However, this indicator must be used with caution, as the presence of metals can change the flame color. In the absence of metals, red flames are the coolest. As the color moves up the spectrum (red, orange, yellow, blue, indigo, and violet) the flame temperature increases. One will often see different colors in different areas of the flame. A sharp flame formed by fuel with high heating values will typically have a blue to violet core surrounded by a yellow to orange zone. Such a flame would be common in a boiler or industrial furnace where coal, fuel oil, or similarly "hot" fuel was being burned.

Another useful piece of operating information is the shape of the flame. A very soft (usually yellow or light orange) flame with many streamers may indicate that the fuel is inhomogeneous and probably

has a heating value approaching the lower range needed to sustain combustion. This is acceptable unless a large amount of soot is observed. Soot (black smoke) released from a flame is indicative of localized lack of oxygen. While a small amount (a few fine streamers) of soot is common in a soft flame, large amounts of soot or a steady stream of soot from one point indicates some form of burner maladjustment.

There are two common causes of large amounts of soot emanating from the flame. First, the burner may not be supplying enough air to the flame. The system should be shut down and the burner inspected for blockage in the air supply. Second, the fuel could contain too much water or other material with a low heating value such as a heavily halogenated organic. In this case, improved fuel (waste) blending may resolve the issue. The production of large amounts of soot is usually associated with a rapid rise in the concentration of CO and hydrocarbon in the flue gas. A CO monitor is often a useful tool for assuring that burners are properly adjusted.

13.3 Combustion Chemistry

Numerous chemical reactions can occur during combustion as illustrated by the following discussion. Consider, for example, one of the simplest combustion processes, the burning of methane in the presence of air. The overall chemical reaction is represented by:

$$CH_4 + 2O_2 \rightarrow CO_2 + 2H_2O \tag{13.2}$$

In fact, many more chemical reactions are possible. If the source of the oxygen is air, nitrogen will be carried along with the oxygen at a ratio of approximately 79 moles (or volumes) of nitrogen for each 21 moles of oxygen. The nitrogen is a diluent for the combustion process, but a small (but important) fraction also oxidizes to form different oxides, commonly referred to as NO_x. In addition, if the combustion is less than complete, some of the carbon will form CO rather than CO_2. Because of the presence of free radicals in a flame, molecular fragments can coalesce and form larger organic molecules. When the material being burned contains elements such as chlorine, numerous other chemical reactions are possible. For example, the combustion of carbon tetrachloride with methane can result in the following products:

$$\begin{aligned} CH_4 + CCl_4 + O_2 + N_2 \rightarrow CO_2 + H_2O + HCl + N_2 + CO + Cl_2 + CH_3Cl + \\ CH_2Cl_2 + CHCl_3 + C_2H_5Cl + C_2H_4Cl_2 + C_2H_3Cl_3 + ? \end{aligned} \tag{13.3}$$

where "?" refers to a variety of trace and possibly unknown compounds that could potentially form.

The goal of a well-designed combustor is to minimize the release of the undesirable products and convert as much of the organics to CO_2, water, and other materials that may safely be released after treatment by an APCD. The combustion products of a typical properly operating combustor will contain on the order of 5 to 12% CO_2, 20 to 100 ppm CO, 10 to 25% H_2O, ppb and parts per trillion (ppt) of different POHCs and PICs, ppm quantities of NO_x, and ppm quantities of SO_x.

If the combustion is poor (poor mixing of the oxygen and fuel or improper atomization of the fuel), localized pockets of gas will form where there is insufficient oxygen to complete the combustion. CO will form in these localized pockets, and because the reaction of CO to CO_2 is slow outside the flame zone (on the order of seconds at the postflame zone conditions), it will not be completely destroyed. This mode of failure is commonly termed "kinetics limiting," because the rate at which the chemical reactions occur was less than the time that the combustor kept the constituents at the proper conditions of oxygen and temperature to destroy the intermediate compound.

Similar explanations can be offered for the formation of other PICs. Many are normal equilibrium products of combustion (usually in minutely small amounts) at the conditions of some point in the combustion process. Because of the similarity, PIC formation is commonly associated with CO emisssions.

Test data (EPA, 1991, 1992) have shown that PICs rarely if ever occur when the CO level is less than 100 ppm (dry and adjusted to 7% O_2). They sometimes occur at CO levels over 100 ppm. It must be noted that PICs occur during the combustion of all fuels, including wood, petroleum products, and coal. Their formation is not characteristic just of the combustion of hazardous wastes.

Hydrogen forms two major products of combustion, depending on whether or not chlorine or other halogens are present in the waste. If chlorinated organic wastes are burned, then the hydrogen will preferentially combine with the chlorine and form HC1. The thermodynamics of HC1 formation are such that all but a small fraction (order of 0.1%) of the chlorine will form HC1; the balance will form chlorine gas. The reaction between free chlorine and virtually any form of hydrogen found in the combustion chamber is so rapid that the Cl_2:HC1 ratio will be equilibrium limiting in virtually all cases. Organically bound oxygen will behave like a source of oxygen for the combustion process.

Fluorine, which is a more electronegative compound than chlorine, will be converted to HF during the combustion process. Like chlorine, it will form an equilibrium between the element and the acid, but the thermodynamics dictates this equilibrium to result in a lower F_2:HF ratio than is the Cl_2:HC1. Bromine and iodine tend to form more of the gas than the acid. Combustion of a brominated or iodinated material will result in significant releases of bromine or iodine gas. This fact is important to incinerator design because Br_2 and I_2 will not be removed by simple aqueous scrubbers. Furthermore, because the production of the elemental gases is equilibrium limiting, modifications to the combustion system will not reduce their concentration in the flue gas significantly. It is, sometimes, possible to increase acid form by the addition of salts, although this is a relatively experimental procedure.

Organic sulfur forms the di- and trioxides during combustion. The vast majority of the sulfur will form SO_2, with trace amounts of SO_3 also forming. The ratio of the two is equilibrium limiting. SO_3 forms a strong acid (H_2S0_4, sulfuric acid) when dissolved in water. It is thus readily removed by a scrubber designed to remove HC1. SO_2 forms sulfurous acid (H_2SO_3), a weak acid that is not controlled well by a typical acid gas scrubber that has been designed for HC1 removal.

Nitrogen enters the combustion process both as the element, with the combustion air, and as chemically bound in the waste or fuel. During combustion, the nitrogen forms a variety of oxides. The ratio between the oxides is governed by a complex interaction between kinetic and equilibrium relationships that is highly temperature dependent. The reaction kinetics are such that the reactions to create, destroy, and convert the various oxides from one to the other occur at a reasonable rate only at the high temperatures of the flame zone. Nitrogen oxides are, therefore, controlled by modifying the shape or temperature distribution of the flame and by adding ammonia to lower the equilibrium NO_x concentration, and to decrease N_2 emissions. NO_x formation and control as well as the concept of equilibrium are discussed below.

Particulate and Metal Fume Formation

The term particulate matter refers to any solid and condensable matter emitted to the atmosphere. Particulate emissions from combustion are composed of varying amounts of soot, unburned droplets of waste or fuel, and ash. Soot consists of unburned carbonaceous residue, consisting of the high molecular weight portion of the POM. The soot can and does condense both on its own and on the other particulate, other inorganic salts such as sodium chloride, and metals. The formation of particulate in a combustor is intimately related to the physical and chemical characteristics of the wastes, fuels, combustion aerodynamics, the mechanisms of waste/fuel/air mixing, and the effects of these factors on combustion gas temperature-time history. The reader is referred to the "Guidance On Metal and HC1 Controls for Hazardous Waste Incinerators" (EPA, 1989c) for further information on this subject. Particulate can form by three fundamental mechanisms:

1. Abrasion
2. Ash formation
3. Volatilization

Abrasion is the simplest mechanism; it forms particulate by the straightforward action of the solid mass rubbing against itself and against the walls of the combustion chamber. Since abrasion tends to form coarse particulate that can be readily removed by a reasonably well-designed APCD, it is not usually of primary concern when evaluating combustors, and it will not be discussed further.

The formation of particulate by ash formation occurs when ash-containing liquid wastes and fuels are burned, the organics are destroyed, and the inorganic ash remains behind. The size of the resulting particulate is a function of the concentration of the inorganic materials in the fuel, the size of the droplets formed by the nozzle, and of the ash's physical characteristics. When a droplet of atomized liquid leaves the nozzle and hits the combustion chamber, the organic portions vaporize and burn leaving the ash behind in suspension. Depending on the composition of the ash, a fraction may volatilize as well (Barton, 1988). Regardless of whether this occurs or not, nearly the entire inorganic fraction is typically entrained by the gas flow.

The particulate formed by volatilization/condensation is especially germane to the emission of metals (EPA, 1989c, 1991, 1992, 2001). Many metals and their salts will form vapors at the temperatures of the flame and the postflame zones of a combustion chamber. When the vapors cool, they condense to form very fine (<1 micron in diameter) particulate, which tends to be relatively difficult to capture in an air pollution control device. Volatilization of metals and other inorganics can occur whether the waste or fuel is a solid or a liquid. As long as it contains an inorganic fraction, it may volatilize. This phenomenon is of especial concern when the inorganic fraction includes toxic metals (i.e., Cr, Cd) or their compounds.

The size of the entrained particles can range from 1 μm to over 50 μm, but typically does not exceed 20 μm in diameter (Petersen, 1984; Goldstein and Siegmund, 1976). The particle size distribution can significantly affect the collection efficiency of air pollution control systems and the ability to meet RCRA particulate standards. Generally, particles less than 1 micron in diameter are more difficult to collect, requiring higher energy wet or dry control devices.

Another source of flue gas entrained particulate is the dissolved salts in quench water and sometimes the scrubber. Particulate forms in the quench when the water is evaporated by the hot flue gases. The solids dissolved and suspended in the water could form particulate. Particulate formation in the scrubber is less common but can occur if the quench does not cool the flue gas completely or if gas velocities in the scrubber are high enough to entrain liquid droplets. The salts, such as NaC1, can escape to the flue gas along with entrained mist. Although mist elimination equipment provides an added measure of control, some of the salts can escape to the stack and will eventually be measured as particulate by conventional sampling methods. The contribution of these salts to the overall particulate loading, while not large, could result in the failure to meet the particulate emission limits.

A model to predict the partitioning of toxic metals was developed but found to be of limited usefulness (Barton et al., 1988). Toxic metal emissions from hazardous waste incinerators can result from the following mechanisms:

- Mercury, a volatile metal, is almost completely emitted from the stack.
- Less volatile metals, such as antimony (Sb), lead (Pb) and cadmium (Cd), vaporize and enter the gas stream. The higher the incinerator temperature, the higher the vaporization rate. As the gas cools, the vapors condense homogeneously to form new, less than one micron particles and heterogeneously on the surface of entrained ash particles, preferentially to fine particulate, because of their large surface area.
- Under combustion conditions, metals react to form compounds like chlorides and sulfides. Because these compounds (especially many metal chlorides) are often more volatile than the original metal species, they more readily vaporize and enter the gas stream. Upon secondary oxidative reactions, these metals can return to their original form and will proceed to condense into new or existing particles as mentioned above
- Metals and their reactive species can also remain trapped in the ash bed of solid waste incinerators contributing the metal loading of the residual ash. Entrainment of particulate from the ash bed into the gas stream can, however, contribute to the flue gas loading of toxic metals.

Material and Energy Balances

Stoichiometry and thermochemistry form the basis for most design calculations for incinerators and, in fact, all combustors. One of the simplest forms of combustion is that of charcoal or coke which may, for the purpose of this calculation, be assumed to be pure carbon. The major chemical reaction is as follows:

$$C + O_2 \rightarrow CO_2 \tag{13.4}$$

One molecule or mole of carbon (12 g or lb depending on the units chosen) combines with one molecule or mole of oxygen gas (32 g or lb) to form one molecule or mole of CO_2 (44 g or lb) gas. If the source of oxygen for the combustion is air (approximately 21 mole or volume percent oxygen and 79 mole or volume percent nitrogen), then the 1 mole of oxygen brings with it 79/21:3.76 moles or 105 g or lb of nitrogen. Note that for combustion calculations, the other components of air (except for possibly the water vapor) are usually ignored. The calculations in the following example are performed using English Units. If metric units are to be used, the volume of one gram-mole of gas at STP, 22.4L, can be used in place of 387 lb-mole/scf.

By the ideal gas law, 1 lb-mole of any gas at STP occupies 387 ft^3, the combustion of 12 lb of carbon will produce 387 scf of CO_2 and will consume 387 scf of oxygen gas. If air is used as the source of oxygen, 1456 scf of nitrogen gas will be moved through the system.

The amount of oxygen or air required to exactly burn all of the fuel available is called the "stoichiometric oxygen," "stoichiometric air," "theoretical oxygen," or "theoretical air." Virtually all combustion devices operate with an excess of combustion air, i.e., at over 100% theoretical air with the amount fed specified by the "equivalence ratio, ER" defined by:

$$ER = \frac{(\text{volume of combustion air})}{(\text{volume of theoretical air required})} \tag{13.5}$$

An alternative method of specifying the amount of air actually fed to the combustor is the "percent excess air," which is defined by:

$$\text{Percent Excess Air} = \%EA = (ER - 1) * 100\% \tag{13.6}$$

If the combustion of carbon were performed using 120% excess air, ER = 2.2, then the same amount of carbon and CO_2 would be involved, but the combustor would be fed 2.2 times the theoretical amount of air than under stoichiometric conditions. Hence, 2.2 lb-moles or 851 scf of oxygen and 8.27 lb-moles (3203 scf) of nitrogen would pass through the system. The mass and volumetric flow rates of the combustion air and flue gas streams can, thus, be computed by using stoichiometry and the concept of excess air. The same calculations can be applied to complex systems.

The percent excess air (also called excess oxygen) can be readily calculated for an actual combustor from the analysis of oxygen and carbon dioxide in the combustion gases. Such a determination is typically performed using an Orsat apparatus or oxygen monitor and the following equation:

$$\%EA = \frac{O_2}{0.266\ N_2 - O_2} \tag{13.7}$$

Equation (13.7) assumes that both the amount of nitrogen in the wastes and fuel and the CO in the flue gas are negligible. Both assumptions are usually acceptable for incinerator applications. The value 0.266 in Eq. (13.7) is simply the quotient 21/79, the ratio of oxygen to nitrogen in air. This equation can be used along with a mass balance and energy balance to cross-check the flue gas flow rate, composition,

and temperature against the feed rate, composition, and heating value of the wastes and fuels fed to the incinerator to determine whether the measurements performed are mutually consistent.

Mass balances on more complex systems are performed in the same way. No matter how complex the system, the calculations can be based on the elemental feed rates of the streams. Consider the combustion of a mixture of methane and carbon tetrachloride in air. The balanced chemical reaction for the combustion is as follows:

$$CH_4 + CCl_4 + 2O_2 + 7.52N_2 \rightarrow 2CO_2 + 4HCl + 7.52N_2 + \Delta H_c$$

One mole of methane reacts with one of carbon tetrachloride and two of oxygen to form two of carbon dioxide and four moles of HC1. The nitrogen does not participate in the main combustion reaction. It is "carried along" with the oxygen. The coefficient, 7.52, for nitrogen is obtained by multiplying the number of moles of oxygen participating in the chemical reaction (2) by the volumetric ratio of nitrogen and oxygen in air (79/21). The combustion produces (2 + 4 + 7.52) = 13.52 moles of flue gas. If the calculations were performed in lb-moles, the combustor will produce $13.52 \times 387 = 5232$ scf of flue gas. If the calculation were performed in metric units, the 13.52 g-moles of flue gas would occupy at 0.02404 scm/g-mole or 0.325 m^3 at STP.

Stoichiometric calculations allow one to determine the amount of gas formed by the combustion process. Thermodynamic calculations allow one to determine the temperature of the gases. The combined material and energy balance is used to determine the temperature, gross composition, and flow rates in an incinerator or combustor. The heat balance is completely analogous to the mass balance that was performed above. The mass balance takes advantage of the fact that matter is neither created nor destroyed in an incinerator, that all of the elements that enter the combustor must come out, although the materials react chemically to form different compounds. The heat balance is based on the fact that all of the energy that goes into the incinerator will be released at some point. Because energy can flow into and out of a system in many ways, a rigorous energy balance can be time-consuming and complex. Fortunately, many simplifying assumptions can be made.

The first step in the heat balance is to calculate the heat input to the combustor. The heat input is simply the sum of the sensible heat released by each component (waste and fuel) to the combustor as it burns, or as it changes phase. The heating values of pure compounds and for fuels such as natural gas or fuel oil can be determined by calorimetric methods or, more frequently, from tabulated heats of formation as in Tables 13.1 and 13.2. Direct measurement of the wastes' heating value by calorimetric techniques is possible, but it is rarely practical. The typical laboratory calorimeter is a very small device that can only measure the heat of combustion of a very small sample. Wastes, on the other hand, tend to consist of large, highly inhomogeneous components. It is usually very difficult to produce a sample of the waste that represents its composition but is small enough to fit in the calorimeter. While multiple samples can be tested, the cost becomes high, and evaluation of the data becomes complex. It is recommended that for critical applications, the heat of formation and anticipated waste compositions be used to calculate the heat of combustion.

The heat of combustion or heating value of any compound can be calculated from the heat of formation by the following formula:

$$\Delta H_{c,298°K} = \Sigma n_p (\Delta H_f)_p - \Sigma n_r (\Delta H_f)_r \qquad (13.8)$$

where $\Delta H_{c,298°K}$ is the heat of combustion at 298°K, n is the stoichiometric coefficient for each of the compounds, ΔH_f is the heat of formation of each compound, and the subscripts p and r refer, respectively, to the compounds that are the products and reactants.

The following example showing how the heat of combustion of 1,3-dichloropropane (liquid) is calculated from the heat of formation. Table 13.1 gives its heat of formation as 388 Btu/lb and its molecular weight at 179. The combustion equation is as shown below:

TABLE 13.1 Heats of Formation and Combustion of Pure Compounds

				Reference condition, 1 atmosphere, 25°C, 77°F

Heat of combustion of chlorinated compounds assumes that all chlorine goes to HCl with addition of liquid water if needed.
Values in parentheses are negative.
Positive values indicate heat released from combustor.

$$C_3H_6Cl_2(L) + 4O_2 \rightarrow 3CO_2 + 2H_2O(L) + 2HCl$$

The heat of formation for each of these compounds is given per unit weight and per mole, and each compound's molecular weight is given below:

	$C_3H_6Cl_2(L)$ +	$4O_2$	$\rightarrow 3CO_2$ +	$2H_2O(L)$ +	2HCl
H_f (Btu/lb)	–3880	0	–3848	–6832	–1088
Mol. Wt.	179	32	44	18	36.5
H_f (Btu/lb-mole)	–69,500	0	–169,000	–123,000	–39,700

The heat of combustion of 1,3-dichloropropane liquid is therefore,

$$\Delta H_f = 3(-169,300) + 2(-123,000) + 2(-39,700) - (-69,500) =$$

$$-594,500 \text{ Btu/lb-mole or } -1,530 \text{ Btu/lb}$$

That is, 1530 Btu are released when liquid 1,3-dichloropropane is burned and the water in the combustion products is condensed. What happens if the water is not condensed and its latent heat not released as when the LHV is computed? The combustion of one mole (179 pounds) of 1,3-dichloropropane forms 2 moles (36 pounds) of water. The latent heat of vaporization of water at ambient temperature is approximately 9500 cal/g-mole, 528 cal/g, 17,100 Btu/lb-mole, or 950 Btu/lb.

The LHV of 1,3-dichloropropane, when the water formed in the reaction does not condense and release its latent heat, is 594,500 - 2(17,100) = 560,300 Btu/lb-mole of 1,3-dichloropropane burned. Dividing this value by the compound's molecular weight, 179, gives its lower heating value per pound, 3130 Btu/lb.

This calculation illustrates the two terms: higher heating value (HHV) and lower heating value (LHV) for a material. The HHV corresponds to the heat released by the combustion of a compound when the water formed condenses and gives up its latent heat. This is heating value measured in a calorimeter. The LHV corresponds to the heat released on combustion when the water leaves the combustion chamber in the vapor form, as occurs in an incinerator. As can be seen, the difference is quite significant. Clearly published heat of combustion (also called heating value) data must be used with full knowledge of whether the value is the HHV or LHV.

Published heating value for halogenated compounds encounter a second problem inherent in calorimetry. Frequently, the calorimetric determination of a compound's heating value is made by placing the compound into a calorimeter and adding just enough oxygen gas to completely oxidize it — termed the stoichiometric quantity. Highly halogenated compounds, such as $CC1_4$, $CHC1_3$, or highly chlorinated benzenes, do not incorporate sufficient hydrogen in the molecule to form HC1. When a system contains more moles of chlorine than hydrogen, a significant fraction of the chlorine is converted to Cl_2 gas rather than to HC1. This condition is counter to the one that occurs in an incinerator, where sources of hydrogen are plentiful. For example, the combustion of chloroform in a calorimeter will occur by the following chemical reaction (the heats of formation for each compound are given directly beneath the formula):

$$CHCl_3 + O_2 \rightarrow CO_2 + HCl + Cl_2$$

$$\Delta H_f \quad (-24,200) + 0 + (-94,052) + (-22,063) + 0$$

$$\Delta H_c = -91,915 \text{ cal/g-mole}$$

When sufficient hydrogen is present, as in an incinerator, the combustion follows the following reaction, with the corresponding free energies of formation given beneath the compounds:

$$CHCl_3 + \tfrac{1}{2}O_2 + H_2O \rightarrow CO_2 + 3HCl$$

$$\Delta H_f \ (-24,200) + 0 + (-57,598) + (-94,052) + (-22,063)$$

$$\Delta H_c = -140,837 \text{ cal/g-mole}$$

As can be seen, the heating value of a chlorinated compound that is determined in a calorimeter without the presence of a hydrogen source, like water, is significantly different from its actual heating value under incinerator conditions when water and other sources of hydrogen are present. It is recommended that the heats of combustion be calculated from the higher and lower heating values of the pure components whenever possible, recognizing the facts that the water produced will never condense inside the combustion chamber and that the chlorine will react with any source of hydrogen to form HCl. See Theodore (1987, pp.143, 146) for a further discussion of this subject.

Waste streams can have a negative heat release in a combustion chamber. For example, if a waste stream is pure water, then it will absorb approximately 1050 Btu/lb (its latent heat of vaporization) when injected into an incinerator. The latent heat of vaporization of organic constituents in the waste is much smaller than that of water (typically one-quarter to one-half that of water) and is usually included in the tabulated heating values.

The heat of combustion of complex materials such as paper, leather, fuel oil, etc., cannot be determined from heats of formation. Table 13.2 lists typical heating values for these types of material.

Having established the heat input rate to the incinerator, it is necessary to then determine the resultant gas temperature. When performing material and energy calculations by hand, this is done by using the gas composition calculated from the material balance and determining through iteration the resultant temperature based on the composition and the enthalpy (heat content) of gases as given in Table 13.3. When doing the calculation on a computer, one normally uses correlations of heat capacity and the resulting enthalpy of each gas constituent.

Two correlations are typically used for calculating the enthalpy versus temperature of the components of a flue gas. One is based on the heat capacity of the gases:

$$C_p = A + BT + CT^{-2} \tag{13.9}$$

$$H = A(T - To) + \tfrac{1}{2}B\left(T^2 - T_o^2\right) - C\left[(1/T) - (1)T_0\right] \tag{13.10}$$

and the second is based on the mean heat capacities over a specified temperature range:

$$C_{p,\,mean} = A + Bt^b + Ct^c + Dt^d \tag{13.11}$$

with the enthalpy calculated by

$$H = \int C_{p,\,mean}(T)(T - T_o)dT \tag{13.12}$$

The coefficients for Eqs. (13.11) and (13.12) are given in Table 13.4. The coefficients for Eqs. (13.9) and (13.10) are given in Table 13.5.

The full power of a material and energy balance is illustrated in Tables 13.6 and 13.7, which show the complete material and energy balance for an incinerator burning three waste streams (solid waste, high Btu liquid, and low Btu liquid) and a supplemental fuel stream of #2 fuel oil. The liquid waste streams are synthetic mixtures of components that may be used as part of a trial burn. The waste stream compositions are shown in the upper half of the first page of the table. As can be seen, the solid waste stream consists of refuse contaminated with chloroform, 1,1-dichloroethane, ethylene glycol, and ethanol. The low Btu liquid stream is water-contaminated ethylene glycol and ethanol, and the liquid waste consists of fuel oil doped with the specific organic compounds.

Enthalpies are for a gaseous system and do not include latent heat of vaporization of water.

L_v = 1059.9 Btu/lb or 50.34 Btu/scf of H_2O vapor at 60° F and 14,696 psia.

Source: Danielson, 1973.

The compositions of each stream are given as ultimate analyses and as mole fractions. For the pure compounds (such as chloroform), one does not normally have an ultimate analysis. In that case, one can use the number of atoms of the elements (carbon, hydrogen, etc.) in the compound. This corresponds to the molecular structure of the compound. For example, chloroform has one carbon, one hydrogen, and three chlorine atoms, and this is shown in the "Number Moles" column for chloroform. The other compounds are similarly filled in.

For complex mixtures, such as refuse, natural gas, or fuel oil, one would normally enter the ultimate analysis. Table 13.6 shows the ultimate and formula analyses for all streams to illustrate how one calculates one from the other. It also shows the LLV and HHV for the components of each of the waste streams. The LHV for the pure compounds were calculated from their heats of formation. The LHV for the refuse was obtained from Niessen (1978).

Note that while heats of combustion are usually given as a negative numbers in the literature, they are shown to be positive in Table 13.6. This change in sign is consistent with the standard nomenclature of positive when heat flows into a system and negative when it flows out. The compounds are the system as defined in the literature; as a result, the heat of combustion is shown as negative. The heat balance calculations are performed using the incinerator as the point of reference; hence, heat released from the waste (a negative quantity) is heat absorbed by the combustion chamber — a positive quantity.

The negative value for the heat of combustion of water needs to be mentioned. The water is fed to the incinerator as a liquid and exits the combustion chamber as a gas, its LHV is equal to its latent heat of vaporization. Its HHV is zero because it is based on the water emerging from the system as a liquid rather than a gas. The -1060 Btu per pound is the heat of vaporization of water at 70°F.

Table 13.7 shows how the composition, size, and temperature of the output stream are determined. The elements fed to the incinerator form the compounds shown in the upper left of Table 13.7. The amounts of the compounds formed are determined by applying the rules for a mass balance described above. This computes the amount of the combustion products formed. The moles of oxygen required to form these combustion products is the sum of the oxygen required to form all of the oxides (CO_2, H_2O from hydrogen, and SO_2 minus the moles of oxygen fed to the combustor). In this example, the stoichiometric (O% excess air) quantity of oxygen required is 208.04 moles/hr. Since each mole of oxygen

Temperature range: 20 to 2000°C.

Temperature must be input in K to obtain the appropriate values for C_P in (cal/g-mole-k) or (Btu/lb-mole-°R); °R = 1.8 × K; (Btu/lb-mole) = (cal/g-mole) × 1.8.

carries with it 79/21 or 3.76 moles of nitrogen, the moles of nitrogen in the flue gas can readily be calculated by multiplying the 208.04 by 3.76. This results in the analysis given in the upper first columns of Table 13.7, identified by "@ 0% excess air."

It is now necessary to compute the composition of the gases at the excess air ratio of the incinerator. To do this, one multiplies the excess air ratio (1.20 in this case, 120% excess air) by the O_2 required value to obtain the moles of oxygen that are fed. This oxygen similarly carries nitrogen with it at the ratio of 3.76 moles of nitrogen for each mole of oxygen, and this nitrogen is added further to the nitrogen calculated at 0% excess air to obtain the actual number of moles of nitrogen in the exit of the combustor. Once the molar flow rate of each of the major component gases of the flue gas are known, their respective SCFMs can be computed by multiplying the moles per hour by 387 SCF/lb-mole and dividing by 60 min/hr. The percent of each component on a wet and dry basis can also be calculated by dividing that component's flow rate by the total gas flow rate including and excluding the water, respectively.

The heat input to the incinerator is obtained by summing the heat input from each of the streams. Either the LHV or HHV can be used to perform the energy calculations. The usage is a matter of personal preference. This computation uses the LHV. If the HHV is used, then the appropriate corrections for the latent heat of vaporization of the water entering and leaving the combustor must be made. The bottom row of Table 13.5 shows the amount of sensible heat released by combustion of each of the waste streams. To illustrate, the fuel oil's LHV is 19,000 Btu/lb, and it is fed at a rate of 760 lb/hr in both the "High Btu Liquid" and "Supplemental Fuel" streams. The total heat contribution is, therefore, 14.4 MMBtu/hr. The other streams' heat contributions are similarly calculated. The total heat input from the fuel is 36.8 MMBtu/hr.

TABLE 13.6 Waste Feed Rates and Composition for System with Heat Exchanger

			Chloroform $CH(Cl)_3$		1,1-Dichloroethane $C_2H_4(Cl)_2$		Ethyleneglycol $C_2H_4(OH)_2$		Ethanol C_2H_5OH		Water H_2O		Fuel Gas or Oil		Refuse
