During the 1970s, concrete having a higher strength (40 to 50 MPa) began to be specified for columns in high-rise buildings because slender columns offered more architectural possibilities and more renting space [Albinger and Moreno 1991]. With the years, the name of these initial high-strength concretes has been changed to high-performance concrete [Aïtcin 2000] because it was realized that these concretes have more than simply a high strength. These concrete started to be used outdoors and faced more severe environments such as offshore platform, bridges, roads, etc. Little by little, it was realized that the market for this concrete was not only the high-strength market, but also more generally the market for durable concrete that represented more or less one third of the present market for concrete.

Definitions

High performance concrete (HPC) was defined by the American Concrete Institute [ACI 1994] as concrete which meets special performance and uniformity requirements that cannot be achieved by using only the conventional materials and normal mixing, placing, and curing practices. The performance requirements may involve enhancements of: placing and compaction without segregation, long-term mechanical properties, early-age strength, toughness, volume stability and service life in severe environments. Most engineers have adopted the term HPC to literally describe concrete which has specifically been formulated or chosen to give a "high performance" in specific applications with no restriction on the type of concreting materials nor production methods. The choice of concrete requires, on the one hand, a good understanding of how concrete properties are derived and varied by its compositions and production processes. On the other hand, it requires the identification of vital properties resisting against the deterioration mechanism(s) associated with the target performance. For example if high "strength" is the required "performance" to carry greater load in high-rise building, a silica fume or silica fume/fly ash low water-to-binder ratio concrete is used with good strong aggregates to produce the required concrete. In most cases, silica fume and superplasticizer are used to boost the strength of the paste. Fly ash is chosen to reduce heat of hydration for large structural members such as columns and transfer girder as well as improve pumpability of the concrete to a greater height or distance or both on a construction site. Selected coarse aggregates may be required to match the paste strength and to control long-term volume stability. If durability such as long-term wear resistance is required for concrete road surface for example, the selection of high wear resistance coarse aggregate becomes the primary issue in HPC used. Other processing requirements are the provision for induced crack at appropriate timing and intervals.

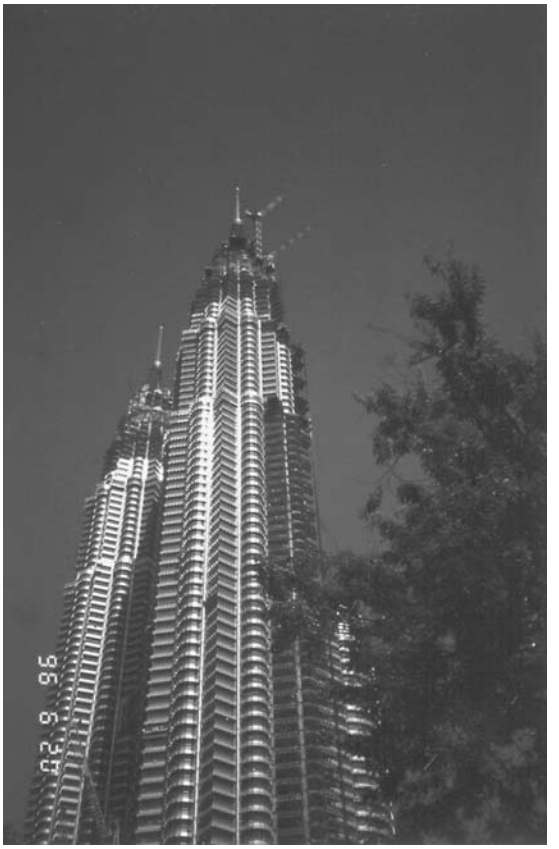

FIGURE 42.1 Petronas Towers, Malaysia.

High Performance Criteria

Modern construction and environmental obligations lead to a demand on a range of performance of modern concrete. They can be classified into those related to production, in-service performance and sustainability:

1. Production: fresh concrete properties, setting time, heat of hydration, early strength and curing requirement.
2. In-service Performance: mechanical, volume stability, and durability properties.
3. Sustainability: embodied energy, ecolabelling and lifecycle cost.

In most cases, there will be one primary and a range of secondary performance requirements necessary for the concrete to fully satisfy its intended function. In order to satisfy these ranges of performance, it is important that performance-based criteria are specified. The key performance must be vigorously acquired without losing sight on a range of secondary but complementary attributes necessary for them to be achieved in practice. (See Figs. 42.1 and 42.2.)

Performance standard and compliance criteria must be selected and tailored to rate the risks associated each performance standard according to its importance. For example, in specifying reinforced concrete subjected to chloride-induced corrosion, both the *quantity* and *quality* of concrete cover to reinforcement are necessary. However, it has been found that the quantity of cover thickness is far more important than the quality of cover influencing the service life. It is therefore necessary not only to specify both cover thickness and concrete quality as performance standard, but also devise a more strict compliance criteria

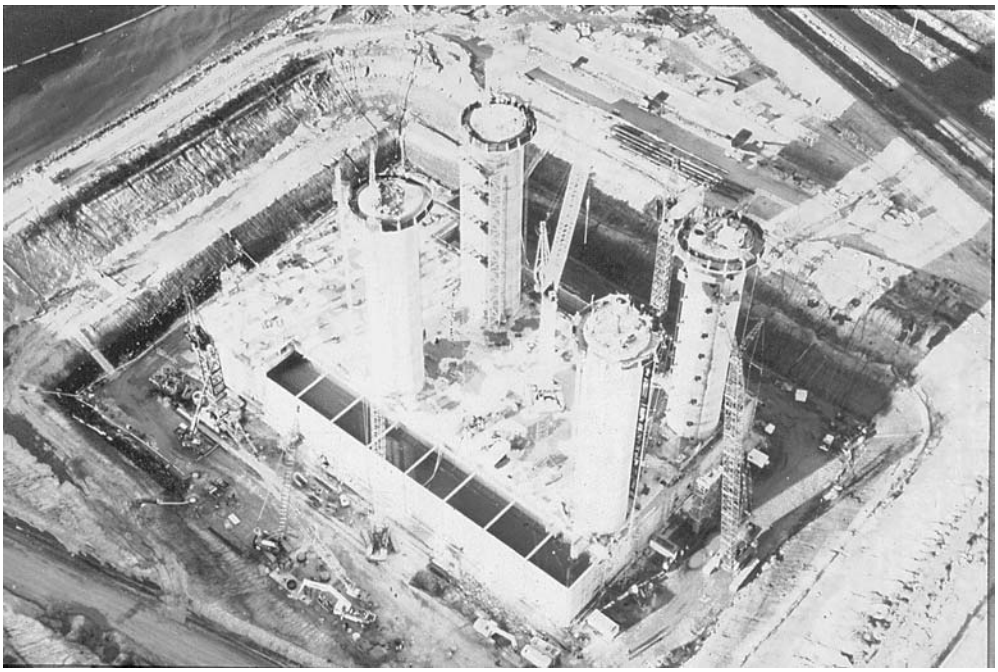

FIGURE 42.2 Wandoo platform under construction in western Australia.

for cover thickness than concrete quality. One method of balancing some of the risks associated with compliance criteria has been discussed [Sirivivatnanon and Baweja 2002].

Formulation of High Performance Criteria

Basic Constituents

Good concrete can usually be proportioned with the very basic constituents of Portland cement, water, a chemical admixture, fine and coarse aggregates. Since aggregates constitute approximately 75% of the volume of concrete, the properties of concrete are highly dependent on them. A careful choice and combinations of aggregates will enable highly dense and workable to be produced.

When greater demand is placed on specific properties of concrete, they can be met by a careful selection of the basic as well as a range of new constituents. They include specific Portland and blended cements, chemical admixtures, mineral additives and non-traditional reinforcement such as galvanized or stainless steel, fine galvanized wire mesh (ferrocement), and various fibers.

Cements, Chemical Admixtures, Mineral Additives, Fibers and Special Reinforcement

There are various Portland cements and blended cements available in many parts of the world. They enable the modification of the hydration products and the pore structures of the concrete. Blended cements incorporating mineral additive such as fly ash, blast furnace slag, silica fume and other natural pozzolans are widely used to modify the durability performance of concrete. When blended-cement concrete is proportioned to give similar mechanical properties to Portland-cement concrete, some slightly modified volume stability properties and enhanced durability properties are usually achieved.

Chemical admixtures such as water reducers are commonly used to reduce the water-to-cement ratio or maintaining the W/C with improved workability. A high-range water reducer or superplasticizer is both a powerful constituent to control the water content and to improve workability or both. It enables concrete of very low water-to-binder ratio (0.3–0.4) to be produced and placed. Either a very high strength

or a highly durable concrete can be produced. A combined use of silica fume and superplasticizer has led to the early production of high strength concrete without excessive quantity of cement. This is important as a large quantity of cement may result in greater heat of hydration and the possible cracking problems.

Ground limestone has been used as an additive to modern Portland cement. It has also been used in the production of self-compacted concrete. Organic and chemical additives are used as corrosion inhibitor [Sorensen et al. 1999, Schießl and Dauberschmidt 2000] in renovation and new concrete. They should be considered when conventional solutions could not be used.

The potential of fiber reinforcement in concrete has been widely researched and published [ACI 1996]. Synthetic fibers such as polypropylene fiber are popularly used to control plastic shrinkage while steel fiber is more commonly used to control cracking and improve the impact resistance of floor slab [Knapton 1999]. Plastic fibers have also been found [Rostam 2001] to improve the fire resistance of high strength concrete. They could become the essential ingredients for structural members susceptible to hydrocarbon fire such as in concrete tunnel lining.

Ferrocement incorporating fine galvanized wire mesh in cement mortar was first developed as an appropriate technology for construction in rural areas. In the 1980s, this thin-wall yet durable material has been found to be the key performance requirement for a range of structural elements in urban construction. They include sunscreens, secondary roofing slabs and water tanks for high-rise buildings [Paramasivam 1994]. In special circumstances, galvanized reinforcement has been successfully used to combat carbonation-induced corrosion whereas stainless steel would be required for chloride-induced corrosion [Rostam 2001].

Special Processes

Apart from varying the constituents, a number of processes have been successfully used in order to enhance specific performance of concrete. They include vacuum suction, controlled permeable formwork and induced crack.

Both vacuum suction and controlled permeable formwork (CPF) are based on the concept of improving the surface quality of concrete by lowering the water-to-cement ratio of the concrete after placing. The former involves a removal of water and air void from the surface by applying a vacuum to formed or unformed surfaces of concrete immediately or very soon after the concrete is placed [U.S. Bureau of Reclamation 1981]. CPF is a special material adhered to the surface of formwork, which allows for the controlled removal of surface water by gravity [Wilson 1994]. The value of such beneficiation processes needs to be evaluated on a case by case basis.

Applications of High Performance Concrete

HPC has been used in prestigious structures such as the Petronas Towers and the Troll Platform. Petronas Towers was the tallest concrete building in the world built in Malaysia in the mid-1990s. In 1998, the deepest offshore platform, the Troll platform, was built in Norway — a structure taller than the Eiffel Tower.

In most applications, one key performance criterion may be critical but so are a number of associated criteria. It is interesting to examine a range of HPC according to their key performance criterion.

Production as Key Criterion

Self-Leveling Concrete for Foundation of Raffles City — Singapore

In order to satisfy the requirement for a large volume of concrete to be placed rapidly in huge foundation elements, a non-segregated flowing and self-leveling concrete was developed [Collepardi 1976] by the use of a superplasticizer combined with a relatively high content of powder materials in terms of Portland cement, mineral additive, ground filler, and/or very fine sand. In late 1970, such a concrete was placed

FIGURE 42.3 Concrete placing at Raffles City, Singapore.

with tremie for the construction of a dry dock [Collepardi et al. 1989]. It was also used in a system of inclined-chutes and distribution boxes for the slab foundation of the Trump Tower in New York in the late 1970s and the Raffles City in Singapore in the early 1980s. Cracking due to differential temperature movement was controlled by limiting the fresh concrete temperature at placement. This type of concrete was subsequently placed in large structural members with highly congested steel and can possibly be considered as the earlier version of self-compacted concrete (SCC) (Fig. 42.3).

Bottom Up Placement at Market City — Australia

A key feature of the Market City project (a 36-story residential tower over a 10-story podium incorporating the new Paddy's Market as well as a range of retail tenancies and cinemas) is the use of high-strength concrete-filled steel tube columns. The system combined the tube column and parallel beam concepts. The combination works well with one of the advantages being the minimization of moment transfer from the floors into the columns, thus allowing minimum column sizes to be used. The concrete was specially formulated to minimize bleeding and was pumped up from the base of the tube without vibration. A full-scale 13-m high prototype column was built prior to construction and used to investigate a number of factors including the construction procedures and the performance of the proposed concrete mix.

The mix finally adopted was an 80 MPa concrete at 28 day. Silica fume and fly ash were used and the maximum aggregate size was 14 mm. A superplasticizer was used to increase the slump from the initial 30 to 35 mm to a value of 200 mm. Actual strengths of up to 100 MPa were achieved. Core samples taken from the prototype column at various levels confirmed that a very dense uniform mix was achieved with no separation from the tube wall. No settlement voids were found in core samples taken around reinforcing bars (Fig. 42.4).

In-service Performance as Key Criterion

High Strength Concrete Projects

Silica fume and fly ash has been widely used since 1980 to produce high strength concrete for high rise buildings. Some silica fume concrete data used in a number of structures in Australia are summarized in Table 42.1. Some of the advantages of silica fume concrete include the ability to obtain high early

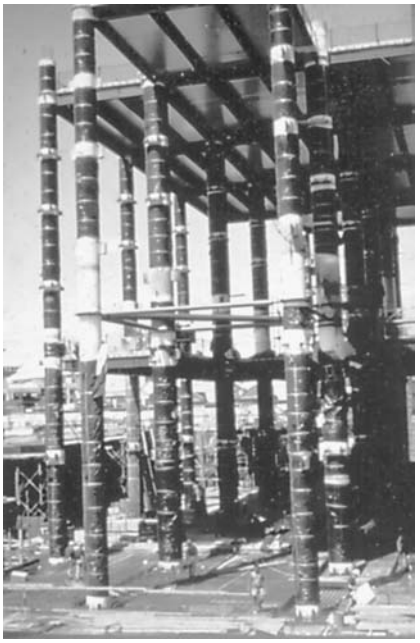

FIGURE 42.4 Steel tube columns at Market City, Australia.

TABLE 42.1 Details of Silica Fume Concretes Used in Selected Melbourne Projects

Structure	Final Slump (mm)	W:B Ratio	28-day Comp. Strength	Drying Shrink. (μstrain)	Mod of Elast. (GPa)	Creep (μstrain/MPa)	Flexural Strength (MPa)
Melbourne Central	160	0.30	89.5	590	38.3	31.5	—

Notes: Final slump was measured after superplasticiser inclusion, modulus of elasticity and flexural strength measured at 28 days, drying shrinkage values are those measured at 56 days.
(After Burnett 1990)

strengths and reduced creep characteristics. The general drawback is the increase in water demand of the concrete due to the fineness of the material.

A mix design for 70 MPa high strength fly ash concrete used for the core of the main tower at the Melbourne Central project is given in Table 42.2. The mix pumped well, having an initial slump of 50 mm and rising to 170 mm in practice.

Cao et al. [1989] conducted studies into the properties of concretes made using silica fume, slag and fly ash. They concluded that the inclusion of silica fume was very effective in achieving strength in excess of 70 MPa at 28 days. Binders having silica fume coupled with either slag or fly ash resulted in concretes having a similar 28 day strength as the above mentioned mix with silica fume alone. For the triple blend mixes, an added 25 kg/m^3 of binder was needed to achieve the strength performance. The triple blend mixes were noted to have a significantly lower superplasticizing admixture demands for given weights of binder when compared to the silica fume concretes alone. In addition, the later age strength gains were greater for the triple blend concretes over the silica fume concretes alone.

TABLE 42.2 F′c (90 days) = 70 MPa Mix Proportions

Cement (kg/m$^{3)}$)	Geelong Type A (OPC)	470
Fly Ash (kg/m$^{3)}$)		150
Aggregates (kg/m$^{3)}$)	Deer Park (14 mm)	950
	Bacchus Marsh (10/7 mm)	310
Sand (kg/m^3)	Bacchus Marsh	430
Admixtures	Water reducing agent	470–600
(ml/100kg of binder)	Superplasticiser	400–800
Water (l/m^3)	Maximum	180

FIGURE 42.5 Towers with batch plant, Malaysia.

In 1998, the tallest concrete building in the world, the Petronas Twin Towers, was built in Malaysia. A silica fume/fly ash blended cement concrete was successfully used to produce high strength, high pumpability with low heat of hydration (Fig. 42.5).

Hibernia Offshore Platform — Grand Banks, offshore Newfoundland, Canada

The Hibernia Offshore Platform was reported by Hoff [1998] to be a gravity base structure (GBS) built for the recovery and processing of hydrocarbons on the Grand Banks, 315-km offshore Newfoundland in 80 m of water (Table 42.3). The platform is essentially a cylindrical concrete caisson that extends from the seabed to 5 m above the waterline. Four shafts extend above the caisson another 26 m to support all the equipment (Topsides) of the platform. It was designed to resist the impact of icebergs in a severe marine environment. It is expected to have a service life for as long as 70 years. The concrete used will undergo continual wetting and drying by seawater, seasonal freezing and thawing, abrasion from floating debris (principally ice), and be subjected to both operational and accidental loads. The concrete had a design strength of 69 MPa but produced concrete typically averaged 80 MPa. The majority of the concrete was pumped and placed by slipforming. The structure was constructed in the period of December 1991 and November 1996.

TABLE 42.3 Hibernia Offshore Platform Concrete Specifications

Performance Requirements		Specifications	
Type	Attributes	Test	Criteria
Physical	Density	Use of normal and light weight aggregate	Unclear
	Watertight	Water permeability under 2760 kPa	10^{-14} m/s
Mechanical	Strength	Compressive strength, MPa	69 at 1 year
	Volume stability	Drying shrinkage and Creep in 23 ± 1°C, 75 ± 4%RH	Tested
Durability	Abrasion	Compressive strength, MPa	49 at 1 year
	Alkali-silica reactivity	Na_2O equivalent [Fournier et al. 1994]	0.72%
	Freezing and thawing in the splash zone	Air entrainment, and ASTM C666 Proc. A	5 ± 1%
	Resistance to chloride	ASTM C1202, coulomb	<1000
Production	Crack controlled	Maximum temperature	70°C
		Max temperature gradient within concrete section	20°C in 300 mm

Performance Requirements		Specifications	
Type	Attributes	Test	Criteria
Physical	Consistent Density	Density, kg/m^3	2260 ± 40
Mechanical	28-day Strength	Compressive strength, MPa	40
	Volume stability	56-day Drying shrinkage, μstrain	500
Durability	Low permeability	Water to binder ratio	0.38
	Crack control	Maximum crack width	0.1 mm
Production	Workability	Initial and superplasticized slump	65 and 150
	Crack controlled	Peak adiabatic temperature rise	40°C
	Strengths	3-day tensile and	2.5 MPa
		5-day compression	10 MPa

Harbour Tunnel — Australia

The Sydney Harbour Tunnel is a 2.3-km long land and underwater tunnel linking the northern and southern suburbs of Sydney. The underwater section is approximately 1 km in length and was constructed from eight precast concrete 'immersed tube' units, floated into position and then sunk into a prepared trench in the harbour bed. The multi-cell immersed tube units were cast at Port Kembla, 60 kms south of Sydney. Concrete thicknesses are typically in the order of 1 m. A HPC was specified for the units as they were required to meet a number of severe constraints, the most important of which are as follows:

- design life of 100 years
- low permeability with high resistance to chloride ingress
- limited cracking from thermal and drying shrinkage effects
- predictable and consistent density (to suit strict tolerances on buoyancy of the floated units)
- composition from readily available materials at an economical price, with consistently high quality control over a two year period.

The specification for the concrete was developed in the mid-1980s and is summarized in Table 42.4.

A blended cement comprising a 40/60 blend of portland cement and slag was selected. The total binder content was 380 kg/m.^{3} The laboratory testing was followed by the construction of a full scale prototype section of wall and floor by the contractor. This trial proved to be extremely valuable for testing construction

FIGURE 42.6 Picture of SHT unit, Australia.

procedures, fine tuning reinforcement retailing, and the like. The trial wall was also instrumented to record temperature and strain profiles against time. Crack widths were also measured against time and generally stabilized after a few days at 0.05 to 0.08 mm, within the 0.05- to 1.0-mm range predicted from earlier finite element analyses (Fig. 42.6).

Parallel Runway Sea Wall — Australia

HPC was specified for major elements in the new Parallel Runway project at Sydney's Kingsford Smith Airport, particularly in the runway and main taxi ways, the sea wall, sewer outfalls and the taxiway bridges.

In the case of the Sea Wall (Fig. 42.7), durability was the key issue for the concrete used. *A 100-year design life was required*. The construction comprised a "reinforced earth" wall faced with reinforced concrete panels and wave deflectors of approximately 180 to 200 mm thickness. The concrete was required to comply with the following specifications shown in Table 42.5 [Laurie and Gross 1993].

The concrete selected was a 90/10 blend of OPC and silica fume mix with a binder content of 380 kg/m^{3}and a well-graded aggregate. A combined water reducer/retarder and a superplasticizer were used to produce a working nominal slump of 100 mm. The reinforced concrete panels and wave deflectors were manufactured at a precast plant, which is approximately 40 km from the site.

Sustainability as Key Criterion

Consideration for sustainability in concrete is a relatively new concept. One key performance criterion adopted is in limiting the greenhouse gas associated with the production of binder such as Portland cement. However, the scope is considerably wider as discussed in the section on Concrete for Sustainable Development.

FIGURE 42.7 Aerial picture of seawall around Sydney Parallel Runway, Australia.

TABLE 42.5 Sea Wall Concrete Specifications

Performance Requirements		Specifications	
Type	Attributes	Test	Criteria
Physical	Consistent density	Density, kg/m^3	2400 ± 20
Mechanical	28-day Strength	Compressive strength, MPa	40
	Volume stability	56-day Drying shrinkage, μstrain	600
Durability to AS3600	Low permeability	Water to cement ratio	0.38
		Minimum binder content, kg/m^3	380
		Chloride permeability, coulomb	1000
Production	Workability	Slump, mm	80
	Strengths	20 hours Compressive strength	7 MPa

42.4 Self-Compacting Concrete

D.W.S. Ho

In terms of construction, self-compacting concrete (SCC) is a relatively new technology. Since its introduction over 10 years ago in Japan, the concept of SCC has captured the imagination of researchers and practitioners around the world. This material can be considered as a high performance composite, which flows under its own weight over a long distance without segregation and without the use of vibrators. For the past decade, the focus on SCC has been on its fresh properties. Research and practical experience were well documented in the first symposium of self-compacting concrete held in Stockholm [RILEM

1999], and later in the state-of-the-art RILEM report [2000]. More information, particularly hardened properties, can be found in the second symposium held in Tokyo [SCC 2001].

The complete elimination of the consolidation process in SCC can lead to many benefits. Besides the obvious benefit of improved concrete quality in difficult sites relating to access and congested reinforcements, the use of SCC increases productivity, reduces the number of workers on site, and improves working environment. The reduction in overall construction cost could be around 2 to 5%. Depending on competition, the supply cost of SCC could be from 10 to about 50% higher than that of conventional concrete of similar grade. This leads to the low consumption of SCC in practice amounting to less than 5% of total concrete production. With improved quality control by suppliers and increased competitiveness in the market, the use of SCC is accelerating in many developed countries.

Fresh SCC must possess high fluidity and high segregation resistance. Fluidity or deformability means the ability of the flowing concrete to fill every corner of the mould as well as the ability to pass through small openings or gaps between reinforcing bars, often referred to as filling ability and passability of SCC respectively. To satisfy this high fluidity requirement, the maximum size of aggregate is generally limited to 25 mm. To improve flow properties, the amount of coarse aggregates is reduced and balanced by the increase in paste volume. Superplasticizer is needed to lower the water demand while achieving high fluidity. The common superplasticizer used is a new generation type based on polycarboxylated polyether, which is considerably more expensive than the traditional type used in conventional concrete. For SCC to have high segregation resistance, high powder content ranging from 450 to 600 kg per cubic meter of concrete should be specified. Powder generally refers to particles of sizes less than 0.125mm. Since cement content of 300 to 400kg/m^3 is often available, SCC usually incorporates 150 to 250 kg/m^3 of inert or cementitious fillers. Limestone powder is the common filler used, with fly ash and blast furnace slag enjoying increased popularity. Viscosity agent is sometimes incorporated to minimize the addition of fillers. This admixture is similar to that used in under-water concreting. It increases the viscosity of water, thereby increasing segregation resistance.

The rheology of fresh concrete is most often described by the Bingham model. According to this model, fresh concrete must overcome a limiting stress (yield stress, τ_o) before it can flow. Once the concrete starts to flow, shear stress increases with increase in strain rate as defined by plastic viscosity, μ. The target rheology of SCC is to reduce the yield stress to as low as possible so that it behaves closely to a Newtonian fluid. The other target property is "adequate" viscosity. The addition of water reduces both the yield stress and viscosity. Too much water can reduce the viscosity to such an extent that segregation occurs. The incorporation of superplasticizer reduces the yield stress but causes limited reduction in viscosity. The use of Bingham parameters is useful in describing the behavior of fresh concrete, but there is no consensus, at least at this stage, on their limiting values appropriate for SCC.

For site quality control, tests requiring simple equipment are often performed to indicate qualitatively or quantitatively the three basic properties of SCC: filling ability, passability, and segregation resistance. Slump-flow test is the most popular test method used because of it simplicity. A representative sample of concrete is placed continuously into an ordinary slump cone with a jug without tampering. The cone is lift and the diameter of the concrete (i.e., slump flow value) after the concrete has stopped is measured. The time to reach a flow diameter of 500 mm and final flow diameter are also noted. The degree of segregation can be judged to a certain extent by visual observation. This test reflects the filling ability, but the passability is not indicated. L-box, U-box, and V-funnel are other common tests available to assess one or more of the basic properties of SCC. Details of these tests can be found in the state-of-the-art RILEM document [2000].

42.5 High Volume Fly Ash Concrete

V. Sirivivatnanon

Fly Ash and High Volume Fly Ash Concrete

The use of fly ash (FA) in structural concrete dates back to 1937 [Davis et al. 1937] with the construction of the Hungry Horse Dam in the U.S. in 1948 and Keepit Dam in Australia in 1957. Its early use in mass concrete structures was in order to reduce the heat of hydration. With the introduction of concrete pump in the 1970s, fly ash concrete was popularly used as pumpable concrete mixture especially in areas where there was a shortage of well-graded sand. In this case, the amount of fly ash (ASTM C618 Type F or its equivalence) in typical concrete mixtures varies from 60–100 kg/m.^{3} This represents about 20 percent or less by weight of the total binder used. This typical dosage also probably reflects the optimum fly ash content in terms of cost related to compressive strength [Butler 1988]. However, when durability is of prime concern, the optimum dosage would need to be re-examined [Sirivivatnanon and Khatri 1998].

High volume fly ash (HVFA) concrete usually refers to structural concrete with fly ash content substantially higher than that used in conventional fly ash concretes. The concept of high volume replacement of cement with fly ash was recognized more than 35 years ago [Mather 1965]. Structural grade high fly ash content concrete has been tried at Didcot Power Station in 1981 [Proctor and Lacey 1984]. The Canadian Centre for Mineral and Energy Technology (CANMET) has carried out a major research project developing high volume fly ash concrete since 1985 [Malhotra 1985]. CANMET has adopted the approach of producing concrete with high volume (>50%) of low-calcium fly ash with water to cementitious materials ratio of 0.32 and a relatively high dosage of superplasticizer to achieve the required consistency. In the U.K., the focus has been on slightly higher water to cementitious materials ratio of 0.40 or more [Swamy and Hung 1986], and the addition of a small amount of highly reactive pozzolan such as silica fume to accelerate early hydration reactivity [Swamy and Hung 1998]. In Australia, a range of HVFA concrete was developed by the CSIRO in the late 1980s [Sirivivatnanon et al. 1995] and concrete with fly ash making up to 40–50 percent by weight (wt.%) of binder was first tried in a large scale in 1991 [Sirivivatnanon et al. 1993]. With the emphasis on concrete with similar fresh concrete characteristics as conventional concrete, the Australian industry has preferred HVFA concrete with no more than 40 wt.% of binder. HVFA concrete is now commonly specified for concrete exposed to aggressive chloride or sulphate environment in the eastern states in Australia. In Japan, HVFA porous concrete is being developed for concrete structures in river or seashore from the viewpoint of providing habitat for living organisms [Torii et al. 2001]. In this chapter, concrete with 30 wt.% and above of binder is classified as HVFA concrete.

Mixture Proportion and Properties

There have been different philosophies to mixture proportioning of HVFA concrete around the world. Details can be sought from literature listed in the "Further Information" section. The Australian approach and some performance data will be discussed in this section.

HVFA concretes can be proportioned using conventional mix design philosophy such as the ACI method [ACI 1989] or those originated from Road Note No. 4 [Teychenne et al. 1975]. Examples of mixture proportions given are those based on the *fixed dosage* of chemical admixture. They enable the design of concrete mixes with a reasonable amount of free water and hence a workability which does not differ significantly from conventional concrete. The *increased dosage* technique is useful in designing concrete mixes with low heat of hydration by limiting the amount of binder used.

Compressive Strength and Water-to-Binder Ratio

The compressive strength of HVFA concrete can be related to water-to-binder or water-to-cement ratio in a similar manner to Portland cement. In Fig. 42.8, the relationships between 28-day compressive strength and the water-to-binder ratio of HVFA concretes manufactured from a fly ash from New South

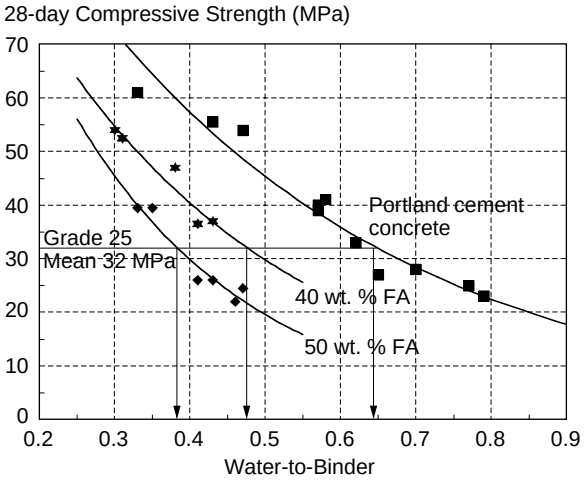

FIGURE 42.8 28-day compressive strength to water-to-binder ratio relationship.

Wales Australia, an ordinary Portland cement, and a 20 mm maximum size crushed basalt aggregate are given. While these relationships are distinguishable for different percentages of fly ash in the binder, they appear to be independent of the type of chemical admixture used. At a fixed water-to-binder ratio, lowering the percentage of fly ash results in an increase of corresponding strength of the concrete.

Fresh Concrete Properties

Water Demand

The water demand is found to depend on the type of chemical admixture used and the total binder content. Typical free water demands are given in Table 42.6. It has been found that the water demand depended more on the binder content than on the percentage of the fly ash in the binder.

Consistency, Setting Times and Early Strength

HVFA concretes generally contain higher binder contents than equivalent grade Portland cement concrete. This usually results in fresh HVFA concretes, which are more cohesive and sometimes very sticky. There is usually some delay in the setting times of HVFA concrete compared to Portland cement concrete. The extent of the delay depends on the particular cement and fly ash combination. In Fig. 42.9, the setting times of Waurn Pond (WP) cement and its combinations with 40 wt.% fly ashes from Eraring (E) and Vales Point (VP) are given. The delays in initial and final set are of the order of 1 and 1.5 hours, respectively. While these lengths of delay are quite acceptable in most applications, the use of a certain type of chemical admixture with a particular cement/fly ash combination could cause an unacceptable length of delay. Precaution should therefore be taken in checking the compatibility between all concreting materials prior to the production of HVFA concretes.

The early strength development of HVFA concrete is found to be slightly lower than Portland cement concrete as shown in Fig. 42.10. The 7-day to 28-day compressive strength ratio was 0.61 and 0.53 for Portland cement and HVFA concretes, respectively.

Mechanical Properties

Three specific types of hardened concrete properties are of interest to engineers. They are mechanical, volume stability and durability properties. In evaluating these properties of HVFA concrete, comparisons are usually made to Portland cement concrete of equivalent 28-day compressive strength.

For specific structural grades, the nominal water-to-binders of Portland cement and HVFA concrete are given in Table 42.7. It should be noted that HVFA concretes have W/B ratio ranging from 0.12 to 0.16 below Portland cement of equivalent grade. These differences will prove to be of significance in durability performance as discussed in a subsequent section.

Note: 1. Creep rate is given in 10^{-6} MPa/ln(t + 1).

Typical mixture proportions of two series of concretes are given in Table 42.8. The first L series is a low 50 ± 15 mm slump HVFA and portland cement concretes designed for pavements (and other slab applications). The other H series are pump mixes with 100 ± 25 mm slump HVFA and portland cement concretes developed for other structural works.

The mechanical properties of the mixtures given in Table 42.8 are summarized in Tables 42.9 and 42.10. The results indicated that the flexural strength and elastic modulus of HVFA concretes are similar to

Portland cement concretes of equivalent 28-day compressive strength. HVFA concretes can thus be used for concrete structures in the same manner as Portland cement concretes. Their elastic properties can also be predicted from the compressive strength and density (ρ) in the same manner as portland cement concretes as given in Concrete Structures standard such as the Australian Standard AS 3600 [SAA 1988].

Drying Shrinkage and Creep Characteristics

HVFA concretes can have a similar or up to 20% lower drying shrinkage than portland cement concretes. The reductions in shrinkage are more significant in concretes of lower grades. Typical drying shrinkages at 56 days for both the low and high slump concretes are given in Tables 42.9 and 42.10. The shrinkage values are well below 700×10^{-6} recommended in AS 3600. The increase in drying shrinkage with time up to 91 days for Portland cement and HVFA concrete is shown in Fig. 42.11 for the pump mix H-series. The reduction in shrinkage of HVFA concrete can be observed as early as 28 days for the lower grade 20 concrete. This trend remains up to 91 days and beyond.

The creep characteristics of concrete are significantly improved with the use of high volume of fly ash as shown in Fig. 42.12. A creep rate, F (K), is determined from the slope of the line relating creep strain per unit stress to the natural logarithm of time $\log_e(t+1)$ where t is the time of loading in days. The creep rates were reduced by 40 and 55 percent in grade 32 and 20 HVFA concretes respectively compared to portland cement concretes of equivalent 28-day compressive strength as shown in Table 42.10. There can therefore be clear advantages in the use of HVFA concretes for structural members that are sensitive to high creep strain such as long span bridge girders and columns in high rise buildings.

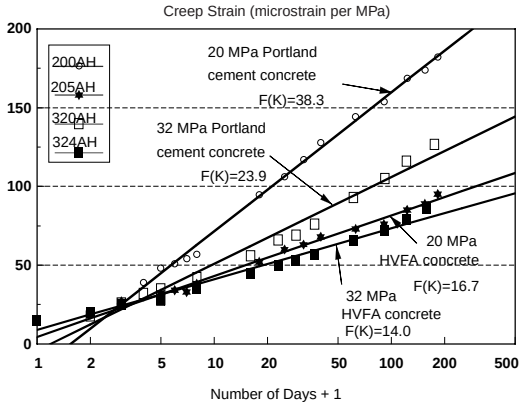

FIGURE 42.12 Strain due to creep of portland cement and high volume fly ash concrete of various grades.

Durability Properties

The durability of HVFA concretes with respect to the protection of steel reinforcement against corrosion and the resistance to deterioration in sulphate environments has been studied. Three fly ashes, FA1, FA2 and FA3 from three different States in Australia were examined. Most durability studies were carried out using mortars.

It is well known that when the pH of the concrete surrounding steel reinforcement is sufficiently lowered by *carbonation* or when there is a sufficient level of *chloride ions* at the steel surface, steel corrosion occurs. This could eventually result in cracking of concrete and loss of structural integrity. The *service life* of reinforced concrete structure is closely related to properties of the concrete such as its resistance to carbonation, carbonation-induced steel corrosion, resistance to chloride penetration and chloride-induced steel corrosion. These properties of HVFA concretes are discussed in this section.

The benefit of the use of fly ash concretes in moderate sulphate environment has been recognized in current British and Australian Standards [BSI 1985, SAA 1978]. In this work, the sulphate resistance of fly ash blended cement concretes in a 5% sodium sulphate solution as well as solutions at pHs of 7 and 3 are given.

Corrosion of Steel Reinforcement

Corrosion of steel reinforcement is one of the most common durability problems in reinforced concrete structures. This problem is caused by carbonation or chloride penetration or both. Generally the deterioration of concrete due to corrosion of steel reinforcement is characterized into three stages, i.e., *initiation*, *propagation* and *accelerated corrosion*. In the initiation stage, steel is protected by its passivation in high pH condition and the absence of chloride ions. The corrosion rate (steel loss) during this stage is very small and is considered negligible for engineering purposes. When the alkalinity of the concrete surrounding the steel is lowered sufficiently by carbonation and/or when there are sufficient chloride ions at the steel/concrete interface, steel passivation is destroyed. Corrosion rate of steel becomes significant. This is the propagation stage. The accelerated corrosion stage occurs when there is severe cracking and damage to the concrete cover caused by the cumulative effect of the steel corrosion.

Carbonation-induced corrosion — The rate of carbonation or the advance of the carbonation front depends on many factors. Some of the important factors are time of exposure, the nature of cementitious matrix, its "permeability" to carbon dioxide and the condition surrounding the concrete (moisture, temperature). The carbonation rate can vary significantly with the climate. Furthermore, carbonation is not a problem in itself but carbonation-induced corrosion of steel reinforcement is. Hence it is necessary to consider the corrosion rate in conjunction with the carbonation rate.

With the length of long-term exposure limited to two years in a standard laboratory condition of 23°C 50% RH, a condition that results in a significantly higher carbonation rate than that expected in an exposed outdoor condition, the depth of carbonation of a range of Portland cement and HVFA concretes is compared on the basis of equivalent 28-day compressive strength (F_c). Figures 42.13 and 42.14 show

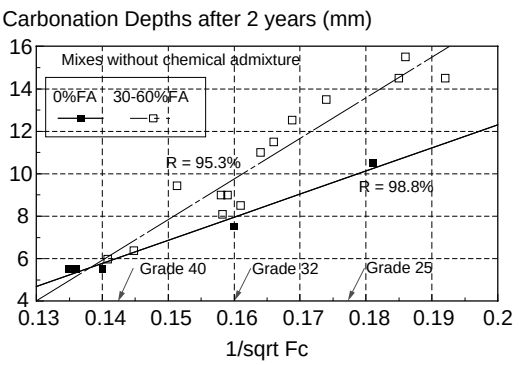

FIGURE 42.13 Carbonation depth of concretes without chemical admixture after 2 years exposure in 23°C 50% RH.

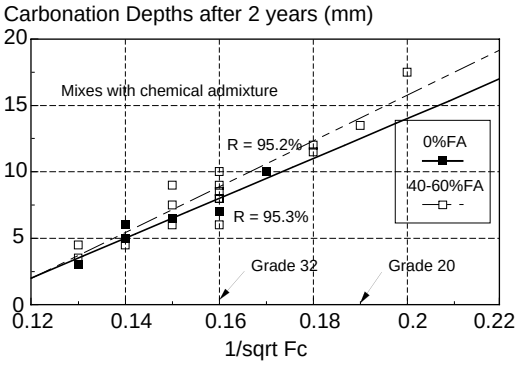

FIGURE 42.14 Carbonation depth of concretes with chemical admixture after 2 years exposure in 23°C 50% RH.

the relationship between carbonation depth and the reciprocal of the square root of compressive strength 1/sqrt F_c of concretes proportioned without and with chemical admixture respectively.

For concretes without chemical admixture, the carbonation depth of HVFA concretes can be higher than that of corresponding portland cement concrete as shown in Fig. 42.13. The differences in the carbonation depth of the two concrete increases with the reduction in the strength level.

For concretes designed with a standard chemical admixture dosage, that is 400 ml of water reducer or 1000 ml of superplasticizer per 100 kilogram of binder, the differences in the carbonation depth of HVFA and portland cement concretes, as shown in Fig. 42.14, are not significant especially for concretes in the grade range of 25–32 MPa. According to AS 3600, grades 25 and 32 are recommended for exposure classification A2 and B1. These classifications cover the conditions where carbonation could pose a threat to the durability of concrete structures.

It is noted that HVFA concretes designed with chemical admixtures are the types of structural concrete that should be chosen for most building and civil engineering works. Based on the short-term data, these HVFA concretes would be expected to perform as well as Portland cement concretes.

Chloride-induced corrosion — Chloride ions can penetrate into concrete through the effect of concentration gradient and/or through the effect of capillary action. The mechanism of chloride penetration is often described as diffusion. This may be an over simplification for the process. The transportation of ionic species into a concrete medium is complicated. This is because of the possible reactions between the chloride ions and the hydrates that constantly alter the pore system. Regardless of the mechanism of transportation of chloride ions, it is known that when the amount of chloride ions at the steel/concrete interface is higher than a critical concentration, steel corrosion will occur. This critical chloride concentration is called the *chloride threshold* level. It is also known that chloride threshold level depends on binder content and the chemistry of the pore solution.

It has been suggested that the hydroxyl concentration is the controlling factor with regard to the chloride threshold level. A relationship, such as $Cl^-/OH^- = 0.6$, has been suggested for the estimation of chloride threshold level. Recent work by *Cao* et al. [1992] indicated that this is not the case since blended cements can have similar chloride threshold level to Portland cements despite having lower OH^- concentrations in their pore solution.

When passivity of steel cannot be maintained, corrosion of steel occurs. The service life of a reinforced concrete structure is directly related to the development of the corrosion and its rate. However, it must be stressed that the mode of corrosion should also be considered. For example, metal loss due to pitting corrosion may be much smaller than that of general corrosion. However, the effect of pitting corrosion (concentrated metal loss in a small area) can be very dangerous to the integrity of the structure in terms of loss in load carrying capacity.

The detection of corrosion and the measurement of corrosion rate of steel can be used to compare the behavior of different binders in the *initiation* and *propagation* stages of the deterioration. One of the

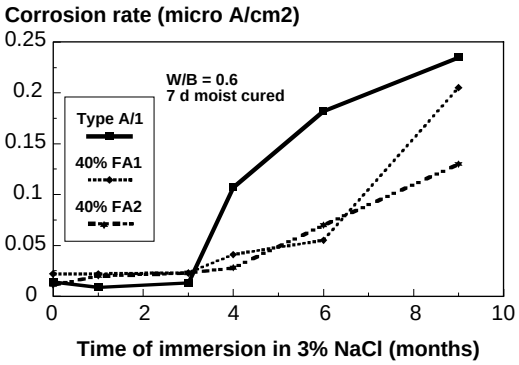

FIGURE 42.15 Effect of binder on the corrosion rate of steel embedded in 7-mm thick mortars.

possible methods of comparatively assessing the initiation stage is by monitoring the corrosion rate of steel embedded in concrete or mortar. The change in corrosion rate from "negligible" to "significant" can be used to determine the effect of binder type on initiation period. These data are presented in Fig. 42.15. The corrosion rate was determined by using polarization resistance technique. It must be stressed that the initiation stage is controlled by the rate of chloride penetration, the chloride threshold level, and the concrete cover thickness.

The effect of 40 wt.% fly ash binder systems on the development of corrosion of steel is shown in Fig. 42.15. From this figure, it can be seen that the use HVFA binders leads to a similar or longer initiation period as compared to portland cement mortar of the same W/B and with limited initial curing period of 7 days. The cover of the mortars over steel sample in this case is about 7 mm. It can be seen that the initiation period where the corrosion rate of steel is negligible for this configuration is about 3 months for portland cement and about 3 to 4 months for both HVFA binders. It is expected that for a realistic concrete cover in a marine environment, say about 50 mm, the effect of HVFA binder in terms of the increase of the initiation period will be further magnified. This conclusion is based on better chloride penetration resistance performance data at larger cover depths [Thomas 1991, Sirivivtnanon and Khatri 1995] and the lower W/B ratio used to produce HVFA concrete of the same strength grade as portland cement concrete (Table 42.2). The propagation period, characterized by significant corrosion rate, is also a very important to the maintenance-free service life. The main reason is that, for a binder system in which a low corrosion rate can be maintained, the service life will be prolonged by an extended propagation period.

The effect of fly ash on the corrosion rate of steel embedded in mortars W/B ration of 0.4 and cured for 7 days, is shown in Fig. 42.16. It is clear that the use of high volume fly ash binder systems can result

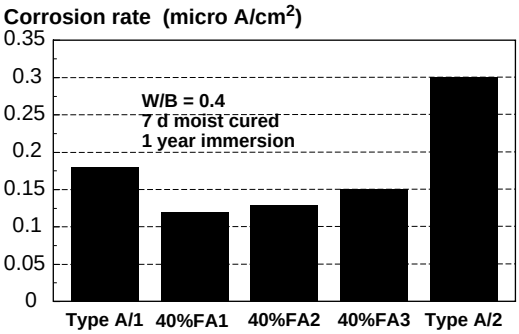

FIGURE 42.16 Effect of binder on the corrosion rate of steel embedded in 7-mm thick mortars after 1 year of immersion in 3% NaCl.

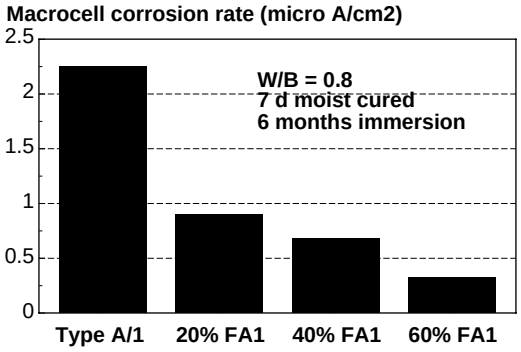

FIGURE 42.17 Effect of varying dosage of fly ash on the *Macrocell* corrosion rate of steel after 6 months of immersion in 3% NaCl.

in reduced corrosion rate of steel in comparison to the Portland cements. The extent of the reduction depends on the source of the fly ash.

It should be noted that the corrosion rate mentioned above is that of *microcell* corrosion rate where the anode and cathode of the corrosion cell are in close proximity and sometimes are not physically distinguishable. For most reinforced concrete applications, there are situations where the anode and cathode of the corrosion cell can be physically separated. In such a situation, termed *macrocell* corrosion, the characteristics of the concrete, such as the resistance to ionic transportation and its resistivity, will have important influence on the corrosion rate of steel. By using fly ash blended cement, both of these characteristics of the concrete will be improved and hence the corrosion rate will be reduced. This has been confirmed experimentally as shown in Fig. 42.17 in which the macrocell corrosion rates were determined using a model of equal areas of anode (chloride contaminated area) and cathode (chloride free area) and the mortar medium was 15 mm. It can be seen that the beneficial effect of HVFA binder systems in reducing the macrocell corrosion rate compared to Portland cement mortar of the same W/B is very significant. The effect of increasing the fly ash proportion on the reduction of macrocell corrosion rate is also clearly evident.

The overall conclusion is that the use of HVFA concrete can result in extended maintenance-free service life of reinforced concrete structure in marine environments. This is based on its potential in increasing the initiation period and reducing the corrosion rate in the propagation period of the deterioration process due to chloride-induced corrosion of steel reinforcement.

Sulphate Resistance

Sulphate resistance of a cementitious material can be broadly defined as a combination of its *physical* resistance to the penetration of sulphate ions from external sources and the resistance of the *chemical* reactivity of its components in the matrix to the sulphate ions. Both factors are important to the overall resistance to sulphate attack of a concrete structure. However, the chemical resistance to sulphate attack is considered to be more critical for long-term performance. The physical resistance can be improved by good concreting practice such as the use of concrete with low W/B, adequate compaction and extended curing. The extent of chemical reactivity of hardened cement paste with sulphate ions, on the other hand, depends very much on the characteristic of the binder system. It may appear obvious that for a long service life, a good concrete is required. However, this will be better assured if the concrete is made from a binder that has low "reactivity" with sulphate ions.

Sulphate resistance of cementitious materials can be assessed by a variety of methods. The performance of two fly ashes and three Portland cements was examined in terms of *expansion characteristic* and *strength development* of mortars immersed in 5% Na_2SO_4 solution. In addition, the performance of mortars in 5% Na_2SO_4 solution at lower pHs of 3 and 7 were determined.

All the expansion mortars were made with a fixed sand-to-binder ratio of 2.75 and variable amount of water to give a similar flow of 110 ± 5%. In most cases, the fly ash mortars had lower W/B than

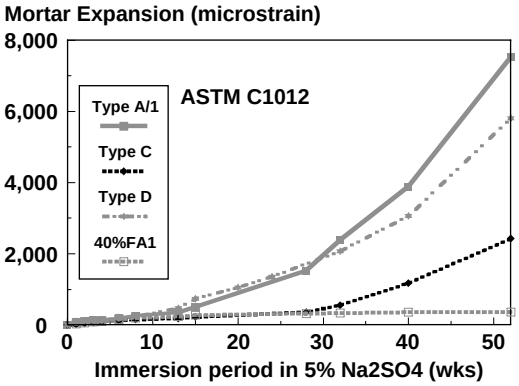

FIGURE 42.18 Expansion of mortar bars in 5% Na_2SO_4 solution to ASTM C1012.

Portland cement mortars. When a test was performed to ASTM C1012 [1989], the samples were cured for 1 day at 35°C and subsequently at 23°C until they reached a compressive strength of 20 MPa before immersion in the Na_2SO_4 solutions. Mortars used in the evaluation of compressive strength retention had the same sand-to-binder ratio of 2.75 and a W/B ratio of 0.6.

Apart from two fly ashes, FA1 and FA2, the three portland cements used were Type A, C and D cement (normal, low heat and sulphate-resisting cement respectively) according the superseded AS 1315–1982.

The effect of fly ash blended cement on expansion of mortar using the ASTM C1012 procedures is shown in Fig. 42.18. A 5% Na_2SO_4 solution, without any control on the pH of the solution, was used in this case.

It can be seen that the use of 40 wt.% fly ash blended cement greatly reduces the expansion of mortar. In fact, the expansion of fly ash blended cement is much lower than that of the three Portland cements Type A, C, and D. When all the mortars were cured for a period of 3 days, the effect of both fly ashes on the reduction of expansion was also very clear, as shown in Fig. 42.19.

The improved expansion characteristic of fly ash blended cement mortars was maintained in sulphate environments of low pHs as shown in Figs. 42.20 and 42.21. In fact, the same effect has been observed for most Australian fly ashes when used at a replacement level of about 40% [1994].

Apart from a much lower expansion characteristic in sulphate environments, the use of binders with "high" fly ash percentage leads to superior strength retention in a sulphate solution. Figure 42.22 shows that for most Portland cements, the loss of compressive strength was observed after about 6 months in sulphate solution. Whereas, the 40 wt.% fly ash blended cement mortars showed strength increases even after 1 year.

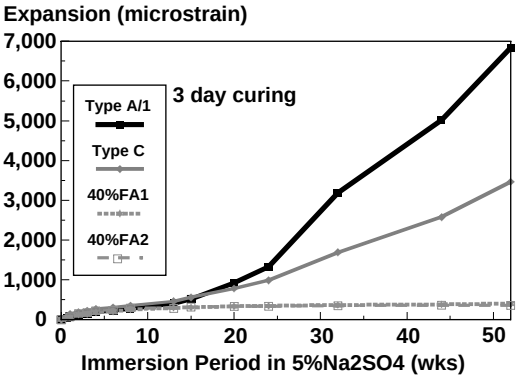

FIGURE 42.19 Expansion of mortar bars in 5% Na_2SO_4 solution to ASTM C1012 but with 3 days moist curing.

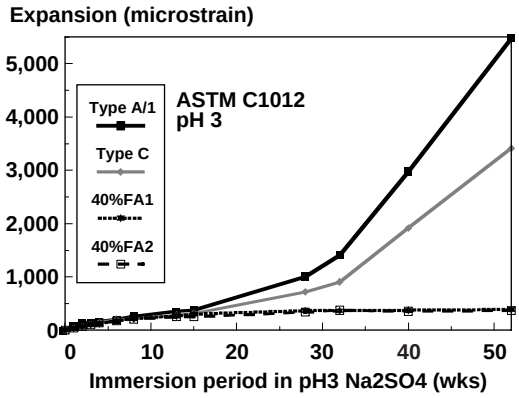

FIGURE 42.21 Expansion of mortar bars in a 5% Na_2SO_4 solution (low pH 3) to ASTM C1012.

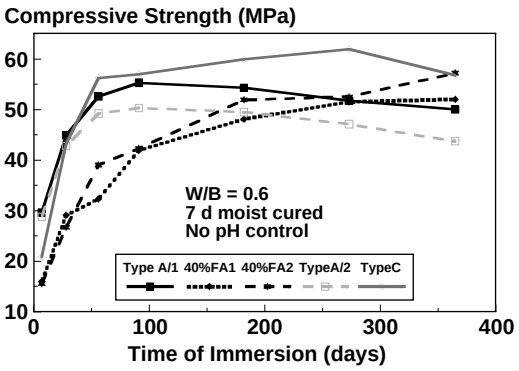

FIGURE 42.22 Compressive strength of mortars after different periods of immersion in sulphate solution.

In low pH sulphate solutions, the beneficial effect of high replacement fly ash binder was even more pronounced as shown in Figs. 42.23 and 42.24.

The results clearly indicate that for concrete application in sulphate environment, particularly in those where the pH is low, the use of HVFA concrete has the highest probability of extending the service life.

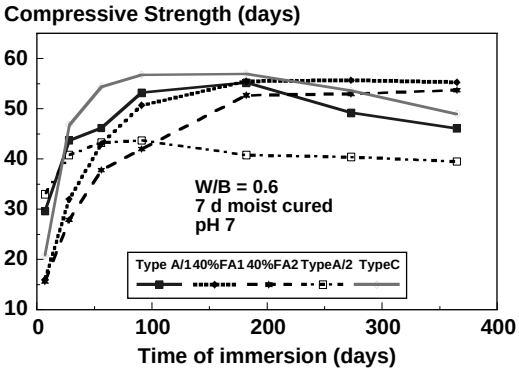

FIGURE 42.23 Compressive strength of mortars after different periods of immersion in a pH 7 sulphate solution.

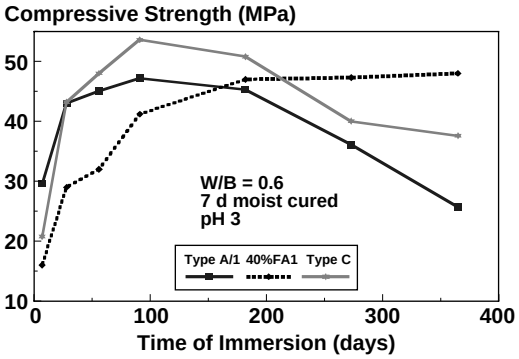

FIGURE 42.24 Compressive strength of mortars after different periods of immersion in a pH 3 sulphate solution.

Optimum Dosage for Durability

In marine and sulphate environments, the optimum dosage of fly ash has not been strictly determined but is expected to be around 40 wt.%. When the proportion of fly ash by weight exceed about 50%, the lowering in compressive strength becomes significant. With the present cost structure of concreting materials including fly ash, a HVFA concrete with 40 wt.% fly ash is marginally more expensive than portland cement concrete of equivalent strength grade. However, with the significantly increased expected service life, it is argued that the optimum dosage with respect to service life of HVFA concrete would be around 40% by weight of binder.

Basis for Applications

Sufficient knowledge is now available on the design, production and properties of HVFA concrete for its applications to be identified. The inherent properties and limitations of HVFA concrete are the keys to its selection in suitable applications. They are given in relative terms to the properties of Portland cement and conventional fly ash concrete as follows:

- good cohesiveness or sticky in mixes with very high binder content;
- some delay in setting times depending on the compatibility of cement, fly ash and chemical admixture;
- slightly lower but sufficient early strength for most applications;
- comparable flexural strength and elastic modulus;
- better drying shrinkage and significantly lower creep;

- good protection to steel reinforcement in high chloride environment;
- excellent durability in aggressive sulphate environments;
- lower heat characteristics; and
- low resistance to de-icing salt scaling [Malhotra and Ramenzanianpour 1985].

Built Structures

Examples of built structures are given in accordance with the primary basis for which HVFA concrete was selected. It is emphasised that the fresh and mechanical properties were usually comparable to conventional concrete it replaced unless highlighted. The economy of HVFA concrete depends on the transport cost. This has resulted in the tendency for its popularity in locations near the supply sources.

Pioneering Firsts

High volume fly ash concretes have already found applications in major structures in many countries. The first field application in Canada, carried out in 1987, was reported by Malhotra and Ramenzanianpour [1985]. This consisted of the casting of a concrete block, 9m × 7m × 3m, at the Communication Research Centre in Ottawa. The block, cast indoors in permanent steel forms, is being used in vibration testing of components for communication satellites and was required to have as few microcracks as possible, a compressive strength of at least 40 MPa at 91 days, and a Young's modulus of elasticity value of at least 30 GPa. The mixture proportions are: 151 kg/m^3 Portland cement ASTM type II, 193 kg/m^3 of ASTM Class F fly ash, 1267 kg/m^3 coarse aggregate, 668 kg/m^3 fine aggregate, 125 kg/m^3 water, 5.6 kg/m^3 superplasticizer, and 680 mL/m^3 AEA. The recommended placing temperature of the concrete and ambient temperature was 7° and 24°C, respectively. At the end of placing, the temperature was reported to be 12°C because of delays in placing. A peak temperature of 37.5°C was reached in the block after 7 days of casting at which time the block was performing satisfactorily for the intended purposes. In 1988, *Langley* [1988] reported its use in the Park Lane and Purdys Wharf Development in Halifax, Nova Scotia, Canada. It is also believed that a 40 to 50% wt. fly ash concrete was used in the construction of the caissons of the famous Thames River Flood Barrier in London and in bridge foundations in Florida by the Florida Department of Transportation.

In 1992, Nelson et al. [1992] reported the application of concrete with 40% wt. fly ash in the construction of sections of road pavement and an apron slab at Mount Piper Power Station in New South Wales, Australia. The casting of the apron slab is shown in Fig. 42.25. At about the same time, Naik et al. [1992] reported the successful use of three fly ash concrete mixtures, 20% and 50% ASTM C618 Class C fly ash and 40% ASTM C618 Class F fly ash to pave a 1.28 km long roadway in Wisconsin.

Service Life Designs

The largest volume of HVFA concrete used in Australia was in the construction of the basement slabs and walls of Melbourne Casino in 1995. Figure 42.26 shows concreting activities on the site. According to *Grayson* (pers. Comm.), of Connell Wagner, low drying shrinkage and durable concrete was required for the construction of the 55,000m^2 basement which was located below the water table. Saline water was found on the site situated near the Yarra River. Slabs with an average thickness of 400 mm were designed to withstand an uplift pressure of 45 kPa. The concrete was specified to contain at least 30 kg/m^3 of silica fume or 30 wt.% of fly ash or 60 wt.% of a combination of slag and fly ash. Drying shrinkage within 650 microstrains was also specified. A 40 MPa HVFA concrete containing 40 wt.% fly ash was selected for the 40,000 m^3 of concrete required for the basement. The fresh concrete was reported to behave similarly to conventional concrete and a drying shrinkage of lesser than 500 microstrains was achieved. In addition, a similar concrete was used in the construction of the pile caps and two raft slabs in the same project. In Malaysia, concrete containing 30 wt.% fly ash was used for the substructure and piers of the Malaysian-built half of the Malaysia Singapore Second Crossway in 1996 (Fig. 42.27). The HVFA concrete was chosen for its chloride and sulphate resistance [Sirivivatnanon and Kidav 1997]. Ordinary Portland cement concrete was used for the superstructure of the Crossway.

One interesting application recently reported [Mehta and Langley 2001] is the use of unreinforced HFVA concrete in the construction of the foundation of the San Marga Iraivan Temple along the Wailua River in Kaua'i, Hawaii. This is a unique temple in the Western Hemisphere as it is constructed of hand carved white granite stone from a quarry near Bangalore in India. The temple is constructed of highly durable stone, which will contribute to the design service life of 1000 years. The foundation slab was required not to settle more than approximately 3.2 mm in a distance of 3.66 meters because the free-standing components such as columns and lintels would separate beyond safe limits. The temple foundation was designed to have low shrinkage, slow strength development, low heat evolution and improved microstructure particularly in the paste aggregate transition zone. A concrete containing a high volume of Class F fly ash was used to meet the design criteria and emulate the ancient structures.

Construction Economy

In Perth, Western Australia, a 50 wt.% fly ash concrete has been used [Ryan and Potter 1994] for the construction of the secant piles at Roe Street Tunnel. The ground water in the area was tested and found to be abnormally acidic, pH = 4.0. Thus it was necessary for all piles to contain a high binder content to limit the attack of the ground water on the concrete. A minimum binder content of 350 kg/m^3 and W/B = 0.5 was specified. The requirements posed problems for the low early-age strength needed to allow the soft piles to be bored. A number of trial mixtures were cast and the preferred option for the binder was a 50:50 Portland cement fly ash blend.

In 1990, Heeley [1999] reported the development and use of HVFA shotcrete in the construction of the Penrith Whitewater Stadium, shown in Fig. 42.28, for the Sydney Olympic Co-ordination Authority. The design was based on shotcrete because conventional formwork would have been prohibitive. In this shotcrete, ultra-fine fly ash was used to replace 44 wt.% of the binder. This provides the cohesiveness normally achieved by the use of silica fume.

Choice for Sustainability

Following the success of the use of HVFA concrete at the Liu Centre on the campus of the University of British Columbia in Canada, a range of HVFA concrete, covered by an EcoSmart™ Concrete Project, with FA contents ranging from 30 to 50 wt.% of binder was successfully used in a number of structures including the Ardencraig residential development and 1540 West 2nd Avenue — an Artist Live/Work studio near Granville Island in Vancouver, 50% *in situ* fly ash concrete and 30% fly ash concrete in precast

FIGURE 42.28 Arial view of the Penrith Whitewater Stadium showing the complexity of forms, which favors the use of shotcrete (picture courtesy of the Sydney Olympic Co-ordination Authority).

elements at the Brentwood and Gilmore SkyTrain Station, and the majority of concrete building elements at Nicola Valley Institute of Technology/University of the Cariboo in the interior of British Columbia [Bilodeau and Seabrook 2001].

With the emphasis on sustainability in the 2000 Sydney Olympic, a HVFA concrete containing 46 wt.% of binder was the chosen for slab-on-grade of a number of houses in the Athletics Village. A 56-day 20 MPa specification was used and achieved.

Current Developments

While the potential applications of HVFA concrete are numerous, three recent developments are worth noting. The first is in the use of fibre-reinforced HVFA shotcrete to cap degraded rock outcrops and to cover mine waste dumps, the second is in High Performance Concrete for massive marine structure, and the third is in the upgrading of dam structures.

Morgan et al. [1990] found polypropylene fiber-reinforced HVFA shotcrete to be applied satisfactorily using conventional wet-mix shotcrete equipment and that it required a minimum amount of cementitious material and water content of around 420 and 150 kg/m^3, respectively. The polypropylene fiber content required to provide a satisfactory flexural toughness index appeared to be between 4 and 6 kg/m^3. They suggested its use in capping rock outcrops which are susceptible to degradation and for covering mine waste dumps. Seabrook [1992] identified the same technology to produce a lower cost shotcrete while maintaining reasonable quality and durability for application on waste piles to prevent leaching of acids and heavy metals. Heeley [ASTM 1989] reported the successful application of HVFA shotcrete in the construction of the Penrith Whitewater Stadium for the Sydney Olympic Co-ordination Authority. The design was based on shotcrete because conventional formwork would have been prohibitive. In marine and offshore structures such as bridges, wharfs, sea walls and offshore concrete gravity structures, concretes with excellent sulphate and chloride durability are required. Where large or long-span structural members are used, low heat development and low creep characteristics are of vital importance. These are applications where HVFA concretes would be considered an ideal solution. Attention would need to be given to the use of compatible concreting materials if high early strength is required in precasting or slip forming construction.

In rehabilitation of massive concrete structures such as the raising of dam height for improved safety and flood mitigation, new high strength and high elastic modulus concrete matching existing concrete is often required. The new concrete must have low shrinkage to minimize the effects of the new concrete

on existing concrete and low heat development characteristics to avoid potential cracking problems during construction. HVFA concretes have been found to have all the required attributes for such use.

Summary

High Volume Fly Ash (HVFA) concrete is relatively new concrete for the concrete industry. The range of engineering properties including: consistency and setting times of fresh concrete, mechanical, volume stability and durability properties of hardened concrete are found to be suitable for a wide range of applications [Malhotra and Ramenzanianpour 1985, Swamy and Hung 1998, Sirivivatnanon et al. 1995]. These are vital to satisfy the structural and serviceability requirements of concrete structures. Experiences gained from field trials and large-scale implementations around the world confirmed the *practicality* of this new concrete. Significant improved volume stability, in terms of reduced drying shrinkage and better creep characteristics, can result in new solutions to many engineering problems. Most important of all, the improved *durability* performance of HVFA concrete in marine and high sulphate environments signaled the tremendous economic gains that could be derived from the expected increased service life. In most cases, such technical benefits can be gained with significant contribution to sustainable development as discussed in the following chapter. Exciting new developments in the applications of HVFA concrete have been highlighted. It remains for the construction industry to adopt and advance this new technology to its full potential.

42.6 Concrete for Sustainable Development

V. Sirivivatnanon

Sustainable Development

Sustainable development means different things to different people. In one context, it deals with how the world's diminishing resources are managed to sustain the rapid increase in the population in terms of provision of infrastructure to the *built environment* to provide physical comfort such as shelters, public utilities and transportation with minimum adverse effect to the *natural environment*. A Brundtland report of the World Commission on Environment and Development [1987], reiterated and broadened at the 1992 Rio Environmental Summit, defines sustainable development as "development that meets the needs of the present without compromising the ability of future generations to meet their own needs."

Sustainable construction is defined by the UK Government Construction Client's Panel [2000] as "the set of processes by which a profitable and competitive industry delivers built assets (buildings, structures, supporting infrastructure and their immediate surroundings) which:

Enhance the quality of life and offer customer satisfaction;
Offer flexibility and the potential to cater for user changes in the future;
Provide and support desirable natural and social environments;
Maximise the efficient use of resources."

In his wisdom in sustainable development, Pierre–Claude Aïtcin [2000] had predicted binders and concrete of tomorrow in a review published in *Cement and Concrete Research* at the beginning of this new millennium. He passionately elaborated that:

> The binders of tomorrow will contain less and less ground clinker; they will not have necessarily such a high C_3S content; they will be made with more and more alternative fuels. The will have to fulfil tighter standard requirements and they will need to be more and more consistent in their properties, because the clinker content will be lower in the blended cements. The binders of tomorrow will be more and more compatible with complex admixtures and their use will result in making more durable concrete rather than simply stronger concrete. The concrete of tomorrow will be GREEN, GREEN AND GREEN. Concrete will have a lower water/binder ratio, it will be more durable and it will have various characteristics that will be quite different from one another for use in different applications. The time is over when concrete could be considered a low-priced commodity product; now is the time for concrete "à la carte.

Contractors and owners have to realize that what is important is not the cost of 1 m^3 of concrete but rather the cost of 1 MPa or 1 year of life cycle of a structure."

Moving Forward

In the U.K., BRE has published the *Green Guide to Specification* [2000], which provides guidance for designers on the relative impact of different construction assemblies against a range of environmental criteria, including resources use, toxicity, embodied energy and durability.

In Denmark, a Green Concrete program [Glavind et al. 1999] was launched in 1998 with the goal to develop the technology necessary to produce resource-saving concrete structures, by means of new binding materials in new concrete combined with the possible reuse of materials.

There is a large European project focused on cleaner technologies in the life cycle of concrete products (TESCOP), which aims to develop and implement cost-effective cleaner technologies to reduced the environmental taxes, fulfill environmental requirements in the concrete industry, and reduce the environmental impact of concrete products [Haugaard and Glavind 1998].

The Australian Government has a clear and definite commitment to ensure that the construction industry moves toward ecological sustainability through voluntary means. There is an increasing aware-

ness amongst practitioners (designer and builders) that there are many environmental issues that need to be considered in the design, construction and operation of buildings to ensure the built environment is sustainable. For example, the Greenhouse Challenge Program was launched by the Commonwealth of Australia in 1995. The Australian cement industry has been a keen supporter of this program, and each cement company has introduced into its operations a Greenhouse Energy Management System modeled on the principles of ISO 14001. Results to date [Cusack 1999] show that the industry's Cooperative Agreement with the Government has been very successful and mirrors the success of the program at the industry level.

In the U.S., Vision 2030 [ACI 2001] establishes goals and describes the future for the U.S. concrete industry, concrete products, suppliers, and customers. It communicates the fact that the U.S. concrete industry is committed to being a model of sound energy use and environment protection; making concrete the preferred construction material based on life-cycle cost and performance; and to improving efficiency and productivity in all concrete manufacturing processes while maintaining high safety and health standards.

The world is moving forward towards sustainable development. Civil engineers have a social responsibility and a leading professional role in implementing sustainable development. Our profession is responsibility for the efficient creation of built assets which require the use of increasingly scarce resources.

Cement and Concrete in Sustainable Development

The technical and economical characteristics of any built asset are comparatively easy to quantify. However, an assessment from the ecological point of view is more difficult to carry out. To address the latter, the concept of life-cycle assessment (LCA) has been evolving and it is considered to be an appropriate tool in sustainable development evaluation. LCA is a method that systematically assesses the environmental effects of a product, process or activity holistically by analyzing its entire life cycle. This includes identifying and quantifying energy and materials used and waste released to the environment, assessing their environmental impact and evaluating opportunities for improvement. The benefits of LCA are summarized as followed [AS/NZS ISO 14040, 1998]:

- Identifying opportunities to improve the environmental aspects of products at various points in their cycles.
- Decision making in industry, governmental or non-governmental organizations (e.g., strategy planning, priority setting, product or process design or redesign).
- Selection of relevant indicators of environmental performance, including measurement techniques.
- Marketing (e.g., an environmental claim, ecolabelling scheme or environmental product declaration).

A number of references are listed for further information on the subject. Aspects relevant to civil engineers follow.

There are three approaches that are considered appropriate for civil engineers:

1. Optimum use of natural, industrial by-products and recycled materials.
2. Choice of cleaner production technologies.
3. The application of design principles with respect to life-cycle cost.

Optimum Use of Natural, Industrial By-Products and Recycled Materials

The balance in the economic and environmental cost of the production of cement and concreting materials from naturally won material sources is rapidly changing. The production of Portland cement has been identified as one of the processes with the highest greenhouse gas emission. While the cement industry has greatly improved its environmental performance [Cusack 1999], well-informed users can further reinforce these measures by correctly specify and using appropriate binders. There is also greater knowledge in the use of industrial by-products, such as fly ash, blast furnace slag and silica fume, and other mineral additives as part of a binder. The result is the possible use of a variety of blended cements

in concrete with improved workability and enhanced durability [Sirivivatnanon et al. 2000, Cao et al. 1997]. The economy of the use of industrial by-products is highly dependent on transport cost and the correct usage to improve the service life of concrete structures in different aggressive environment [Khatri and Sirivivatnanon 2001]. The economic balance is likely to change with improved quantification of the environmental cost associated with their disposal and reduction of greenhouse gas emission of the Portland cement they replace. Industrial by-products are used in larger proportions in a range of special concrete such as roller-compacted concrete (RCC), self-compacting concrete (SCC) and high performance concrete such as HVFA and high slag blended cement concrete.

Concrete waste can be processed to produce roadbase/fill material, recycled concrete aggregate and recycled concrete fines. Recycled concrete aggregate (RCA) may result in higher absorption, water demand, shrinkage and creep, and lower density, durability, permeability and strength [Sagoe–Crentsil 1999]. Its use in structural elements is therefore limited. However, RCA concrete is readily suitable for footpaths, bike paths and low strength concrete (e.g., 15 MPa concrete for footing, blinding). The primary use of recycled concrete in Australia, for example, is for use as roadbase material, which not only reduces the need for natural fill, but is also commercially viable [Sautner 1999].

There are also economical and technical benefits in the use of industrial by-products in roads and embankment stabilisation [ADAA 1997, ASA 1993], as well as in asphalt and thin bituminous surfacing. Electric arc furnace slag [CSIRO 2001] can also be used as synthetic aggregates.

Cleaner and Greener Production Technologies

There is a range of cleaner and greener technologies that are readily applicable in the production of construction materials. However, because of the high capital investment associated with the current production industry, their introductions are more likely in new plants and in countries with an environmental protection policy in place.

Examples include the temperature reduction in cement kilns by having a better control of the use of some mineralizers [Taylor 1997] and the elimination of numerous pollutants or industrial waste [Uchikawa 1996]. Low-Energy Accelerated Processing (LEAP) technologies are being developed by CSIRO for rapid curing of precast concrete products. Compared to conventional heating practice, energy consumption per tonne of product processed can be significantly lower using industrial microwave heating technology. With no significant liquid or gas emissions at the site of use, properly designed industrial microwave heating technology can potentially provide a clean manufacturing solution for the precast concrete industry [Mak et al. 2001]. Low-energy vertical concrete pipe-making technology is also replacing traditional horizontal concrete pipe manufacturing technology. In many applications, the use of flowing concrete [Collepardi 2001] since the 1970s or SCC may prove to be economical in energy saving and noise-sensitive environment. A new internal curing admixture has also been developed for self-curing concrete [Marks et al. 2001].

Application of Design Principles With Respect to Life-Cycle Cost

With increasing emphasis on service life design and a greater knowledge in the use of mineral additives, there is a huge potential for greater use of industrial wastes as mineral additives to improve the durability of concrete structures. Thus, two positive aspects are simultaneously realised in sustainable development. There are many examples given of the applications of HPC. The choice will be quite clear if the design for durability principle and life-cycle analysis is applied in the preliminary stage of project design. The correct use of fly ash, slag or silica fume has generally been found to improve durability of concrete with respect to chloride-induced corrosion, sulphate attack and alkali–aggregate reactivity. Their use in high proportions may, however, result in an increased risk of carbonation-induce corrosion. It is important to note that the performance of these mineral additives tends to vary from source to source. Performance data of local materials should be examined. A great deal of research findings have been published in a number of international conferences such as the CANMET/ACI international conference series on durability of concrete and a series on fly ash, silica fume, slag and natural pozzolans in concrete; University of Dundee series of international congresses; and a series of three international seminars on blended

cements — Singapore in 1992, Kuala Lumpur in 1994 and Singapore in 1998. These are given in the "Further Information" section.

It has been realized very recently that HPC is more ecologically friendly, in the present state of technology, than usual concrete because it is possible to support a given structural load with less cement and, in some cases, one-third of the amount of aggregates necessary to make a normal strength concrete [Aïtcin 2000]. Moreover, the life cycle of high-performance concrete can be estimated to be two or three times that of usual concrete. In addition, high-performance concrete can be recycled two or three times before being transformed into a roadbase aggregate when structures have reached the end of their life.

Applications

LCA has been applied widely to buildings rather than civil engineering structures. The Quebec Ministry of Transportation has calculated that the initial cost of a 50 to 60 MPa concrete bridge is 8% less than that of a 35 MPa concrete without taking into consideration the increase in the life of the bridge [Coulombe and Quellet 1994]. The Internationale Nederlanden (ING) Bank headquarters in Amsterdam, completed in 1987, uses only 10% of the energy of the bank's old building and has cut worker absenteeism by 15%. The combined savings are estimated at U.S.$2.6 million per year [Romm and Browning 1998]. The outcome of an LCA study of different building types with various forms of construction in Australia [Slattery and Guirguis 2001] has shown that for each building type, there was no significant difference between the different forms of construction studied in terms of energy and greenhouse gas emissions, but significant differences in ozone depletion and heavy metal over three life cycles of 50, 75 and 100 years. The operation was the most important phase of the life cycle for energy usage. It was thus recommended that the environmental assessment of a building should not be based on just one or two indicators (e.g., energy and greenhouse gas).

43.1 Introduction

This brief introduction to wood as a material is written primarily to inform the practicing civil engineer about what wood is; its cellular makeup; and, therefore, how it may be expected to react under various loading conditions. Space limitations preclude much detail; instead, references are given to lead the reader to detailed cause-effect relationships. Emphasis is placed on those items and relationships that most often lead to wood misuse or problems of proper wood use in structural applications and that may provide useful, practical guidelines for successful wood use.

What Is Wood?

Next to stone, wood is perhaps the building material used earliest by humans. Despite its complex chemical nature, wood has excellent properties which lend themselves to human use. It is readily and economically available; easily machinable; amenable to fabrication into an infinite variety of sizes and shapes using simple on-site building techniques; exceptionally strong relative to its weight; a good heat and electrical insulator; and—of increasing importance—it is a renewable and biodegradable resource. However, it also has some drawbacks of which the user must be aware. It is a "natural" material and, as

such, it comes with an array of defects (**knots**, irregular grain, etc.); it is subject to decay if not kept dry; it is flammable; and it is anisotropic.

Definitions

In order to understand how best to use wood as a structural material, a few terms must be understood. A tree is a marvel of nature; it comes in a variety of species, sizes, shapes, and utilization potentials. However, all trees have some basic characteristics in common:

Growth ring: The portion of wood of a tree produced during one growing season. In the temperate zones this is also called an *annual ring*.

Earlywood: The portion of a growth ring that is formed early in the growing season. It normally contains larger cells with thinner walls. Earlywood is relatively low in **density** and is followed by latewood as the growing season progresses.

Latewood: The portion of a growth ring that is formed later in the growing season. Cells tend to be smaller in size and have thicker, denser cell walls.

Heartwood: The innermost growth rings of a tree; may be darker in color than the outermost growth rings (called sapwood). Contains phenolic compounds that in some species impart decay resistance to the heartwood.

Sapwood: The outermost growth rings of a tree; always light brown to cream-colored in all species; never decay- or insect-resistant. Sapwood and heartwood together make up the "wood" of commercial use.

Bark: The outside covering of a tree, which protects the tree from invasion by insects, disease, and decay. The bark is separated from the wood of a tree by a thin layer of cells, the *cambium,* which is able to produce new cells annually to increase a tree in diameter as an annual ring is added.

Hardwood: Trees that are deciduous, i.e., trees whose leaves are broad and are generally shed each year in the temperate zones. Typical hardwoods include oaks, maples, and poplar. It is important to realize that not all hardwoods are "hard"; balsa is a hardwood, for example. The major use of hardwoods is in furniture and cabinet manufacture.

Softwood: Typically "evergreen" trees with needle-like leaves. Includes Douglas fir, pines, spruces, cedars, and hemlock. Traditionally softwoods have been used primarily for structural timbers and are graded specifically for this purpose. The wood of softwoods ranges from soft to quite hard.

Wood cells: Long, thin, hollow units that make up wood. Most cells are oriented with their long axis roughly parallel to the axis of the tree. However, cell orientation may vary, as around a tree branch to form a knot in a board cut from a tree, and some cells are in groups called **wood rays**, which are oriented horizontally and radiate outward from the center of the tree.

Wood rays: A band of cells radiating outward from the center of the tree toward the bark. The long axis of these ray cells is horizontal; ray cells are used for food storage and horizontal translocation of fluids in a tree.

Wood Chemistry and Anatomy

Chemically, wood of all species is composed of five basic components: **cellulose**, in the form of long-chain molecules in large groups that make up threadlike structures called **microfibrils**; **hemicellulose**; **lignin**; *extractives*; and *ash*. Cellulose gives the wood its strength, particularly along the microfibrillar direction, and constitutes 40 to 50% of the wood by volume, depending upon species. Hemicellulose is about 20 to 35% of the wood of a tree by volume and is a more readily soluble form of cellulose; it is a polysaccharide often referred to as "fungi food." Lignin is the natural adhesive that glues the cellulose molecules and wood cells together to give the wood its rigidity and its viscoelastic and thermoplastic properties. Extractives typically constitute about 1 to 5% of the wood, and while they have little or no effect on wood strength, they impart resistance to decay and insects to those species that are termed durable. Extractives may also impart color to the heartwood. It is important to note that while all species

probably contain some amount of extractives in the heartwood portion of a tree, they do not necessarily create a coloration different from that of the sapwood, nor do they necessarily impart any degree of durability or toxicity to insects and fungi to the heartwood. Ash is normally about 1% of the volume of wood.

The microfibrils are oriented at 5 to 30° to the cell axis; it is their orientation within a cell, as well as their very small shrinkage along their length as wood dries compared to their relatively large shrinkage between adjacent microfibrils, that is directly responsible for two major characteristics of wood: disparate strength properties and shrinkage properties along and across the grain, i.e., wood's anisotropic nature. Wood's cellular orientation, with most of the cells oriented longitudinally (approximately parallel to the axis of the tree) and bands of ray cells oriented radially, produces wood properties that are generally taken as *orthotropic:* longitudinal, radial, or tangential (tangent to the growth rings and perpendicular to the wood rays). From a practical point of view, radial and tangential properties are of a similar order of magnitude; thus, wood is usually viewed as having properties "along the grain" and "across the grain." A study of compression strength values in Table 43.1 will emphasize the fact that wood is widely variable in its properties and is generally much stronger along the grain than it is across the grain.

Wood species differ one from another, despite the fact that all wood is made up of basically the same chemical components. Inter- and intraspecies differences may be accounted for by several factors:

1. *Different cell types*. Softwoods have primarily one cell type: an all-purpose cell called a *tracheid,* which is responsible for both wood strength and vertical translocation of fluids. Hardwoods, on the other hand, have a number of different cell types with more specialized functions. Wood strength reflects those different cell types. Likewise, particularly in hardwoods, the proportions, or mix, of cell types also affect wood properties.
2. *Proportion of wood ray cells and size of wood rays*. In general, the softwood species tend to have small, narrow wood rays. Hardwoods, on the other hand, have rays that range in size from too small to be easily seen with the eye (buckeye, willow, cottonwood) to large (oak species). Ray size and appearance, along with more distinctive heartwood coloration, have led to the preference for hardwoods in furniture and panel manufacture as well as to species strengths and use differences.
3. *Site*. This may broadly include numerous aspects of tree growth: wet vs. dry site, low vs. high elevation (differences in water and temperature), weather cycles, shaded vs. sunny site, fertile vs. less fertile site, etc. These factors in turn affect the length of a tree's growing season and, hence, the width of the growth rings. The width of an annual growth ring tends to affect overall wood density and, thereby, species and individual tree properties. As a rough rule of thumb, softwoods with wider-than-normal growth rings (say, less than four rings per inch as seen on a tree cross-section) tend to be low in density and have lower strength properties. Hardwoods in general tend to have normal or higher-than-normal strength properties as growth ring width increases.

Wood strength properties also vary from the center (pith) of the tree outward toward the bark. The innermost growth rings for most species studied (particularly for softwood species) tend to be lower in density, weaker, and more prone to **warp** in product form than the outer rings. Although this characteristic varies between species, it is generally limited to the first 10 to 20 growth rings from the pith, with those nearest the pith being generally weakest and gradually increasing in strength as rings are added. Since these innermost rings contain the most knots, they also tend to become relegated to the lower grades of lumber and do not usually end up in structurally critical members. Their warpage characteristics also tend to relegate them to nonstructural uses. (One exception to this, however, is sometimes found in the use of pith-centered, nominal 4-by-4s used as concrete formwork.)

43.2 Wood Defects as They Affect Wood Strength

The major problems that arise in wood use may be attributed either to the effects of grain distortions (cell orientation or alignment), to the effects of excess moisture, or to defects that occur as a result of the drying process. The specific defects taken into account in the grading of lumber products include

[e] A coefficient of variation of 28% can be used as an approximate measure of variability of individual values about the stresses tabulated.

[f] The regional description of Douglas fir is that given on pp. 54–55 of U.S. Forest Service Research Paper FPL. 27, "Western Wood Density Survey Report No. 1."

Knots: The result of cutting across a branch in lumber manufacture. If the branch is cut perpendicular to its axis, the knot is round or oblong and presents a miniature aspect of a tree with visible growth rings. Knots may be *live* (cut through a living branch with intact tissue) or *dead* (cut through a dead branch stub with loose bark, usually resulting in a knothole). If the saw is oriented so as to cut along the length of a branch, the knot is greatly elongated and is termed a *spike knot*. Due to the obvious grain distortion around knots, they are areas of severe strength reduction. The lumber grading process takes this into account by classifying lumber grade by knot size, number, type, and location within the member. Knots located along the edge of a piece are, for example, restricted in size more than are knots located along the centerline of the member.

Slope of grain: A deviation of cell orientation from the longitudinal axis of the member. Slope of grain may be a natural phenomenon wherein the grain is at some angle to the tree axis (termed *spiral grain*), or it may be the result of sawing the member nonparallel to the tree axis. Slope of grain has a negative effect upon wood strength properties. A slope of 1:20 has minimal effect, but a slope of 1:6 reduces strength to about 40% in bending and to about 55% in compression parallel to the grain. Tensile strength is even more adversely affected.

Wane: Lack of wood. Wane occurs whenever a board is sawn so as to intersect the periphery of the tree, resulting in one edge or portion of an edge of a board being rounded or including bark. Limited amounts of wane are permitted, depending upon lumber grade. The effect of wane on wood strength or nailing surface is obvious.

Shake: A lengthwise separation of the wood, which usually occurs between or through the annual growth rings. Shakes are limited in grading since they present a plane of greatly reduced shear strength. Shake may occur as a result of severe wind that bends a tree to produce an internal shear failure, or as a result of subsequent rough handling of the tree or its products.

Splits and cracks: Separations of the wood cells along the grain, most often the result of drying stresses as the wood shrinks. Cracks are small, whereas splits extend completely through the thickness of a piece. Splits at the ends of the member, particularly along the central portion of a beam, are limited in grading.

Insect attack: Insect attack may range from small blemishes that do not affect strength to large voids or extensive damage in the wood as the result of termite or other insect infestation. Insect attack is usually treated as equivalent to the effect of similarly sized knotholes.

Decay: Decay, caused by wood-destroying fungi, is precluded from wood use except for certain species in lower grades because the strength-reducing effects of fungal attack are quite significant even before visible evidence (wood discoloration, punkiness) appears. It is important to note that decay organisms require moisture to live and grow; hence, the presence of active decay or mold implies access to a source of moisture. Moist wood will *always* decay, unless the wood is **preservative**-treated or is of a very durable species.

43.3 Physical Properties of Wood

The practicing civil engineer should be knowledgeable about several important physical properties of wood:

Specific Gravity (SG)

As a general rule, specific gravity (SG) and the major strength properties of wood are directly related. SG for the major native structural species ranges from roughly 0.30 to 0.90. The southern pines and Douglas fir are widely used structural species that are known to exhibit wide variation in SG; this is taken into account in the lumber grading process by assigning higher allowable design values to those pieces having narrower growth rings (more rings per inch) or more dense latewood per growth ring and, hence, higher SG.

Moisture Content (MC) and Shrinkage

Undoubtedly, wood's reaction to moisture provides more problems than any other factor in its use. Wood is *hygroscopic*; that is, it picks up or gives off moisture to equalize with the relative humidity and temperature in the atmosphere. As it does so, it changes in strength; bending strength can increase by about 50% in going from green to a **moisture content (MC)** found in wood members in a residential structure, for example. Elasticity values can also increase, but only about 20%, over a similar moisture change range. Wood also shrinks as it dries, or swells as it picks up moisture, with concomitant warpage potential. Critical in this process is the **fiber saturation point (fsp)**, the point (about 25% moisture content, on **oven-dry** basis) below which the hollow center of the cell has lost its fluid contents, the cell walls begin to dry and shrink, and wood strength begins to increase. The swelling and shrinkage processes are reversible and approximately linear between fiber saturation point and 0% MC. Due to its chemical and cellular makeup, wood shrinks along the grain only about 0.1 to 0.2%. Shrinkage across the grain may range from about 3 to 12% in going from *green* (above fiber saturation point) to 0% MC, depending not only on species but also on grain orientation (radial vs. tangential). Wood decay or fungal stain do not occur when the MC is below 20%.

There is no practical way to prevent moisture change in wood; most wood finishes and coatings only slow the process down. Thus, vapor barriers, adequate ventilation, exclusion of water from wood, or preservative treatment are absolutely essential in wood construction. The *National Design Specification for Wood Construction*® (NDS®) (American Forest and Paper Association, 1991) contains explicit guidelines for the treatment of wood moisture content in regard to various structural design modes, including fastener design.

Moisture content is defined by the equation

$$\mathrm{MC}(\%) = \frac{\text{Wet weight} - \text{Oven-dry weight}}{\text{Oven-dry weight}} \times 100 \tag{43.1}$$

The MC of wood may be in excess of 200% as it is cut from a log, particularly in species that are low in SG and contain thin-walled cells. It is important to note that a wood member dries most rapidly from the ends and that as it dries below fsp, shrinkage stresses may result in cracks, checks, splits, and warpage. These defects are limited in stress-grades of lumber.

Thermal Properties/Temperature Effects

Although wood is an excellent heat insulator, its strength and other properties are affected adversely by exposure for extended periods to temperatures above about 100°F. Refer to NDS (American Forest and Paper Association, 1991). The combination of high relative humidity or MC and high temperatures, as in unventilated attic areas, can have serious effects on roof sheathing materials and structural elements over and above the potential for attack by decay organisms. Simple remedies and caution usually prevent any problems. At temperatures above 220°F, wood takes on a *thermoplastic* behavior. This characteristic, which is rarely encountered in normal construction, is an advantage in the manufacture of some reconstituted board products, where high temperatures and pressures are utilized.

Durability

Although design texts classify various species as nondurable, moderately resistant to decay, or resistant to decay, it is best to note that only the heartwood of a species may be resistant to decay and of the readily available species, only a few are effectively resistant in their natural state (redwood, cypress, western red cedar, and black locust). On the other hand, many structural softwood species are made very durable against fungal and insect attack when properly preservative-treated with creosote, pentachlorophenol, chromated copper arsenate (CCA), or ammoniacal copper arsenate (ACA).

Chemical Effects

Wood is relatively chemically inert. Although, obviously, wood will deteriorate when in contact with some acids and bases, some species have proven very useful for food containers (berry boxes and crates) because they are nontoxic and impart no taste to the foods contained therein. Wood structures have also found widespread use as storage facilities for salt and fertilizer chemicals.

43.4 Mechanical Properties of Selected Species

Major Engineering Properties

As stated before, wood strength depends on several factors unique to wood as a material; these factors include species (and associated inherent property variability), wood (properties parallel or perpendicular to the grain), MC at time of use, **duration of load**, and lumber grade (reflective of type and degree of defects present). Tables 43.1 and 43.2 present average strength property values for selected structural species. It is important to note that these values are for wood that is straight-grained, defect-free, and at a green MC (i.e., above fsp). The data are best used for property comparisons between species. These basic properties are modified to arrive at allowable design properties (refer to Section 43.7 and to [ASTM, 1992] and [ASTM, 1988]) following a general format of

$$F = \frac{\left(\overline{X} - 1.645\ \mathrm{SD}\right)}{F_{\mathrm{ADJ}}}\left(F_{\mathrm{MC}}\right)\left(F_{\mathrm{SIZE}}\right)\left(F_{\mathrm{DENS}}\right)\left(F_{\mathrm{SR}}\right)$$

where F = allowable design stress

$\overline{X}$ = average property value, green MC

SD = standard deviation for the property; this reduction of 1.645 standard deviations from the mean establishes a 95% lower exclusion value on the mean. Design values for E and compression perpendicular to the grain, considered to be non-life-threatening properties, are derived directly from mean values, however, with no adjustment for property variability.

F_{MC} = a factor to correct for an increase in property value if the product is dried. The factor applies only to members of nominal 4 in. or less in least dimension. (Larger members are not dried prior to installation, and subsequent drying defects in large sizes may act to nullify much of the strength increase due to drying.)

F_{SIZE} = a correction for member size. Test observation shows that larger-depth beams fail at lower stress levels than smaller beams, and allowable bending stress values are corrected by a factor of $(2/d)^{1/9}$, where d = member depth in inches.

F_{DENS} = a density correction factor for southern pine or Douglas fir members that are slow-grown and of a high density.

F_{SR} = a "strength ratio" factor for lumber grade (defects). Current grades for visually graded structural lumber are Select Structural (SR 65), No. 1 (SR 55), No. 2 (SR 45), and No. 3 (SR 26). The SR value, as a percentage, expresses the ratio of the strength of a member with its permitted defects to the strength it would have if defect-free.

F_{ADI} = an adjustment factor to convert table values from short-time duration of load to "normal" duration (assumed to be an accumulated 10-year period of full design load) plus a factor of safety.

The reader is referred to the ASTM documents (ASTM, 1988, 1992) and the lumber grade rules manuals for stress grading details and for the factors that apply to related products, such as scaffold plank, etc.

[b] Modulus of rupture values are applicable to material 51 mm (2 in.) in depth.

[c] Modulus of elasticity values are applicable at a ratio of shear span to depth of 14.

[d] Based on a 51 mm (2 in.) wide steel plate bearing on the center of a 51 mm (2 in.) wide by 51 mm (2 in.) thick by 152 mm (6 in.) long specimen oriented with growth rings parallel to load.

[e] A coefficient of variation of 28% can be used as an approximate measure of variability of individual values about the stresses tabulated.

[f] The regional description of Douglas fir is that given on pp. 54–55 of U.S. Forest Service Research Paper FPL. 27, "Western Wood Density Survey Report No. 1."

Note that while this format is still in use and indicates major factors considered in lumber grade-strength assessment, it has been largely replaced for some properties by "in-grade testing" data, described in Section 43.7.

Strengths and Weaknesses

Wood in bending is amazingly strong for its weight; however, in many applications beam size is limited more by deflection criteria than by strength. Young's modulus (E) values for native species will range from about 3450 MPa (0.5 million psi) to about 17,250 MPa (2.5 million psi). Wood in tension parallel to the grain is exceedingly strong; however, it is readily affected by wood defects, particularly by knots and slope of grain. For this reason tensile allowable design properties are taken as 0.55 • bending values. Also, tension perpendicular to the grain properties are very weak, and fracture in this mode is abrupt; design for this mode of possible failure is not acceptable (a singular exception to this rule is made for laminated arches, haunched frames, and similar members where shear stress is unavoidable; allowable design values in these cases are in the range of only 0.10 MPa to 0.20 MPa (15 to 30 psi).

Wood strength in compression necessarily must consider grain angle since compressive strength varies inversely with grain angle from 0° (parallel to the grain) to 90° (perpendicular to the grain). This relationship is described by Hankinson's formula:

$$N = \frac{C_{\parallel} \yen C_{\wedge}}{\left(C_{\parallel}\right)\left(\sin^2 \phi\right) + C_{\wedge}\left(\cos^2 \phi\right)} \tag{43.2}$$

where N = normal stress on a surface
$C_{\parallel}$ = compressive strength parallel to the grain
$C_{\wedge}$ = compressive strength perpendicular to the grain
ϕ = grain angle measured in degrees from parallel to the member long axis

This relationship is also used in the design of fasteners in a joint where members converge from different angles or where eccentric bearing occurs.

Stability must be taken into account for columns with a ratio of column length to least cross-sectional dimension greater than around 10. Column stability is a function of compressive strength, E, end fixation, and manufacture (sawn lumber vs. round piles vs. **glu-lam**) (American Forest and Paper Association, 1991). Wood is very strong in shear across the grain, but very weak and variable in shear along the grain; for this reason horizontal shear stress over supports in bending beams is often a critical design consideration, particularly for short, deep beams. The designer of wood structures must at all times be aware of wood species, grade, grain angle in localized areas, and MC effects.

Recent design criteria for bending beams (American Forest and Paper Association, 1991) take beam stability into account. As in column design, beam strength, elasticity, and other factors enter in. In cases where combined stresses occur (tension or compression combined with bending, as in roof or ceiling loads applied to timber trusses), possible two-dimensional bending is also taken into account.

In general, structures made of stress-graded material do not fail; their performance record is excellent. Several reasons may account for this. Wood tends to be resilient; members also tend to "share" their loads. Load-sharing design factors (called *repetitive member factors*) may be applied, but they are considered to be conservative. Three or more bending members fastened together and stabilized, as by flooring over joists, in sizes limited to nominal 2 to 4 in. thick may be termed **repetitive member use**, and allowable bending design stresses may be increased by a conservative 15%. In addition, allowable design stresses are, in general, also conservative; there are several built-in safety factors in the derivation process. The visual grading process for structural lumber is predicated upon setting an upper limit on permissible defect sizes and number; most pieces within a grade have defects somewhat less in size or degree than is permitted in the grade, resulting in an additional margin of safety. Wood structural failure is most often attributed to poor design or failure of the fasteners.

TABLE 43.3 Frequently Used Load Duration Factors for Wood Construction[a]

Load Duration	Factor	Typical Design Load
Permanent	0.9	Dead load
10 years	1.0	Occupancy live load
2 months	1.15	Snow load
7 days	1.25	Construction load
10 minutes	1.6[b]	Wind/earthquake load
Impact	2.0	Impact load

[a] *Source:* Taken from Table 2.3.2, NDS. 1991. *National Design Specification for Wood Construction.* American Forest and Paper Association, Washington, D.C.
[b] The 1.6 factor was 1.33 in previous editions of NDS; some code agencies may not accept the new value.

Duration of Load Effects

Wood is one of those materials that exhibits duration of load (DOL) effects; it will withstand higher loads at failure if the load is applied over a shorter period of time as opposed to a longer time to create failure. All strength properties show this effect except *E* and compression perpendicular to the grain. For design purposes, **normal duration of load** for full design load is taken as 10 years; other load durations are accounted for by multiplier factors, given in Table 43.3. There is some evidence indicating, however, that for lower grades of material the limiting defect (a large knot, for example) is the major factor in determining failure and that for low-grade lumber the DOL factors for short DOLs should be ignored or applied with caution.

Wood, due to its plastic nature, creeps under load. A safety factor is recommended in designing where deformation is important. In beam design, a general rule of thumb is that instantaneous bending deflection under load is about half that which will result over the normal life of the structure. For long columns subject to buckling, a safety factor of 3 for *E* is recommended. An increasing rate of creep deformation is indicative of impending failure; measurement of beam deflection over time, for example, may be used to indicate potential problems (as in flat roof ponding) and required reinforcement.

Strength Variability

As a biological material, wood is variable in all its properties. Variability is measured by coefficient of variation values, Table 43.4, where the values listed are broad species values.

A property variability effect is also imposed by the presence of minor defects within the wood (small grain deviations near knots; rapid growth in some annual rings of conifers, which tend to lower density; very slow growth in any species; or wood in close proximity to the pith, which is inherently low in density and has a propensity to shrink excessively). Generally this is taken into account mathematically in the design stress determination and grading processes; however, caution must be used whenever load situations require the loading of single members, as in scaffolding.

TABLE 43.4 Coefficient of Variation (COV) Values for Wood Properties[a]

Property	COV
SG	0.10
Modulus of Rupture	0.16
E	0.22
Compression, parallel	0.18
Compression, perpendicular	0.28
Shear	0.14

Age Effects

If wood in use is kept dry and free from mechanical and insect damage, it will remain nearly unchanged in its properties over time. Timbers removed from old structures may be reused. The only cautionary

action is to have any structural members regraded to account for any increase in cracks or splits due to the continued drying of a piece in use. Most wood members will be in the range of 12 to 20% MC at time of installation. They may, over time, dry to as low as 5 to 7% MC, depending on their ambient conditions. Although wood strength may be expected to increase as the MC decreases, defects that occur due to the drying process tend to offset or nullify strength increases. This is particularly evident in large, heart-centered members, which may develop large cracks from the outer surface of the piece to the center (pith) of the piece. Shear strength may be affected in beams, and column strength/stability may also be affected.

43.5 Structural Products and Their Uses

Beginning with small trees and limbs, then lumber and plywood, structural uses of wood have evolved slowly into "artificial" products, such as wood composite beams and laminated veneer lumber, which have greatly expanded the architectural design capabilities of wood structures as well as conserving a valuable natural resource through more complete utilization. Thin-kerf saws, improved veneer production techniques, better adhesives, and extensive research and development on modern timber products have led not only to new products but also to the efficient utilization of more of the tree and of a much wider range of species.

The simplest form of wood for use is the *pole* or *piling*. This is merely a delimbed and debarked tree. Common species used for this purpose are the southern pines and Douglas fir, both of which must be preservative-treated prior to use. Western red cedar is also used extensively but does not need to be treated. Poles are often **incised** (surface perforated to permit deeper, more uniform preservative penetration) before treatment. Poles have wide usage in farm structures, in the utility field, and to obtain a rustic appearance in restaurants and residential construction. Piling is, of course, used in marine structures or as foundation supports when driven into the ground. Piling has been known to have been used for several decades, removed, inspected, and reused; the exclusion of oxygen underground essentially eliminates the danger of decay except at ground level. For this reason poles and piling should be inspected regularly for signs of deterioration at any point where wood, moisture, and oxygen meet for any significant period of time and where the ambient temperature lies between 15° and 35°C. In dealing with poles and piling (long columns) it is essential that lateral stability and adequate bracing against buckling be carefully considered.

Lumber is the most common wood construction material. Allowable design stresses for the many softwood species and grades of lumber are available; refer to NDS (American Forest and Paper Association, 1991) or to lumber grade rules books. Some hardwood species have assigned design stresses; however, stress-graded hardwoods are virtually nonexistent in most areas. Paradoxically, hardwoods have long been used in the East and Midwest regions for farm structures, but as general construction lumber, not with allowable stress ratings. The reason for this is because most hardwoods are valued for their esthetic appearance and, therefore, command considerably higher prices in the furniture trade than most softwoods do in the structural markets.

Structural lumber comes in several grades and is manufactured in 2-foot increments of length. It is important to note that structural lumber (synonymous with the term *stress-graded lumber*) is graded to be used as single, unaltered members. Cutting the piece along its length or across its width essentially nullifies any grade marking.

Since lumber is purchased in discrete lengths by grade and by width and thickness (2-by-6, etc.), the stocking and marketing of a vast multitude of different sizes, lengths, and grades has necessitated species grouping. Species of similar properties and uses have been grouped (via specific procedures outlined in ASTM D-2555 [ASTM, 1988]) for marketing ease. For example, "southern pine" consists of a mixture of as many as eight distinct hard pines; "hem-fir" is made up of western hemlock combined with several fir species. The allowable design values are derived to reflect the mix of species, with limits imposed by the species with the lowest average property values. Lumber is also categorized by size and use classes as

TABLE 43.5 American Standard Lumber Sizes for Structural Lumber [a]

Item	Thickness (in.)			Face Width (in.)		
	Nominal	Minimum Dry	Dressed Green	Nominal	Minimum Dry	Dressed Green
Dimension	2	1½	1⅝	2	1½	1⅝
	2½	2	2⅛	3	2½	2⅝
	3	2½	2⅝	4	3½	3⅝
	3½	3	3⅛	6	5½	5⅝
	4	3½	3⅝	8	7¼	7½
	4½	4	4⅛	10	9¼	9½
				12	11¼	11½
				14	13¼	13½
Timbers	5 and larger	—	½ in. less than nominal	5 and larger	—	½ in. less than nominal

[a] Adapted from Table 5-6, Forest Products Laboratory. 1987. *Wood Handbook: Wood as an Engineering Material*. Agricultural Handbook 72, USDA, Washington, D.C.

1. dimension lumber (often referred to as "joists and planks"): nominal 2 in. or 4 in. thick and nominal 2 in. or more in width; graded primarily for edgewise or flatwise bending
2. beams and stringers: nominal 5 in. and thicker with a width at least 5 cm (2 in.) greater than nominal thickness; graded for strength in bending when loaded on the narrow face
3. posts and timbers: pieces of square or nearly square cross-section, 5 in. by 5 in. nominal thickness or larger; graded primarily for use as posts or columns
4. stress-rated boards: lumber less than 2 in. in thickness and 2 in. or wider

These classes do not preclude use for other purposes; e.g., post and timber grades also have allowable bending stresses assigned to them.

Lumber is purchased by its **nominal size**, e.g., 2-by-6; its actual size is somewhat less. The nominal size represents the member as it would be before reduction in size due to the removal of saw kerf, shrinkage due to drying, and reduction in size due to planing smooth after drying. Nominal and actual green and dry sizes are given in Table 43.5.

Plywood was the first of a large number of wood panel products produced for structural purposes. It is made of an odd number of layers of veneer; each alternate layer is laid with the grain at right angles to adjacent layers. The odd number of layers ensures that the panel is "balanced" in terms of strength and shrinkage about the panel neutral axis. Obviously, this necessitates that the grain on the face plies be placed so as to utilize the panel's strength along the grain. Plywood is manufactured in several standard thicknesses; 0.64 cm to 3.8 cm ($^1/_4$ to $1^1/_2$ in.) are common thicknesses. The most common species used on the outermost plies for structural purposes are southern pine and Douglas fir; however, dozens of different species may be used for the interior, or core, plies. Only the face plies are required to be of the designated species. Plywood is typically manufactured in 122 cm ¥ 244 cm (4 ft by 8 ft) panels, but special sizes are available. Plywood is typically used as floor underlayment and roof sheathing, but it has been largely replaced by other panel products for these uses. It is also widely used for concrete forming where special, surface-treated panels are available. Plywood is produced in several grades in regard to glueline durability. Panels may be rated as *interior* (for interior use only; the glueline is not to be exposed to moisture) or *exterior*. Exterior panels are classed as Exposure 1, which has a fully waterproof bond and is designed for applications where long construction delays may be expected or where high moisture conditions may be encountered in service; or Exposure 2, which is intended for protected construction applications where only moderate delays in providing protection from moisture may be expected. Structural plywood panels are grade-stamped with glueline type and recommended span rating. A special grade, *marine plywood*, is also available; it has improved durability and a higher grade of veneer in the inner plies. Consult the American Plywood Association for technical advice on plywood design and use (*American Plywood Association,* 1992a,b).

TABLE 43.6 Ranges of Physical and Mechanical Property Values for Commercially Available Flakeboard[a]

Type of Flakeboard	Density		Modulus of Rupture		Modulus of Elasticity

[a] Excerpted from Table 22-5, Forest Products Laboratory. 1987. *Wood Handbook: Wood as an Engineering Material*. Agricultural Handbook 72, USDA, Washington, D.C.

Whereas lumber is sawn from a log with a considerable waste factor for slabs and sawdust, and plywood is made from thin sheets of veneer peeled from higher-quality logs, other panel products have been developed from technology that permits the conversion of entire logs into particles, chips, or carefully sized flakes with insignificant waste factors, and subsequently into panels with predictable engineering properties and a wide array of marketable sizes and thicknesses. **Particleboard**, the oldest of these products, is made from particles bonded under pressure with, usually, a urea-formaldehyde adhesive. Its intended use is as a substrate for overlaid sheet materials or as underlayment. Strength properties are relatively low. A majority of the particleboard produced is utilized by the furniture and related industries. Like all panel products, its properties depend upon the material input and process: species, size and shape of the particles or flakes, orientation of the flakes, adhesive used, density of the finished product, thickness of the panel, and pressure and temperature at which the panels are formed. Particleboards are not generally considered as "structural" materials because of lower levels of strength and use of a nondurable adhesive.

However, as a subset of generic particleboard, composites made from large flakes and exterior-grade/waterproof adhesives have evolved into structural-use panels. They may be "engineered" for a specific purpose by varying the pressing temperature, pressure, adhesive amount, and flake orientation. Board strength may be designed into the product. However, unlike lumber and most materials where bending strength and E tend to be properties of primary importance, panel products need to be evaluated as well for their internal bond strength, shear properties, and fastener strength. This has resulted in a wide variety of panel products with properties patterned toward specific end uses. Oriented-strand board (OSB) is one of the most recent such products; its flakes are mechanically oriented to align them to be closely parallel to the long axis of the panel on the outer faces of the panel in order to attain properties more closely resembling those of plywood in bending, while still maintaining relatively low density and the economic advantage of maximum resource use and low cost. Panel weight can be varied by producing a layered product with the inner portion of the panel made up to have different properties than the faces. Typical uses of OSB panels are roof sheathing, floor sheathing, and web material in composite wood I-beams or in shear walls. Physical and mechanical property values for various flakeboard types are given in Table 43.6; note that the tabled values are *not* design allowable values, and manufacturers' specifications should be referred to.

Glued-laminated beams (glu-lam) have been in use for decades and have the distinct advantage of being able to be produced in nearly any size or shape desired. The only practical limitation is the difficulty in transporting large structural beams or arches to the building site. Glu-lam is made by gluing thin boards, usually 1 or 2 in. (2.5 or 5.1 cm) thick lumber, together over forms to achieve the desired size and shape of a solid member. All the boards used are dried prior to lay-up of the member to greatly

reduce drying defects associated with large, sawn timbers, and by using thin layers, natural defects are evenly distributed throughout the beam. Current technology in this field is centered on methods to combine accurate grade separation of high-quality lumber with computerized design placement of high-strength outer laminations balanced against lower-strength and lower-grade material in the inner laminations to achieve maximum material utilization at economical cost. The boards used in glu-lam, particularly for outer laminations, are a specialty grade with special grading criteria. Laminating grades of L1, L2, and L3 are graded with additional restrictions on permitted defects and growth rates over the normal visual grades. "Standard" beam lay-up configuration and sizes, as well as design criteria, are available from the American Institute of Timber Construction. Lumber used in glu-lam manufacture is generally of a softwood species, although glu-lam from hardwoods is available. Manufacture is in conformance with ANSI/AITC A190.1-1983. Finished beams come in three appearance grades: Industrial, Architectural, and Premium. Beams may be preservative-treated if necessary. Sizes and shapes will vary, but "standard" widths are 6.3 cm (2½ in.), 7.9 cm (3⅛ in.), 13.0 cm (5⅛ in.), 17.1 cm (6¾ in.), 22.2 cm (8¾ in.), and 27.3 cm (10¾ in.); number of laminations and depth of member can be as many as 50 or more laminations and several feet in depth. The American Institute of Timber Construction has a technical staff to aid in glu-lam design.

A new breed of product, **structural composite lumber** (SCL), has appeared recently on the market; it is a panel product made of thin layers of veneer or of wood strands mixed with a waterproof adhesive. The veneered product, termed **laminated-veneer-lumber** (LVL), is a miniature glu-lam. The strand products are known as *parallel-strand-lumber* (PSL) and *laminated-strand-lumber* (LSL); the latter, being the newest, evolved directly from the oriented-strand board-manufacturing process. SCL products are generally produced in flat panels or *billets* (of selected species) 122 cm to 244 cm (4 to 8 ft) wide, 3.8 cm (1½) in. or more thick, and up to 12.3 m (40 ft) long. These products are available in larger sizes than sawn lumber and tend to be significantly stronger than lumber of equal size (due to redistribution and minimization of defects), but, due to the stringent manufacturing process, they also tend to be somewhat more expensive. They are normally used for purposes requiring high strength or stiffness in both residential and light industrial/commercial construction. Table 43.7 lists design stress values for building code-approved LVL products.

With the plethora of engineered specialty products, it is no surprise that a vast array of structural composite products has also become available. Solid lumber structural members, while still preferred for many traditional uses, particularly in residential construction, are being replaced by wood I-beams with LVL flanges and OSB webs. Metal bar webs and lumber or LVL flanges are common. Toothed, stamped metal plate connectors are used as fasteners for a myriad of structural frames, trusses, and components. Design software has kept pace with these trends and is able to factor into a design the various decisions on temperature effects, moisture effects, duration of load, and combined stress situations as well (Triche and Suddarth, 1993).

TABLE 43.7 Design Stress Values for Code-Approved LVL Products[a]

Design Stress	MPa	Range psi
Flexure	15.17–28.96	2200–4200
Tension parallel-to-grain	11.03–19.31	1600–2800
Compression parallel-to-grain	16.55–22.06	2400–3200
Compression perpendicular to grain:		
Perpendicular to glueline	2.76–4.14	400–600
Parallel to glueline	2.76–5.52	400–800
Horizontal shear:		
Perpendicular to glueline	1.38–2.07	200–300
Parallel to glueline	0.69–1.38	100–200
Modulus of elasticity	12,410–19,310	1.8×10^6–2.8×10^6

TABLE 43.8 Preservative Retention Level–Use Recommendations

Retention Level (lbs/cu. ft)	Use/Exposure
0.25	Above ground
0.40	Ground contact/fresh water
0.60	wood foundation
2.50	Salt water

43.6 Preservatives

For all practical purposes only a few native species are truly immune to fungal deterioration, and then, as stated earlier, only the heartwood portion of the wood is decay-resistant. Availability and economy usually dictate that where decay resistance is required, preservative treatment is a must. Any structural component that is in contact with the ground, subject to periodic wetting (leakage or rain), or in a high-relative-humidity atmosphere for extended time periods, may be expected to decay.

There are several preservatives available; degree of exposure and the use of the member will indicate which specific preservative to use. In all cases a pressure treatment is required; dip treating, soaking, or painting the surface with a preservative solution are only temporary deterrents at best and are not recommended where structural integrity is required. Creosote, one of the oldest and most effective treatments, is used primarily for treating utility poles and marine piling. It is an oilborne preservative of high toxicity and is not recommended where human contact is anticipated. A number of arsenic-containing treatments are commonly used. CCA (chromated copper arsenate) is used with dimension lumber, particularly with southern pine, and ACA (ammoniacal copper arsenate) is also commonly used. Both CCA and ACA are waterborne preservatives that are pressure-impregnated into dry (below fsp) lumber; the chemicals become permanently bonded to the wood as the wood becomes redried after treatment. It is very important to know that until the wood has become dry again after treatment, it is dangerous to handle. Resawn wood that is wet on the inside of the piece, even if it appears dry on the outside, can produce arsenic poisoning. It is also important to know that even under high impregnation pressures, the depth of penetration of the preservative into the wood may be incomplete. Resawing may expose untreated wood to decay; treatment after cutting or boring members to final size is recommended. CCA and ACA treatments are commonly used for foundations, decks, and greenhouses. Dry CCA- and ACA-treated lumber is approved for human contact use. Under no circumstances are wood scraps of CCA- or ACA-treated wood to be burned in the open air; this will ultimately release poisonous arsenic and chromium compounds into the air.

Borate compounds are effective wood preservatives and are economical and nontoxic to humans and animals. Unfortunately, they also leach out of the wood rather readily when subjected to rain or wet conditions. Research on these and other compounds may result in a new family of leach-resistant, nontoxic-to-humans preservatives for wood in the future.

Preservative-treated structural lumber is available in several grades, depending upon intended use and retention level. Table 43.8 lists desired use-retention levels; retention levels are part of the information given on the grade stamp of treated lumber.

43.7 Grades and Grading of Wood Products

Lumber stress-grading procedures for structural purposes are under the jurisdiction of the American Lumber Standards Committee and follow guidelines given in several ASTM documents. Although several rules-writing agencies publish grading rules with grade descriptions, they all conform to ALSC guidelines and restrictions and, therefore, the common grades are identical for American and Canadian producers. There are currently two grading methodologies: visual grading and machine stress rating (MSR). Visual

grading is accomplished by skilled graders who visually assess the size and location of various defects and other characteristics on all four faces of a board. The main defects assessed include slope of grain, knots (size, number, and location relative to the edges of the piece), wane, checks and splits, decay (not permitted except for "white speck" in some grades), and low density for the species. Strength reductions for various defects are termed **strength ratio** (SR) values and are applied to strength values representing a statistical 95% lower confidence limit on mean strength for the property and species. Strength ratio factors delimit the grades as Select Structural (SR = .65), No. 1 (SR = .55), No. 2 (SR = .45), No. 3 (SR = .26). Because E and compression perpendicular to the grain are not considered to be life-threatening properties, their use is treated differently. The SR value for all grades of lumber for compression perpendicular to the grain is 1.00. E values do not use an SR term; instead "quality factors" are used. Quality factors, dictated by ASTM standard (ASTM, 1992), are less severe than SR factors. Special dense grades (Dense Select Structural, etc.) are assigned to slow-growing, dense pieces of southern pine and Douglas fir.

Structural lumber is produced in three MC categories: S-GRN (surfaced in the green MC condition, above 19% MC); S-DRY (surfaced in the dry condition, maximum MC of any piece is 19%); and MC-15 (surfaced at a maximum MC of 15%). Southern pine grade rules have additional designations of KD for kiln-dried material and AD for air-dried material; drying lumber in a kiln is accomplished at temperatures high enough to effectively kill insects and to dry areas of accumulated pitch. Southern pine may be labeled MC-15AD, MC-15KD, MC-19AD, etc. Pieces over nominal 4 in. in thickness are normally sold S-GRN.

The various strength characteristics, as outlined in ASTM documents, including an appropriate safety factor, are applied to each board by the grader to arrive at a relatively conservative assessment of a grade. Every stress-graded piece is required to have a grade stamp on it; the grade stamp contains five pieces of information: producing mill number; grading association under which the grade rules have been issued; species or species group; moisture content at time of grading (e.g., S-DRY); and lumber grade.

For the most common softwood species and a few hardwood species used in construction, the recently completed, and very extensive, in-grade testing program has brought about some shifting of the allowable design stress values. These tests of numerous grades of lumber in various species and across most nominal 2-by and 4-by sizes were conducted to ascertain whether the design stresses accurately represented what was in the marketplace. Up-to-date knowledge of within-grade variability in property values and information on the presence or absence of basic forest resource quality shifts were also obtained. After careful analysis, many of the design values were reassigned; some species-size-grade categories warranted an increase while others were reduced. Fewer species groups are now marketed. More realistic values have resulted across the board, leading to improved reliability in wood structures.

The machine stress rating (MSR) grading process relies on a statistical relationship between a nondestructively determined E value and the bending strength of the piece. Thus, each piece is rapidly flexed flatwise in a machine to obtain an average E for the piece and a low-point E; the average E is then statistically, by species, used to assign a bending stress value, with the low-point E serving as a limiting factor in the process of assigning a grade. The MSR process lends itself to more accurate strength/E evaluation and also to closer quality control programs because it makes an actual piece-by-piece test for one property. In general, this process has been limited to identifying higher-quality material for use in specialized industries, e.g., truss and wood I-beam manufacture. The MSR grading process has an added advantage in that lumber graded by this process is grade-stamped with a combination bending stress and E value; e.g., $2100F_b$-$1.8E$. Different combinations may easily be selected to meet special market demands. Currently over a dozen grade categories are available, ranging from $900F_b$-$1.0E$ to $2850F_b$-$2.3E$. Although the MSR grading process is somewhat capital-intensive, it has definite advantages in terms of grading accuracy and reliability.

Panel products are produced and graded in close relationship to quality control (QC) program results. That is, panels are produced according to strict manufacturing parameters, and quality is monitored via regular production line QC test procedures. The reader is referred to APA documents or manufacturer's specifications for the many various grades and uses of panel products such as siding, sheathing, structural plywood, OSB products, etc. (American Plywood Association, 1992a, 1992b).

43.8 Wood Fasteners and Adhesives

Fasteners come in a wide variety of sizes, shapes, and types. Nails are the most common fastener used in construction. Design loads for nails depend upon type of nail (common wire, threaded hardened steel, spike, coated, etc.), wood species or density, thickness of the members being fastened together, nail diameter and length, depth of penetration of the point into the main member, and failure mode. Various failure mode criteria have been incorporated into fastener design in the 1991 edition of NDS. Fastener design for bolts, lag screws, and shear connectors have similar design considerations. Most wood fasteners used in construction tend to have rather large safety factors incorporated into their design and tend to form tenacious joints; however, small deformations of fasteners at a joint also tend to result in serious deformations and structural deficiency over time. Inadequate or inappropriate joint design is a common cause of building problems that are often mistakenly attributed to "wood failure." For all fastener designs the following aspects must be kept in mind: DOL (shorter term loads allow higher design values per fastener); MC factors for dry, partially seasoned, or wet conditions at time of fabrication or in subsequent service; service temperature; group action (a reduction of design load for a series of fasteners in a row); the effect of having a metal side plate in lieu of a wood side plate; and whether the fastener is loaded in lateral or withdrawal mode. In general, placing fasteners into the end grain of wood is to be avoided, certainly so in a withdrawal mode.

Metal plate connectors are also commonly used; they are almost universally used in truss fabrication for residential and light frame construction. Although accurate plate placement is critical, their performance has proven their utility for decades, and numerous computer software packages are available to design structural frames or components that integrate metal plate fasteners into the design. Various types of joist hangers and heavier metal fixtures are also readily available and tend to speed construction of larger structures, particularly where modular components can be fabricated on site. Various fastener manufacturers provide engineering specifications for use of their specific products.

There are several wood-to-wood adhesives which produce joints stronger than the wood itself; however, their use is generally restricted to controlled factory conditions where temperature, adhesive age and formulation, press time, pressure, and adequate QC can be carefully monitored. Wood-to-wood bonds that are well made perform satisfactorily, but they require adequate, uniform pressure on smooth, clean, well-mated surfaces with an even glue spread. A waterproof adhesive is strongly recommended if adhesives are used as a fastener for wood in construction; phenol-resorcinol-formaldehyde is one that is waterproof (it is also widely used for plywood and panel product manufacture). Field gluing is generally to be avoided; however, the use of epoxy resins, particularly for repair work, is practiced successfully.

43.9 Where Do Designers Go Wrong? Typical Problems in Wood Construction

Wood and wood products are relatively simple engineering materials, but the conception, design, and construction process is fraught with problems and places to err. In using wood in its many forms and with its unique inherent characteristics, there are problem areas which seem to present easily overlooked pitfalls. As gentle reminders for caution, some of these areas are discussed below.

Wood and water do not mix well — Wood is hygroscopic and, unless preservative-treated, rots when its MC rises above 20%. It must be protected in some way. Minor roof leakage often leads to pockets of decay, which may not be noticed until severe decay or actual failure has occurred. Stained areas on wood siding or at joints may indicate metal fastener rust associated with a wet spot or decay in adjoining, supporting members. In many cases what appears to be a minor problem ends up as major and sometimes extensive repair is required. Improper installation or lack of an adequate vapor barrier can result in serious decay in studs within a wall as well as paint peel on exterior surfaces. Ground contact of wood members can lead to decay as well as providing ready access to wood-deteriorating termites. Placement

of preservative-treated members between the ground and the rest of the structure (as a bottom sill in a residence) is usually a code requirement. Timber arches for churches, office buildings, and restaurants are usually affixed to a foundation by steel supports; if the supports are not properly installed, they may merely form a receptacle for rain or condensation to collect, enter the wood through capillary action, and initiate decay. Once decay is discovered, major repair is indicated; preservative treatment to a decayed area may prevent further decay, but it will not restore the strength of the material. Elimination of the causal agent (moisture) is paramount. Visible decay usually means that significant fungal deterioration has progressed for 1 to 2 feet along the grain of a member beyond where it is readily identifiable.

Pay attention to detail — In an area that has high relative humidity, special precautions should be taken. A structure that is surrounded by trees or other vegetation or that prevents wind and sun from drying action, is prone to high humidity nearly every day, particularly on a north side. Likewise, if the structure is near a stream or other source of moisture, it may have moisture problems. Home siding in this type of atmosphere may warp or exhibit heavy mildew or fungal stain. Buildings with small (or nonexistent) roof overhangs are susceptible to similar siding problems if the siding is improperly installed, allowing water or condensation to enter and accumulate behind the siding. Inadequate sealing and painting of a surface can add to the problem. In a classic example, a three-story home on a tree-shaded area next to a small stream and with no roof overhang had poorly installed siding, which subsequently warped so badly that numerous pieces fell off of the home. Poor architecture, poor site, poor construction practice, and poor judgment combined to create a disaster. This type of problem becomes magnified in commercial structures, where large surfaces are covered with wood panel products that tend to swell in thickness at their joints if they are not properly sealed and protected from unusual moisture environments. If properly installed, these materials provide economical, long-term, excellent service.

Wood is viscoelastic and will creep under load — This has created widespread problems in combination with clogged or inadequate drains on flat roofs. Ponding, with increasing roof joist deflection, can lead to ultimate roof failure. In situations where floor or ceiling deflection is important, a rule of thumb to follow is that increased deflection due to long-term creep may be assumed to be about equal to initial deflection under the design loading. In some cases the occupants of a building will report that they can hear wood members creaking, particularly under a snow load or ponding action. This is a good indication that the structure is overstressed and failure, or increasing creep deformation with impending failure, is imminent. Deflection measurements over a several-week period can often isolate the problem and lead to suitable reinforcement.

Repair structural members correctly — Epoxy resin impregnation and other techniques are often used to repair structural members. These methods are said to be particularly effective in repairing decayed areas in beams and columns. Removal of decayed spots and replacement by epoxy resin is acceptable only if the afflicted members are also shielded from the original causal agent—excess moisture or insect attack. Likewise, if a wood adhesive must be used as a fastener in an exposed area, use a waterproof adhesive; "water-resistant" or carpenter's glue won't do. Although several wood adhesives will produce a wood-to-wood bond stronger than the wood itself, most of these adhesives are formulated for, and used in, furniture manufacture, where the wood is dry (about 6 to 7% MC) at time of fabrication and is presumed to be kept that way. Structural-use adhesives (unless they are specially formulated epoxy or similar types) may be used where the wood is not above about 20% MC. Structural-use adhesives must also be gap-fillers; i.e., they must be able to form a strong joint between two pieces of wood that are not always perfectly flat, close-fitting surfaces. In addition, the adhesive should be waterproof. The most common and readily available adhesive that meets these criteria is a phenol-resorcinol-formaldehyde adhesive, a catalyzed, dark purple-colored adhesive which is admirably suited to the task.

Protect materials at the job site — Failure to do so has caused plywood and other panel products to become wet through exposure to rain so that they delaminate, warp severely, or swell in thickness to the point of needing to be discarded. Lumber piled on the ground for several days or more, particularly in

hot, humid weather, will pick up moisture and warp or acquire surface fungi and stain. This does not harm the wood if it is subsequently dried again, but it does render it esthetically unfit for exposed use. To repeat, wood and water do not mix.

Take time to know what species and grades of lumber you require, and then inspect it — Engineers and architects tend to order the lumber grade indicated by mathematical calculations; carpenters use what is provided to them. Unlike times past, no one seems to be ultimately responsible for appropriate quality until a problem arises and expensive rework is needed. Case in point: a No. 2 grade 2-by, which is tacitly presumed to be used in conjunction with other structural members to form an integrated structure, is not satisfactory for use as scaffolding plank or to serve a similar, critical function on the job site where it is subjected to large loads independent of neighboring planks.

Inspect the job site — Make sure that panel products, such as plywood, OSB, or flakeboard, are kept under roof prior to installation. Stacked on the ground or subjected to several weeks of rainy weather, not only will these panels warp, but they may lose their structural integrity over time. "An ounce of prevention," etc.

Be aware of wood and within-grade variability due to the uniqueness of tree growth and wood defects — It is often wise to screen lumber to cull out pieces that have unusually wide growth rings or wood that is from an area including the pith (center) of the tree. This material often tends to shrink along its length as much as ten times the normal amount due to an inherently high microfibrillar angle in growth rings close to the pith. In truss manufacture this has resulted in the lower chords of some trusses in a home (lower chords in winter being warmer and drier) to shorten as they dry, while the top chords do not change MC as much. The result is that the truss will bow upward, separating by as much as an inch from interior partitions — very disconcerting to the inhabitants and very difficult to cure. A good component fabricator is aware of this phenomenon and will buy higher-quality material to at least minimize the potential problem. Conversely, avoid the expensive, "cover all the bases" approach of ordering only the top grade of the strongest species available.

Inspect all timber connections during erection — Check on proper plate fasteners on trusses and parallel chord beams after installation; plates should have sufficient teeth fully embedded into each adjoining member. Occasionally in a very dense piece the metal teeth will bend over rather than penetrate into the wood properly. A somewhat similar problem arises if wood frames or trusses are not handled properly during erection; avoid undue out-of-plane bending in a truss during transport or erection since this will not only highly stress the lumber but may also partially remove the plates holding the members together. Bolted connections must be retightened at regular intervals for about a year after erection to take up any slack due to subsequent lumber drying and shrinkage.

Perhaps one of the major causes of disaster is the lack of adequate bracing during frame erection — This is a particularly familiar scenario on do-it-yourself projects, such as by church groups or unskilled erection crews. Thin, 2-by lumber is inherently unstable in long lengths; design manuals and warning labels on lumber or product shipments testify to this, yet the warnings are continually disregarded. Unfortunately, the engineer, designer, or architect and materials supplier often are made to share the resulting financial responsibility.

Be aware of wood's orthotropicity — A large slope of grain around a knot or a knot strategically poorly placed can seriously alter bending or compressive strength and are even more limiting in tension members. Allowable design values for tension parallel to the grain are dictated by an ASTM standard (ASTM, 1992) as being 55% of allowable bending values because test results have indicated that slope of grain or other defects greatly reduce tensile properties. Different orthotropic shrinkage values, due to grain deviations or improper fastening of dissimilar wood planes, can lead to warpage and subsequent shifts in load-induced stresses. Care must be taken when using multiple fasteners (bolts, split rings, etc.) to avoid end splits as wood changes MC, particularly if the members are large and only partially dried at the time of installation. When installing a deep beam that is end-supported by a heavy steel strap hanger,

it is often best to fasten the beam to the hanger by a single bolt, installed near the lower edge of the beam. This will provide the necessary restraint against lateral movement, whereas multiple bolts placed in a vertical row will prevent the beam from normal shrinkage in place and often induce splits in the ends of the beam as the beam tries to shrink and swell with changes in relative humidity. Not only are the end splits unsightly, but they also reduce the horizontal shear strength of the beam at a critical point. In addition, if the beam has several vertically aligned bolts and subsequently shrinks, the bolts will become the sole support of the beam independent of the strap hanger, as shrinkage lifts the beam free of the supporting strap hanger.

Use metal joist hangers and other fastening devices; they add strength and efficiency in construction to a job — Toe-nailing the end of a joist may restrain it from lateral movement, but it does little to prevent it from overturning if there is no stabilizing decking. Erection stresses caused by carpenters and erection crews standing or working on partially completed framework are a leading cause of member failure and job site injury.

In renovating old structures, as long as decay is not present, the old members can be reused — However, because large sawn timbers tend to crack as they dry in place over a period of time, the members must be regraded by a qualified grader. The dried wood (usually well below 19% MC) has increased considerably in strength, perhaps counterbalancing the decrease in strength due to deep checking and/or splitting. End splits over supports should be carefully checked for potential shear failure.

Wood and fire pose a unique situation — Wood burns, but in larger sizes—15 cm (6 in.) and larger—the outer shell of wood burns slowly and, as the wood turns to charcoal, the wood becomes insulated and ceases to support combustion. Once the fire has been extinguished, the wood members can be removed, planed free of char, and reused, but at a reduced section modulus. Smaller members can also be fire retardant–treated to the degree that they will not support combustion. However, treating companies should be consulted in regard to any possible strength-reducing effects due to the treatment, particularly where such members are to be subjected to poorly ventilated areas of high temperature and high relative humidity, as in attic spaces. In recent years newly developed fire retardant treatments have reacted with wood when in a high temperature–high relative humidity environment to seriously deteriorate the wood in treated plywood or truss members. These chemicals, presumably withdrawn from the marketplace, act slowly over time, but have contributed to structural failure in the attics of numerous condominium-type buildings. Preventive measures where such problems may be anticipated include the addition of thermostatically controlled forced-air venting (the easiest and probably most effective measure); the addition of an insulation layer to the underside of the roof to reduce the amount of heat accumulation in the attic due to radiant heat absorption from the sun; and the installation of a vapor barrier on the floor of the attic to reduce the amount of water vapor from the underlying living units.

In using preservative-treated wood it is always best—certainly so when dealing with larger members—to make all cuts to length, bore holes, cut notches, etc., prior to treatment. Depth of preservative treatment in larger members is usually not complete, and exposure of untreated material through cutting may invite decay. Determination of the depth of penetration of a preservative by noting a color change in the wood is hazardous; penetration may be more or less than is apparent to the eye. Deep checking as a large member dries will often expose untreated wood to fungal organisms or insects. Periodic treatment by brushing preservative into exposed cracks is highly recommended. This is particularly true for log home–type construction. Modern log home construction utilizes partially seasoned materials with shaped sections, which not only increase the insulative quality of the homes but also tend to balance, or relieve, shrinkage forces to reduce cracking. Treated or raised nonwood foundations are recommended.

Wood is an excellent construction material, tested and used effectively over the years for a myriad of structural applications—provided one takes the time to understand its strengths and weaknesses and to pay appropriate attention to detail. Knowing species and lumber grade characteristics and how a member is to be used, not only in a structure but also during erection, can go a long way toward trouble-free construction.

43.10 Wood and the Environment

Trees are nature's only renewable resource for building materials. Trees use energy from the sun and carbon dioxide to create cellulose while cleansing the atmosphere and giving off oxygen. Wood is a significant "storehouse" for carbon, and it does all this with little or no input from people. Converting trees into useful products requires much less energy than is needed for other construction materials. Considering any other structural material in terms of production costs to the environment and use through recycling and ultimate disposal, wood is certainly the most environmentally benign material in use today. It is renewable, available, easily converted into products, recyclable, and biodegradable with no toxic residues.

What is the current status of the forest resource? What are the factors affecting the resource and its use? The answers seem to depend upon whom you ask, because there are no explicit, easy answers. Environmental concerns and the "green movement" have resulted in national policy shifts regarding forest use. Large acreages have been set aside as wilderness areas to remain totally unavailable for timber management and harvest. Harvesting on national timberlands has been drastically curtailed. This will necessarily shift harvesting pressure more to industrial and private commercial forestland. While commercial forestland, which is held by numerous wood products companies, is quite productive and provides more product per acre than other sources, privately held timberlands tend to be the least managed of the nation's forested acres. Thus, even though a valid argument can be made for sequestering national timberlands or reducing their production of timber products, shifting the nation's demand for wood to the private, noncommercial sector may not be wise in the long run. On a brighter note, in many traditional timber states, regulations require that cut areas be properly and promptly restocked and waste greatly reduced. It has been estimated that in several western states six trees are planted for each one that is harvested (but under normal forest growth patterns only one or two of the six survive to reach maturity). In most regions of the U.S. increases in tree growth significantly exceed harvest and mortality due to fire, old age, and disease. In other words, there is more timber being produced annually than is being harvested by a significant margin. But that is not the whole story. Average tree diameter has been steadily declining as we have harvested the biggest, best, and most economically available trees. Likewise, individual tree quality has been decreasing, and many forested areas are inaccessible or uneconomical for harvesting operations. Balanced against these factors is the impact of advancing technology. Such products as structural composite lumber, LVL, OSB, glu-lam, and other products, as well as improved grading and strength assessment techniques, have stretched the resource remarkably. We use nearly 100% of the tree for useful products; waste has been significantly reduced. Lesser-known species are being utilized; for example, aspen, a "junk tree" species not long ago, is now the mainstay for many OSB plants in the upper Midwest because of its low density, availability in large quantities, and desirable panel properties. Thin-kerf saws, improved kiln-drying technology, environmentally friendly preservatives, waste conversion to fuel energy (modern integrated paper mills may be over 90% energy self-sufficient, paper industry average energy self-sufficiency value is 56%), and more reliable product grading and QC programs are just a few successful resource-stretching innovations.

New technologies have made tremendous strides and old technologies are being updated. In some areas it is predicted that by the turn of the century wood will be a significant fuel source. Fast-grown tree plantations of hardwoods represent an economical fuel source that does not require mining and is there when the sun is not shining or the wind is not blowing. Wood chips added to coal significantly reduce sulfur and carbon emissions. Over 1000 wood-burning plants are in operation, and their combined output is reputed to be the equivalent of three large nuclear reactors (Anonymous, 1993). Wood waste from manufacturing operations and demolition refuse may become a valuable, environmentally acceptable fuel source.

Although controversy regarding just how we are to allocate the nation's timber resource to provide for endangered species, increased demand for "wild" areas, and increasing numbers of products made from wood will certainly continue, it is possible to retain many of the "natural" aspects of forests and still obtain products from this remarkable resource on a sustainable basis if attention is paid to proper

management and skillful utilization. Current (1990s) controversy over environmental policies will lead to acceptable compromise in time. However, the nature of trees and all the wood products derived from them will assure wood a prominent place as a highly preferred, environmentally desirable, and economically competitive building material.

Defining Terms

Bark — The outside covering of a tree which protects the tree from invasion by insects, disease, and decay.

Cellulose — A long-chain molecule that constitutes the major building block of plant material. Cellulose is the element responsible for wood's strength along the grain.

Check — Often referred to as a "seasoning check"; a separation of the wood cells as a result of shrinkage during drying. Checks tend to reduce shear strength.

Decay — Results from fungal attack of wood. Fungi may attack either the wood cellulose and hemicellulose or the lignin; in either case even the early stages of decay seriously reduce wood strength and make it unsuitable for any structural purpose.

Density — Weight per unit volume of wood. The weight is always in the oven-dry condition (i.e., 0% MC); the volume, however, may be measured at any stated MC (most often green, 12%, or oven-dry). Since wood shrinks as it dries, density values vary, and the MC base must be stated as, for example, "volume measured at 12% MC." Similarly, specific gravity values will vary depending on the MC at which volumetric measurements are made.

Duration of load (DOL) — The ability of wood members to sustain larger loads for shorter periods of time without failure than they can sustain without failure for longer periods of time. Structures that will have design loads imposed upon them for shorter than "normal" DOL are permitted to have an increase in allowable design stresses in bending, compression parallel to the grain, tension parallel to the grain, and shear. Normal DOL is defined as a 10-year cumulative loading duration.

Earlywood — The portion of a growth ring that is formed early in the growing season. It normally contains larger cells with thinner walls. Earlywood is relatively low in density and is followed by latewood as the growing season progresses. See **Latewood**.

Fiber saturation point (fsp) — A point (about 25% MC, depending on species) in the drying of wood at which the hollow centers of the wood cells have lost their moisture, leaving the cell walls fully saturated. Wood does not begin to shrink until its MC has dropped below fsp.

Flat-sawn — Lumber that has its wide face in a tangential plane (i.e., cut approximately tangent to the annual growth rings); also called plain-sawn. See **Quarter-sawn**.

Glu-lam — A structural product made by gluing structural boards together; the grain of all pieces is oriented along the long axis of the member. Glu-lam may be manufactured into a variety of curved beams, arches, or irregular shapes. See also **Laminated-veneer-lumber**.

Growth ring — The portion of wood of a tree produced during one growing season. In the temperate zones this is also called an annual ring.

Hardwood — Trees that are deciduous; that is, trees whose leaves are broad and are generally shed each year in the temperate zones. Typical hardwoods include oaks, maples, and poplar.

Heartwood — The innermost growth rings of a tree; may be darker in color than the outermost growth rings (called *sapwood*). Contains phenolic compounds that in some species impart decay resistance to the heartwood.

Hemicellulose — A long-chain molecule similar to cellulose, but more easily soluble in dilute acid or basic solutions.

Incising — Perforation of the surface of a pole or wood member by a series of chisel-like knives prior to preservative treatment to permit deeper and more uniform infusion of the preservative into the wood.

Knots — The result of a branch having been cut in the manufacture of a board. If the branch is cut at a right angle to its length, the knot appears as a branch cross-section; if the branch is cut along its length, appearing to go across the face of a board, it is termed a spike knot.

Laminated-veneer-lumber (LVL) — A board product made by gluing pieces of thin lumber or veneer together to make a larger member, usually formed into long flat panels suitable for remanufacture into common lumber sizes. The grain of all pieces is oriented along the long axis of the panel. See also **Glu-lam** and **Plywood**.

Latewood — The portion of a growth ring that is formed later in the growing season. Cells tend to be smaller in size and have thicker, denser cell walls than in earlywood. See **Earlywood**.

Lignin — A highly complex molecule that acts as an adhesive to bond wood cellulose units together. Although plastic in nature, especially at elevated temperatures, lignin gives wood its rigidity.

Microfibrils — Groups of cellulose or hemicellulose molecules that form long, threadlike macro-molecules. Layers of microfibrils form the wood cell walls and are ultimately responsible for wood's anisotropic properties.

Moisture content (MC) — The amount (weight) of water in a piece of wood, expressed as a percent of the weight of an oven-dry (0% MC) piece.

Nominal size — A convenient size nomenclature that approximates the size of a member in a log prior to being sawn into lumber; a nominal 2-by-4, when sawn, dried, and surfaced, has an actual, usable size of 1½ ¥ 3½ in., for example.

Normal duration of load — Ten years, cumulative, of the load for which a member or structure has been designed. Allowable design stresses may be modified for shorter or longer load periods.

Oriented-strand board (OSB) — A flat board product made from wood flakes that are long and narrow and are oriented along the length of the panel, and a waterproof adhesive, so that the properties and characteristics resemble those of solid lumber.

Oven-dry weight — The weight of a piece of wood at 0% MC; normally determined by drying a small block of wood at 103°C until repeated weighings indicate that all moisture has been removed from the block.

Particleboard — A flat board product made from wood particles or flakes mixed with an adhesive and formed under pressure and elevated temperature. Not sold for structural use. See also **Oriented-strand board**.

Preservative — A chemical, usually in solution form, that is forced into wood (usually under pressure) to preserve the wood from attack by insects and decay organisms.

Plywood — A flat glued panel made from thin sheets of veneer with alternate plies having grain directions oriented 90 degrees to adjacent plies.

Quarter-sawn — Lumber that has its wide face in a radial plane (i.e., cut approximately parallel to the wood rays). Lumber is quarter-sawn to accentuate the wood figure due to the large wood rays in some species. See **Flat-sawn**.

Repetitive member use — A structural situation wherein three or more bending members in sizes of 2 to 4 in. in nominal thickness (as for floor joists) are fastened together and stabilized, as by flooring, to form an interactive unit. Repetitive members are permitted a 15% increase in allowable bending stress.

Sapwood — The outermost growth rings of a tree; always light brown to cream-colored in all species; never decay- or insect-resistant. Sapwood and heartwood together make up the "wood" of commercial use.

Shake — A lengthwise separation of the wood that may occur between or through annual growth rings.

Slope of grain — A deviation of cell orientation from the longitudinal axis of a member; measured as rise/run (as in 1 in 10). Slope of grain may be a growth phenomenon (as when grain deviates around a knot) or a manufacturing defect caused by failure to cut a member "along the grain."

Softwood — Typically "evergreen" trees with needle-like leaves. Includes Douglas fir, pines, spruces, cedars, and hemlock.

Specific gravity (SG) — The ratio of the density of a material to that of an equal volume of water. See **Density**.

Split — A separation of wood cells along the grain; splits are deeper and more serious than cracks or checks in that splits penetrate completely through the thickness of a member. Splits most often occur at the ends of a member and reduce shear strength.

Strength ratio (SR) — A factor applied in lumber stress grading to account for wood defects. It represents a ratio of the strength of a piece with all its defects to the strength the piece would have if no defects were present.

Structural composite lumber (SCL) — A panel product made of thin layers of veneer or wood strands mixed with a waterproof adhesive. See **LVL**.

Wane — A lack of wood that occurs in lumber manufacture when the edge of a member intersects the periphery (bark) of a tree so that the edges are not "square."

Warp — Any deviation from a true or plane surface, including bow, crook, cup, and twist. *Bow* is a deviation flatwise from a straight line drawn from end to end of a piece. *Crook* is a deviation edgewise from a straight line drawn from end to end of a piece. *Cup* is a deviation in the face of a piece from a line drawn from edge to edge of a piece. *Twist* is a deviation flatwise, or a combination flatwise and edgewise, of a piece, resulting in the raising of one corner of a piece while the other three corners remain in contact with a flat surface.

Wood cells — Long, thin, hollow units that make up wood. Most cells are oriented with their long axis roughly parallel to the axis of the tree.

Wood rays — Groups of cells whose long axes are oriented horizontally and that radiate outward from the center of a tree. Wood rays are responsible for horizontal translocation of fluids in a tree and are partially responsible for the difference in radial vs. tangential shrinkage and swellage in wood.

44.1 Properties and Processes

Types of Steel

The term *structural steel* is generally taken to include a wide variety of elements or components used in the construction of buildings and many other structures. These include beams, girders, columns, trusses, floor plates, purlins and girts. Many of these elements are made from standard hot rolled structural shapes, cold formed shapes or made up from plates using welding. They are joined at connections made using plate, structural shapes, welding, and fasteners. Fasteners include bolts, nuts, washers and stud shear connectors. For a more complete listing of *structural steel* elements see the American Institute of Steel Construction (AISC) Code of Standard Practice for Steel Buildings and Bridges, Section 2.1.

A variety of steel types are used to produce these structural shapes, plates and other components depending on the intended use and other factors such as the importance of cost, the weight of the structure and corrosion resistance. The properties of steel products result from a combination of the chemical composition, the manufacturing processes and the heat treatment. The properties most commonly used as a basis for specification and design are the specified minimum yield stress (yield point or yield strength) and the specified minimum tensile strength (or ultimate strength), both obtained from tensile tests on small representative specimens of the steel (see below). Other properties also required are ductility, weldability, and fracture toughness (or notch ductility) although these requirements are often not explicitly stated. The steels most commonly used are:

- carbon steels
- high-strength low-alloy steels
- corrosion resistant, high-strength low-alloy steels
- quenched and tempered alloy steels

The elastic modulus is virtually the same for each of these types of steel, but their yield stress and ultimate strength vary widely. The range of strengths for each of these types of steel is shown along with the typical products and uses in Table 44.1.

The production of structural steel structures and buildings is a complex process involving making the steel, processing it into useful products, fabricating these products into useful assemblies or structures,

TABLE 44.1 Types and Usage of Steel Used In Construction

Steel Type	ASTM Specification	Grade	Products	Usage
Carbon	A36	36	Shapes, plates and bars	Riveted, bolted or welded bridges, buildings and general structural purposes
	A529	50	Shapes, plates and bars	Riveted, bolted or welded buildings and general structural purposes
		55	Shapes, plates and bars	
High-strength, low-alloy	A572	42	Shapes, plates, sheet piling and bars	Riveted, bolted or welded structures
		50		
		55		
		60		Riveted or bolted bridges, or riveted, bolted or welded construction in other applications
		65		
	A992	50	W shapes	Building framing
Corrosion-resistant, high strength low-alloy	A242	50	Shapes, plates and bars	Riveted, bolted or welded construction for weight saving or added durability
	A588	50	Shapes, plates and bars	Riveted, bolted or welded construction, primarily for welded bridges or buildings for weight saving, added durability or good notch toughness
Quenched and tempered alloy steels	A852	70	Plates	Riveted, bolted or welded construction, primarily for welded bridges or buildings for weight saving or added durability
	A514	90	Plates to 6 in thickness	Welded bridges and other structures
		100		
	A913	50	Shapes	Riveted, bolted or welded bridges, buildings and other structures
		60		
		70		

and erecting and assembling these components, assemblies, and structures into buildings, bridges, cranes, and the myriad of other structures and pieces of machinery and equipment constructed using structural steel. It requires a team effort on the part of specialists who understand in detail the processes and pitfalls that are associated with each step in the overall process. Such is the complexity of each of these areas that specialists are required in each area and each in turn must contribute appropriately for the final product to be successful.

The first step in the production process, steel making and rolling to form finished products suitable for use in buildings and structures, are themselves very complex processes requiring extensive knowledge of the metallurgy and mechanical forming of steel. Designers should be aware of the importance of certain parameters and processes because they can have a major effect on the performance of a steel structure, but they normally do not specify or need details of precisely how the steel is produced, rolled or formed. Indeed structural steels are usually specified in terms of a very limited number of parameters that describe their essential attributes.

Structural steels are usually produced by rolling steel cast from the steelmaking process after reheating it to the austenizing range (above 850°C). Rolling consists of passing the steel through a series of rolls that form the cast steel into the shape and/or thickness required. A very wide range of shapes and sizes are currently rolled or available in the U.S. (Table 44.2). The shapes are designated as follows:

- W shapes are parallel flanged I or **H** sections used as beams and columns
- S shapes are I sections with inside flange surfaces that slope used as beams
- HP shapes are parallel flanged **H** sections used as beams with flanges and webs of similar thickness
- M shapes are I sections not qualifying as W, S or HP shapes

TABLE 44.2 Range of Structural Shapes Available in the U.S.

Shape Size Groupings for Tensile Property Classification\ (as given in ASTM A6/A6M – 1998)				
Group 1	Group 2	Group 3	Group 4	Group 5
	W40 × 149 to 268	W40 × 277 to 328	W40 × 362 to 655	
	W36 × 135 to 210	W36 × 230 to 300	W36 × 328 to 798	W36 × 920
	W33 × 118 to 152	W33 × 201 to 291	W33 × 318 to 619	
	W30 × 90 to 211	W30 × 235 to 261	W30 × 292 to 581	
	W27 × 84 to 178	W27 × 191 to 258	W27 × 281 to 539	
W24 × 55 & 62	W24 × 68 to 162	W24 × 176 to 229	W24 × 250 to 492	
W21 × 44 to 57	W21 × 62 to 147	W21 × 166 to 223	W21 × 248 to 402	
W18 × 35 to 71	W18 × 76 to 143	W18 × 158 to 192	W18 × 211 to 311	
W16 × 26 to 57	W16 × 67 to 100			
W14 × 22 to 53	W14 × 61 to 132	W14 × 145 to 211	W14 × 233 to 550	W14 × 605 to 873
W12 × 14 to 58	W12 × 65 to 106	W12 × 120 to 190	W12 × 210 to 336	
W10 × 12 to 45	W10 × 49 to 112			
W8 × 10 to 48	W8 × 58 & 67			
W6 × 9 to 25				
W5 × 16 & 19				
W4 × 13				
M shapes to 18.9 lb/ft				
S shapes to 35 lb/ft				
	HP shapes to 102 lb/ft	HP shapes over 102 lb/ft		
C shapes to 20.7 lb/ft	C shapes over 20.7 lb/ft			
MC shapes to 28.5 lb/ft	MC shapes over 28.5 lb/ft			
L shapes to ½ in	L shapes over ½ in to ¾ in	L shapes over ¾ in		
Tees cut from W, M and S shapes remain within the group of the shape from which they are cut.				

- C shapes are channels with inside flange surfaces that slope similarly to S shapes
- MC shapes are channels that do not qualify as C shapes
- L shapes are equal and unequal legged angles

The groups in Table 41.2 are convenient groups based on the thickness of the shape at the point where standard tension test (see below) specimens are taken and are used in the ASTM materials specifications and in design specifications such as the American Institute of Steel Construction Load and Resistance Factor Design Specification for Structural Steel Buildings. They are useful because in some material specifications the specified minimum tensile properties differ for different thicknesses of steel and care must be exercised in design to use appropriate properties and fabrication and welding procedures for the shapes used.

The properties of steel largely result from the influence of microstructure and grain size though other factors such as non-metallic inclusions are also important. The grain size is strongly influenced by the cooling rate, to a lesser extent by other aspects of heat treatment and by the presence of small quantities of elements such as niobium, vanadium and aluminium. The chemical composition of steel is largely determined when the steel is liquid but for a given chemical content the structure is largely determined by the rate at which it is cooled and may be altered by subsequent reheating and cooling under controlled conditions. The microstructure of steel is classified in terms of several crystal structures called ferrite, austenite, pearlite, and cementite. Phase diagrams are used to map the steel structure in relation to temperature and carbon content and transformation diagrams are used to map the structure in terms of temperature and time. If steel is allowed to cool slowly, the crystal lattice structure and microstructure reaches equilibrium dependent on the steel temperature and the carbon concentration (represented by the phase diagram). If it is cooled faster, the structure is dependent on the cooling rate and the chemical content of the steel (represented by transformation diagrams).

There are several terms associated with cooling and heat treatment that will now be briefly introduced. Normalized steel is allowed to cool in air from temperatures above 850°C, developing a reasonably fine grain structure, moderate strength and good toughness. Controlled rolling involves rolling the steel to the desired form within a comparatively narrow temperature range and then allowing it to cool naturally in air. This results in higher strength than achieved through conventional rolling. Quenching is rapid cooling by immersing the steel in water or oil to produce a higher strength but less ductile and tough product. Tempering is a subsequent process in which the temperature is again raised, but not to the austenitizing range, and cooled more slowly resulting in a reduction in strength but increased ductility and toughness. All of these processes are used in producing the steel types listed in Table 44.1. In addition some structural steel shapes are produced by a patented process of quenching and self-tempering (QST) which produces shapes with mechanical properties equivalent to those that would normally be obtained using reheating after rolling.

Carbon steels are largely composed of iron with up to 1.7% carbon, but the addition of relatively small quantities of other elements greatly influences its behavior and properties. For structural purposes it is desirable that steel be ductile and weldable, and consequently most structural carbon steels are "mild steel" with carbon in the range 0.15 to 0.29% and may include small quantities of manganese, silicon and copper.

High-strength low alloy steels include alloying elements such as chromium, copper, nickel, silicon and vanadium. In addition to their higher strength these steels may also possess greater corrosion resistance than carbon structural steels.

Corrosion resistant, high-strength low-alloy steels, due to the addition of greater quantities of copper, have corrosion resistance properties substantially greater than carbon and low-alloy structural steels. Under suitable environmental conditions, including several cycles of wetting and drying, a stable layer of corrosion products is developed on the surface of these steels and further corrosion is inhibited.

Quenched and tempered alloy steels contain greater concentrations of alloying elements than carbon and low-alloy structural steels and specific heat treatments are incorporated in the manufacturing process primarily to increase their strength. Generally this increased strength is obtained at the cost of reduced ductility and great care must be exercised in their use.

Table 44.1 summarizes the range of structural steels available in the U.S. according to their American Society for Testing and Materials (ASTM) specification, the grades available and the products and uses for which they are intended. It should be understood that many shapes, plates and bars are not readily available in all of these grades and that their availability should be checked with suppliers or fabricators before they are specified in designs. The more readily available types and grades are:

- W shapes — A992
- M, S, HP, C and L shapes — A36 (and increasingly A572 Grade 50)
- HSS — A500 Grade B for round and A501 Grade B for square and rectangular (and increasingly Grade C for both)
- Plate — A36 and A572 Grade 50

Structural Properties

As mentioned above structural steels are primarily designated in terms of their strength as measured in tensile tests. In these tests normally conducted in accordance with ASTM 370 (Test Methods and Definitions) specimens of the steel cut from the shape or plate are tested in tension. Figure 44.1 shows a typical stress-strain diagram obtained from such a test for a carbon steel. It shows a well defined yield point and yield plateau, with subsequent strain hardening and substantial elongation before rupture. Figure 44.2 shows the low initial (low strain) portion of the stress-strain diagram shown in Fig. 44.1 in more detail.

The behavior shown in Figs. 44.1 and 44.2 with an extended yield plateau and substantial strain hardening results in structures that have a great capacity for deformation and redistribution of stresses before failure.

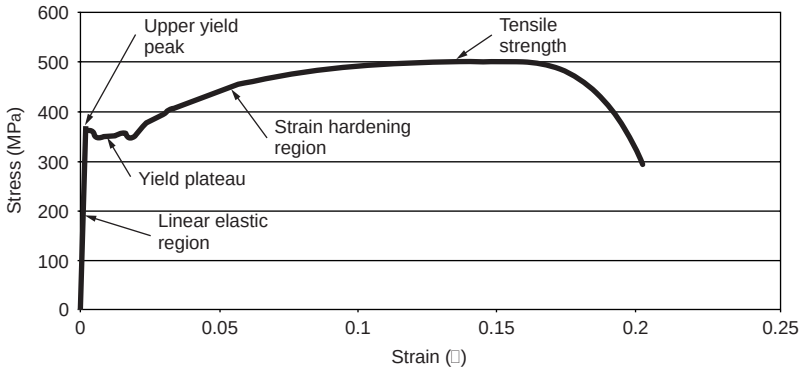

FIGURE 44.1 Typical stress-strain curve for carbon steel.

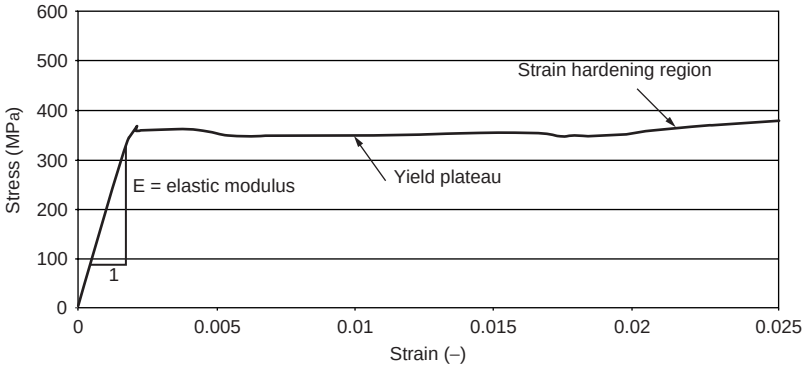

FIGURE 44.2 Detail of low strain region of stress-strain curve shown in Fig. 44.1.

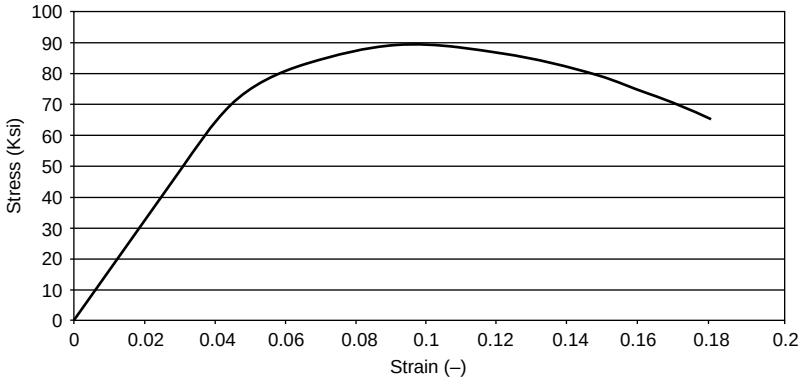

FIGURE 44.3 Form of stress-strain curve for high strength steels.

Higher strength structural steels (low alloy and quenched and tempered) do not show the well-defined yield plateau seen in Figures 44.1 and 44.2. The form of stress-strain curve obtained for such steels is shown in Fig. 44.3. The yield stress for these steels is determined from the yield strength, which is the stress at which a nominated strain is reached. The yield strength is determined by either the 0.2% offset method or the 0.5% extension-under-load method as shown in Fig. 44.4. Steels with this form of stress-strain curve do not exhibit the same elongation capability and stress redistribution capability as mild steels.

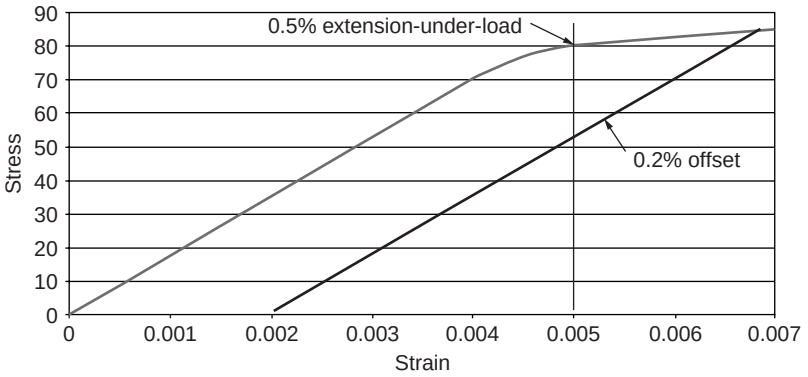

FIGURE 44.4 0.2% Offset and 0.5% elongation-under-load yield strength.

TABLE 44.3 Strength and Elongation Requirements for Structural Steels

Steel Type	ASTM Specification	Grade	Specified Minimum Yield Stress* Ksi (MPa)	Specified Minimum Tensile Strength* Ksi (MPa)	Elongation*
Carbon	A36	36	36 (250)	58 (400)	20%
	A529	50	50 (345)	70 (485)	18%
		55	55 (380)	70 (485)	17%
High-strength, low-alloy	A572	42	42 (290)	60 (415)	20
		50	50 (345)	65 (450)	18%
		55	55 (380)	70 (485)	17%
		60	60 (415)	75 (520)	16%
		65	65 (450)	80 (550)	15%
	A992	50	50 (345) max. 65 (450)	65 (450)	18%
Corrosion-resistant, high strength low-alloy	A242	50	50 (345)	70 (485)	18%
	A588	50	50 (345)	70 (485)	18%
Quenched and tempered alloy steels	A852	70	70 (485)	90 (620)	19%#
	A514	90			
		100	100 (690)	110 (760)	18%#
	A913	50	50 (345)	65 (450)	18%
		60	60 (415)	75 (520)	16%
		65	65 (450)	80 (550)	15%
		70	70 (485)	90 (620)	14%

* Note: 1. In some cases specified minimum elongation varies with thickness or product. Check specification for details.
2. # = elongation on 2 in. gauge length, elsewhere it is on an 8 in. gauge length

Typical specified minimum yield stress, ultimate stress and elongation for structural steels used in the USA are given in Table 44.3.

Heat Treatment

The production of steel and steel products involves heat and the effects of heating and cooling throughout. A brief description of some of the forms of heat treatment that may be used in producing structural steel plate and shapes was covered in Section 44.1. This section contains a brief description of forms of heat treatment that may be used in the subsequent processes of fabrication and erection of steel buildings and structures.

Many of the processes used in forming, fabricating and erecting structural steel can have an effect on the steel that is undesirable or that may affect the performance of the structure. These effects can include high residual stresses after forming or welding, excessive hardening (or softening) substantially altering the as-rolled properties of the steel, etc.

The processes that were described earlier can be used during or after the fabrication processes to reduce or repair some of these changes or effects.

Heat is sometimes used during fabrication to straighten or camber members and to bend or straighten plates. Welding always introduces residual stresses into the steel, but excessive welding or welding in restrained situations can be particularly concerning in that it can introduce residual stress fields that can significantly affect the performance of structural members or connections between members. It is possible to relieve (reduce) these residual stresses by uniformly heating the entire assembly or by heating a suitable portion of it.

In carrying out such heat treatment, it is important that full cognizance be given to the processes by which the components were made and possible changes in the structure or properties of the steel that can occur with incorrect or inappropriate heat treatment. This may involve limiting the maximum temperature to which the assembly is raised or limiting the duration of high temperatures.

Welding

Welding is perhaps the most important process used in the fabrication and erection of structural steelwork. It is used very extensively to join components to make up members and to join members into assemblies and structures. Welding used and done well helps in the production of very safe and efficient structures because welding consists of essentially joining steel component to steel component with steel that is intimately united to both. It can lead to very efficient paths for actions and stresses to be transferred from one member or component to another. Conversely, welding used or done badly or inappropriately can lead to potentially unsafe or ineffective structures – welds containing defects or inappropriate types or forms of joints can cause failure or collapse of members or structures with little or no warning. Thus care is required in the design of welds, in the design or specification of welding processes, in the actual process of welding components one to another, and in the inspection of welding to assure that it is as specified and fit for purpose.

As with the production of the structural steel components, specialist expertise is required for successful welding. This is built on a foundation of knowledge of the metallurgy of steel but also requires knowledge of the processes and materials involved in welding.

Welding of structural steel is usually the process of joining two pieces of similar (not necessarily identical) steel by casting a further quantity of steel between them and fused to each of them, but it may equally involve no filler material, simply the melting together of the two pieces to be joined. The process involves heating and melting the surfaces of the pieces to be joined and, when required, the steel to make the weld.

Currently the most common methods of welding may be classified as arc and resistance welding. Arc welding involves the process of striking an arc to pass a large electric current from one piece of metal to another. The arc itself is at a very high temperature and heats the materials nearby. The arc is normally struck between the metal that is to form the filler material and the workpiece, but in some processes is struck between a separate electrode and the workpiece. Resistance welding involves the very rapid discharge of a very high current between the two pieces to be joined resulting in the release of heat and the melting of the mating surfaces. Both processes involve rapid heating and cooling of the weld metal and the material adjacent to the weld and thus may alter the metallurgy and properties of these materials. Thus great care needs to be taken with the design, specification and execution of the welds to ensure that the final product is sound, has appropriate properties and does not lead to unintended effects such as excessive residual stresses.

There are several arc welding processes commonly used in structural steel fabrication and erection. Shielded metal arc welding (SMAW) is a manual process involving a consumable electrode (stick) which consists of a length of wire that is coated with a flux. The arc is struck between the electrode and the workpiece with the electrode coating forming a gas shield that protects the arc and molten metal from

the air, stabilizing the arc and preventing the oxidation of the metal. After the weld is complete the solid residue of the coating (slag) solidifies over the weld metal and may be removed mechanically (chipping, etc). In gas metal arc welding (GMAW) the short stick of SMAW is replaced by a continuous uncoated wire electrode from a coil which is fed through a lightweight gun that also feeds a protective gas (often carbon dioxide) to protect the arc. GMAW has the advantage over SMAW of a continuous process and results in high deposition rates (of the filler metal).

A welding process often used in fabrication shops is submerged arc welding (SAW), which is usually performed automatically or semi-automatically. SAW usually uses a continuous wire electrode and the arc struck between the rod and the workpiece is protected by granular flux that covers the end of the electrode, arc and workpiece in the area near the arc. Thus the arc is submerged in flux and is not visible. Very high deposition rates can be achieved using SAW. Flux-core arc welding (FCAW) also uses a continuous electrode but in this case it is hollow and contains flux as a core. Often gas shielding in addition to the shielding provided by the flux material is provided to protect the work area.

Defects of various kinds can result from welding. These can be conveniently classified as planar and volume discontinuities (solid, such as slag, or gaseous inclusions) and shape (or profile) imperfections. In all cases these defects can result in the area of the weld being less than that intended and, often more importantly, in stress concentrations that increase residual and load induced stresses. The greatest stress concentrations arise from the planar discontinuities that in turn can be classified as arising from lack of penetration or fusion, hot cracking, cold cracking, lamellar tearing, and reheat cracking.

Lack of penetration or fusion (and slag inclusions) normally results from operator error or incorrect procedure specification. Hot or solidification cracking occurs during the solidification of the weld due to impurities such as sulfur and phosphorus deposited near the centerline of the weld. It is controlled by minimizing such impurities and by avoiding deep narrow welds. Cold or hydrogen-induced cracking results from the combination of a hardened microstructure and the effect of hydrogen in the steel lattice, and is avoided by keeping the hydrogen concentration to very low levels through control of electrode coatings and electrode storage. Lamellar tearing results from excessive non-metallic inclusions in rolled steel plates and shapes. Such inclusions result in planes of weakness within plates and the flanges and webs of shapes that split if subjected to high stresses produced by restraint of shrinkage as the weld metal cools. The problem is avoided by again keeping impurities low (in this case sulfides and silicates), and also by testing the tensile properties through the thickness (rather than along the length of the element as is usual) and requiring adequate ductility, and by avoiding welds where there is excessive restraint of welds in vulnerable locations. Reheat cracking occurs during stress relief treatment or prolonged high temperature exposure of steelwork, particularly of steels containing molybdenum or vanadium.

Steels are not uniformly suited to welding. Certain steel compositions make the resultant welds more likely to be hard and brittle, and thus more likely to be subject to cold cracking or brittle fracture. The weldability (that is suitability of a steel for welding using conventional practice) of steels is often assessed using the "carbon equivalent"(CE), particularly of carbon-manganese and low-alloy steels [ASTM A6]:

$$CE = C + Mn/6 + (Cr + Mo + V)/5 + (Ni + Cu)/15$$

This formula uses the concentrations of the various elements and effectively "scales" the propensity of each element to harden the steel compared with that of carbon.

44.2 Service Performance

Brittle Fracture

Structural steel members or elements may become liable to brittle fracture under some conditions, although this rarely occurs in practice.

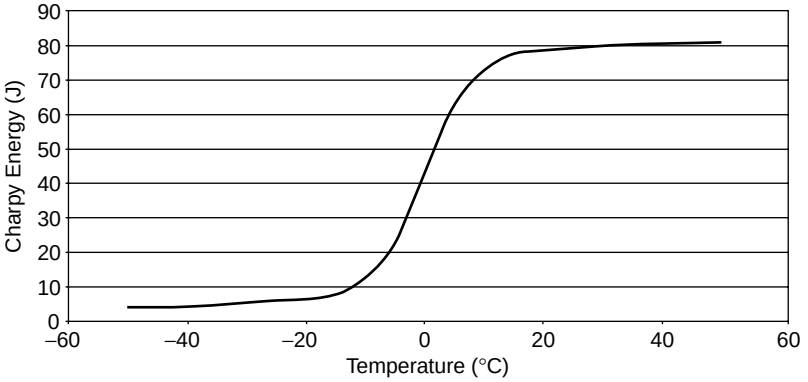

FIGURE 44.5 Illustrative Charpy energy transition curve.

Brittle fracture normally only occurs when a critical combination of the following exist:

- a severe stress concentration due to a notch or severe structural discontinuity
- a significant tensile force occurs across the plane of the notch (or equivalent)
- low fracture toughness of the steel at the service temperature
- dynamic loading

The potential for brittle fracture is generally addressed by eliminating or minimizing the effect of each of these factors. Thus, using structural steels that have suitable notch ductility at the expected service temperatures, reduction in stress, particularly residual stresses due to welding or forming, and the use of details that do not give rise to severe notches or structural discontinuities are the preferred methods of reducing the risk of brittle fracture.

The fracture behavior of steel changes from brittle to ductile as the temperature increases. The Charpy V Notch impact test is used as a relatively low cost test that can be used to monitor the potential for brittle fracture of steel. For a given steel, the energy required to fracture the Charpy V Notch specimens typically is low at low temperatures, rises quickly with increase in temperature through a transition range and is relatively high at higher temperatures (Fig. 44.5). The change in energy required reflects a change in the mode of fracture: from brittle fracture at the lower temperatures to ductile or fibrous fracture at the higher temperatures, with a very variable mixture of the two through the transition temperature range.

The need for steel with high fracture toughness depends on the expected service temperature range. If the service temperature is expected to become low it is necessary to ensure that the transition from brittle to ductile fracture behavior under service conditions occurs at a temperature below the expected service temperature. The transition under service conditions normally takes place at temperatures substantially below those at which it takes place in the Charpy V notch test because the strain rate under service conditions is usually much lower than that which occurs during the test. Thus, specifications do not require the transition temperature to be lower than the service temperatures, for example, for bridges the steel specifications require the test to be performed at a temperature 38°C greater than the expected minimum service temperature. These specifications also provide different requirements for members depending on whether the members are fracture critical or not and more stringent requirements for weld metal compared with the steel in the members.

In general, designing structures so that they only incorporate details that provide good fatigue performance is a very effective way of reducing brittle fracture. Normally, structures such as bridges that have the potential to suffer both fatigue damage and brittle fracture, it is fatigue damage that is more likely to occur.

Fatigue

Fatigue of steel structures is damage caused by repeated fluctuations of stress leading to gradual cracking of a structural element. Most steel structures are not subjected to sufficiently great or sufficiently many fluctuations in load (and thus stress) that fatigue is a consideration in design. However, road and rail bridges, cranes and crane supporting structures, other mechanical equipment and machinery supporting structures are examples of steel structures that may be subject to fatigue.

In design for fatigue it is normal to design the structure for all of the other requirements (static strength, serviceability) first and then to assess the structure for fatigue. Fatigue design is normally undertaken with the actual (or estimated) loads that will apply to the structure rather than factored loads that are used in strength aspects of design. It is important in design for fatigue to ensure that all parts of the structure are considered and that structural details and connections are carefully detailed and specified as it is these details that will greatly influence the likelihood of fatigue damage occurring during the life of the structure.

The loads used in design should be the best estimates that can be made of those that will occur in practice and should take into account dynamic effects (for example, impact loads) and loads induced by oscillations of the structure or, for example, suspended loads. Moving or rolling loads may result in more than one cycle of load during their passage over a structure or part of the structure. Care should be taken to ensure that all of the load cycles on each element of the structure are considered in assessing the structure for fatigue.

In general in considering fatigue in steel structures it is not fatigue in the as rolled parent or base metal (that is, the steel from which structural elements are made away from connections or changes in shape or direction) that is important. Of far greater importance are points in the structure incorporating welds or bends or, to a lesser extent, bolts. At these points the general stress field in the elements is concentrated or amplified due to the presence of defects, notches, changes in section, etc or additional stresses are imposed on the steel due to residual stresses caused by the heating and cooling of welding or by the permanent deformation due to bending. These result in fatigue cracks generally initiating at such details.

The fatigue life of structures or structural elements can be considered to consist of two parts:

- the period until the commencement of cracking
- the period of crack growth from initiation until the crack grows catastrophically and the element fails

In design, consideration of these stages is not important as the basis for design is a classification of structural details (mainly weld types and configurations) in groups based on large numbers of tests of such details. For a given detail the number of cycles a structural element will endure before failure depends on the load on the element. The higher the load the lower the number of cycles. However, because there are many factors that influence the fatigue life of a particular element, there is much variability in the actual number of cycles before failure of a group of seemingly similar elements. The life can easily vary by a factor of ten around the mean for the whole group.

It has been found that the fatigue life (number of cycles to failure) for welded structures is best defined in terms of the stress range on the element or detail and the notch severity of the detail. The stress range is defined as the algebraic difference between the two extremes of stress that occur during a cycle of loading on the element or detail (Fig. 44.6).

The yield stress and tensile strength of the steel and the minimum, average or maximum stress in the components at the detail have little or no influence on the fatigue strength for a wide range of structural steel grades. Current design specifications base design for fatigue on full-scale testing of details carried out over many years and design largely consists of identifying an appropriate stress category for the detail under consideration, estimation of the stress range that results from the fluctuating loads and the number of cycles of load that the detail is likely to be subjected to during the intended life of the structure and comparing these with S-N curves provided in the relevant specification.

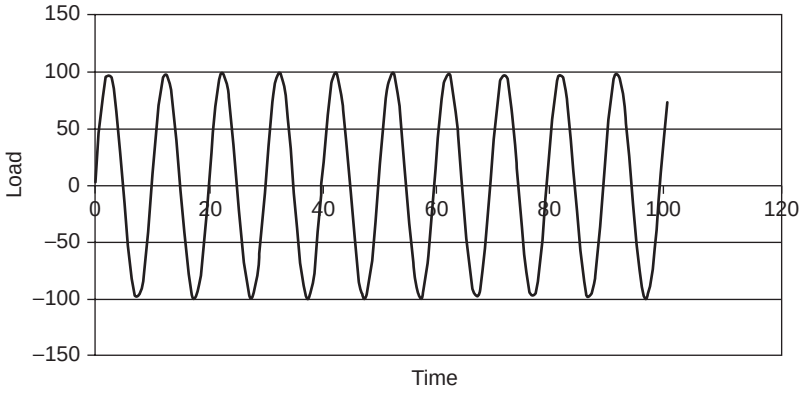

FIGURE 44.6 Uniform amplitude cycles of stress.

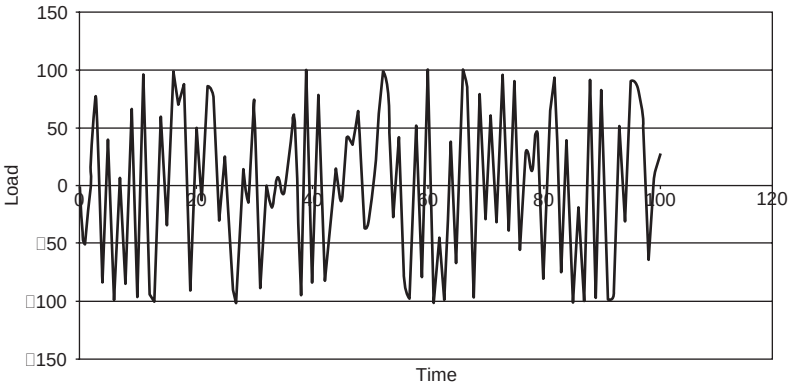

FIGURE 44.7 Varying amplitude stress cycles.

It is not necessary to consider fatigue at a detail if the stresses in the region are always compressive or if the stress range is always below a limiting value known as the threshold fatigue stress range for that detail. However, if any of the stress cycles that the detail is subjected to produces a stress range that is over the threshold value then all stress ranges including those below the threshold value must be considered in estimating the design life.

In practice, structures and structural elements are generally not subjected to uniform repeated applications of load such as those shown in Fig. 44.6. More usually the loads and stresses vary to some degree in the short term and through the life of the structure (Fig. 44.7). The design life is normally based on constant amplitude tests, so it is necessary to have a basis for determining the equivalence between the number of cycles to failure at a given constant stress range in tests and the number of cycles to failure when the stress range varies with each cycle either systematically or randomly.

This is usually done through the use of Miner's rule, which is the sum of the actual number of cycles at each stress range level divided by the number of cycles that are expected to cause failure, for each stress range level considered.

That is:

$$\sum_{i=1}^{m} \frac{n_i}{N_i}$$

where n_i = number of cycles for stress range group i
N_i = permissible number of cycles for stress range group i
m = number of stress range groups

When the stresses in a structural element vary during the life of a structure (as in Fig. 44.7) the "cycles" of stress are not obvious, and procedures have been developed for "identifying" and counting stress cycles using methods such as rainflow counting. Effectively histograms of the stress range are produced with stress ranges accumulated in groups so that the number of cycles that the structure or element will be exposed to at each stress range level during the life of the structure is determined and then used in Miner's rule (Fig. 44.8).

For fatigue design the structure is analysed using elastic analysis. This is appropriate because the peak stresses of all of the cycles must remain well below the yield strength of the steel. If the stresses induced are close to or exceed the yield strength the fatigue life (number of cycles to rupture) will be extremely limited. This case is usually not considered suitable for design purposes and is not covered in design codes.

The classification of details for fatigue is now fairly standard internationally and the relevant US specifications (AISC, AWS, AASHTO and AREMA) all have similar classifications. The S-N curves used for this classification are shown in Fig. 44.9. Comprehensive descriptions of the details are included in the specifications along with drawings of each detail. The parameters used to define each line in the S-N

TABLE 44.4 Stress Category Details

Stress Category	C_f	I	F_{TH}
A	250×10^8	0.333	24
B	250×10^8	0.333	16
B′	250×10^8	0.333	12
C	250×10^8	0.333	10
D	250×10^8	0.333	7
E	250×10^8	0.333	4.5
E′	250×10^8	0.333	2.6
F	250×10^8	0.0.167	8

TABLE 44.5 General Description of Stress Category Details

General Description of Detail (See relevant specification for full description and diagram of details)	Stress Categories
Plain material away from welding	A, B, C
Connected material in mechanically fastened joints	B, D, E
Welded joints joining components of built-up members	B, B′, D, E, E′
Longitudinal fillet welded end connections	E, E’
Welded joints transverse to direction of stress	B, B′, C, C′, C″
Base metal at welded transverse member connections	B, C, D, E
Base metal at short attachments	C, D, E, E’
Miscellaneous details	C, E, E′, F

diagram are included in Table 44.4 along with the threshold fatigue stress range. The lines are defined by the equation:

$$F_{SR} = \left(\frac{C_f}{N} \right)^I$$

where F_{SR} = design stress range
C_f = fatigue constant
I = index
N = estimated number of stress range cycles in design life

Table 44.5 provides a very brief general description of each stress category detail.

Fatigue damage in structures occurs due to stresses whether they are primary stresses resulting directly from applied loads or secondary stresses resulting from distortion or relative displacements that are not normally considered in strength and serviceability design. In designing structures for fatigue it is generally best (where possible) to avoid the use of details that have low fatigue lives and to ensure that details that might result in unintended secondary stresses are also avoided.

Performance in Fire

The occurrence of fire in buildings and industrial installations is frightening and sometimes costly in lives, injuries, property damage and other consequences. Often the structures involved are not threatened, with most human losses occurring because of exposure of occupants to smoke and sometimes heat, or both. However, the structure is often incorporated in the fire safety system in the building as a means to separate the occupants from the effects of a fire so that they may leave the building safely and as a means to prevent fire spread and thus minimize property loss resulting from a fire.

Traditionally the requirements for structures have been incorporated in building codes (UBC, SBC, BCC, etc) in terms of the fire resistance rating required to be exhibited by building elements and

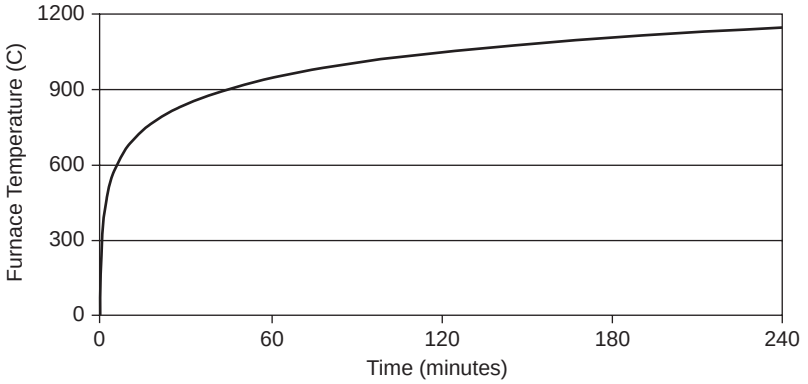

FIGURE 44.10 ASTM E119 furnace temperature — time relationship.

assemblies in standard fire tests such as the ASTM E119 test, which is similar to the ISO 834 test adopted in many countries. The time for which the element or system must survive without failure in the test is nominated as the required fire resistance in the building codes. In these tests the specified furnace temperatures are required to rise approximately as shown in Fig. 44.10.

In these tests the element or system to be tested, whether loaded or not loaded, is exposed to the standard temperature-time regime and the test continues with the element deemed not to have failed until specified failure criteria are reached. These failure criteria include limits on the deflection that may occur for a loaded element or on the temperature reached by the element or at some point on an assembly for unloaded tests. These tests are expensive and time consuming and consequently methods have been developed to allow estimation by calculation of the performance of elements in standard fire tests.

In the last few years "performance-based" design has become more common and estimation of the behaviour of structures in real fires is used in design more often than in the past. This has become more practical with the availability of faster computers that allow the complex calculations to be undertaken in reasonable time.

The performance of steel structures in fire (whether in standard fire tests or in unwanted fires in buildings) depends on:

- the severity of the fire
- the protection applied to the steel
- the loads applied to the steel
- the size and properties of the steel members

Each of these may contribute to variation in the performance of a real fire, but the severity of the fire and in the loads applied to the structure at the time of the fire generally contribute most to this variation, with variability in the steel behavior and properties generally being the least important contributor. Nevertheless an understanding of the behavior of steel under the elevated temperature conditions likely to be experienced during a fire is important in assessing the fire safety in buildings.

Steel when it is heated it expands, and when heated to a high enough temperature begins to lose strength and stiffness. Thus at high temperatures steel structures deform more than they would at normal ambient temperatures and their ultimate strength is lower. If the temperature of the steel increases sufficiently the structure will collapse.

The deformation of the structure that takes place can be thought of as the sum of several components:

- thermal (due to changes in temperature)
- stress related or "elastic" (dependent on temperature and load or stress)
- creep (dependent on temperature, load or stress, and time)

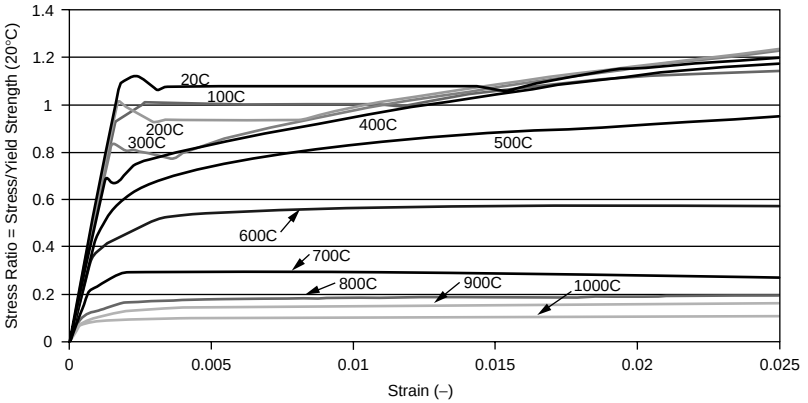

FIGURE 44.11 Effect of temperature on stress-strain relationship structural steel.

Testing of the properties of steel at high temperatures is more complex than at normal ambient temperatures because of the dependence on time of the creep component. This results in a much greater effect of the strain rate on the resulting stress-strain curves. Below about 400°C there is little effect on the stress-strain behavior of structural steels. However, above about 400°C the shape of the stress-strain curves is greatly influenced by the strain rate.

The shape of the stress-strain curve changes with temperature as shown in Fig. 44.11. In this figure the strain rate is fairly high, thus reducing the effect of creep. The stress-strain curves shown in Fig. 44.11 have been "normalized" by dividing the stress by the yield stress at 20°C. The relationships between high temperature properties and normal ambient temperature properties for many grades of structural steel are quite similar and curves of the form shown in this figure can, with reasonable accuracy, be applied to other grades of structural steel.

Each of the tests represented in Fig. 44.11 was conducted at a constant temperature and at a constant strain rate. The curves would be different if the strain rate was changed, particularly the higher temperature curves.

Mathematical relationships of varying complexity have been developed to model the stress-strain-temperature-time relationship of structural steel for use in fire engineering calculations.

However, for many calculations simpler relationships such as those shown in Fig. 44.12 can be used. This is based on the curves in Fig. 44.11 and shows that the yield strength (or 0.2% proof stress at higher temperatures) decreases slowly up to about 500°C, then more rapidly until about 700°C, when about 73% of the ambient temperature yield strength has been lost. It then falls more slowly and falls to about 10% of the ambient value at 1000°C.

Creep and Relaxation

Creep is generally defined as time-dependent deformation that results from sustained loading and results in permanent deformation.

Steel at room temperature is not subject to creep or relaxation at normal ambient temperatures (say <50°C) unless subject to very high stresses. As pointed out above when subjected to high temperatures (say >400°C) steel can creep quite rapidly. At these temperatures and above steel creeps at a rate that is dependent on the applied stress. Creep is not required to be considered for most steel structures as they are not usually exposed to high temperatures.

In structures or structural elements that are subjected to high temperatures for long periods, it may be required to consider creep. This is normally covered in specialist codes and specifications appropriate to the usage.

In many cases this is simply done by specifying limits on long term stresses according to the temperature and the lifetime required. Thus the allowable stresses will be higher for a given grade of steel with lower

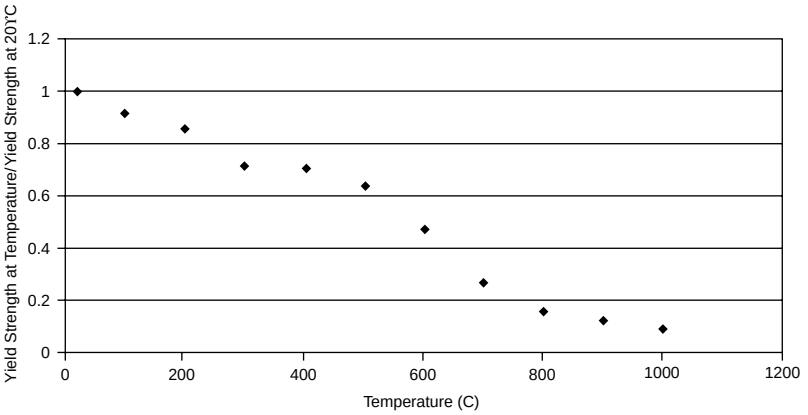

FIGURE 44.12 Effect of temperature on yield strength of structural steel.

temperatures or shorter exposure periods (design life). Allowable stresses will be correspondingly lower for higher temperatures or longer exposure periods.

Corrosion and Corrosion Protection

Many types of steel, including most common grades of structural steel will corrode if exposed to moisture and oxygen. If either or both of these are prevented from contacting the steel it will not corrode under normal circumstances.

Corrosion of steel takes place by a complex electro-chemical reaction between the steel and oxygen that is facilitated by the presence of moisture. In certain circumstances, corrosion can be exacerbated by pollutants or other contaminants in the water. Such materials can include common salt (sodium chloride) and many industrial chemicals. Where such materials are present special precautions should be taken to adequately protect exposed steelwork.

In the absence of such materials structural steel that is contained within the envelope of a building or structure and which is thus not subjected to periodic wetting by rain or other sources of moisture requires no corrosion protection.

Structural steelwork that is not protected in this way requires additional protection and the usual methods are paint systems and galvanizing. In considering a protection system it is necessary to consider the type of building or structure under consideration, its use, its expected life and the relative merits of initial cost against maintenance costs.

Paint systems vary between simple barrier systems that provide a protective film over the steel separating it from oxygen and moisture, and complex systems that include components that provide additional means of protection should, for example, the paint system be damaged by small scratches or holes.

Galvanizing consists of coating the steel with zinc (in some cases with significant quantities of other materials) to provide both barrier protection and cathodic (sacrificial) protection. Sacrificial protection means that the coating preferentially corrodes, leaving the steelwork intact. The zinc coating is metallurgically bonded to the steel providing a tough barrier. In addition, in most commonly occurring circumstances zinc is anodic to steel and thus provides cathodic protection should damage or minor discontinuities occur to the barrier.

An important attribute of all barrier systems is adhesion to the surface of the element to be protected. Thus careful preparation of the surface to be protected is required.

All corrosion systems have a limited life and the system used must be appropriate to the exposure and the lifetime required.

Additional information may be found through the American Institute of Steel Construction, the Society for Protective Coatings or the American Galvanizers Association.

Some grades of structural steel possess high enough levels of corrosion resistance that they can be used in certain applications uncoated. These are usually termed weathering grade steels and are most commonly used in highway bridges, but are also used in buildings and other structures. Although weathering grade steels are more expensive than equivalent normal grades of steel they can be cost effective through the elimination of painting. Successful use of weathering grade steels requires appropriate locations and careful detailing of the structure. Guidelines have been published by the Federal Highway Authority which provide advice on these matters and on appropriate maintenance practices.

Non-destructive Testing

Steel structures, particularly those that are at risk of fatigue damage or brittle fracture, may be required to be inspected using non-destructive testing methods such as dye-penetrant, magnetic particle, ultrasonic and radiographic examination.

The most common form of examination is visual inspection and for many steel structures this is sufficient to ensure a satisfactory level of workmanship in fabrication and erection. This form of inspection can only be used to detect defects in the fit-up of components, in the shape or form of welds and lack of fusion or cracks that are visible on the finished surface.

Methods that can be used to detect smaller surface or near surface defects include dye-penetrant and magnetic particle inspection.

Detection of subsurface defects is usually done using ultrasonic or radiographic techniques.

The choice of appropriate methods of examination is important as the cost of inspection varies widely depending on the method used. This requires consideration of the importance of the weld as well as consideration of the type and location of defects to be detected as the methods mentioned above have differing capabilities in relation to the size, orientation, depth and shape of defects that they can be used to detect.

Welding inspection is normally carried out to the requirements of AWS D1.1.

45.1 Introduction

The term *bituminous materials* is generally used to denote substances in which bitumen is present or from which it can be derived [Goetz and Wood, 1960]. *Bitumen* is defined as an amorphous, black or dark-colored, (solid, semi-solid, or viscous) cementitious substance, composed principally of high molecular weight hydrocarbons, and soluble in carbon disulfide. For civil engineering applications, bituminous materials include primarily *aphalts* and *tars*. Asphalts may occur in nature (natural asphalts) or may be obtained from petroleum processing (petroleum asphalts). Tars do not occur in nature and are obtained as condensates in the processing of coal, petroleum, oil-shale, wood or other organic materials. *Pitch* is formed when a tar is partially distilled so that the volatile constituents have evaporated off from it. *Bituminous mixtures* are generally used to denote the combinations of bituminous materials (as binders), aggregates and additives.

This chapter presents the basic principles and practices of the usage of bituminous materials and mixtures in pavement construction. In recent years, the use of tars in highway construction has been very limited due to the concern with the possible emission of hazardous flumes when tars are heated. Thus, this chapter deals primarily with asphalts and asphalt mixtures.

45.2 Bituminous Materials

Types of Bituminous Materials Used in Pavement Construction

Asphalt cement is an asphalt that has been specially refined as to quality and consistency for direct use in the construction of asphalt pavements. An asphalt cement has to be heated to an appropriate high temperature in order to be fluid enough to be mixed and placed.

Cutback asphalt is a liquid asphalt that is a blend of asphalt and petroleum solvents (such as gasoline and kerosine). A cutback asphalt can be mixed and placed with little or no application of heat. After a cutback asphalt is applied and exposed to the atmosphere, the solvent will gradually evaporate, leaving the asphalt cement to perform its function as a binder.

Emulsified asphalt (or *asphalt emulsion*) is an emulsion of asphalt cement and water that contains a small amount of emulsifying agent. In a normal emulsified asphalt, the asphalt cement is in the form of minute globules in suspension in water. An emulsified asphalt can be mixed and applied without any application of heat. After an asphalt emulsion is applied, sufficient time is required for the emulsion to break and the water to evaporate to leave the asphalt cement to perform its function as a binder. In an *inverted emulsified asphalt*, minute globules of water are in suspension in a liquid asphalt, which is usually a cutback asphalt. Inverted asphalt emulsions are seldom used in pavement applications.

Conventional Tests on Asphalt Cements and Their Significance

In this section, the purpose and significance of the commonly used tests on asphalt cements are described. Readers may refer to the appropriate standard test methods for detailed description of the test procedures.

Penetration Test

The penetration test is one of the oldest and most commonly used tests on asphalt cements or residues from distillation of asphalt cutbacks or emulsions. The standardized procedure for this test can be found in ASTM D5 [ASTM, 2001]. It is an empirical test that measures the consistency (hardness) of an asphalt at a specified test condition. In the standard test condition, a standard needle of a total load of 100 g is applied to the surface of an asphalt sample at a temperature of 25 °C for 5 seconds. The amount of penetration of the needle at the end of 5 seconds is measured in units of 0.1 mm (or penetration unit). A softer asphalt will have a higher penetration, while a harder asphalt will have a lower penetration. Other test conditions that have been used include (1) 0°C, 200 g, 60 sec., and (2) 46°C, 50 g, 5 sec.

The penetration test can be used to designate grades of asphalt cement, and to measure changes in hardness due to age hardening or changes in temperature.

Flash Point Test

The flash point test determines the temperature to which an asphalt can be safely heated in the presence of an open flame. The test is performed by heating an asphalt sample in an open cup at a specified rate and determining the temperature at which a small flame passing over the surface of the cup will cause the vapors from the asphalt sample temporarily to ignite or flash. The commonly used flash point test methods include (1) the Cleveland Open Cup (ASTM D92) and (2) Tag Open Cup (ASTM D1310). The Cleveland Open-Cup method is used on asphalt cements or asphalts with relatively higher flash points, while the Tag Open-Cup method is used on cutback asphalts or asphalts with flash points of less than 79°C.

Minimum flash point requirements are included in the specifications for asphalt cements for safety reasons. Flash point tests can also be used to detect contaminating materials such as gasoline or kerosine in an asphalt cement. Contamination of an asphalt cement by such materials can be indicated by a substantial drop in flash point. When the flash point test is used to detect contaminating materials, the Pensky-Martens Closed Tester method (ASTM D93), which tends to give more indicative results, is normally used. In recent years, the flash point test results have been related to the hardening potential of asphalt. An asphalt with a high flash point is more likely to have a lower hardening potential in the field.

Solubility Test

Asphalt consists primarily of bitumens, which are high-molecular-weight hydrocarbons soluble in carbon disulfide. The bitumen content of a bituminous material is measured by means of its solubility in carbon disulfide. In the standard test for bitumen content (ASTM D4), a small sample of about 2 g of the asphalt is dissolved in 100 ml of carbon disulfide and the solution is filtered through a filtering mat in a filtering crucible. The material retained on the filter is then dried and weighed, and used to calculate the bitumen content as a percentage of the weight of the original asphalt.

Due to the extreme flammability of carbon disulfide, solubility in trichloroethylene, rather than solubility in carbon disulfide, is usually used in asphalt cement specifications. The standard solubility test using trichloroethylene is designated as ASTM D 2042.

The solubility test is used to detect contamination in asphalt cement. Specifications for asphalt cements normally require a minimum solubility in trichloroethylene of 99.0 percent.

Unfortunately, trichloroethylene has been identified as a carcinogen and contributing to the depletion of the earth's ozone layer. The use of trichloroethylene will most likely be banned in the near future. There is a need to use a less hazardous and non-chlorinated solvent for this purpose. Results of several investigations have indicated that the solvent n-Propyl Bromide appears to be a feasible alternative to trichloroethylene for use in this application [Collins-Garcia et al, 2000].

Ductility Test

The ductility test (ASTM D113) measures the distance a standard asphalt sample will stretch without breaking under a standard testing condition (5 cm/min at 25°C). It is generally considered that an asphalt with a very low ductility will have poor adhesive properties and thus poor performance in service. Specifications for asphalt cements normally contain requirements for minimum ductility.

Viscosity Tests

The viscosity test measures the viscosity of an asphalt. Both the viscosity test and the penetration test measure the consistency of an asphalt at some specified temperatures and are used to designate grades of asphalts. The advantage of using the viscosity test as compared with the penetration test is that the viscosity test measures a fundamental physical property rather than an empirical value.

Viscosity is defined as the ratio between the applied shear stress and induced shear rate of a fluid. The relationship between shear stress, shear rate and viscosity can be expressed as:

$$\text{Shear Rate} = \text{Shear Stress} / \text{Viscosity} \tag{45.1}$$

When shear rate is expressed in units of 1/sec. and shear stress in units of Pascal, viscosity will be in units of Pascal-seconds. One Pascal-second is equal to 10 Poises. The lower the viscosity of an asphalt, the faster the asphalt will flow under the same stress.

For a Newtonian fluid, the relationship between shear stress and shear rate is linear, and thus the viscosity is constant at different shear rates or shear stress. However, for a non-Newtonian fluid, the relationship between shear stress and shear rate is not linear, and thus the apparent viscosity will change as the shear rate or shear stress changes. Asphalts tend to behave as slightly non-Newtonian fluids, especially at lower temperatures. When different methods are used to measure the viscosity of an asphalt, the test results might be significantly different, since the different methods might be measuring the viscosity at different shear rates. It is thus very important to indicate the test method used when viscosity results are presented.

The most commonly used viscosity test on asphalt cements is the Absolute Viscosity Test by Vacuum Capillary Viscometer (ASTM D2171). The standard test temperature is 60°C. The absolute viscosity test measures the viscosity in units of Poise. The viscosity at 60°C represents the viscosity of the asphalt at the maximum temperature a pavement is likely to experience in most parts of the U.S.

When the viscosity of an asphalt at a higher temperature (such as 135°C) is to be determined, the most commonly-used test is the Kinematic Viscosity Test (ASTM D2170), which measures the kinematic viscosity in units of Stokes or centi-Stokes. Kinematic viscosity is defined as:

$$\text{Kinematic Viscosity} = \text{Viscosity} / \text{Density} \tag{45.2}$$

When viscosity is in units of Poise and density in units of g/cm,^{3} the kinematic viscosity will be in units of Stokes. To convert from kinematic viscosity (in units of Stokes) to absolute viscosity (in units of Poises), one simply multiplies the number of Stokes by the density in units of g/cm^3. However, due

to the fact that an asphalt might be non-Newtonian and that the kinematic viscosity test and the absolute viscosity test are run at different shear rates, conversion by this method will not produce accurate results and can only serve as a rough estimation. The standard temperature for the kinematic test on asphalt cement is 135°C. The viscosity at 135°C approximately represents the viscosity of the asphalt during mixing and placement of a hot mix.

Thin Film Oven and Rolling Thin Film Oven Tests

When an asphalt cement is used in the production of asphalt concrete, it has to be heated to an elevated temperature and mixed with a heated aggregate. The hot asphalt mixture is then hauled to the job site, placed and compacted. By the time the compacted asphalt concrete cools down to the normal pavement temperature, significant hardening of the asphalt binder has already taken place. The properties of the asphalt in service are significantly different from those of the original asphalt.

Since the performance of the asphalt concrete in service depends on the properties of the hardened asphalt binder in service rather than the properties of the original asphalt, the properties of the hardened asphalt in service need to be determined and controlled.

The Thin Film Oven Test (TFOT) procedure (ASTM D1754) was developed to simulate the effects of heating in a hot-mix plant operation on an asphalt cement. In the standard TFOT procedure, the asphalt cement sample is poured into a flat-bottomed pan to a depth of about 1/8 in. (3.2 mm). The pan with the asphalt sample in it is then placed on a rotating shelf in an oven and kept at a temperature of 163°C for five hours. The properties of the asphalt before and after the TFOT procedure are measured to determine the change in properties that might be expected after a hot-mix plant operation.

The Rolling Thin Film Oven Test (RTFOT) procedure (ASTM D2872) was developed for the same purpose as the TFOT and designed to produce essentially the same effect as the TFOT procedure on asphalt cement. The advantages of the RTFOT over the TFOT are that (1) a larger number of samples can be tested at the same time, and (2) less time is required to perform the test. In the standard RTFOT procedure, the asphalt cement sample is placed in a specially designed bottle, which is then placed on its side on a rotating shelf, in an oven kept at 163°C, and rolled continuously for 85 minutes. Once during each rotation, the opening of the bottle passes an air jet, which provides fresh air to the asphalt in the bottle for increased oxidation rate.

While the RTFOT and TFOT have generally worked well on pure asphalts, problems were encountered when modified asphalts were used. Asphalts modified with crumb rubber and SBR tended to spill out from the RTFOT bottles during the RTFOT process. When TFOT was used on these modified binders, a thin skin tended to form on the surface of the modified asphalt, which reduced the homogeneity and the aging of the samples.

A feasible alternative to the RTFOT and TFOT for use on modified asphalts appears to be the modified rotavapor aging procedure [Sirin et al, 1998]. The rotavapor apparatus, which was originally used for recovery of asphalt from solution (ASTM D5404), was modified to work as an aging device for asphalt. The binder to be aged is placed in a rotating flask, which is immersed in a temperature-controlled oil bath. An air pump is used to provide a controlled air flow to the flask. Different aging effects can be produced by using different combinations of process temperature, process duration and sample size. Using a process temperature of 163°C, process duration of 165 minutes and a sample size of 200 g has been found to produce aging severity similar to that of the RTFOT.

Ring & Ball Softening Point Test

The ring and ball softening point test (ASTM D36) measures the temperature at which an asphalt reaches a certain softness. When an asphalt is at its softening point temperature, it has approximately a penetration of 800 or an absolute viscosity of 13,000 poises. This conversion is only approximate and can vary from one asphalt to another, due to the non-Newtonian nature of asphalts and the different shear rates used by these different methods.

The softening point temperature can be used along with the penetration to determine the temperature susceptibility of an asphalt. Temperature susceptibility of an asphalt is often expressed as:

$$M = \left[\log(p_2) - \log(p_1)\right] / (t_2 - t_1) \tag{45.3}$$

where M = temperature susceptibility
t_1, t_2 = temperatures in °C
p_1 = penetration at t1
p_2 = penetration at t2

Since an asphalt has approximately a penetration of 800 at the softening point temperature, the softening point temperature can be used along with the penetration at 25°C to determine the temperature susceptibility as:

$$M = \left[\log(\text{pen at } 25°C) - \log(800)\right] / (25 - \text{S.P. Temp.}) \tag{45.4}$$

The M computed in this manner can then be used to compute a Penetration Index (PI) as follows:

$$PI = (20 - 500\ M) / (1 + 50\ M) \tag{45.5}$$

The Penetration Index is an indicator of the temperature susceptibility of the asphalt. A high PI indicates low temperature susceptibility. Normal asphalt cements have a PI between -2 and +2. Asphalt cements with a PI of more than +2 are of low temperature susceptibility, while those with a PI of less than -2 are of excessively high temperature susceptibility.

Conventional Methods of Grading and Specifications of Asphalt Cements

There are three conventional methods of grading asphalt cements. These three methods are (1) grading by penetration at 25°C, (2) grading by absolute viscosity at 60°C, and (3) grading by absolute viscosity of aged asphalt residue after the rolling thin film oven test (RTFOT) procedure. These three methods of grading and the associated ASTM specifications of asphalt cements are presented and discussed in this section.

The method of grading of asphalt cements by standard penetration at 25°C is the first systematic method developed and is still used by a few highway agencies in the world. The standard grades by this method include 40/50, 60/70, 85/100, 120/150 and 200/300 asphalts, which have penetrations of 40 to 50, 60 to 70, 85 to 100, 120 to 150, and 200 to 300, respectively. The Asphalt Institute recommends the use of a 120/150 or 85/100 pen. asphalt in the asphalt concrete for cold climatic condition with a mean annual temperature of 7°C or lower. For warm climatic condition with a mean air temperature between 7 and 24°C, a 85/100 or 60/70 pen. asphalt is recommended. For hot climatic condition with a mean annual air temperature of 24°C or greater, the use of a 40/50 or 60/70 pen. asphalt is recommended [Asphalt Institute, 1991].

ASTM D946 [ASTM, 2001] provides a specification for penetration-graded asphalt cements. Table 45.1 shows the specification for 60/70 and 85/100 pen asphalts as examples. According to this specification, the only requirement on the consistency of the asphalt cements is the penetration at 25°C. There is no requirement on the consistency at either a higher or lower temperature, and thus no requirement on the temperature susceptibility of the asphalt cements. Two asphalts may be of the same penetration grade and yet have substantially different viscosities at 60°C. This problem is illustrated in Fig. 45.1. Thus, it is clear that specifying the penetration grade alone will not ensure that the asphalt used will have the appropriate viscosities at the expected service temperatures. Other requirements in the specification are (1) minimum flash point temperature, (2) minimum ductility at 25°C, (3) minimum solubility in trichloroethylene, and (4) penetration and ductility at 25°C of the asphalt after aging by the TFOT procedure.

Since penetration is an empirical test, grading by penetration was thought to be unscientific. Considerable efforts were made in the 1960s to grade asphalts using fundamental units. Early attempts were

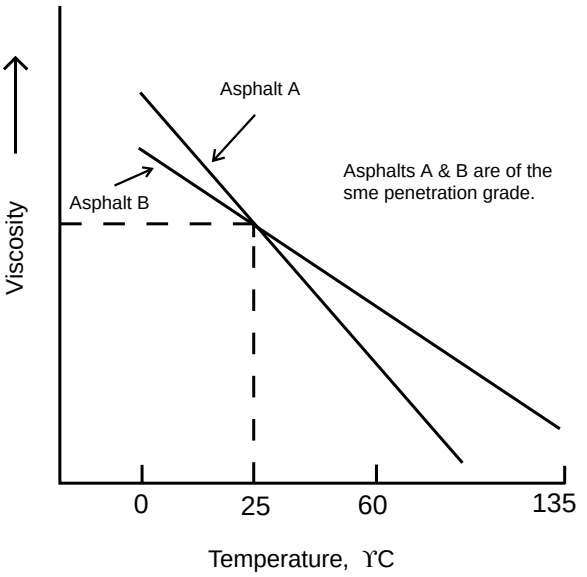

FIGURE 45.1 Variation in viscosity of two penetration-graded asphalts at different temperatures.

made to grade asphalts by viscosity at 25°C and 20°C. However, problems were encountered in measuring viscosity at such low temperatures. With some reluctance, the temperature for grading asphalt by viscosity was moved to 60°C, which represents approximately the highest temperature pavements may experience in most parts of the United States. When an asphalt is graded by this system, it is designated as AC followed by a number which represents its absolute viscosity at 60°C in units of 100 poises. For example, an AC-20 would have an absolute viscosity of around 2,000 poises at 60°C. An AC-20 roughly corresponds to a 60/70 pen. asphalt. However, due to the possible effects of different temperature susceptibility and non-Newtonian behavior, the conversion from a viscosity grade to a penetration grade may be different for different asphalts. Figure 45.2 shows the effects of different temperature susceptibility on the viscosity variation of two asphalts that have the same viscosity grade. In an effort to control this variation, the requirements for a minimum penetration at 25°C and a minimum viscosity at 135°C were added to the specification.

ASTM D3381 [ASTM, 2001] provides two different specifications for asphalt cements graded by absolute viscosity of the original asphalt at 60°C. Table 45.2 shows the requirements for AC-10 and AC-20 grade asphalts in the two specifications as examples. The main difference between these two specifications is that one of them requires a lower temperature susceptibility than the other. Limits on temperature

susceptibility are specified through a minimum required penetration at 25°C and a minimum required kinematic viscosity at 135°C. The other requirements are similar to those in the specification of penetration-graded asphalts. The other requirements are (1) minimum flash point temperature, (2) minimum ductility at 25°C, (3) minimum solubility in trichloroethylene, and (4) required properties of the asphalt after aging by the TFOT procedure (by means of maximum viscosity at 60 °C and ductility at 25°C).

The third asphalt grading system is to grade asphalts according to their viscosity when placed on the road (after aging due to the heating and mixing process). This grading system has been adopted by several western states in the U.S. Grading is to be based on the absolute viscosity at 60°C of the asphalt residue after the Rolling Thin Film Oven Test (RTFOT) procedure, which simulates the effects of the hot-mix plant operation. An asphalt graded by this system is designated as AR followed by a number which represents the viscosity of the aged residue at 60°C in units of poises. For example, an AR-6000 would have an aged residue with an absolute viscosity of around 6000 poises. An AR-6000 would roughly correspond to an AC-20 or a 60/70 pen. asphalt. However, it should be recognized that the conversion from an AR grade to an AC grade depends on the hardening characteristics of the asphalt.

ASTM D3381 [ASTM, 2001] provides a specification for asphalt cements graded by viscosity of aged residue after the RTFOT process. Table 45.3 shows the specification for AR-4000 and AR-8000 grade

TABLE 45.3 Requirements for AR-4000 and AR-8000 Asphalt Cements

		Viscosity Grade	
Test on Residue from RTFOT		AR-4000	AR-8000

asphalts as examples. According to this specification, temperature susceptibility is specified through requiring a minimum penetration at 25°C and a minimum kinematic viscosity at 135°C of the residue after the RTFOT. Similar to the requirements in the specifications for the other two grading systems, there are requirements on (1) ductility at 25°C of the aged residue, (2) minimum flash point of the original asphalt, and (3) minimum solubility in trichloroethylene of the original asphalt. Another requirement in this specification is a minimum percent of retained penetration after the RTFOT, which can serve as a check on the composition and aging characteristics of the asphalt.

Superpave Binder Tests

The Strategic Highway Research Program (SHRP) conducted a $50 million research effort from October 1987 through March 1993 to develop performance-based test methods and specifications for asphalts and asphalt mixtures. The resulting product is a new system called Superpave (SUperior PERforming asphalt PAVEments), which includes a binder specification and an asphalt mixture design method. The Superpave binder tests and specifications have been standardized by the American Association of State Highway and Transportation Officials (AASHTO). The significance of the Superpave binder tests are described in this section. The detailed procedures can be found in the AASHTO publications for these tests [AASHTO, 1999].

Pressure Aging Vessel

The Superpave Pressure Aging Vessel (PAV) procedure is used for simulation of long-term aging of asphalt binders in service. According to the method (AASHTO Designation PP1–98), the asphalt samples are first aged in the standard RTFOT. Pans containing 50 grams of RTFOT residue are then placed in the PAV, which is pressurized with air at 2.1 ± 0.1 MPa, and aged for 20 hours. As many as 10 pans can be placed in the PAV. The proposed range of PAV temperature to be used is between 90 and 110°C. The PAV temperature to be used will depend on the climatic condition of the region where the binders will be used. A higher PAV temperature could be used for a warmer climatic condition, while a lower temperature could be used for a colder climatic condition.

Dynamic Shear Rheometer Test

The dynamic shear rheometer test measures the viscoelastic properties of an asphalt binder by testing it in an oscillatory mode. The general method had been used by researchers long before the SHRP researchers adopted and standardized the method for the purpose of asphalt specification. Typically, in a dynamic shear rheometer test, a sample of asphalt binder is placed between two parallel steel plates. The top plate is oscillated by a precision motor with a controlled angular velocity, w, while the bottom plate remains fixed. From the measured torque and angle of rotation, the shear stress and shear strain can be calculated. The oscillatory strain, γ, can be expressed as:

$$\gamma = \gamma_o \sin wt \tag{45.6}$$

where γ_o = peak shear strain
w = angular velocity in radian/second

The shear stress, τ, can be expressed as:

$$\tau = \tau_o \sin(wt + \delta) \tag{45.7}$$

where τ_o = peak shear stress
δ = phase shift angle

The following parameters are usually computed from the test data:

$$\text{(1) Complex Shear Modulus, } G^* = \tau_o/\gamma_o \tag{45.8}$$

$$\text{(2) Dynamic Viscosity, } \eta^* = G^*/w \tag{45.9}$$

$$\text{(3) Storage Modulus, } G' = G^* \cos\delta \tag{45.10}$$

$$\text{(4) Loss Modulus, } G'' = G^* \sin\delta \tag{45.11}$$

$$\text{(5) Loss Tangent, } \tan\delta = G''/G' \tag{45.12}$$

How are the results of a dynamic rheometer test related to the basic rheologic properties of the tested binder? This question can be answered by analyzing how a viscoelastic material would behave in such a test. For simplicity, the test binder is modeled by a Maxwell model with a shear modulus of G and a viscosity of η. When the test binder is modeled in this manner, it can be shown analytically that the complex shear modulus, G^* is equal to:

$$G^* = \tau_o/\gamma_o = w\eta \Big/ \left(1 + \eta^2 w^2/G^2\right)^{1/2} \tag{45.13}$$

It can be noted that, from the above equation, at very high w, the dynamic modulus G^* will approach the true shear modulus G.

The dynamic viscosity, η^*, can be derived to be:

$$\eta^* = G^*/w = \eta \Big/ \left(1 + \eta^2 w^2/G^2\right)^{1/2} \tag{45.14}$$

It can be noted that, at very low w, the dynamic viscosity η^* will approach the true viscosity η. The dynamic viscosity determined at very low w has been referred to as "zero shear viscosity".

The loss tangent, $\tan\delta$, can be derived to be:

$$\tan\delta = G/w\eta \tag{45.15}$$

SHRP standardized the dynamic shear rheometer test for use in measuring the asphalt properties at high and intermediate service temperatures for specification purposes. In the standardized test method (AASHTO Designation TP5–98), the oscillation speed is specified to be 10 radians/second. The amplitude of shear strain to be used depends on the stiffness of the binder, and varies from 1% for hard materials tested at low temperatures to 13% for relatively softer materials tested at high temperatures. There are two standard sample sizes. For relatively softer materials, a sample thickness (gap) of 1 mm and a sample diameter (spindle diameter) of 25 mm are to be used. For harder materials, a sample thickness of 2 mm

and a sample diameter of 8 mm are to be used. The two values to be measured from each test are the complex shear modulus, G*, and the phase angle, δ. These two test values are then used to compute G*/sin δ and G*sin δ. In the Superpave asphalt specification, permanent deformation is controlled by requiring the G*/sin δ of the binder at the highest anticipated pavement temperature to be greater than 1.0 kPa before aging and 2.2 kPa after the RTFOT process. Fatigue cracking is controlled by requiring that the binder after PAV aging should have a G*sin δ value of less than 5000 kPa at a specified intermediate pavement temperature.

Bending Beam Rheometer Test

The bending beam rheometer test (AASHTO Designation TP1–98) was used to measure the stiffness of asphalts at low service temperatures. The standard asphalt test specimen is a rectangular prism with a width of 12.5 mm, a height of 6.25 mm and a length of 125 mm. The test specimen is to be submerged in a temperature-controlled fluid bath and to be simply supported with a distance between supports of 102 mm. For specification testing, the test samples are to be fabricated from PAV-aged asphalt binders, which simulate the field-aged binders. In the standard testing procedure, after the beam sample has been properly pre-conditioned, a vertical load of 100 gram-force is applied to the middle of the beam for a total of 240 seconds. The deflection of the beam at the point of load is recorded during this period, and used to compute for the creep stiffness of the asphalt by the following equation:

$$S(t) = PL^3 / 4bh^3\delta(t) \tag{45.16}$$

where: S(t) = creep stiffness at time t
P = applied load, 100 g
L = distance between beam supports, 102 mm
b = beam width, 12.5 mm
h = beam height, 6.25 mm
δ(t) = deflection at time t

The above equation is similar to the equation that relates the deflection at the center of the beam to the elastic modulus of an elastic beam according to the classical beam theory. The instantaneous deflection in the original equation is replaced by the time dependent deflection δ(t), while the elastic modulus in the original equation is replaced by the time dependent creep stiffness S(t).

For Superpave binder specification purpose, the bending beam rheometer test is to be run at 10°C above the expected minimum pavement temperature, T_{min}. SHRP researchers [Anderson & Kennedy, 1993] claimed that the stiffness of an asphalt after 60 seconds at T_{min} + 10°C is approximately equal to its stiffness at T_{min} after 2 hours loading time, which is related to low-temperature cracking potential. The Superpave binder specification as stated in AASHTO Designation MP1–98 [AASHTO, 1999] requires the stiffness at the test temperature after 60 seconds to be less than 300 MPa to control low-temperature cracking.

The second parameter obtained from the bending beam rheometer test result is the m-value. The m-value is the slope of the log stiffness versus log time curve at a specified time. A higher m-value would mean that the asphalt would creep at a faster rate to reduce the thermal stress and would be more desirable to reduce low-temperature cracking. The Superpave binder specification as stated in AASHTO MP1–98 requires the m-value at 60 seconds to be greater than or equal to 0.30.

Direct Tension Test

The Superpave direct tension test (AASHTO Designation TP3–98) measures the stress-strain characteristics of an asphalt binder in direct tension at low temperature. In this test, a small "dog bone" shaped asphalt specimen is pulled at a constant rate of 1 mm/min until it breaks. The amount of elongation at failure is used to compute the failure strain. The maximum tensile load taken by the specimen is used to compute the failure stress. The test specimen is 30 mm long and has a cross section of 6 mm by 6 mm at the middle portion. For Superpave binder specification purpose, the direct tension test is to be run

on PAV-aged binders at the same test temperature as for the bending beam rheometer test, which is run at 10°C above the minimum expected pavement temperature. According to the Superpave binder specification as stated in AASHTO Designation MP1–98, the failure strain at this condition should not be less than 1% in order to control low temperature cracking.

Brookfield Rotational Viscometer Test

The Superpave binder specification uses the Brookfield rotational viscometer test as specified by ASTM D4402 for use in measuring the viscosity of binders at elevated temperatures to ensure that the binders are sufficiently fluid when being pumped and mixed at the hot mix plants. In the Brookfield rotational viscometer test, the test binder sample is held in a temperature-controlled cylindrical sample chamber, and a cylindrical spindle, which is submerged in the sample, is rotated at a specified constant speed. The torque that is required to maintain the constant rotational speed is measured and used to calculate the shear stress according to the dimensions of the sample chamber and spindle. Similarly, the rotational speed is used to calculate the shear rate of the test. Viscosity is then calculated by dividing the computed shear stress by the computed shear rate.

As compared with the capillary tube viscometers, the rotational viscometer provides larger clearances between the components. Therefore, it can be used to test modified asphalts containing larger particles, which could plug up a capillary viscometer tube. Another advantage of the rotational viscometer is that the shear stress versus shear rate characteristics of a test binder can be characterized over a wide range of stress or strain levels.

For Superpave binder specification purpose, the rotational viscosity test is to be run on the original binder at 135°C. The maximum allowable viscosity at this condition is 3 Pa-s.

Superpave Binder Specification

The Superpave performance graded asphalt specification (AASHTO Designation MP1–98) uses grading designations which correspond to the maximum and minimum pavement temperatures of the specified region. The designation starts with "PG," and is followed by the maximum and the minimum anticipated service temperature in °C. For example, A "PG-64–22" grade asphalt is intended for use in a region where the maximum pavement temperature (based on average 7-day maximum) is 64°C and the minimum pavement temperature is –22°C. A "PG-52–46" grade asphalt is for use where the maximum pavement temperature is 52°C and the minimum pavement temperature is –46°C.

Table 45.4 shows the Superpave specification for three different performance grades of asphalts (PG-52–16, PG-52–46 & PG-64–22) as examples. The specified properties are constant for all grades, but the temperatures at which these properties must be achieved vary according to the climate in which the binder is to be used. It is possible that an asphalt can meet the requirements for several different grades.

All grades are required to have a flash point temperature of at least 230°C for safety purpose, and to have a viscosity of no greater than 3 Pa-s at 135°C to ensure proper workability during mixing and placement.

Dynamic shear rheometer tests are to be run on the original and RTFOT-aged binders at the maximum pavement design temperature. The minimum required values of $G^*/\sin\delta$ at this temperature are 1.0 kPa and 2.2 kPa for the original and RTFOT-aged binders, respectively. These requirements are intended to control pavement rutting.

Dynamic shear rheometer tests are also to be run on PAV-aged binders at an intermediate temperature, which is equal to 4°C plus the mean of the maximum and minimum pavement design temperatures. For example, for a PG-52–46 grade, the intermediate temperature is 7°C. The maximum allowable value of $G^*\sin\delta$ at this condition is 5000 kPa. This requirement is intended to control pavement fatigue cracking.

Bending beam rheometer tests and direct tension tests are to be run on PAV-aged binders at a temperature which is 10°C above the minimum pavement design temperature. For example, for a PG-52–46, the test temperature is -36°C. At a loading time of 60 seconds, the stiffness is required to be no greater than 300 MPa, and the m-value is required to be no less than 0.3. The failure strain from the

Source: AASHTO 1999. AASHTO Designation MP1 Standard Specification for Performance Graded Asphalt Binder, *AASHTO Provisional Standard*, Washington, D.C.

direct tension test is required to be at least 1%. However, the direct tension test criterion is applicable only if an asphalt does not meet the bending beam rheometer stiffness requirement and has a stiffness between 300 MPa and 600 MPa.

It is to be pointed out that AASHTO is in the process of revising the low-temperature criteria based on the bending beam rheometer and direct tension test results. It is expected that the revised criteria will be incorporated in an AASHTO Designation MP1(a), which is to be published in 2002.

Effects of Properties of Asphalt Binders on the Performance of Asphalt Pavements

Effects of Viscoelastic Properties of Asphalt

When an asphalt concrete surface is cooled in winter time, stresses are induced in the asphalt concrete. These stresses can be relieved by the flowing of the asphalt binder within the asphalt mixture. However, if the viscosity of the asphalt binder is too high at this low temperature, the flow of the asphalt binder may not be fast enough to relieve the high induced stresses. Consequently, low-temperature cracking may occur. The viscosity of asphalt at which low-temperature cracking would occur is dependent on the cooling rate of the pavement as well as the characteristics of the asphalt concrete. However, as a rough prediction of low-temperature cracking, a limiting viscosity of 2×10^{10} poises could be used [Davis, 1987]. If the viscosity of the asphalt binder at the lowest anticipated temperature is kept lower than this limiting value, low-temperature cracking would be unlikely to occur.

The effects of the elastic property of asphalt on low-temperature cracking can be understood by analyzing how a viscoelastic material as modeled by a Maxwell model with a shear modulus of G and a viscosity of η would release its stress after it is subjected to a forced strain γ_o (which could be caused by a sudden drop in pavement temperature). If the material is subjected to a forced strain of γ_o at t = 0, the instantaneous induced stress would be equal to $\gamma_o G$, but the stress will decrease with time according to the following expression:

$$\tau = \gamma_o G\, e^{-Gt/\eta} \tag{45.17}$$

It can be seen that the rate of stress release is proportional to G/η. The reciprocal of this parameter, η/G, is commonly known as the relaxation time. To maximize the rate of relaxation, it is desirable to have a low relaxation time, η/G, or a higher G/η. As presented in Section 45.15, the parameter tan δ as obtained from the dynamic shear rheometer test is directly proportional to G/η. Thus, a high tan δ value would be desirable to reduce the potential for low-temperature pavement cracking. Experimental data show that tan δ of an asphalt always decrease with decreasing temperature. Goodrich [1991] stated that when testing is done at an angular velocity, w, of 0.1 radian/second, the temperature at which tan δ of the binder is equal to 0.4 corresponds approximately to the temperature at which the asphalt mixture would reach its limiting stiffness.

Another critical condition of an asphalt concrete is at the highest pavement temperature, at which the asphalt mixture is the weakest and most susceptible to plastic flow when stressed. When the other factors are kept constant, an increase in the viscosity of the asphalt binder will increase the shear strength and subsequently the resistance to plastic flow of the asphalt concrete. With respect to resistance to plastic flow of the asphalt concrete, it is preferable to have a high asphalt viscosity at the highest anticipated pavement temperature. Results by Goodrich [1988] indicate that a low tan δ value of the binder (as obtained from the dynamic rheometer test) tends to correlate with a low creep compliance of the asphalt mixture, which indicates high rutting resistance. Thus, a low tan δ value of the binder is desirable to reduce rutting potential.

The effectiveness of the mixing of asphalt cement and aggregate, and the effectiveness of the placement and compaction of the hot asphalt mix are affected greatly by the viscosity of the asphalt. The Asphalt Institute recommends that the mixing of asphalt cement and aggregate should be done at a temperature where the viscosity of the asphalt is 1.7 ± 0.2 poises. Compaction should be performed at a temperature where the viscosity of the asphalt cement is 2.8 ± 0.3 poises [Epps et al, 1983]. These viscosity ranges are only offered as guidelines. The actual optimum mixing and compaction temperatures will depend on the characteristics of the mixture as well as the construction environment.

In the selection of a suitable asphalt cement to be used in a certain asphalt paving project, the main concerns are (1) whether the viscosity of the asphalt at the lowest anticipated service temperature would not be low enough to avoid low-temperature cracking of the asphalt concrete, (2) whether the viscosity of the asphalt at the highest anticipated temperature would be high enough to resist rutting, and (3) whether the required temperatures for proper mixing and placement would not be too high.

Effects of Newtonian and Non-Newtonian Flow Properties of Asphalt

The flow behavior of asphalt cements can be classified into four main categories, namely (1) Newtonian, (2) pseudoplastic, (3) Bingham-plastic, and (4) dilatant. Asphalt cements usually exhibit Newtonian or near-Newtonian flow behavior, especially at temperatures in excess of 25°C. A Newtonian flow behavior is characterized by a linear shear stress-shear rate relationship, as shown in Figure 45.3. The shear susceptibility, C, is defined as the slope of the plot of log(shear stress) vs. log(shear rate). For a Newtonian flow behavior, C is equal to 1.00.

The type of flow behavior where a reduction in viscosity is experienced with increased stress is termed "pseudoplastic." The shear stress-shear rate relationship for a pseudoplastic fluid is shown in Fig. 45.4. It can be seen that the shear rate increases more rapidly at higher stresses. The shear susceptibility, C, is less than 1.0 in this case.

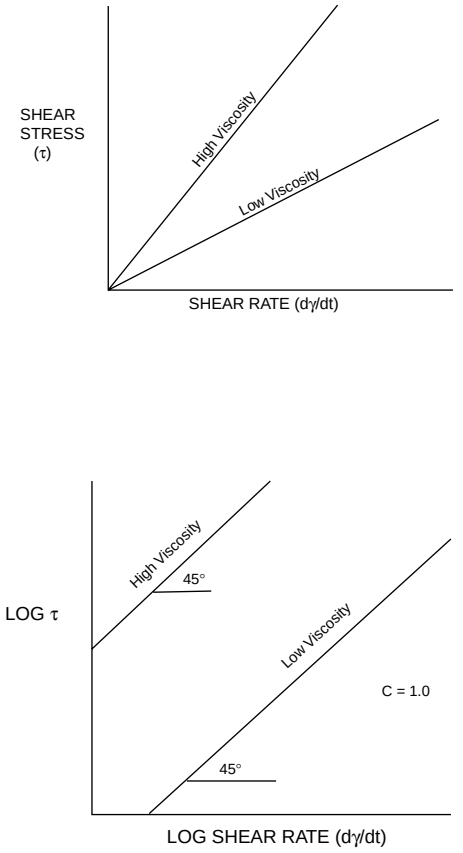

FIGURE 45.3 Newtonian flow characteristics.

The shear stress-shear rate relationship for a "Bingham plastic" material is illustrated in Figure 45.5. When the stress is below a certain stress level, there is no flow. When the stress is above the yield point, the flow characteristic is likely to be highly pseudoplastic with a C of less than 0.5. Highly air-blown asphalts usually exhibit Bingham plastic behavior at low temperatures.

The type of flow behavior where the apparent viscosity increases with increased stress is referred to as "dilatant." The shear stress-shear rate characteristics of dilatant behavior are shown in Fig. 45.6. For this type of flow behavior, C is greater than 1.

What are the effects of the flow behavior of the asphalt cement on the performance of the asphalt pavement? The answer to these questions is still not definitive at this point. However, some research results have indicated that asphalts with high shear susceptibility (c) have been related to tender mixes [Epps, Button and Gallaway 1983], and to high temperature susceptibility and high aging indices [Kandhal, Sandvig and Wenger 1973].

The effect of non-Newtonian flow behavior on the measured viscosity is clear. When an asphalt exhibits a non-Newtonian flow behavior, the measured viscosity will change as the shear stress or shear rate used for the test changes. This effect must be properly accounted for. When the viscosity of the asphalt is used to predict the behavior of the asphalt concrete in service, the viscosity at a stress level close to the anticipated stress level in service should be used.

Effects of Hardening Characteristics of Asphalt

An important factor that affects the durability of an asphalt concrete is the rate of hardening of the asphalt binder. The causes of hardening of asphalt have been attributed to oxidation, loss of volatile oils,

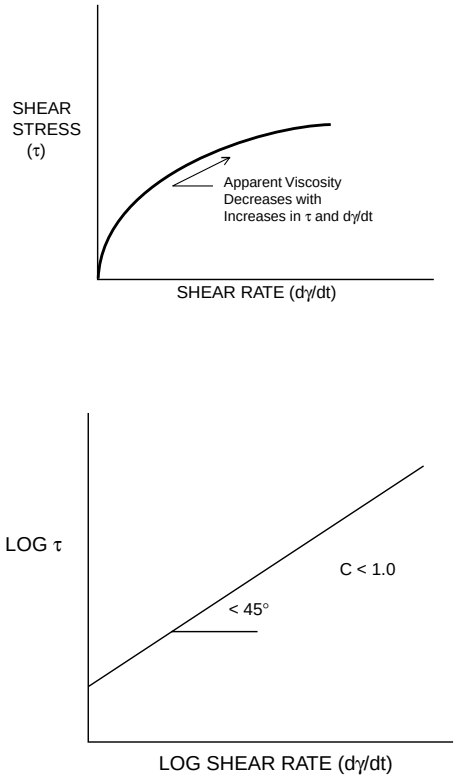

FIGURE 45.4 Pseudoplastic flow characteristics.

and polymerization (changes in structure). Among all these possible factors, oxidation is generally considered to be the prime cause of asphalt hardening.

The most severe hardening of asphalt occurs during the mixing process. The viscosity of the asphalt binder immediately after the asphalt concrete is placed on the road is usually 2 to 4 times the viscosity of the original asphalt cement. The asphalt binder continues to harden through service; its viscosity could reach as high as 10 to 20 times the viscosity of the original asphalt cement. The rate of asphalt hardening is dependent on asphalt composition, mixing temperature, air voids content, and climatic conditions. It usually increases with increased mixing temperature, increased air voids content in the asphalt mix, and increased service (air) temperature.

Excessive hardening of the asphalt binder will cause the asphalt concrete to be too brittle and low-temperature cracking to occur. It may also cause the asphalt binder to partially lose its adhesion and cohesion, and subsequently it may cause raveling (progressive disintegration of pavement material and separation of aggregates from it) in the asphalt concrete.

A certain amount of hardening of the asphalt binder during the mixing process is usually expected and designed for. If an asphalt binder has not hardened sufficiently during the mixing process (due to low mixing temperature or the peculiar nature of the asphalt), the asphalt binder may be too soft at placement. This may cause the asphalt mix to be difficult to compact (tender mix) and to have a low resistance to rutting in service. If the tenderness of an asphalt concrete disappears within a few weeks after construction, the problem is most likely caused by slow setting asphalt. This type of asphalt requires an excessive amount of time to "set up" after they are heated up and returned to normal ambient temperature. Asphalts containing less than 10 percent asphaltenes appear to have a greater probability of producing slow-setting asphalt mixtures. Asphaltenes are the high molecular weight fraction of asphalt which can be separated from the other asphalt fractions by dissolving an asphalt in a specified solvent (such as n-heptane as used in the ASTM D4124 Methods for Separation of Asphalt into Four Fractions)

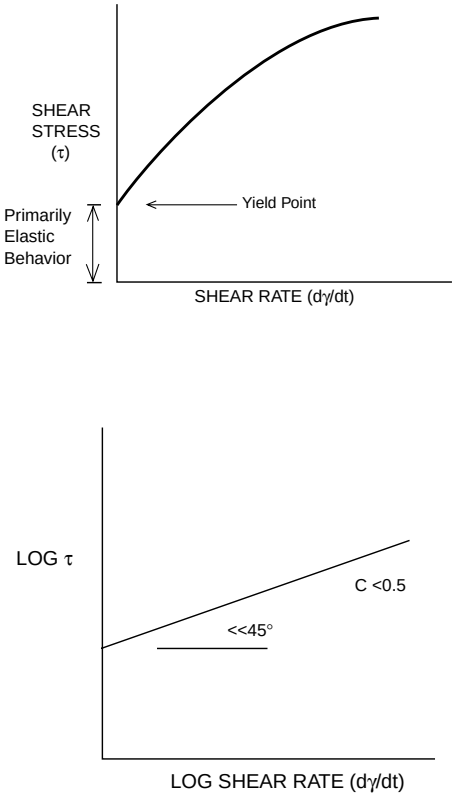

FIGURE 45.5 Bingham-plastic flow characteristics.

[ASTM, 2001]. The asphaltenes, which are insoluble in the solvent, would be precipitated out in this method.

Types and Grades of Cutback Asphalts

Cutback asphalts are classified into three main types on the basis of the relative speed of evaporation of the solvents in them. A Rapid-Curing (RC) cutback asphalt is composed of an asphalt cement and a solvent of a volatility similar to that of naphtha or gasoline, which evaporates at a fast speed. A Medium-Curing (MC) cutback asphalt contains a solvent of a volatility similar to that of kerosine, which evaporates at a medium speed. A Slow-Curing (SC) cutback asphalt contains an oil of relatively low volatility.

Within each type, cutback asphalts are graded by kinematic viscosity at 60°C. It is designated by the type followed by the lower limit of the kinematic viscosity at 60°C in units of centi-stokes (cSt). The upper limit for the viscosity is twice its lower limit. For example, an "RC-70" designates a rapid-curing cutback asphalt with a kinematic viscosity at 60°C ranging between 70 and 140 cSt, while an "SC-800" designates a slow-curing cutback asphalt with a viscosity ranging between 800 and 1600 cSt. The standard specifications for SC, MC and RC cutback asphalts can be found in ASTM Designation D2026, D2027 and D2028, respectively [ASTM, 2001].

The standard practice for selection of cutback asphalts for pavement construction and maintenance can be found in ASTM Designation D2399 [ASTM, 2001].

Types and Grades of Emulsified Asphalts

Emulsified asphalts (or asphalt emulsions) are divided into three major kinds, namely anionic, cationic and nonionic, on the basis of the electrical charges of the asphalt particles in the emulsion. An anionic

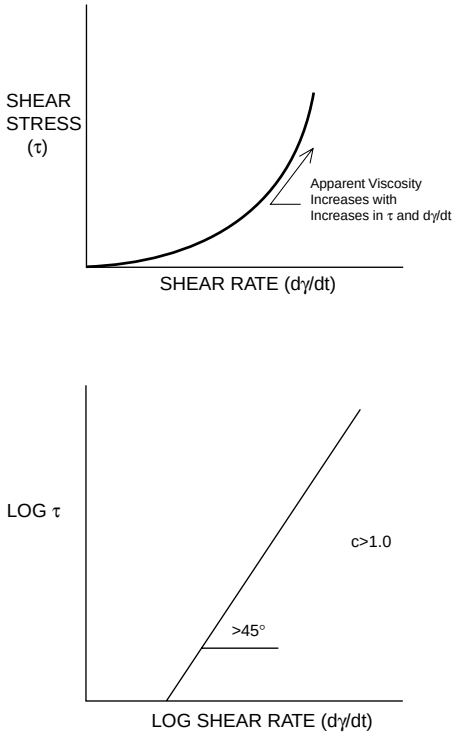

FIGURE 45.6 Dilatant flow characteristics.

asphalt emulsion has negatively-charged asphalt particles, and is usually more suitable for use with calcareous aggregates, which tend to have positive surface charges. A cationic asphalt emulsion has positively charged asphalt particles, and is usually more suitable for use with siliceous aggregates, which tend to have negative surface charges. A nonionic asphalt emulsion contains asphalt particles that are electrically neutral. Nonionic asphalt emulsions are not used in pavement applications.

Asphalt emulsions are further classified into three main types on the basis of how quickly the suspended asphalt particles revert to asphalt cement. The three types are Rapid-setting (RS), Medium-Setting (MS) and Slow-Setting (SS). An RS emulsion is designed to demulsify (to break away from the emulsion form such that asphalt particles are no longer in suspension) upon contact with an aggregate, and thus has little or no ability to mix with an aggregate. It is best used in spraying applications where mixing is not required but fast setting is desirable. An MS emulsion is designed to have good mixing characteristics with coarse aggregates and to demulsify after proper mixing. It is suitable for applications where mixing with coarse aggregate is required. An SS emulsion is designed to be very stable in the emulsion form, and is suitable for use where good flowing characteristics are desired or where mixing with fine aggregates is required. The three types of cationic asphalt emulsions are denoted as CRS, CMS and CSS. The absence of the letter "C" in front of the emulsion type denotes an anionic type.

Two other standard types of anionic asphalt emulsions available are High-Float Rapid Setting (HFRS) and High-Float Medium Setting (HFMS). This type of asphalt emulsion contains an asphalt cement which has a Bingham plastic characteristic (resistant to flow at low stress level). This flow property of the asphalt permits a thicker film coating on an aggregate without danger of runoff.

Within each type, asphalt emulsions are graded by the viscosity of the emulsion and the hardness of the asphalt cement. The lower viscosity grade is designated by a number "1" and the higher viscosity grade is designated by a number "2," which is placed after the emulsion type. A letter "h" that follows the number "1" or "2" designates that a harder asphalt cement is used. For example, an "RS-1" designates a rapid-setting anionic type with a relatively low viscosity. An "HFMS-2h" designates a high-float medium

setting anionic type having a relatively higher viscosity and containing a hard base asphalt. A "CSS-1h" designates a slow-setting cationic type having a relatively lower viscosity and containing a hard base asphalt. Standard specifications for anionic and cationic emulsified asphalts can be found in ASTM Designations D977, and D2397, respectively.

The standard practice for selection and use of emulsified asphalts in pavement construction and maintenance can be found in ASTM Designation D3628 [ASTM, 2001].

45.3 Bituminous Mixtures

Types of Bituminous Mixtures used in Pavement Construction

A *bituminous mixture* is a combination of bituminous materials (as binders), properly graded aggregates and additives. Since tar is rarely used in bituminous mixtures in recent years and asphalt is the predominant binder material used, the term "*asphalt mixture*" is now more commonly used to denote a combination of asphalt materials, aggregates and additives.. Asphalt mixtures used in pavement applications are usually classified by (1) their methods of production, or (2) their composition and characteristics.

Classification by Method of Production

Hot-mix asphalt (*HMA*) is produced in a hot asphalt mixing plant (or hot-mix plant) by mixing a properly controlled amount of aggregate with a properly controlled amount of asphalt at an elevated temperature. The mixing temperature has to be sufficiently high such that the asphalt is fluidic enough for proper mixing with and coating the aggregate, but not too high as to avoid excessive aging of the asphalt. A HMA mixture must be laid and compacted when the mixture is still sufficiently hot so as to have proper workability. HMA mixtures are the most commonly used paving material in surface and binder courses in asphalt pavements.

Cold-laid plant mix is produced in an asphalt mixing plant by mixing a controlled amount of aggregate with a controlled amount of liquid asphalt without the application of heat. It is laid and compacted at ambient temperature.

Mixed-in-place or *road mix* is produced by mixing the aggregates with the asphalt binders in proper proportions on the road surface by means of special road mixing equipment. A medium setting (MS) asphalt emulsion is usually used for open-graded mixtures while a slow setting (SS) asphalt emulsion is usually used for dense-graded mixtures.

Penetration macadam is produced by a construction procedure in which layers of coarse and uniform-size aggregate are spread on the road and rolled, and sprayed with appropriate amounts of asphalt to penetrate the aggregate. The asphalt material used may be hot asphalt cement or a rapid setting (RS) asphalt emulsion.

Classification by Composition and Characteristics

Dense-graded HMA mixtures, which use a dense-graded aggregate and have a relatively low air voids after placement and compaction, are commonly used as surface and binder courses in asphalt pavements. The term *Asphalt Concrete* is commonly used to refer to a high-quality, dense-graded HMA mixture.

A dense graded HMA mixture with maximum aggregate size of greater than 25 mm (1 in.) is called a *large stone dense-grade HMA* mix. A dense-grade HMA mix with 100% of the aggregate particles passing the 9.5 mm (3/8 in.) sieve is called a *sand mix*.

Open-graded asphalt mixtures, which use an open-graded aggregate and have a relatively high air void after placement and compaction, are used where high water permeability is desirable. Two primary types of open-graded mixes are (1) *open-graded base mix* and (2) *open-graded friction course* (*OGFC*).

Open-graded base mixes are used to provide a strong base for an asphalt pavement as well as rapid drainage for subsurface water. Open-graded base mixes usually use a relatively larger size aggregate that contains very little or no fines. Due to the lower aggregate surface area, these mixes have relatively lower

asphalt content than that of a dense-graded HMA mix. Open-graded base mixes can be produced either hot or cold in an asphalt plant.

Open-graded friction courses (OGFC) are placed on top of surface courses to improve skid resistance and to reduce hydroplaning of the pavement surface. OGFC mixtures use aggregates with a small proportion of fines to produce high air voids and good drainage characteristics. Even though the voids content is higher, the asphalt film thickness is usually greater than that for a dense-graded HMA, and thus a typical OGFC mixture has about the same or higher asphalt content than that of a dense-graded HMA. A typical OGFC uses an aggregate of ½ in. (12.5mm) maximum size, and is placed at a thickness of ¾ in. (19 mm). An OGFC mixture is produced in a hot-mix plant in the same way as a dense-graded HMA mixture. Crumb rubber modified asphalt has been used in OGFC mixtures in recent years to improve their performance and durability. Due to the higher viscosity of the crumb rubber modified binder, thicker film thickness can be used. This results in a higher binder content and thus better durability for the crumb rubber modified OGFC mixtures.

Stone Matrix Asphalt (SMA), which was originally developed in Europe, was a special asphalt mixture of improved rutting resistance and increased durability. SMA mixtures are designed to have a high coarse aggregate content (typically 70–80%), a high binder content (typically over 6%) and high filler content (typically about 10%). Asphalts modified with polymers and/or fibers are typically used. The improved rutting resistance of the SMA mixture is attributed to the fact that it carries the load through the coarse aggregate matrix (or the stone matrix), as compared with a dense-graded HMA, which carries the load through the fine aggregate. The use of polymer and/or fiber modified asphalts, which have increased viscosity, and the use of high filler content, which increases the stiffness of the binder, allow the SMA mixtures to have a higher binder film thickness and higher binder content without the problem of draindown of asphalt during construction. The increased durability of the SMA mixtures can be attributed to the higher binder film thickness and the higher binder content. SMA mixtures require the use of strong and durable aggregates with a relatively lower L.A. Abrasion Loss. SMA mixtures can be produced in a hot-mix plant in a similar way as a dense-grade HMA mixture. The main disadvantage of using a SMA as compared with a dense-grade HMA is its relatively higher cost due to the requirement for the use of higher quality aggregates, polymer, fibers and fillers.

Effects of Aggregate Characteristics on Performance of Asphalt Pavements

Aggregate makes up 90 to 95% by weight and 75 to 85% by volume of most asphalt paving mixtures. Aggregate provides most of the load-bearing capacity of the asphalt mixture. Thus, the performance of an asphalt mixture is greatly influenced by the properties of the aggregate used. The effects of aggregate characteristics on the performance of asphalt pavements, and the commonly used methods to determine these aggregate characteristics are presented in this section.

Aggregate Gradation

One of the most important characteristics of an aggregate, which affect the performance of an asphalt mixture, is its gradation. The properties of an asphalt mixture could be changed substantially when the aggregate gradation is altered.

What is the ideal gradation of an aggregate to be used in asphalt mixture? From the standpoint of achieving maximum strength and bearing capacity of the asphalt mixture, since an asphalt mixture derives its strength mainly from the aggregate, it would be preferable to have a well-graded aggregate to achieve maximum volume of aggregate in the mix. However, if the aggregate is too well graded, the voids in mineral aggregate (VMA) of the mix may be too low to accommodate the proper amount of asphalt, which is needed to produce a certain minimum asphalt film thickness on the aggregate surface. If the VMA is too low and the required amount of asphalt is added to the mix, the phenomenon of bleeding may occur as there would not be enough voids in the mix to accommodate the asphalt. However, if a lower asphalt content is used, the asphalt film thickness on the aggregate may be too low. The asphalt concrete produced would not be durable, and the problem of raveling may occur. Thus, the ideal aggregate

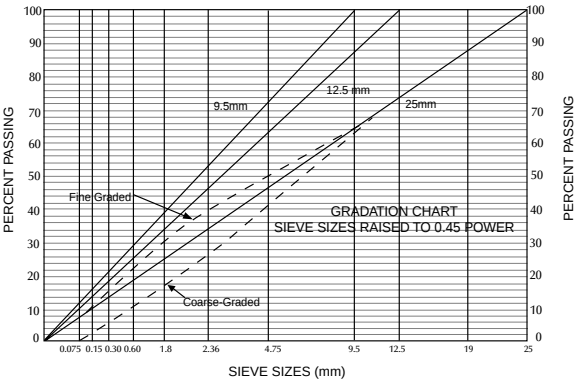

FIGURE 45.7 Maximum density gradations plotted on a 0.45 power gradation chart.

should be fairly well graded to produce a high volume of aggregate in the asphalt mix, but it should not be too well graded such that the VMA becomes too low.

Figure 45.7 shows a 0.45 power gradation chart, which was developed by the Federal Highway Administration (FHWA) of the U.S. in 1962 to plot aggregate gradation. The 0.45 power gradation chart was chosen so that a gradation that plots as a straight line on the chart would define the maximum density gradation. Three different maximum-density aggregate gradations are shown in Fig. 45.7, each with a different top size coarse aggregate. The equation for the FHWA's maximum density gradation is:

$$P = 100\left(d/D\right)^{0.45} \tag{45.18}$$

where P = total percent passing the specific sieve
d = the specific sieve size in question
D = maximum size of the aggregate

Asphalt mixes that have aggregate gradations that plot above the maximum density line are called fine-graded mixtures. Conversely, mixes that have gradations that fall below the maximum density line are called coarse-graded mixes. When the other factors are constant, the coarser-graded aggregate will require less asphalt binder in the mix to achieve adequate coating and mix properties. It is also more tolerant to an increase in asphalt content than the finer-graded mixtures. In general, the coarser mixes, when properly designed, are more resistant to permanent deformation [Ruth et al, 1989].

Recommended aggregate gradation specifications for dense-grade asphalt mixtures of various nominal maximum aggregate sizes can be found in ASTM Standard Specification D3515 [ASTM, 2001]. For the most part, the FHWA maximum density curves fall inside the limits of these gradation specifications for the corresponding maximum aggregate sizes.

The aggregate gradation specification in the Superpave mix design method is presented in the subsection "Superpave Mix Design Method" in this section.

Maximum Aggregate Size

Maximum aggregate size is the smallest sieve through which 100% of the aggregate particle pass. Generally, using a larger maximum aggregate size in the asphalt mixture will increase the bearing capacity and rutting resistance of the asphalt pavement. Using a larger maximum aggregate size also reduces the design asphalt content and cost of the mix. However, mixtures using a larger stone size are harder to place and to compact to the desired smoothness. The lift thickness also limits the maximum aggregate size to be used. The maximum aggregate size is limited to 0.5 times the lift thickness.

Asphalt mixture designations typically use the *nominal maximum aggregate size* rather than the maximum aggregate size. However, the definition of nominal maximum size may vary from one agency to another. ASTM C125 Standard [ASTM, 2001] defines nominal maximum size as the smallest sieve

opening through which the entire amount of the aggregate is permitted to pass, but up to 10 percent of the aggregate may be retained on the nominal maximum size. In the Superpave mix design system, nominal maximum size is defined as one sieve size larger than the first sieve to retain more than 10 percent, while maximum size is one sieve larger than the nominal maximum size.

Mineral Filler

Mineral filler is the aggregate finer than the No. 200 mesh size. Proper amount of mineral filler added to an asphalt mixture could improve the performance of the mix. Adding mineral filler to an asphalt mixture has the effect of increasing the apparent viscosity of the asphalt binder. It could be used to decrease mixture tenderness during placement. Increased filler content reduces the VMA in the asphalt mixture. A mineral filler content of 2 to 6% is usually used in dense-grade HMA mixtures. General requirements for mineral filler can be found in ASTM D242 Standard Specification for Mineral Filler For Bituminous Paving Mixtures [ASTM, 2001].

Affinity for Asphalt

The affinity for asphalt of an aggregate is its tendency to accept and retain an asphalt coating. An asphalt concrete using an aggregate with high affinity for asphalt will be less susceptible to stripping of asphalt when exposed to water and thus more durable. Aggregates that are basic, such as limestone and dolomite, are usually less susceptible to stripping. Aggregates that are more acidic, such as sand and gravel, are usually more susceptible to stripping. However, there are exceptions to this generalization. Some limestones have been known to have stripping problems, while some gravels have been known to have no stripping problem at all.

Stripping resistance of an aggregate is typically evaluated by testing the asphalt aggregate mixture. A commonly used test for this purpose is AASHTO Designation T 283 Standard Test for Resistance of Compacted Bituminous Mixture to Moisture Induced Damage [AASHTO 1997]. In this test, a set of replicate specimens of the asphalt mixtures to be evaluated are compacted to 7 ± 1% air voids. The specimens are divided into two subsets. One subset is tested in the dry condition for indirect tensile strength. The other subset is subjected to vacuum saturation followed by a freeze and warm-water soaking cycle and then tested for indirect tensile strength. The tensile strength ratio, which is calculated by dividing the average tensile strength of the conditioned subset by the average tensile strength of the dry subset, is used as a indicator of stripping resistance.

Other tests for stripping resistance include ASTM D1075 Standard Test Method for Effect of Water on Compressive Strength of Compacted Bituminous Mixtures [ASTM, 2001], and AASHTO T182 Standard Specification for Coating and Stripping of Bitumen-Aggregate Mixtures [AASTHTO 1997].

It is to be pointed out that none of the existing stripping resistance tests have been found to be completely reliable in predicting the performance of the asphalt-aggregate mixtures in actual service.

Aggregate Shape and Texture

The shape of an aggregate used in an asphalt mixture has a great effect on the tendency of the mix to deform. Rounded aggregates have no interlocking ability and can easily "slide by" each other when subjected to shear stresses. Increasing the amount of crushed coarse and fine aggregates in an asphalt mixture can significantly increase the resistance of the mix to plastic deformation. Thus, in order to increase the rutting resistance of the asphalt mixtures, many asphalt mixture specifications have required a large percentage of the coarse aggregate to have at least one or two crushed faces, and have limited the percentage of natural sand to be used.

Flat or elongated particles are typically defined as particles having a ratio of maximum to minimum dimension greater than five. Flat or elongated particles are undesirable. These particles can be easily broken by traffic compaction and can reduce the strength of the asphalt mixture. These particles also reduce the workability of the asphalt mixture and can impede the compaction of the mixture during construction. Flat or elongated particles can be determined using ASTM D4791 Standard Test Method for Flat or Elongated Particles in Coarse Aggregate [ASTM, 2001].

Surface texture of aggregate particles also has a great effect on the ability of the mix to resist plastic deformation. Some researchers consider this factor to be more important than particle shape. A rough aggregate surface texture can provide good skid resistant characteristics of the pavement surface. Asphalt can bond better to rough surfaces than to smooth ones. Aggregates that have smooth surfaces, such as gravels, have a higher tendency to rut than do crushed limestone aggregate, which have rougher surfaces.

The overall measure of particle shape and texture characteristics of an aggregate can be quantified by a *particle index value* by means of ASTM D3398 Standard Test for Index of Aggregate Particle Shape and Texture [ASTM, 2001]. In this test, the aggregate to be evaluated is sieved into different specified size fractions. The aggregate from each of the different size fractions is placed in 3 layers in a special cylindrical steel mold and each layer is compacted with 10 tamps by a special tamping rod. This procedure is repeated using a compaction of 50 tamps per layer. The percent of voids in the compacted aggregate in each condition is determined from the weight of the compacted aggregate and the bulk specific gravity of the aggregate. The particle index for the aggregate in each size fraction is calculated from the following equation:

$$I_a = 1.25\, V_{10} - 0.25\, V_{50} - 32.0 \tag{45.19}$$

where I_a = particle index value
V_{10} = percent voids in the aggregate compacted with 10 tamps per layer
V_{50} = percent voids in the aggregate compacted with 50 tamps per layer

The particle index of the aggregate is computed as the weighted average of the particle index values from the different size fractions based on the percentages of the fractions in the original aggregate. An aggregate containing round particles with smooth surface texture may have a low particle index of 5 to 8, while an aggregate containing highly angular particles with rough texture may have a particle index of 15 to 20.

A test that has been used to measure the angularity and texture characteristics of fine aggregates is ASTM C1252 or AASHTO TP56–99 Method for Uncompacted Void Content of Fine Aggregate (as Influenced by Particle Shape, Surface Texture, and Grading) [AASHTO, 1999]. In this test, the fine aggregate to be evaluated is dropped through the orifice of a funnel into a calibrated 100-cm^3 cylinder. Excess material is struck off and the cylinder with aggregate is weighed. Uncompacted void content of the sample is computed using this weight and the bulk specific gravity of the aggregate. There are three different variations of this method. Method A uses a sample of specified gradation. Method B uses three different size fractions. Method C uses the actual gradation of the aggregate to be evaluated. Superpave mix design system uses Method A.

A higher uncompacted void content is generally associated with higher angularity and rougher texture of the fine aggregate. However, since the results of the uncompacted void content test are influenced by the gradation of the aggregate, comparisons between different aggregates can only be made when they are tested in the same grading.

Strength and Toughness

Since the aggregates provide most of the load carrying capacity of the asphalt mixtures, aggregates must be sufficiently strong and tough to resist the applied loads. Insufficiently strong and tough aggregates in the asphalt mixtures can be excessively broken and degraded by the applied loads during construction and by traffic during service.

The Los Angeles (L.A.) abrasion test is commonly used to control the desired strength and toughness of the aggregate. ASTM C131 Standard Test Method for Resistance to Degradation of Small-Size Aggregate by Abrasion and Impact in the Los Angeles Machine is used for coarse aggregate smaller than 37.5 mm (1½ in.). ASTM C535 Standard Test Method for Resistance to Degradation of Large-Size Coarse Aggregate by Abrasion and Impact in the Los Angeles Machine is used for coarse aggregate larger then 19 mm (3/4 in.) and up to 76 mm (3 in.) maximum aggregate size.

The L.A. abrasion test reports the results in terms of percent L.A. abrasion loss. A higher percent L.A. abrasion loss generally indicates a less abrasion-resistant aggregate. Typical test results range from 10% for extremely hard rocks to more than 60% for soft aggregates. Specifications for aggregate for use in HMA mixtures typically limit the maximum allowable L.A. abrasion loss to a certain level, which may vary from 40% by some agencies to 60% by others.

It is to be pointed out that the L.A. abrasion loss is mainly a measure of the resistance to abrasion. Many aggregates have given satisfactory performance even though their L.A. abrasion loss is high.

Durability

In order to ensure a durable aggregate, specifications for coarse aggregate for use in asphalt mixtures typically include a soundness test using sodium or magnesium sulfate (ASTM C88). This test involves submerging the different size fractions of the aggregate in a solution of sodium or magnesium sulfate for 18 hours followed by oven drying. The process is repeated for a specified number of cycles. The loss in weight for each size fraction is determined, and the weighted average percent loss for the entire sample is computed and reported as percent soundness loss. A higher percent soundness loss indicates a less durable aggregate. ASTM D692 Standard Specification for Coarse Aggregate for Bituminous Paving Mixtures specifies a maximum of 12% loss after 5 cycles when using sodium sulfate and 18% loss when using magnesium sulfate.

The sodium and magnesium sulfate soundness test was originally developed to simulate the damaging effects of freezing and thawing on aggregates. However, this test is now used to screen aggregates regardless of whether or not the aggregate is to be used in a freezing and thawing environment.

Cleanliness

Clean aggregates that are free of deleterious materials are desirable for use in asphalt mixtures. Deleterious materials that are to be avoided include clay, dust, friable particles and organic impurities.

The sand equivalent test (ASTM D2419) is used to determine the proportions of clay and sands in a fine aggregate. In this test, a sample of the fine aggregate to be tested is placed in a specified transparent cylinder filled with water and a flocculating agent. The mixture is agitated, and allowed to settle for 20 min. The sand will separate from the flocculated clay, and the heights of clay and sand in the cylinder are measured. The sand equivalent is the ratio of the height of sand to the height of clay times 100. A higher sand equivalent value indicates a cleaner aggregate. Specifications for aggregates in asphalt mixtures typically specify a minimum sand equivalent of 25 to 35.

Clay and friable particles in aggregate can be determined in accordance with ASTM C142 Standard Test Method for Clay Lumps and Friable Particles in Aggregates. The amount of clay lumps and friable particles are typically limited to a maximum of 1%.

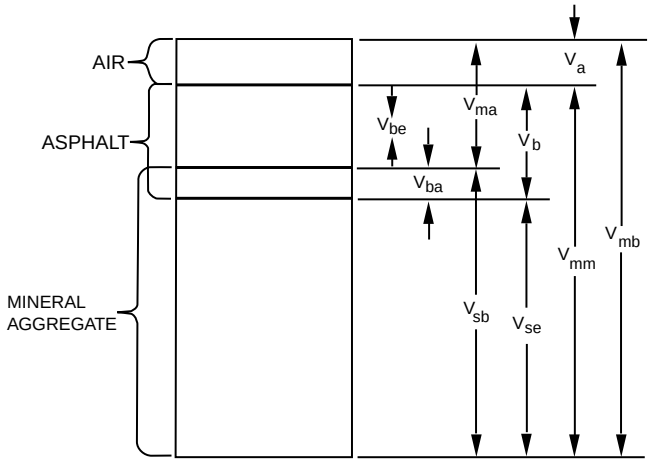
The amount of plastic fines in a fine aggregate can be indicated by the plasticity index (PI) (ASTM D4318). ASTM D1073 Standard Specification for Fine Aggregate for Bituminous Paving Mixtures limits the PI of the fraction passing the No. 40 (425 μm) to 4.0.

Volumetric Properties of Asphalt Mixtures

A compacted asphalt mixture consists primarily of aggregate, asphalt and air. The composition of an asphalt mixture can be characterized by the proportioning of the volumes of these three components. *Volumetric properties* of asphalt mixtures are properties that are directly related to the proportioning of the volumes of these three components. Volumetric properties have been widely used in the design and control of production of asphalt mixtures. The commonly used volumetric properties of asphalt mixtures are presented in this section.

Different Volumes in a Compacted Asphalt Mixture

Although there are only three components in a compacted asphalt mixture, numerous different volumes can be computed when different combinations of the three components are combined. This is further



V_{ma} = Volume of voids in mineral aggerate
V_{mb} = Bulk volume of compacted mix
V_{mm} = Voidless volume of paving mix
V_a = Volume of air voids
V_b = Volume of asphalt
V_{ba} = Volume of absorbed asphalt
V_{be} = Volume of effective asphalt
V_{sb} = Volume of mineral aggergate (by bulk specific gravity)
V_{se} = Volume of mineral aggergate (by effective specific gravity)

FIGURE 45.8 Representation of volumes in a compacted asphalt mixture.

complicated by the fact that some asphalt can be absorbed into the aggregate and occupy part of the bulk volume of the aggregate. The representation of the different volumes in a compacted mixture is shown in Fig. 45.8.

These volumes and their corresponding notations will be used to define the volumetric properties in the subsequent subsections.

Percent Air Voids

The percent air voids (P_a) of a compacted mixture is the ratio of the volume of air voids to the total volume of the mixture. It can be expressed by the following equation:

$$P_a = \left(V_a / V_{mb}\right) \times 100\% \tag{45.20}$$

Percent Voids in Mineral Aggregate

Percent voids in mineral aggregate (VMA) is the ratio of the volume of voids in mineral aggregate to the total volume of the mixture. It can be expressed by the following equation:

$$VMA = V_{ma} / V_{mb} \times 100\% = \left(V_a + V_{be}\right) / V_{mb} \times 100\% \tag{45.21}$$

Percent Voids Filled with Asphalt

Voids filled with asphalt (VFA) is the ratio of the volume of effective asphalt to the volume of the voids in mineral aggregate. It can be expressed by the following equation:

$$VFA = V_{be} / V_{ma} \times 100\% = V_{be} / \left(V_{be} + V_a\right) \times 100\% \tag{45.22}$$

Computation of Volumetric Properties

The maximum specific gravity (G_{mm}) of the asphalt mixture is needed in order to calculate the percent air voids. The maximum specific gravity is the specific gravity when there are no air voids in the mixture. The maximum specific gravity of the mixture can be determined by running the ASTM D2041 Standard Test Method for Theoretical Maximum Specific Gravity and Density of Bituminous Paving Mixture on the loose mixture. This test is also known as the Rice test.

The percent air voids (P_a) can be computed from the maximum specific gravity (G_{mm}) and the bulk specific gravity of the mixture (G_{mb}) as follows:

$$P_a = \left(G_{mm} - G_{mb}\right) / G_{mm} \times 100 \tag{45.23}$$

The percent voids in mineral aggregate (VMA) can be computed as follows:

$$VMA = 100 - \left(G_{mb}\, P_s\right) / G_{sb} \tag{45.24}$$

where P = aggregate percent by total weight of the mixture
G = bulk specific gravity of aggregate

The percent voids filled with asphalt (VFA) can be computed as follows:

$$VFA = \left(VMA - P_a\right) / VMA \times 100 \tag{45.25}$$

Design of HMA Mixtures

The design of an asphalt paving mixture usually involves selecting the aggregates, asphalt and additives to be used, testing the asphalt mixtures at various different proportions of the ingredients, and selecting the optimum mix design which would give the best anticipated performance in service. Ideally, the mixtures to be tested should be prepared and compacted to as close to the field condition as possible, so that they can be representative of the mixtures to be produced and put in service. The properties of the mixtures to be determined should be good indicators of performance of the mixtures in service, so that these properties can be used to determine the acceptability of the mixtures and to select the optimum mix design to be used.

A design procedure for asphalt mixtures generally involves (1) preparing and compacting the asphalt mixtures in the laboratory to simulate the field condition, (2) characterizing the laboratory compacted specimens, and (3) determining the optimum mix design based on the properties of the tested specimens and the set criteria for these properties. Different design methods generally differ from one another by (1) the equipment and method used to prepare and compact the asphalt mixtures, (2) the properties of the compacted specimens to be measured, and (3) the criteria used for selecting acceptable and optimum mix designs.

This section presents the general methodologies of four different mix design methods for dense-grade HMA mixtures, which include the Marshall, Hveem, Superpave and GTM methods. Emphasis is placed on the three main elements as described above, so that these different design methods could be compared with one another in a more meaningful manner.

Marshall Mix Design Method

The concept of the Marshall method of mix design was originally conceived by Mr. Bruce Marshall, formerly a bituminous engineer with the Mississippi State Highway Department. The Marshall method was later further improved by the U.S. Corps of Engineers who added certain features and developed the mix design criteria. The Marshall mix design method and criteria were originally developed for airfield pavements, but were later also adopted for use in highway pavements. Due to its simplicity, the Marshall method of mix design was the most commonly used mix design method in the U.S. before the introduction

of the Superpave design system, and it is still the most commonly-used mix design methods in the rest of the world.

The Marshall mix design procedure as recommended by the Asphalt Institute is described in detail in the Manual "Mix Design Methods for Asphalt Concrete and Other Hot-Mix Types" by the Asphalt Institute [1997]. The Marshall mix design procedure consists of the following main elements:

1. Selection of aggregates — The aggregates must meet all the requirements as specified by the local highway agency. These requirements typically include limits on L.A. abrasion loss, soundness loss, sand equivalent, percent of deleterious substance, percent of natural sand, percent of particles with crushed faces, and percent of flat or elongated particles. (See Section 45.3 for a description of aggregate properties.) The gradation of the aggregate blend to be used must meet the gradation requirements for dense-grade HMA mixture as set by the local highway agency.
2. Selection of asphalt binder — The asphalt must meet the specification requirements as set by the local highway agency.
3. Preparation of asphalt mixture samples — Samples of asphalt mixtures at five different asphalt contents, with three replicates per asphalt content are prepared. The asphalt contents are selected at 0.5% increments with at least two asphalt contents above the estimated optimum and at least two below it. The aggregate and asphalt are mixed at a temperature at which the asphalt kinematic viscosity is 170 ± 20 centistokes.
4. Compaction of the asphalt mixtures — The asphalt mixture is compacted in a 101.6-mm (4-in.) diameter cylindrical mold by a Marshall compaction hammer, which is 6.5 kg (10 lb) in weight and dropped from a height of 457 mm (18 in.) for a specified number of blows per side of the specimen. The number of blows to be applied per side is 35, 50 or 75 for light, medium or heavy designed traffic, respectively. Light traffic is defined as having less than 10^4 ESALs. Medium traffic has between 10^4 and 10^6 ESALs, while heavy traffic has more than 10^6 ESALs. Compaction of the mixtures is done at a temperature at which the asphalt kinematic viscosity is 280 ± 20 centistokes. The compacted specimen is 101.6 mm (4 inches) in diameter and approximately 63.5 mm (2.5 in.) in height.
5. Testing of the compacted Marshall specimens — The tests to be run on the Marshall specimens include (1) determination of bulk specific gravity in accordance with AASHTO T166 [AASHTO, 1997] or ASTM D2726 [ASTM, 2001] and (2) Marshall stability test, which measures the Marshall stability and Marshall flow, in accordance with ASTM D1559 [ASTM, 2001].

The Marshall stability is the maximum load the specimen can withstand before failure when tested in the Marshall stability test. The configuration of the Marshall stability test is close to that of the indirect tensile strength test, except for the confinement of the Marshall specimen imposed by the Marshall testing head. Thus, the Marshall stability is related to the tensile strength of the asphalt mixture.

The Marshall flow is the total vertical deformation of the specimen, in units of 0.01 in., when it is loaded to the maximum load in the Marshall stability test. The Marshall flow can provide some indication of the resistance of an asphalt mixture to plastic deformation. Mixtures with low flow numbers are stiff and may be difficult to compact. However, these mixtures are more resistant to rutting than those with high flow numbers. Mixtures with flow numbers above the normal range may be "tender mixes," which are susceptible to permanent deformation.

1. Computation of volumetric properties of the specimens — Using the bulk specific gravity of the specimen, the maximum specific gravity of the mixture and the bulk specific gravity of the aggregate, the percent air voids and VMA of the specimen are determined. Percent air voids of the specimen can be computed from the bulk specific gravity of the specimen and the maximum specific gravity of the mixture according to Eq. (45.23). VMA can be computed from the bulk specific gravity of the mixture, the bulk specific gravity of the aggregate and the aggregate percent by weight of the mix according to Eq. (45.24).
2. Marshall mix design criteria — The Marshall mix design method as recommended by the Asphalt Institute uses five mix design criteria. They are (1) a minimum Marshall stability, (2) a range of

TABLE 45.5 Marshall Mix Design Requirements on Stability, Flow, Air Voids and VFA

Traffic Category Compaction, No. of blows/side	Light 35		Medium 50		Heavy 75

acceptable Marshall flow, (3) a range of acceptable air voids, (4) percent voids filled with asphalt (VFA), and (5) a minimum amount of VMA. Table 45.5 shows the requirements for stability, flow, air voids and VFA, while Table 45.6 shows the requirements for VMA. A mix design to be adopted must satisfy all these five criteria.

3. Determination of design asphalt content — To facilitate the selection of optimum asphalt content, the following six plots are made:

   a. Average unit weight versus asphalt content
   b. Average air voids versus asphalt content
   c. Average Marshall stability versus asphalt content
   d. Average Marshall flow versus asphalt content
   e. Average VMA versus asphalt content
   f. Average VFA versus asphalt content

From the plot of air voids versus asphalt content, determine the asphalt content at an air voids content of 4%. Using plots (3) through (6), determine the Marshall stability, Marshall flow, VMA and VFA at this asphalt content, and compare them with the Marshall mix design criteria as given in Tables 45.5 and 45.6. If all the mix criteria are met, this asphalt content is the preliminary design asphalt content. The preliminary design asphalt content can then be adjusted within the range where all the mix criteria are met according to the special need of the project to arrive at the final design asphalt content.

If one or more of the mix criteria cannot be met, adjustments in aggregate type, aggregate gradation and/or asphalt type will need to be made and the mix design procedure will need to be re-conducted.

Hveem Mix Design Method

The Hveem mix design method was developed in the1930s by Francis N. Hveem and his co-workers at the California Division of Highways. The Hveem mix design method has been adopted by several western states in the U.S., and is still being used by the California Department of Transportation Department today. The Hveem mix design procedure as recommended by the Asphalt Institute is described in detail in the Manual "Mix Design Methods for Asphalt Concrete and Other Hot-Mix Types" by the Asphalt Institute [1997]. The Hveem mix design procedure consists of the following main elements:

1. Selection of aggregate and asphalt — The selection of aggregate and asphalt to be used is similar to that in the Marshall mix design method as described in the subsection on Marshall mix design method.
2. Estimation of optimum asphalt content — The Centrifuge Kerosene Equivalent test is run on the fine aggregate to determine the CKE (percentage of kerosene retained by the fine aggregate). The surface capacity test is run on the coarse aggregate to determine the Percent Oil Retained. The CKE and Percent Oil Retained, along with the calculated surface area of the aggregate and apparent specific gravities of the fine and coarse aggregates, are then used to estimate the optimum asphalt content through a series of five charts.
3. Preparation of asphalt mixtures — Samples of asphalt mixtures at seven different asphalt contents are prepared. The asphalt contents are selected at 0.5% increments with four asphalt contents above the estimated optimum, one at the estimated optimum and two below it. Mixing temperature is a function of the grade of the asphalt. For an AC-10, the specified mixing temperature is 135 to 149°C, while for an AC-40, it is 149 to 163°C.
4. Compaction of specimens — After mixing, the mixture is placed in oven for a 15-hour curing period at 60°C. After curing is complete, the mixture is reheated to 110°C and compacted in the California kneading compactor. The detailed description of the compaction equipment and procedure are given in ASTM D1561. Basically, the specimen is compacted in a 101.6-mm (4-in.) diameter cylindrical mold by means of the kneading action of a compactor ram without impact, followed by a static load to smoothen out the surface of the compacted specimen. The compacted specimen is 101.6 mm (4 in.) in diameter and approximately 63.5 mm (2.5 in.) in height.
5. Testing of the compacted mixture — The compacted Hveem specimens are tested at 60°C in the Hveem stabilometer to determine the Hveem Stabilometer (S) value. Since the Hveem stabilometer test is a non-destructive test, the bulk specific gravity of the specimen is determined after the completion of the Hveem stabilometer test.

   The Hveem stabilometer apparatus and test procedure are described in details in ASTM D1560. Hveem S-value is expressed as a number that may vary from 0 to 100. A higher Hveem S-value would indicate a mix of higher stability. In the development of the Hveem method, it was found that a Hveem S-value of 28 to 30 could be used to distinguish between pavements that would be susceptible to rutting and those that would not. The minimum required Hveem S-value was later increased to 37 (for heavy traffic condition) to account for the increased traffic loads. The Hveem S- value is generally considered to be a measure of the angle of internal friction in the Coloumb shear strength equation. Thus the Hveem S-value is related to the shear strength and thus to the rutting resistance of the asphalt mixture.

   A swell test is also run on the compacted specimens to determine the mixture's resistance to water. Basically, a swell test measures the swelling of a compacted specimen after it is submerged in water for 24 hours. A detailed description of the swell test can be found in the Manual "Mix Design Methods for Asphalt Concrete and Other Hot-Mix Types" by the Asphalt Institute [1997].
6. Computation of air voids of the specimens – The air voids of the specimens are computed from the bulk specific gravity of the specimen and the maximum specific gravity of the mixture by according to Equation 45.23.
7. Hveem mix design criteria — The three mix design criteria used by the Hveem method are (1) a minimum required Hveem S-value, (2) a minimum air voids of 4 percent, and (3) a maximum

allowable swell as measured by the swell test. The minimum required Hveem S-value as recommended by the Asphalt Institute is 30, 35 and 37 for light, medium and heavy designed traffic.

8. Determination of optimum asphalt content — The optimum asphalt content is the highest possible asphalt content such that the three Hveem mix design criteria are met.

Superpave Volumetric Mix Design Method

The Superpave mix design method is a new mix design method, which was introduced as a result of the Strategic Highway Research Program (SHRP) conducted from 1988 through 1993. When the Superpave mix design method was first developed by the SHRP researchers, it was intended to have three levels of sophistication and design effort. Level 1 design would involve only materials selection and volumetric proportioning, and was intended for use on low-traffic roads with less than 1 million ESALs. Level 2 design would include Level 1 design effort plus conductance of performance prediction tests, and was intended for use on pavements with between 1 and 10 million ESALs. Level 3 design would include Level 1 design effort plus conductance of enhanced performance prediction tests, and was intended for use on high-traffic pavements with over 10 million ESALs. However, at present, only Level 1 design has been implemented, and Level 1 design has been used for all levels of traffic. Superpave Level 1 mix design is now also referred to as Superpave volumetric mix design.

The detailed specification for Superpave Volumetric Design can be found in AASHTO MP2–99 [AASHTO, 1999]. The description of the Superpave volumetric mix design procedure can be found in AASHTO PP28–99 [AASHTO, 1999]. However, it is to be pointed out that since the Superpave design method is not well established yet and changes are still being made to it periodically, the most updated versions of these documents should be consulted when performing a Superpave volumetric mix design.

The Superpave volumetric mix design procedure consists of the following main elements:

1. Selection of asphalt — The asphalt binder should be a PG grade asphalt meeting the requirements of AASHTO MP1, which is appropriate for the climate and traffic condition at the project site.
2. Selection of aggregate — The combined aggregate must meet the following requirements:
   a. Nominal maximum size — Nominal maximum aggregate size should be 9.5 to 19.0 mm for surface course HMA and 19.0 to 37.5 mm for base course HMA.
   b. Gradation control points — The gradation must pass through the control points as specified in Table 45.7.
   c. Gradation restricted zone — It is recommended that the gradation does not pass through the restricted zones as specified in Table 45.8. However, results of recent research studies have indicated that mixtures which had aggregate gradations that violated the restricted zone could perform similarly or better than those that had not violated it [NCAT, 2001].

TABLE 45.7 Superpave Mix Design Criteria on Aggregate Gradation Control Points

d. Consensus aggregate property requirements — There are four consensus aggregate property requirements. The coarse aggregate must meet the angularity requirements in terms of the minimum percentages of particles with crushed faces as measured by ASTM D5821. The fine aggregate must meet the fine aggregate angularity requirements in terms of the minimum uncompacted void contents as measured by AASHTO T304 Method A. The aggregate must meet the sand equivalent requirement in terms the minimum sand contents as measured by AASHTO T176. The aggregate must meet the requirement on the maximum allowable percentage of flat and elongated particles as measured by ASTM D4791. The Superpave mix design criteria for these four consensus properties are shown in Table 45.9.
e. Aggregate source property requirements — The aggregate must meet all the source property requirements, such as L.A. abrasion loss, soundness and deleterious materials as specified by the local highway agency.

3. Preparation of asphalt mixtures — Aggregate and asphalt are mixed at the temperature at which the kinematic viscosity of the asphalt is 170 ± 20 cSt. The loose asphalt mixture is then cured in a forced-draft oven at 135°C for 4 hours before compaction. The detailed description of the curing procedure can be found in AASHTO PP2–99 [AASHTO, 1999].
4. Compaction of asphalt mixtures — Compaction of the asphalt mixture is done in the Superpave gyratory compactor, as described in AASHTO TP4–99. The Superpave gyratory compactor differs from the Corps of Engineers GTM in that the angle of gyration in the Superpave gyratory compactor is fixed, while the gyratory angle in the GTM can vary according to the stability of the tested mixture. The Superpave gyratory compactor configurations are as follows:

TABLE 45.10 Numbers of Gyrations for Superpave Gyratory Compaction

Design Traffic (million ESALs)	$N_{initial}$	N_{design}	N_{max}
<0.3	6	50	75
0.3 to <3	7	75	115
3 to 30	8	100	160
≥30	9	125	205

Source: AASHTO 1999. AASHTO PP28–99 Standard Practice for Superpave Volumetric Mix Design for Hot Mix Asphalt, *AASHTO Provisional Standards*, Interim Edition, AASHTO, Washington, D.C.

a. Vertical ram pressure: 600 kPa (87 psi)
b. Gyratory angle: 1.25° fixed angle
c. Speed: 30 gyrations per minute
d. Specimen diameter: 150 mm (5.9 in.)
e. Specimen height: 115 mm (4.5 in.)

4. Compaction is done at a temperature at which the kinematic viscosity of the asphalt is 280 ± 30 cSt. The number of gyrations to be applied is a function of the designed traffic level, as given in Table 45.10. For each level of designed traffic, there are three levels of compaction, namely N_{ini}, N_{des} and N_{max} gyrations. The specimen is compacted to N_{des} gyrations, while the specimen height is recorded continuously. After compaction, the specimen is removed from the mold and its bulk specific gravity and $\%G_{mm}$ is determined. $\%G_{mm}$ is equal to 100% minus % air voids. The actual measured bulk density is compared with the calculated density based on the specimen height, and a correction factor is calculated. This correction factor and the specimen height at N_{ini} are then used to calculate the density and $\%G_{mm}$ of the specimen at N_{ini}. After the determination of the design asphalt content, duplicate samples at the design asphalt content are also compacted to N_{max} gyrations to determine the $\%G_{mm}$ of the mixture at N_{max} gyrations.
5. Determination of design asphalt content — The design asphalt content is the asphalt content at which the asphalt mixture has an air voids content of 4% (or a $\%G_{mm}$ of 96%) when compacted to N_{des} gyrations, while all the mix design requirements are met. These mix design requirements are presented in the next section..
6. Superpave mix design requirements — The asphalt mixture design must meet all the following requirements:
   a. The asphalt and the aggregate must meet all the requirements as presented in the preceding sections.
   b. The asphalt mixture must have a target air voids of 4% when compacted to N_{des} gyrations.
   c. The VMA of the compacted mixture at N_{des} gyrations must meet the minimum VMA requirements as shown in Table 45.11.
   d. The VFA (Voids Filled with Asphalt) of the compacted mixture at N_{des} gyrations must fall within the range as shown in Table 45.11.
   e. The dust-to-binder ratio, which is the ratio of the weight of the mineral filler to the weight of the binder, must be between 0.6 and 1.2.
   f. The $\%G_{mm}$ of the asphalt mixture compacted to N_{ini} must not exceed the limits as shown in Table 46.11. The $\%G_{mm}$ of the mixture compacted to N_{max} must not exceed 98%.
   g. The asphalt mixture, when compacted by the Superpave gyratory compactor to 7% air voids and tested in the AASHTO Designation T 283 Standard Test for Resistance of Compacted Bituminous Mixture to Moisture Induced Damage, must have a retained tensile-strength ratio of at least 80%.

TABLE 45.11 Superpave Mix Design Criteria on $\%G_{mm}$, VMA, VFA and Dust-to-Binder Ratio

Design Traffic (million ESALs)	VFA (%)	Required $\%G_{mm}$			Required minimum VMA (%) Nominal Max.Agg. Size, mm					Dust-to-Binder Ratio

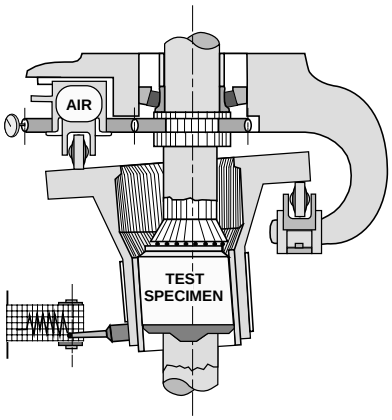

FIGURE 45.9 Schematic of the Gyratory Testing Machine (GTM).

GTM Mix Design Method

The Gyratory Testing Machine (GTM) was developed by John McRae while working for the U.S. Corps of Engineers Waterway Experimental Station in Mississippi. The GTM is both a compaction device and a testing machine for asphalt mixture. A description of the GTM and testing procedure can be found in ASTM D 3387. The schematic of the GTM is shown in Fig. 45.9. The compaction variables in the GTM include the following:

1. Ram pressure — The vertical ram pressure simulates the tire contact pressure on the pavement as the pavement is compacted by roller during construction and by traffic during service. A ram pressure of 120 psi is typically used to simulate the highest anticipated tire contact pressure on highway pavements.
2. Gyratory angle — The gyratory angle used is empirically related to the applied strain on the pavement. A higher gyratory angle will produce relatively higher compactive effort. Typically an initial gyratory angle of 1 to 3 degrees is used.
3. Type of roller — Three different types of rollers can be used. They are fixed, oil and air rollers. Fixed rollers are the easiest to use. However, the use of the oil rollers or air rollers enables the loads applied by the rollers to be measured, and the gyratory shear strength of the specimen to be determined.
4. Number of gyrations — Compactive effort increases with higher number of gyrations. Typically 60 to 300 gyrations are used to produce ultimate compaction condition.

The following properties are measured during GTM compaction and testing:

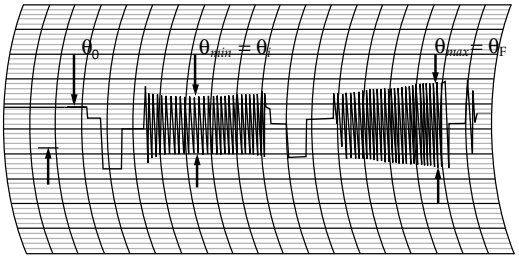

FIGURE 45.10 Gyrograph from a GTM test.

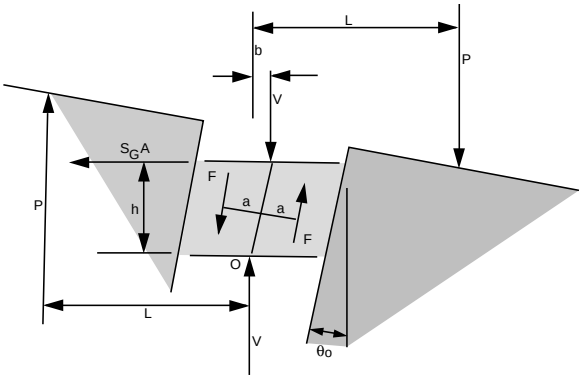

FIGURE 45.11 Forces acting on a GTM test sample.

1. Gyrograph — gyrograph is a recording of the shear strain experienced by the sample during compaction. An example of gyrograph is shown in Fig. 45.10. From the gyrograph, the following property can be calculated:

$$\text{Gyratory Stability Index}\left(\text{GSI}\right) = \theta_F / \theta_I \tag{45.26}$$

where θ_F = maximum gyratory angle
θ_I = intermediate gyratory angle

A stable mix will have a GSI of 1.0. A GSI of greater than 1 indicates instability of the mix.

2. Gyratory shear strength — when the oil or air roller is used, the shear strength of the sample during compaction can be measured. Figure 45.11 shows all the forces acting on the sample during the GTM compaction. By balancing the moments acting around point O as shown in the figure, the following equation can be written:

$$2\,P\,L = S_G\,A\,h + 2\,F\,a - V\,b \tag{45.27}$$

The gyratory shear strength, S_G can be determined as:

$$S_G = \left[2\left(P\,L - F\,a\right) + V\,b\right] / Ah \tag{45.28}$$

Neglecting wall friction (F) and moment due to eccentricity (V b), the gyratory shear shrength can be determined as:

$$S_G = 2\,P\,L / Ah \tag{45.29}$$

3. Specimen height — specimen heights can be measured during compaction, and can be used to determine the density of the sample at different stages of compaction.

The GTM mix design method uses an approach which is completely different from that of the Superpave volumetric design method. The GTM design method does not use volumetric properties as mix design criteria. Instead, it uses properties that are directly related to shear strength and rutting resistance as indicators of performance. ASTM D3387–83 describes a mix design procedure using the GTM. This standard is currently being updated. The latest GTM mix design method, which will be described in the updated ASTM D3387 standard, uses the following GTM test configurations:

1. Ram pressure: maximum anticipated tire contact pressure.
2. Roller type: Air or oil
3. Initial gyratory angle: 2°
4. Initial roller pressure: A roller pressure that would give a computed gyratory shear strength equal to the maximum anticipated shear stress in the pavement.
5. Compaction temperature: Anticipated plant temperature

The mix design procedure consists of the following main steps:

1. Prepare at least two replicate specimens for each combination of aggregate and binder to be tested. Use at least three asphalt contents - one at estimated optimum, one at 0.5% below, and one at 0.5% above.
2. Mix the aggregate and binder at the anticipated plant temperature.
3. Compact the mixture in the GTM until equilibrium condition is reached. Equilibrium condition is considered to be reached when density changes by less than 0.5 lb/ft^3 (0.008 g/cm^3) per 50 gyrations.
4. Determine GSI (from gyrograph) and S_G (from roller pressure) at equilibrium condition.
5. Optimum asphalt content is the maximum asphalt content such that GSI is equal to 1, and S_G is equal to or greater than the maximum anticipated pavement shear stress. A conservative estimate of the maximum pavement shear stress can be taken to be equal to (max. tire contact pressure)/π.

Defining Terms

Bingham-plastic material — A material which behaves as a solid (which would not flow) when the shear stress is below its yield strength, but behaves as a fluid (which would flow under stress) when the shear stress is above this yield point.

Dilatant fluid — A non-Newtonian fluid whose viscosity increases as the shear rate or shear stress increases.

Newtonian fluid — A fluid whose viscosity remains constant with changes in shear rate or shear stress. The relationship between shear stress and shear rate is linear for this type of fluid.

Pseudoplastic fluid — A non-Newtonian fluid whose viscosity decreases as the shear rate or shear stress increases.

Rutting — Permanent vertical depression of pavement surface along the wheel paths.

Shear susceptibility — The slope of the plot of log(shear stress) versus log(shear rate). It is usually denoted as "C." For a Newtonian fluid, C is equal to 1.

Structural engineering is concerned with the application of structural theory, theoretical and applied mechanics, and optimization to the design, analysis, and evaluation of building structures, bridges, cable structures, and plate and shell structures. The science of structural engineering includes the understanding of the physical properties of engineering material, the development of methods of analysis, the study of the relative merits of various types of structures and method of fabrication and construction, and the evaluation of their safety, reliability, economy, and performance.

The study of structural engineering includes such typical topics as strength of materials, structural analysis in both classical and computational methods, structural design in both steel and concrete as well as wood and masonry, solid mechanics, and probabilistic methods. The types of structures involved in a typical structural engineering work include bridges, buildings, offshore structures, containment vessels, reactor vessels, and dams. Research in structural engineering can include such topics as high-performance computing, computer graphics, computer-aided analysis and design, stress analysis, structural dynamics and earthquake engineering, structural fatigue, structural mechanics, structural models and experimental methods, structural safety and reliability, and structural stability.

The scope of this section is indicated by the outline of the contents. It sets out initially to examine the basic properties and strength of materials and goes on to show how these properties affect the analysis and design process of these structures made of either steel or concrete. The topic of composite steel–concrete structures was selected because it has become popular for tall building, offshore, and large-span construction. The final chapter deals with some of the mathematical techniques by which the safety and reliability issues of these structures so designed may be evaluated and their performance assessed.

Recent demands for improvements and upgrades of infrastructure, which includes, among other public facilities, the highway system and bridges, have increased the number of structural engineers employed by highway departments and consulting firms. Graduates with advanced degrees in structural engineering in the areas of experimental works, computing and information technology, computer-aided design and engineering, interactive graphics, and knowledge-based expert systems are in great demand by consulting firms, private industry, government and national laboratories, and educational institutions. The rapid advancement in computer hardware, particularly in the computing and graphics performance of personal computers and workstations, is making future structural engineering more and more oriented toward computer-aided engineering. Increased computational power will also make hitherto unrealized approaches feasible. For example, this will make the rigorous consideration of the life-cycle analysis and performance-based assessment of large structural systems feasible and practical. Advanced analysis and high-performance computing in structural engineering are now subjects of intense research interest. Good progress has been made, but much more remains to be done.

46.1 Introduction

The subject of *mechanics of materials* involves analytical methods for determining the *strength*, *stiffness* (deformation characteristics), and *stability* of the various members in a structural system. Alternatively, the subject may be called the strength of materials, mechanics of solid deformable bodies, or simply mechanics of solids. The behavior of a member depends not only on the fundamental laws that govern the equilibrium of forces, but also on the mechanical characteristics of the material. These mechanical characteristics come from the laboratory, where materials are tested under accurately known forces and their behavior is carefully observed and measured. For this reason, mechanics of materials is a blended science of experiment and Newtonian postulates of analytical mechanics.

The advent of computer technology has made possible remarkable advances in the analytical methods, notably the *finite element method*, for solving problems of mechanics of materials. Prior to the computer, practical solutions were largely restricted to simple and idealized problems. Today, the technology is capable of analyzing complex three-dimensional structural systems with nonlinear material properties. Although this chapter will be limited to presenting the classical topics, the relatively simple methods employed are unusually useful as they apply to a vast number of technically important and practical problems of structural engineering.

46.2 Stress

Method of Sections

Engineering mechanics is in large part the study of the nature of forces within a body. To study these internal forces a uniform approach — the method of sections — is applied. In this approach an arbitrary plane cuts the original solid body into two distinct parts (see Fig. 46.1). If the body as a whole is in equilibrium, then each part must also be in equilibrium, which leads to the fundamental conclusion that the external forces are balanced by the internal forces.

Definition of Stress

Stress is defined as the intensity of forces acting on infinitesimal areas of a cut section (Fig. 46.1). The mathematical definition of stress t is

$$\tau = \lim_{\Delta A \to 0} \frac{\Delta P}{\Delta A} \tag{46.1}$$

It is advantageous to resolve these intensities perpendicular and parallel to the section (see Fig. 46.1). The perpendicular component is called the normal stress. The parallel component is called the shearing stress. Normal stresses that pull away from the section are tensile stresses, while those that push against it are compressive stresses. Normal stresses are alternatively designated by the letter σ.

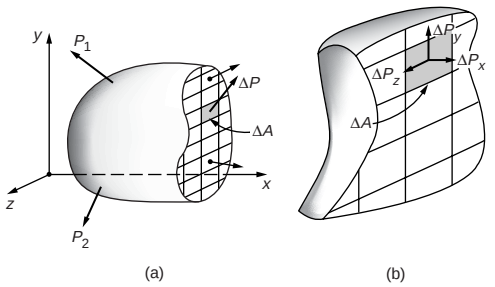

FIGURE 46.1 Sectioned body: (a) free body with some internal forces; (b) enlarged view with components of ΔP.

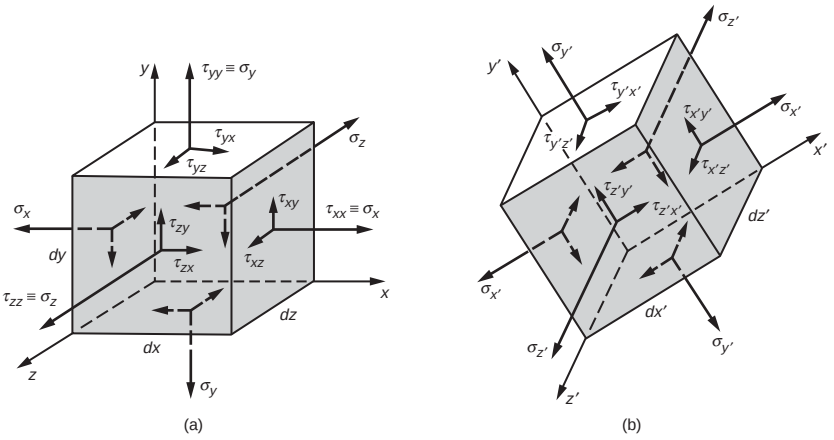

FIGURE 46.2 (a) General state of stress acting on an infinitesimal element in the initial coordinate system. (b) General state of stress acting on an infinitesimal element defined in a rotated system of coordinate axes. All stresses have positive sense.

Stress Tensor

A cube of infinitesimal dimensions is isolated from a body, as shown in Fig. 46.2. All stresses acting on this cube are identified on the figure. The first subscript of τ gives reference to the axis that is perpendicular to the plane on which the stress is acting; the second subscript gives the direction of the stress. Using this cube, the state of stress at any point can be defined by three components on each of the three mutually perpendicular axes. In mathematical terminology this is called a tensor, and the matrix representation of the stress tensor is

$$\begin{bmatrix} \tau_{xx} & \tau_{xy} & \tau_{xz} \\ \tau_{yx} & \tau_{yy} & \tau_{yz} \\ \tau_{zx} & \tau_{zy} & \tau_{zz} \end{bmatrix} \tag{46.2}$$

This is a second-rank tensor requiring two indices to identify its components. There are three normal stresses, $\tau_{xx} = \sigma_x$, $\tau_{yy} = \sigma_y$, $\tau_{zz} = \sigma_z$, and six shearing stresses, τ_{xy}, τ_{yx}, τ_{yz}, τ_{zy}, τ_{zx}, τ_{xz}. For brevity, a stress tensor can be written in indicial notation as τ_{ij}, where it is understood that i and j can assume designations x, y, and z. To satisfy the requirement of moment equilibrium, a stress tensor is symmetric, i.e., $\tau_{ij} = \tau_{ji}$. Thus subscripts of t are cummutative, and shear stresses on mutually perpendicular planes are numerically equal. Moment equilibrium cannot be satisfied by a single pair of shear stresses; two pairs are required, with their arrowheads meeting at diametrically opposite corners of an element.

When stresses on the z plane do not exist, the third column and third row of Eq. (46.2) are zeros, and this two-dimensional state is referred to as plane stress. If all shear stresses are absent, only the diagonal terms remain and the stresses are said to be triaxial; for plane stress $\tau_{zz} = 0$, and the state of stress is biaxial. If τ_{yy} is further eliminated, the state of stress is referred to as uniaxial.

Differential Equations for Equilibrium

For an infinitesimal element to be in equilibrium the following equation must hold in the x direction:

$$\frac{\partial \sigma_x}{\partial x} + \frac{\partial \tau_{yx}}{\partial y} + \frac{\partial \tau_{zx}}{\partial z} + X = 0 \tag{46.3}$$

where X is the inertial or body forces. Similar equations hold for the y and z directions. These equations are applicable whether a material is elastic, plastic, or viscoelastic. Note that there are not enough

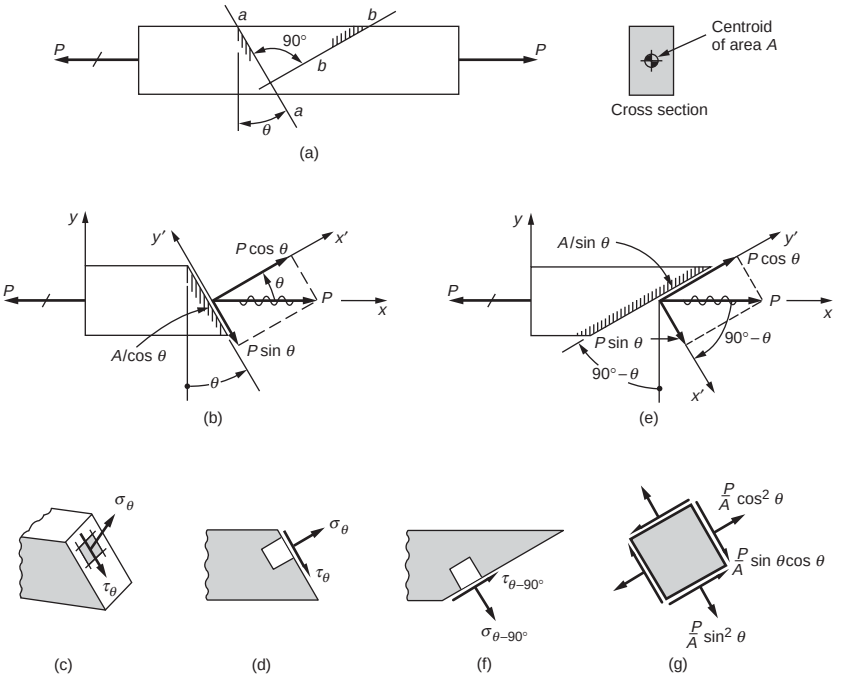

FIGURE 46.3 Sectioning of a prismatic bar loaded axially.

equations of equilibrium to solve for the unknown stresses. Thus all problems in stress analysis are internally intractable or indeterminate and can be solved only when supplemented by other equations given by kinematic requirements and the mechanical properties of the material.

Stress Analysis of Axially Loaded Bars

Figure 46.3 shows a bar loaded axially by a force P and a free body diagram isolated by the section *aa*, which is at an angle θ with the vertical. The equilibrium force on the inclined section is equal to P and is resolved into the two components: the normal force component, $P\cos\theta$, and the shear component, $P\sin\theta$. The area of the inclined section is $A/\cos\theta$. Therefore, given the definition of stress as force per unit area, the normal stress and the shear stress are given by the following equations:

$$\sigma_\theta = \frac{P}{A}\cos^2\theta \tag{46.4}$$

and

$$\tau_\theta = \frac{P}{A}\sin\theta\cos\theta \tag{46.5}$$

These equations show that the normal and shear stresses vary with the angle. Therefore the maximum normal stress is reached when $\theta = 0$ or when the section is perpendicular to the x axis, and $\sigma_{max} = \sigma_x = P/A$. By differentiating Eq. (46.5), the maximum shear stress occurs on planes either $\pm 45°$ with the axis of the bar, and $\tau_{max} = P/2A = \sigma_x/2$. It is important to note that the basic procedure of engineering mechanics of solids used here gives the average or mean stress at a section.

46.3 Strain

Normal Strain

A solid body deforms when subjected to an external load or a change of temperature. When an axial rod, shown in Fig. 46.4, is subjected to an increasing force P, a change in length occurs between any two points, such as A and B. The gage length L_0 is the initial distance between A and B. If after loading the observed length is L, the gage elongation $\Delta L = L - L_0$. The elongation ε per unit of initial gage length is then given as

$$\varepsilon = \frac{L - L_0}{L_0} = \frac{\Delta L}{L_0} \tag{46.6}$$

This expression defines the *extensional strain*, which is a dimensionless quantity. Since this strain is associated with the normal stress, it is usually called the *normal strain*.

In some applications, where strains are large, one defines the *natural* or *true strain* $\bar{\varepsilon}$. The strain increment d for this strain is defined as dL/L, where L is the instantaneous length of the specimen and dL is the incremental change in length. Analytically,

$$\bar{\varepsilon} = \int_{L_0}^{L} dL/L = \ln L/L_0 = \ln(1+\varepsilon) \tag{46.7}$$

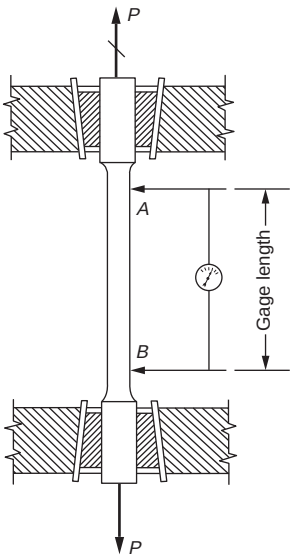

FIGURE 46.4 Diagram of a tension specimen in a testing machine.

Stress–Strain Relationships

The mechanical behavior of real materials under loads is of primary importance. Information of this behavior is generally provided by plotting stress against strain from experiments, as shown in Fig. 46.5, for a variety of engineering materials. Each material has its own characteristics. Typical physical properties of some common materials are given in Table 46.1. It should be noted that even for the same material the stress–strain diagram will differ, depending on the temperature at which the test was conducted, the speed of the test, and a number of other variables. The vast majority of engineering materials are generally assumed to be completely *homogeneous* (sameness from point to point) and *isotropic* (having essentially the same physical properties in different directions). Materials capable of withstanding large strains without a significant increase in stress are referred to as *ductile* materials (see Fig. 46.6). The converse applies to *brittle* materials.

When stresses are computed on the basis of the original area of a specimen, they are referred to as *conventional* or *engineering stresses*. For some materials, such as mild steel and aluminum, significant transverse contraction or expansion takes place near the breaking point, referred to as *necking*. Dividing the applied load by the corresponding actual area of a specimen gives the so-called *true stress*; see Fig. 46.6(a).

Hooke's Law

As illustrated by Fig. 46.6(a), the experimental values of stress versus strain obtained for mild steel lie essentially on a straight line for a limited range from the origin. This idealization is known as Hooke's law and can be expressed by the equation

$$\sigma = E\varepsilon \tag{46.8}$$

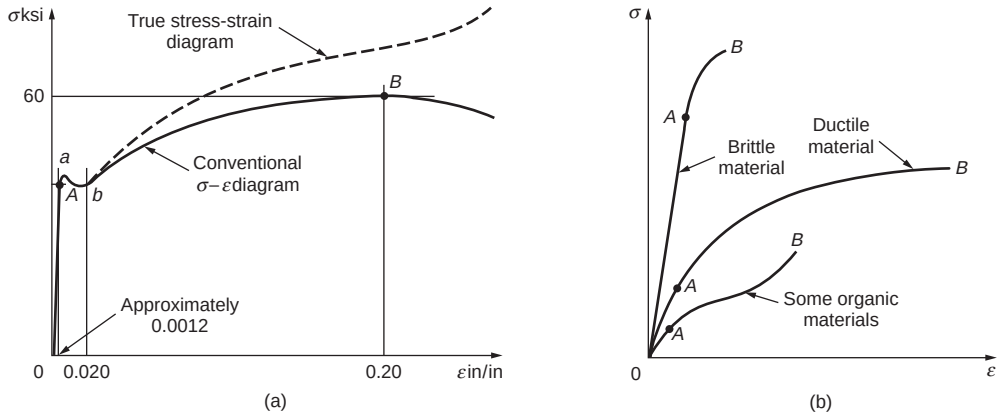

FIGURE 46.6 Stress–strain diagrams: (a) mild steel; (b) typical materials.

which simply means that stress is directly proportional to strain. The constant of proportionality E is called the *elastic modulus*, *modulus of elasticity*, or *Young's modulus*. Graphically, E is the slope of the straight line from the origin to point A, which is the *proportional* or *elastic limit* of the material. Physically, the elastic modulus represents the stiffness of the material to an imposed load, and it is a definite property of a material (Table 46.1). Almost all materials have an initial range where the relationship between stress and strain is linear and Hooke's law is applicable.

In Fig. 46.6(a), the highest point B corresponds to the *ultimate strength* of the material. Stress associated with the plateau ab in Fig. 46.6(a) is called the *yield strength* of the material. The yield strength is often so near the proportional limit that the two may be taken to be the same. For materials with no well-defined yield strength, the *offset method* is usually used where a line offset of an arbitrary amount — generally 0.2% of strain — is drawn parallel to the straight-line portion of the material; the yield strength is taken where the line offset intersects the stress–strain curve.

Constitutive Relations

The relationships between stress and strain are frequently referred to as *constitutive relations* or laws. A *linear elastic* material implies that stress is directly proportional to strain and Hooke's law is applicable. A *nonlinear elastic* material responds in a nonproportional manner, yet when unloaded returns back along the loading path to its initial stress-free state. If in stressing an *inelastic* or *plastic* material its elastic limit is exceeded, then on unloading it usually responds approximately in a linearly elastic manner, but a permanent deformation, or set, develops at no external load. Figure 46.7 shows three other types of

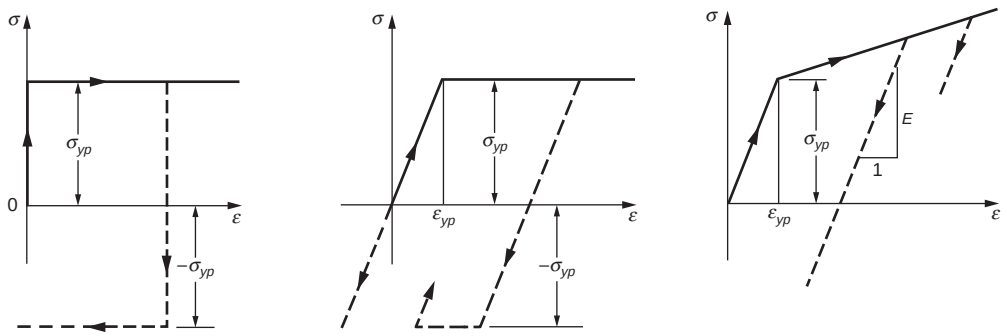

FIGURE 46.7 Idealized stress–strain diagrams: (a) rigid-perfectly plastic material; (b) elastic-perfectly plastic material; elastic-linearly hardening material.

idealized stress–strain diagrams. A rigid, perfectly plastic diagram of Fig. 46.7(a) is applicable to problems in which the elastic strains can be neglected in relation to the plastic ones. If both the elastic and perfectly plastic strains have to be included, Fig. 46.7(b) is more appropriate. Beyond the elastic range, many materials resist additional stress, a phenomenon referred to as *strain hardening*; then Fig. 46.7(c) would provide a reasonable approximation. For a more accurate idealization, equations capable of representing a wide range of stress–strain curves have been developed, for example, by Ramberg and Osgood [1943]. This equation is

$$\frac{\varepsilon}{\varepsilon_0} = \frac{\sigma}{\sigma_0} + \frac{3}{7}\left(\frac{\sigma}{\sigma_0}\right)^n \tag{46.9}$$

where the constants ε_0 and σ_0 correspond to the yield point and n is a characteristic constant of the material. This equation has the important advantage of being a continuous mathematical function by which an *instantaneous* or *tangent modulus* E_t, defined as

$$E_t = \frac{d\sigma}{d\varepsilon} \tag{46.10}$$

can be uniquely determined.

Deformation of Axially Loaded Bars

Consider the axially loaded bar shown in Fig. 46.8 and recast Eq. (46.6) for a differential element dx. Let du be the change in length; then the normal strain in the x direction is

$$\varepsilon_x = \frac{du}{dx} \tag{46.11}$$

Assuming the origin of x at B, and integrating, the change in length Δ between points D and B is

$$\Delta = \int_0^L \varepsilon_x dx \tag{46.12}$$

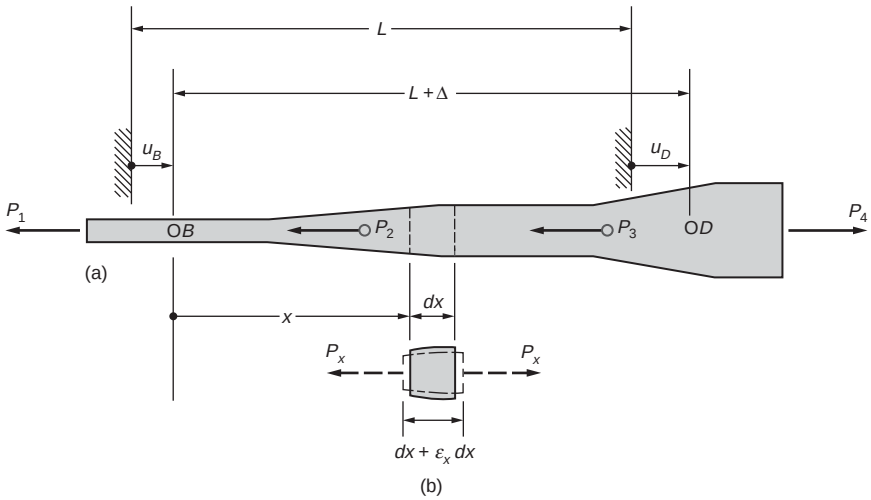

FIGURE 46.8 An axially loaded bar.

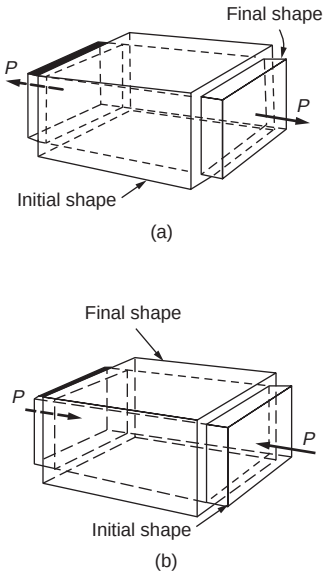

FIGURE 46.9 (a) Lateral contraction and (b) lateral expansion of solid bodies subjected to axial forces (Poisson's effect).

For linear elastic materials, according to Hooke's law, $\varepsilon_x = \sigma_x/E$, where $\sigma_x = P_x/A_x$. Thus,

$$\Delta = \int_0^L \frac{P_x dx}{A_x E_x} \tag{46.13}$$

where the force P_x, area A_x, and elastic modulus E_x can vary along the length of a bar. For a beam of length L with a constant cross-sectional area A and an elastic modulus E, $\Delta = PL/AE$.

Poisson's Ratio

As illustrated by Fig. 46.9, when a solid body is subjected to an axial tension, it contracts laterally; when it is compressed, the material "squashes" out sideways. These lateral deformations on a relative basis are termed *lateral strains* and bear a constant relationship to the axial strains. This constant is a definite property of a material and is called Poisson's ratio. It is denoted by ν and is defined as follows:

$$\nu = \left| \frac{\text{Lateral Strain}}{\text{Axial Strain}} \right| \tag{46.14}$$

The value of ν fluctuates for different materials over a relatively narrow range. Generally, it is on the order of 0.25 to 0.35. The largest possible value is 0.5 and is normally attained during plastic flow and signifies constancy of volume.

Thermal Strain and Deformation

With changes of temperature, solid bodies expand on an increase of temperature and contract on its decrease. The thermal strain ε_T caused by a change in temperature from T_0 to T can be expressed as

$$\varepsilon_T = \alpha(T - T_0) \tag{46.15}$$

where α is an experimentally determined coefficient of linear thermal expansion (see Table 46.1).

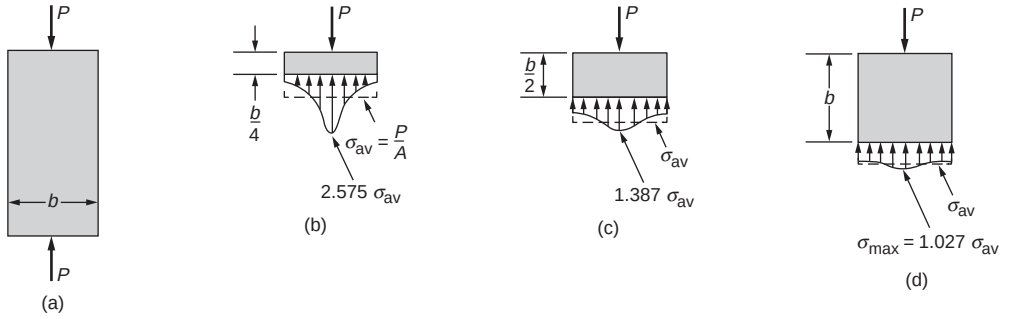

FIGURE 46.10 Stress distribution near a concentrated force in a rectangular elastic plate.

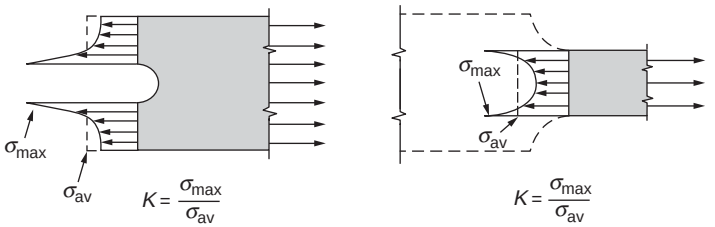

FIGURE 46.11 Meaning of the stress-concentration factor *K*.

For a body of length L subjected to a uniform temperature, the extensional deformation Δ_T due to a change in temperature of $\delta T = T - T_0$ is

$$\Delta_T = \alpha(\delta T)L \tag{46.16}$$

Saint-Venant's Principle and Stress Concentrations

Saint-Venant's principle states that the manner of force application on stresses is important only in the vicinity of the region where the force is applied. Figure 46.10 illustrates how normal stresses at a distance equal to the width of the member are essentially uniform. Only near the location where the concentrated force is applied is the stress nonuniform. Saint-Venant's principle also applies to changes in a cross section, as shown by Fig. 46.11. The ratio of the maximum stress to the average stress is called the *stress concentration factor K*, which depends on the geometrical proportions of the members. The maximum normal stress can then be expressed as

$$\sigma_{maz} = K\sigma_{av} = K\frac{P}{A} \tag{46.17}$$

Many stress concentration factors K can be found tabulated in the literature [Roark and Young, 1975].

Elastic Strain Energy for Uniaxial Stress

The product of force (stress multiplied by area) and deformation is the internal work done in a body by the externally applied forces. This internal work is stored in an elastic body as the internal elastic energy of deformation or the elastic strain energy. The internal elastic strain energy U for an infinitesimal element subjected to uniaxial stress is

$$dU = \tfrac{1}{2}\sigma_x\varepsilon_x dV \tag{46.18}$$

where dV is the volume of the element.

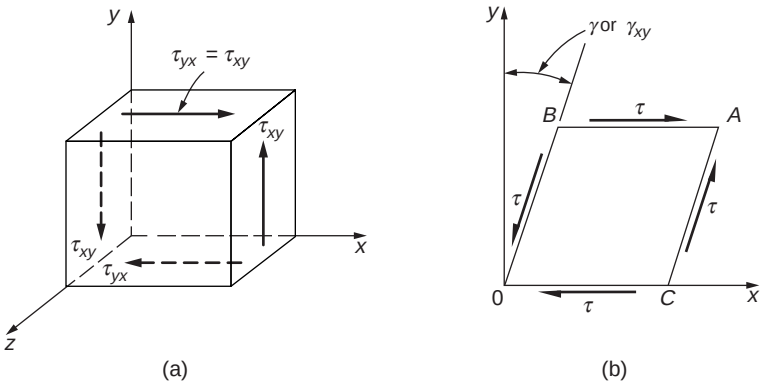

FIGURE 46.12 Element in pure shear.

In the elastic range, Hooke's law applies, $\sigma_x = E\varepsilon_x$. Then

$$U = \int_{vol} \frac{\sigma_x^2}{2E} dV \tag{46.19}$$

The strain energy stored in an elastic body per unit volume of the material (its *strain-energy density*), U_0, is equal to $\sigma^2/2E$. Substituting the value of the stress at the proportional limit gives the *modulus of resilience*, an index of a material's ability to store or absorb energy without permanent deformation. Analogously, the area under a complete stress–strain diagram gives a measure of a material's ability to absorb energy up to fracture and is called its *toughness*.

46.4 Generalized Hooke's Law

Stress–Strain Relationships for Shear

An element in pure shear is shown in Fig. 46.12. The change in the initial right angle between any two imaginary planes in a body defines *shear strain* γ. For infinitesimal elements, these small angles are measured in radians. Below the yield strength of most materials, a linear relationship exists between pure shear and the angle γ. Therefore, mathematically, extension of Hooke's law for shear stress and strain reads

$$\tau = G\gamma \tag{46.20}$$

where G is a constant of proportionality called the *shear modulus of elasticity*, or the *modulus of rigidity*.

Elastic Strain Energy for Shear Stress

An expression for the elastic strain energy for shear stresses may be established in a manner analogous to that for one in uniaxial stress, given in the previous section. Thus,

$$U_{shear} = \int_{vol} \frac{\tau^2}{2G} dV \tag{46.21}$$

Mathematical Definition of Strain

Since strains generally vary from point to point, the definitions of strain must relate to an infinitesimal element. As shown in Fig. 46.13(a), consider an extensional strain taking place in one direction. Points

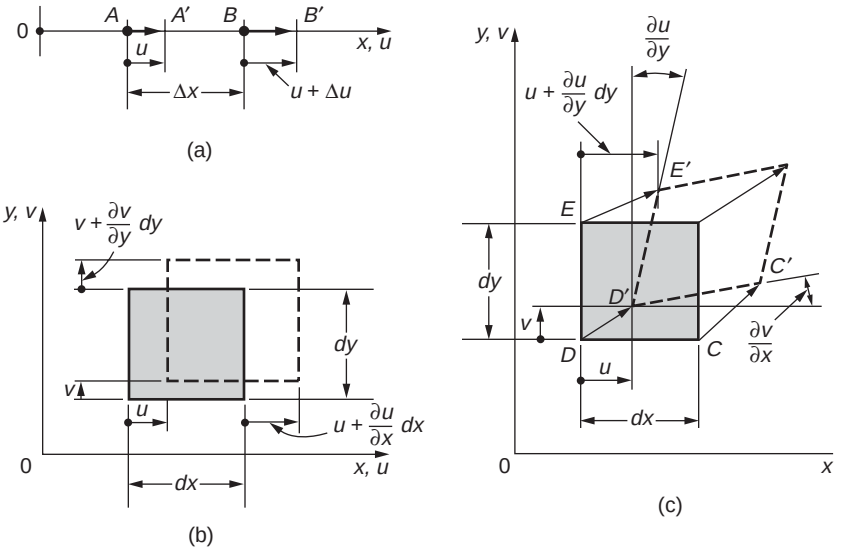

FIGURE 46.13 One- and two-dimensional strained elements in initial and final positions.

A and B move to A' and B', respectively. During straining, point A experiences a displacement u. Point B experiences a displacement $u + \Delta u$, since in addition to the rigid-body displacement u, common to the whole element Δx, a stretch Δu takes place within the element. On this basis, the definition of the extensional or normal strain is

$$\varepsilon = \lim_{\Delta x \to 0} \frac{\Delta u}{\Delta x} = \frac{du}{dx} \tag{46.22}$$

For the two-dimensional case shown in Fig. 46.13(b), a body is strained in orthogonal directions and subscripts must be attached to differentiate between the directions of the strains, and it is also necessary to change the ordinary derivatives to partial ones. Therefore, if at a point of a body, u, v, and w are the three displacement components occurring in the x, y, and z directions, respectively, of the coordinate axes, the basic definitions of normal strain become

$$\varepsilon_x = \frac{\partial u}{\partial x} \quad \varepsilon_y = \frac{\partial v}{\partial y} \quad \varepsilon_z = \frac{\partial w}{\partial z} \tag{46.23}$$

In addition to normal strain, an element can also experience shear strain as shown in Fig. 46.13(c) for the xy plane. This inclines the sides of the deformed element in relation to the x and the y axes. Since v is the displacement in the y direction, as one moves in the x direction, $\partial v/\partial x$ is the slope of the initially horizontal side of the infinitesimal element. Similarly, the vertical side tilts through an angle $\partial u/\partial y$. On this basis, the initially right angle CDE is reduced by the amount $\partial v/\partial x + \partial u/\partial y$. Analogous descriptions can be used for shear strains in the xz and yz planes. Therefore, for small angle changes, the definitions of the shear strain become

$$\begin{aligned} \gamma_{xy} &= \gamma_{yx} = \frac{\partial v}{\partial x} + \frac{\partial u}{\partial y} \\ \gamma_{xz} &= \gamma_{zx} = \frac{\partial w}{\partial x} + \frac{\partial u}{\partial z} \\ \gamma_{yz} &= \gamma_{zy} = \frac{\partial w}{\partial y} + \frac{\partial v}{\partial z} \end{aligned} \tag{46.24}$$

It is assumed that tangents of small angles are equal to angles measured in radians, and a positive sign applies for the shear strain when the element is deformed, as depicted in Fig. 46.13(c).

Strain Tensor

In order to obtain the strain tensor, an entity that must obey certain laws of transformation, it is necessary to redefine the shear strain $\varepsilon_{xy} = \varepsilon_{yx}$ as one half of γ_{xy}. The strain tensor in matrix representation can then be assembled as follows:

$$\begin{bmatrix} \varepsilon_x & \frac{\gamma_{xy}}{2} & \frac{\gamma_{xz}}{2} \\ \frac{\gamma_{yx}}{2} & \varepsilon_y & \frac{\gamma_{yz}}{2} \\ \frac{\gamma_{zx}}{2} & \frac{\gamma_{zy}}{2} & \varepsilon_z \end{bmatrix} \equiv \begin{bmatrix} \varepsilon_{xx} & \varepsilon_{xy} & \varepsilon_{xz} \\ \varepsilon_{yx} & \varepsilon_{yy} & \varepsilon_{yz} \\ \varepsilon_{zx} & \varepsilon_{zy} & \varepsilon_{zz} \end{bmatrix} \tag{46.25}$$

The strain tensor is symmetric. Just as for the stress tensor, using indicial notation, one can write ε_{ij} for the strain tensor. For a two-dimensional problem, the third row and column are eliminated, and one has a case of *plane strain*.

Generalized Hooke's Law for Isotropic Materials

Six basic relationships between a general state of stress and strain can be synthesized using the principle of superposition. This set of equations is referred to as the generalized Hooke's law, and for isotropic linearly elastic materials it can be written for use with Cartesian coordinates as

$$\begin{aligned} \varepsilon_x &= \frac{\sigma_x}{E} - \nu\frac{\sigma_y}{E} - \nu\frac{\sigma_z}{E} \\ \varepsilon_y &= -\nu\frac{\sigma_x}{E} + \frac{\sigma_y}{E} - \nu\frac{\sigma_z}{E} \\ \varepsilon_z &= -\nu\frac{\sigma_x}{E} - \nu\frac{\sigma_y}{E} + \frac{\sigma_z}{E} \\ \gamma_{xy} &= \frac{\tau_{xy}}{G} \\ \gamma_{yz} &= \frac{\tau_{yz}}{G} \\ \gamma_{zx} &= \frac{\tau_{zx}}{G} \end{aligned} \tag{46.26}$$

E, G, and Relationship

Using the relationship between shear and extensional strains and the fact that a pure shear stress at a point can be alternatively represented by the normal stresses at 45° with the directions of the shear stresses, one can obtain the following relationship among E, G, and ν:

$$G = \frac{E}{2(1+\nu)} \tag{46.27}$$

Dilatation and Bulk Modulus

For volumetric changes in elastic materials subjected to stress, change in volume per unit volume, often referred to as *dilatation*, is defined as

$$e = \varepsilon_x + \varepsilon_y + \varepsilon_z \tag{46.28}$$

The shear strains cause no change in volume.

If an elastic body is subjected to hydrostatic pressure of uniform intensity p, then, based on the generalized Hooke's law, it can be shown that

$$\frac{-p}{e} = k = \frac{E}{3(1-2\nu)} \tag{46.29}$$

The quantity k represents the ratio of the hydrostatic compressive stress to the decrease in volume and is called the *modulus of compression*, or *bulk modulus*.

The six equations of Eq. (46.26) have an inverse that can be solved to express stresses in terms of strain and may be written as

$$\begin{aligned}
\sigma_x &= \lambda e + 2G\varepsilon_x \\
\sigma_y &= \lambda e + 2G\varepsilon_y \\
\sigma_z &= \lambda e + 2G\varepsilon_z \\
\tau_{xy} &= G\gamma_{xy} \\
\tau_{yz} &= G\gamma_{yz} \\
\tau_{zx} &= G\gamma_{zx}
\end{aligned} \tag{46.30}$$

where

$$\lambda = \frac{\nu E}{(1+\nu)(1-2\nu)} \tag{46.31}$$

46.5 Torsion

Torsion of Circular Elastic Bars

To establish a relation between the internal torque and the stresses it sets up in members with circular solid and tubular cross sections, it is necessary to make two assumptions (Fig. 46.14): (1) A plane section

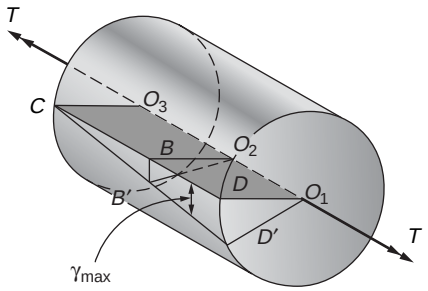

FIGURE 46.14 Variation of strain in circular member subjected to torque.

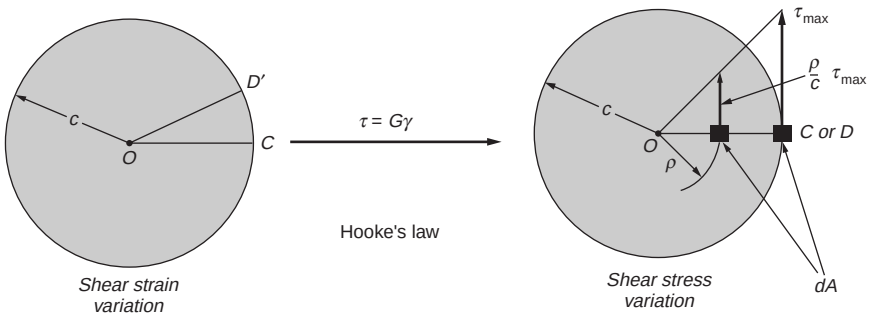

FIGURE 46.15 Shear strain assumption leading to elastic shear stress distribution in a circular member.

of material perpendicular to the axis of a circular member remains plane after the torque is applied, i.e., no warpage or distortion of parallel planes normal to the axis of member takes place; (2) shear strains γ vary linearly from the central axis, reaching γ_{max} at the periphery. This means that in Fig. 46.14 an imaginary plane such as DO_1O_3C moves to $D'O_1O_3C$ when the torque is applied, and the radii O_1D and O_2B remain straight. In the elastic case, shear stresses vary linearly from the central axis of a circular member, as shown in Fig. 46.15. Thus the maximum stress, τ_{max}, occurs at the radius c from the center, and at any distance ρ from O, the shear stress is $(\rho/c)\tau_{max}$. For equilibrium, the internal resisting torque must equal the externally applied torque T. Hence,

$$\frac{\tau_{max}}{c}\int_A \rho^2 dA = T \tag{46.32}$$

However, $\int_A \rho^2 dA$ is the *polar moment of inertia* of a cross-sectional area and is a constant. By using the symbol J for the polar moment of inertia of a circular area, that is, $J = \pi c^4/2$, Eq. (46.32) may be written more compactly as

$$\tau_{max} = \frac{Tc}{J} \tag{46.33}$$

For a circular tube with inner radius b, $J = (\pi c^4/2) - (\pi b^4/2)$.

Angle-of-Twist of Circular Members

The governing differential equation for the angle-of-twist for solid and tubular circular elastic shafts subjected to torsional loading can be determined by referring to Fig. 46.16, which shows a differential shaft of length dx under a differential twist $d\phi$. Arc DD' can be express as $\gamma_{max}\,dx = d\phi c$. Then substituting Eq. (46.33) and assuming Hooke's law is applicable, the governing differential equation for the angle-of-twist is obtained:

$$\frac{d\phi}{dx} = \frac{T}{JG} \quad \text{or} \quad d\phi = \frac{T dx}{JG} \tag{46.34}$$

Hence, a general expression for the angle-of-twist between any two sections A and B on a shaft is

$$\phi = \phi_B - \phi_A = \int_A^B d\phi = \int_A^B \frac{T_x dx}{J_x G} \tag{46.35}$$

where ϕ_B and ϕ_A are the global shaft rotations at ends B and A, respectively. In this equation, the internal torque T_x and the polar moment of inertia J_x may vary along the length of a shaft. The direction of the

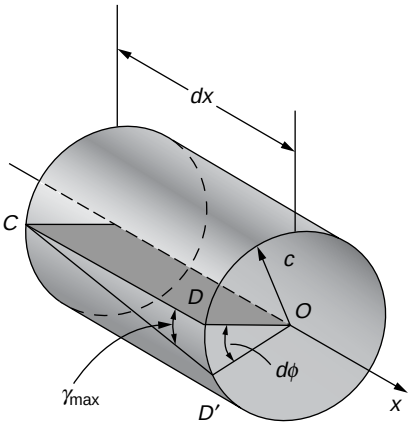

FIGURE 46.16 Deformation of a circular bar element due to torque.

angle of twist ϕ coincides with the direction of the applied torque. For an elastic shaft of length L and constant cross section $\phi = TL/JG$.

Torsion of Solid Noncircular Members

The two assumptions made for circular members do not apply for noncircular members. Sections perpendicular to the axis of a member warp when a torque is applied. The nature of the distortions that take place in a rectangular section can be surmised from Fig. 46.17. For a rectangular member, the corner elements do not distort at all. Therefore shear stresses at the corners are zero; they are maximum at the midpoints of the long sides. Analytical solutions for torsion of rectangular, elastic members have been obtain [Timoshenko and Goodier, 1970]. The methods used are mathematically complex and beyond

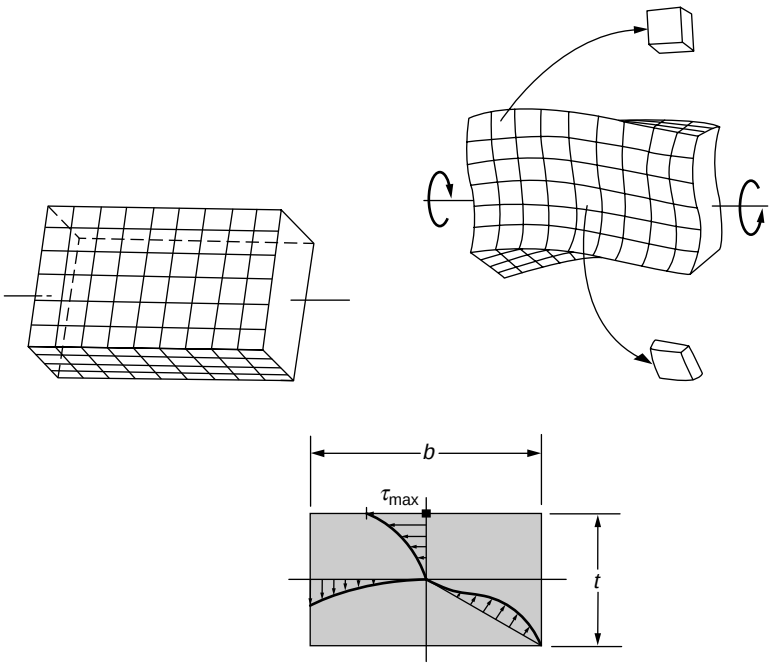

FIGURE 46.17 Rectangular bar (a) before and (b) after a torque is applied. (c) Shear stress distribution in a rectangular shaft subjected to a torque.

TABLE 46.2 Table of Torsional Coefficients for Rectangular Bars

b/t	1.00	1.50	2.00	3.00	6.00	10.0	8
α	0.208	0.231	0.246	0.267	0.299	0.312	0.333
β	0.141	0.196	0.229	0.263	0.299	0.312	0.333

the scope of the present discussion. However, the results for the maximum shear stresses and the angle-of-twist can be put into the following form:

$$\tau_{max} = \frac{T}{\alpha b t^2} \quad \text{and} \quad \phi = \frac{TL}{\beta b t^3 G} \tag{46.36}$$

where T is the applied torque, b is the length of the long side, and t is the thickness or width of the short side of a rectangular section. The values of parameters α and β depend on the ratio b/t, given in Table 46.2. For thin sections, where b is much greater than t, the values of α and β approach 1/3. It is useful to recast the second Eq. (46.36) to express the torsional stiffness k_t for a rectangular section, giving

$$k_t = \frac{T}{\phi} = \beta b t^3 \frac{G}{L} \tag{46.37}$$

For cases that cannot be conveniently solved mathematically, the *membrane analogy* has been devised. It happens that the solution of the partial differential equation that must be solved in the elastic torsion problem is mathematically identical to that for a thin membrane, such as a soap film, lightly stretched over a hole. This hole must be geometrically similar to the cross section of the shaft being studied. Then the following can be shown to be true:

1. The shear stress at any point is proportional to the slope of the stretched membrane at the same point (Fig. 46.18).
2. The direction of a particular shear stress at a point is at right angles to the slope of the membrane at the same point.
3. Twice the volume enclosed by the membrane is proportional to the torque carried by the section.

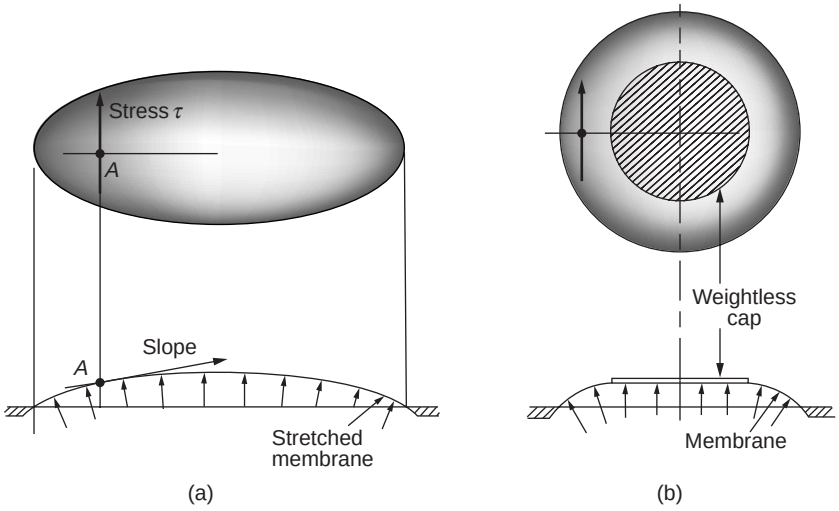

FIGURE 46.18 Membrane analogy: (a) simply connected region; (b) multiply connected (tubular) region.

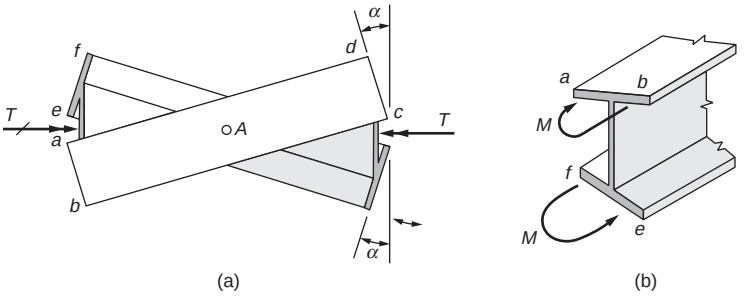

FIGURE 46.19 Cross-sectional warpage due to applied torque.

For plastic torsion, the *sand-heap analogy* has been developed, and it has similar interpretations as those in the membrane analogy [Nadai, 1950]. Dry sand is poured onto a raised flat surface having the shape of the cross section of the member. The surface of the sand heap so formed assumes a constant slope. The volume of the sand heap, hence its weight, is proportional to the fully plastic torque carried by a section.

Warpage of Thin-Walled Open Sections

For a narrow rectangular bar, no shear stresses develop along a line bisecting its thickness. This means that no in-plane deformation can take place along the entire width and length of the bar's middle surface. In this sense, an I section, shown in Fig. 46.19, consists of three flat bars, and during twisting, the three middle surfaces of these bars do not develop in-plane deformations. By virtue of symmetry, this I section twists around its centroidal axis, which in this case is also the center of twist. During twisting, as the beam flanges displace laterally, the undeformed middle surface *abcd* rotates about point A, Fig. 46.19(a). Similar behavior is exhibited by the middle surface of the other flange. In this manner, plane sections of an I beam warp, i.e., cease to be plane, during twisting.

Cross-sectional warpage, or its restraint, may have an important effect on member strength, particularly on its stiffness. Warpage of cross sections in torsion is restrained in many applications. For example, by welding an end of a steel I beam to a rigid support, the attached cross section cannot warp. To maintain required compatibility of deformations, in-plane flange moments M, shown in Fig. 46.19(b), must develop. Such an enforced restraint effectively stiffens a beam and reduces its twist. This effect is local in character and, at some distance from the support, becomes unimportant. Nevertheless, for short beams, cutouts, etc., the warpage-restraint effect is dominant. For further details, refer to the reference of Oden and Ripperger [1981].

Torsion of Thin-Walled Hollow Members

Unlike solid noncircular members, thin-walled tubes of any shape can be rather simply analyzed for the magnitude of the shear stresses and the angle-of-twist caused by a torque applied to the tube. Thus, consider a tube of an arbitrary shape with varying wall thickness, such as shown in Fig. 46.20(a), subjected to torque T. Isolate an element from this tube, as shown enlarged in Fig. 46.20(b). This element must be in equilibrium under the action of forces F_1, F_2, F_3, and F_4. These forces are equal to the shear stresses acting on the cut planes multiplied by the respective areas. From summation of forces, and since the longitudinal sections were taken an arbitrary distance apart, it follows that the product of the shear stress and the wall thickness is the same, i.e., constant, on any such planes. This constant will be denoted by q, which is measured in the units of force per unit distance along the perimeter, since shear stresses on mutually perpendicular planes are equal at a corner of an element. Hence, at a corner such as A in Fig. 46.20(b), $\tau_2 = \tau_3$; similarly, $\tau_1 = \tau_4$. Therefore, $\tau_4 t_1 = \tau_3 t_2$, or, in general, q is constant in the plane of a section perpendicular to the axis of a member. The quantity q has been termed the shear flow. Next consider the cross section of the tube as shown in Fig. 46.20(c). The force per unit distance of the

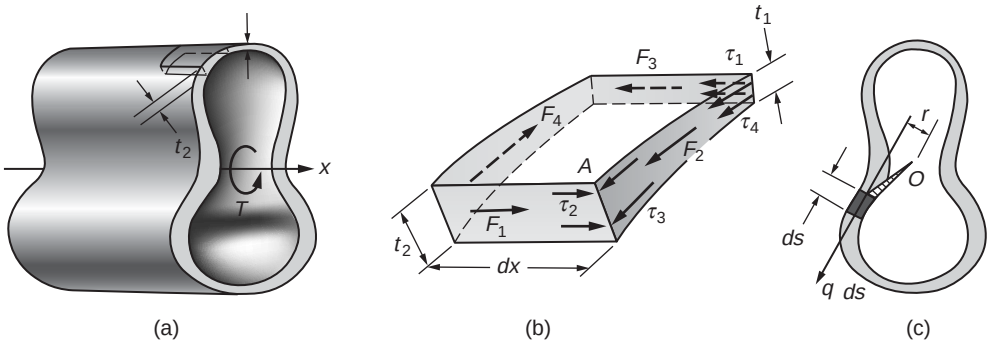

FIGURE 46.20 Thin-walled tubular member of variable thickness.

perimeter of this tube, by virtue of the previous argument, is constant and is the shear flow q. This shear flow multiplied by the length ds of the perimeter gives a force $q\,ds$ per differential length. The product of this infinitesimal force $q\,ds$ and r around some convenient point such as 0, Fig. 46.20(c), gives the contribution of an element to the resistance of applied torque T. Adding or integrating this,

$$T = q\oint r\,ds \tag{46.38}$$

where the integration process is carried around the tube along the center line of the perimeter. A simple interpretation of the integral is available. It can be seen from Fig. 46.20(c) that rds is twice the value of the shaded area of an infinitesimal triangle of altitude r and base ds. Hence, the complete integral is twice the whole area bounded by the center line of the perimeter of the tube. Defining this area by the special symbol Ⓐ, one obtains

$$T = 2Ⓐq \text{ or } q = \frac{T}{2Ⓐ} \tag{46.39}$$

This equation applies only to thin-walled tubes. The area Ⓐ is approximately an average of the two areas enclosed by the inside and the outside surfaces of a tube, or, as noted, it is an area enclosed by the center line of the wall's contour. It is not applicable at all if the tube is slit.

Since for any tube the shear flow q is constant, from the definition of shear flow, the shear stress at any point of a tube where the wall thickness is t is

$$\tau = \frac{q}{t} \tag{46.40}$$

In the elastic range, Eqs. (46.39) and (46.40) are applicable to any shape of tube. For inelastic behavior, Eq. (46.40) applies only if thickness t is constant. For linearly elastic materials, the angle of twist for a hollow tube can be found by applying the principle of conservation of energy. Equating the elastic strain energy to the external work per unit length of member, the following governing differential equation is obtained,

$$\theta = \frac{d\phi}{dx} = \frac{T}{4Ⓐ^2 G}\oint\frac{ds}{t} \tag{46.41}$$

It is useful to recast this equation to express the torsional stiffness k_t for a thin-walled hollow tube. Since for a prismatic tube subjected to a constant torque, $\phi = \theta L$,

$$k_t = \frac{T}{\phi} = \frac{4Ⓐ^2}{\oint ds/t}\frac{G}{L} \tag{46.42}$$

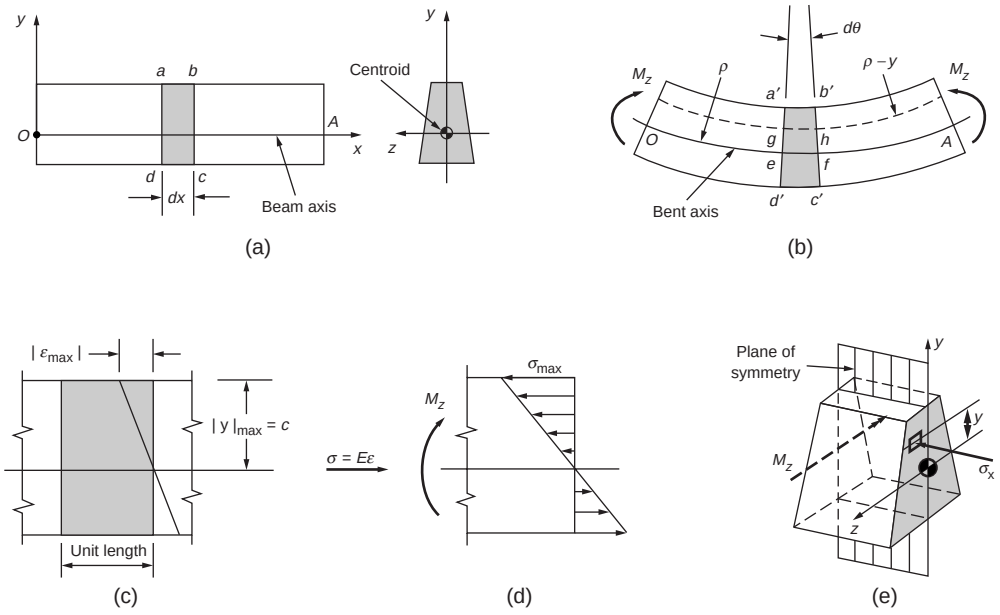

FIGURE 46.21 Assumed behavior of elastic beam in bending.

46.6 Bending

The Basic Kinematic Assumption

Consider a typical element of the beam between two planes perpendicular to the beam axis, as shown in Fig. 46.21. In side view, such an element is identified in the figure as *abcd*. When such a beam is subjected to equal end moments M_z acting around the z axis, Fig. 46.21(b), this beam bends in the plane of symmetry, and the planes initially perpendicular to the beam axis tilt slightly. Nevertheless, the lines such as *ad* and *bc* becoming $a'd'$ and $b'c'$ remain straight. This observation forms the basis for the fundamental hypothesis of the flexure theory. It may be stated thus: plane sections through a beam taken normal to its axis remain plane after the beam is subjected to bending.

In pure bending of a prismatic beam, the beam axis deforms into a part of a circle of radius ρ, as shown by Fig. 46.21(b). For an element defined by an infinitesimal angle $d\theta$, the fiber length *ef* of the beam axis is given as $ds = \rho d\theta$. Hence,

$$\frac{d\theta}{ds} = \frac{1}{\rho} = \kappa \tag{46.43}$$

where the reciprocal of ρ defines the axis *curvature* κ.

The fiber length *gh* located on a radius $(\rho - y)$ can be found similarly, and the difference between fiber lengths *gh* and *ef* can be expressed as $(-yd\theta)$, which is equal to du, since the deflection and rotations of the beam axis are very small. Then one obtains the normal strain $\varepsilon_x = du/dx$, as

$$\varepsilon_x = -\kappa y \tag{46.44}$$

This equation establishes the expression for the basic kinematic hypothesis for the flexure theory: the strain in a bent beam varies along the beam depth linearly with y.

The Elastic Flexure Formula

By using Hooke's law, the expression for the normal strain given by Eq. (46.44) can be recast into a relation for the normal longitudinal stress:

$$\sigma_x = E\varepsilon_x = -E\kappa y \tag{46.45}$$

To satisfy equilibrium, the sum of all forces at a section in pure bending must vanish,

$$\int_A \sigma_x dA = 0$$

which can be rewritten as

$$-E\kappa \int_A y dA = 0$$

By definition, the integral

$$\int_A y dA = \bar{y}A$$

where $\bar{y}$ is the distance from the origin to the centroid of an area A. Since the integral equals zero here and area A is not zero, distance $\bar{y}$ must be set equal to zero. Therefore, the z axis must pass through the centroid of a section. In bending theory, this axis is also referred to as the neutral axis of a beam. On this axis both the normal strain ε_x and the normal stress σ_x are zero. Based on this result, linear variation in strain is schematically shown in Fig. 46.21(c). The corresponding elastic stress distribution in accordance with Eq. (46.45) is shown in Fig. 46.21(d). Both the absolute maximum strain ε_{max} and the absolute maximum stress σ_{max} occur at the largest value of y.

Equilibrium requires the additional condition that the sum of the externally applied and the internal resisting moments must vanish. For the beam segment in Fig. 46.21(d), this yields

$$M_z = E\kappa \int_A y^2 dA$$

In mechanics, the last integral, depending only on the geometrical properties of a cross-sectional area, is called the rectangular moment of inertia or the second moment of inertia of the area A and is designated by I. Since I must always be determined with respect to a particular axis, it is often meaningful to identify it with a subscript corresponding to such an axis. For the case considered, this subscript is z, that is,

$$I_z = \int_A y^2 dA \tag{46.46}$$

With this notation, the basic relation giving the curvature of an elastic beam subjected to a specified moment is expressed as

$$\kappa = \frac{M_z}{EI_z} \tag{46.47}$$

By substituting Eq. (46.47) into Eq. (46.45), the elastic flexure formula for beams is obtained:

$$\sigma_x = -\frac{M_z}{I_z} y \tag{46.48}$$

It is customary to recast the flexure formula to give the maximum normal stress σ_{max} directly and to designate the value $|y|_{max}$ by c, as in Fig. 46.21(c). It is also common practice to dispense with the sign, as in Eq. (46.48), as well as with the subscripts on M and I. Since the normal stresses must develop a couple statically equivalent to the internal bending moment, their sense can be determined by inspection. On this basis, the flexure formula becomes

$$\sigma_{max} = \frac{Mc}{I} \tag{46.49}$$

Elastic Strain Energy in Pure Bending

Using the section "Elastic Strain Energy for Uniaxial Stress" as the basis, the elastic strain energy for beams in pure bending can be found. By substituting the flexure formula into Eq. (46.18) and integrating over the volume, V, of the beam, the expression for the elastic strain energy, U, in a beam in pure bending is obtained:

$$U = \int_0^L \frac{M^2}{2EI} dx \tag{46.50}$$

Unsymmetric Bending and Bending with Axial Loads

Consider the rectangular beam shown in Fig. 46.22, where the applied moments M act in the plane *abcd*. By using the vector representation for M shown in Fig. 46.22(b), this vector forms an angle α with the z axis and can be resolved into the two components, M_y and M_z. Since the cross section for this beam has symmetry about both axes, Eqs. (46.45) to (46.49) are directly applicable. By assuming elastic behavior of the material, a superposition of the stresses caused by M_y and M_z is the solution to the problem. Hence, using Eq. (46.48),

$$\sigma_x = -\frac{M_z y}{I_z} + \frac{M_y z}{I_y} \tag{46.51}$$

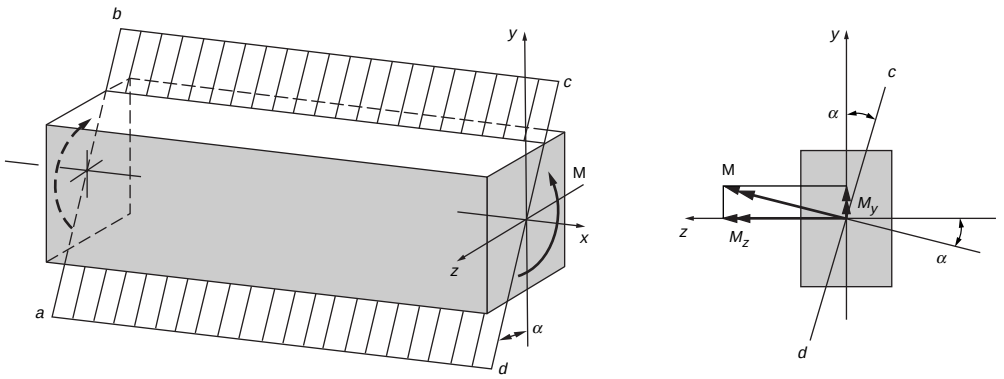

FIGURE 46.22 Unsymmetrical bending of a beam with doubly symmetric cross section.

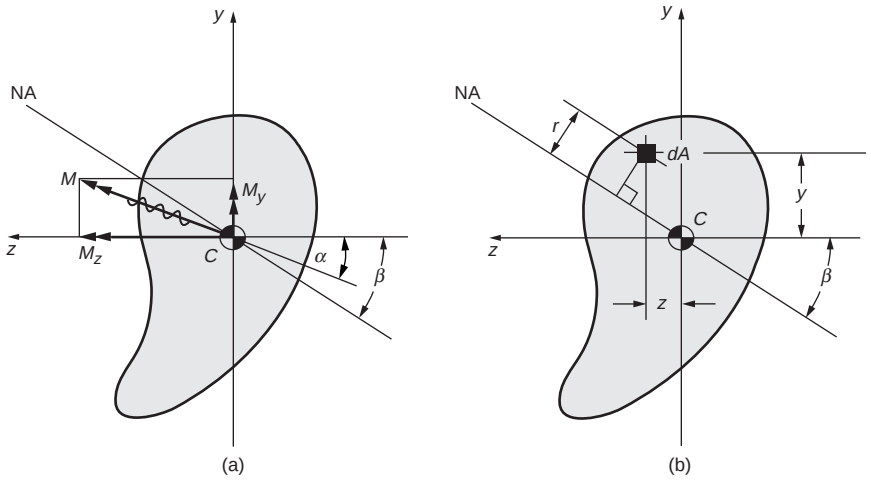

FIGURE 46.23 Bending of unsymmetric cross section.

A line of zero stress, i.e., a neutral axis, forms at an angle with the z axis and can be determined from the following equation:

$$\tan\beta = \frac{I_z}{I_y}\tan\alpha \tag{46.52}$$

In general, the neutral axis does not coincide with the normal of the plane in which the applied moment acts.

Superposition can again be employed to include the effect of axial loads, leading Eq. (46.51) to be generalized into

$$\sigma_x = \frac{P}{A} - \frac{M_z y}{I_z} + \frac{M_y z}{I_y} \tag{46.53}$$

where P is taken positive for axial tensile forces and bending takes place around the two principal y and z axes. Further, if an applied axial force causes compression, a member must be stocky, lest a buckling problem of the type considered in a later section arises.

Bending of Beams with Unsymmetric Cross Section

A general equation for pure bending of elastic members of an arbitrary cross section (Fig. 46.23), whose reference axes are not the principal axes, can be formulated using the same approach as for the symmetrical cross sections. This *generalized flexure formula* is

$$\sigma_x = -\frac{M_z I_y + M_y I_{yz}}{I_y I_z - I_{yz}^2} y + \frac{M_y I_z + M_z I_{yz}}{I_y I_z - I_{yz}^2} z \tag{46.54}$$

By setting this equation equal to zero, the angle β for locating the neutral axis in the arbitrary coordinate system is obtained, giving

$$\tan\beta = \frac{y}{z} = \frac{M_y I_z + M_z I_{yz}}{M_z I_y + M_y I_{yz}} \tag{46.55}$$

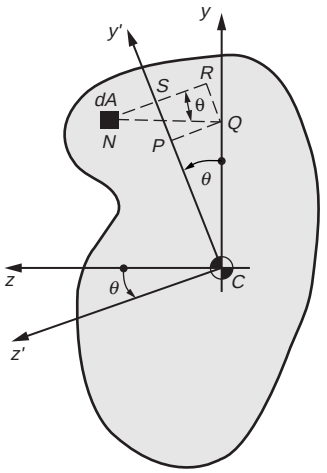

FIGURE 46.24 Rotation of coordinate axes.

Area Moments of Inertia

The concept of moments of inertia is generalized here for two orthogonal axes for any cross-sectional shape (Fig. 46.24). With the *yz* coordinates chosen as shown, by definition, the moments and product of inertia of an area are given as

$$I_z = \int y^2 dA \qquad I_y = \int z^2 dA \qquad I_{yz} = \int yz\, dA \tag{46.56}$$

Note that these axes are chosen to pass through the centroid *C* of the area, and the product of the inertia vanishes for either doubly or singly symmetric areas.

If the orthogonal axes are rotated by θ, forming a new set of $y'z'$ coordinates, it can be shown that the moments and product of inertia are transformed to the following quantities:

$$\begin{aligned} I_{z'} &= \frac{I_z + I_y}{2} + \frac{I_z - I_y}{2}\cos 2\theta + I_{yz}\sin 2\theta \\ I_{y'} &= \frac{I_z + I_y}{2} - \frac{I_z - I_y}{2}\cos 2\theta - I_{yz}\sin 2\theta \\ I_{z'y'} &= -\frac{I_z - I_y}{2}\sin 2\theta + I_{yz}\cos 2\theta \end{aligned} \tag{46.57}$$

Note that the sum of the moments of inertia around two mutually perpendicular axes is invariant, that is, $I_{y'} + I_{z'} = I_y + I_z$.

Table 46.3 provides formulas for the areas, centroids, and moments of inertia of some simple shapes. Most cross-sectional areas used may be divided into a combination of these simple shapes. To find *I* for an area composed of several simple shapes, the *parallel-axis theorem* (sometimes called the *transfer formula*) is necessary. It can be stated as follows: the moment of inertia of an area around any axis is equal to the moment of inertia of the same area around a parallel axis passing through the area's centroid, plus the product of the same area and the square of the distance between the two axes. Hence,

$$I_z = I_{zc} + Ad_z^2 \tag{46.58a}$$

The area for any segment of a parabola is $A = \frac{2}{3}hl$

where d_z is the distance from the centroid of the subarea to the centroid of the whole area, as shown in Fig. 46.25. In calculation, Eq. (46.58a) must be applied to each subarea for which a cross-sectional area has been divided and the results summed to obtain I_z for the whole section:

$$I_z(\text{whole section}) = \sum \left(I_{zc} + Ad_z^2\right) \tag{46.58b}$$

46.7 Shear Stresses in Beams

Shear Flow

Consider an elastic beam made from several continuous longitudinal planks whose cross section is shown in Fig. 46.26. To make this beam act as an integral member, it is assumed that the planks are fastened at intervals by vertical bolts. If an element of this beam, Fig. 46.26(b), is subjected to a bending moment

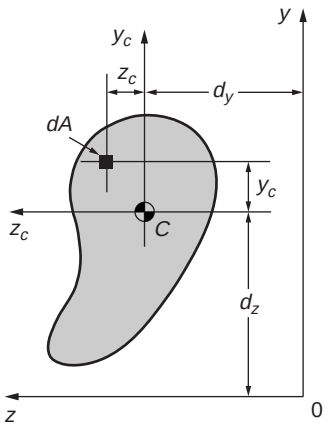

FIGURE 46.25 Area for deriving the parallel-axis theorem.

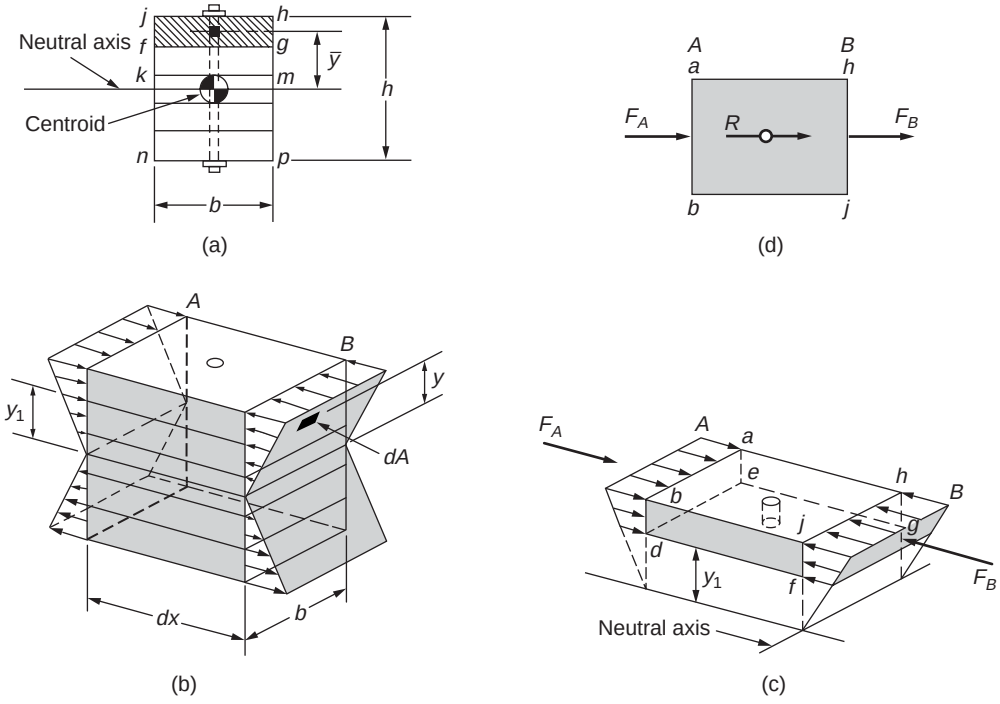

FIGURE 46.26 Elements for deriving shear flow in a beam.

$+M_A$ at end A and $+M_B$ at end B, bending stresses that act normal to the sections are developed. These bending stresses vary linearly from the neutral axis in accordance with the flexure formula My/I. The top plank of the beam element is isolated, as shown in Fig. 46.26(c). The forces acting perpendicular to the ends A and B of this plank may be determined by summing the bending stresses over their respective areas. Denoting the total force acting normal to the area $fghj$ by F_B, and remembering that, at section B, M_B and I are constants, one obtains the following relation:

$$F_B = -\frac{M_B}{I} \int_{\text{area}=fghj} y\,dA = -\frac{M_B Q}{I} \tag{46.59}$$

where

$$Q = \int_{\text{area}=fghj} y\,dA = A_{fghj}\bar{y} \tag{46.60}$$

The integral defining Q is the *first*, or *statical*, *moment* of area *fghj* around the neutral axis. By definition, y is the distance from the neutral axis to the centroid of A_{fghi}. Similarly, one can express the total force acting normal to the area *abcd* as $F_A = -M_A Q/I$. If M_A is not equal to M_B, which is always the case when shears are present at the adjoining sections, F_A is not equal to F_B. Equilibrium of the horizontal forces in Fig. 46.26(c) may be attained only by developing a horizontal resisting force in the bolt R, as in Fig. 46.26(d). Taking a differential beam element of length dx, $M_B = M_A + dM$ and $dF = |F_B| - |F_A|$, and substituting these relations into the expression for F_A and F_B found above, one obtains $dF = dM\ Q/I$. It is more significant to obtain the force per unit length of beam length, dF/dx, which will be designated by q and referred to as the *shear flow*. Then, noting that $d\mathrm{M}/dx = \mathrm{V}$, one obtains the following expression for the shear flow in beams:

$$q = \frac{VQ}{I} \tag{46.61}$$

In this equation, I is the moment of inertia of the entire cross-sectional area around the neutral axis, and Q extends only over the cross-sectional area of the beam to one side, at which q is investigated.

Shear-Stress Formula for Beams

The shear-stress formula for beams may be obtained by modifying the shear flow formula. In a solid beam, the force resisting dF may be developed only in the plane of the longitudinal cut taken parallel to the axis of the beam, as shown in Fig. 46.27. Therefore, assuming that the shear stress τ is uniformly distributed across the section of width t, the shear stress in the longitudinal plane may be obtained by dividing dF by the area $t\,dx$. This yields the horizontal shear stress τ, which for an infinitesimal element is numerically equal to the shear stress acting on the vertical plane (see Fig. 46.27(b)). Since $q = dF/dx$, one obtains

$$\tau = \frac{VQ}{It} = \frac{q}{t} \tag{46.62}$$

where t is the width of the imaginary longitudinal cut, which is usually equal to the thickness or width of the member. The shear stress at different longitudinal cuts through the beam assumes different values as the values of Q and t for such sections differ.

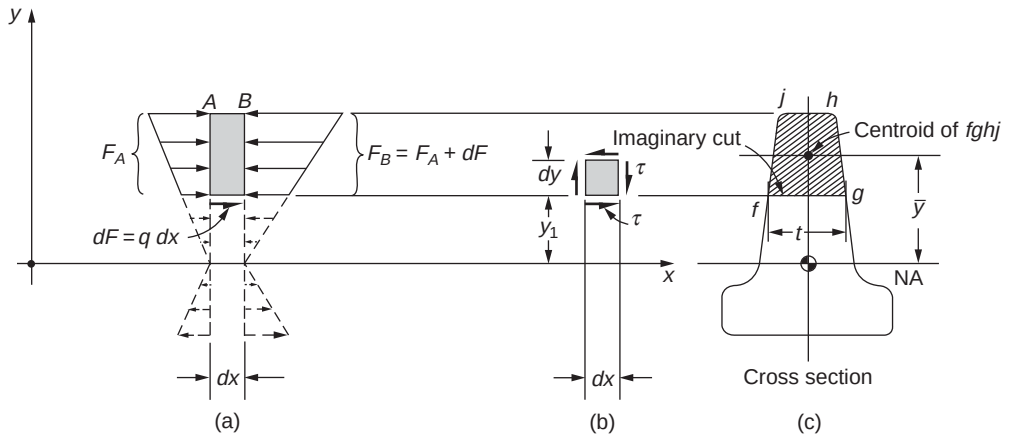

FIGURE 46.27 Derivation of shear stress in a beam.

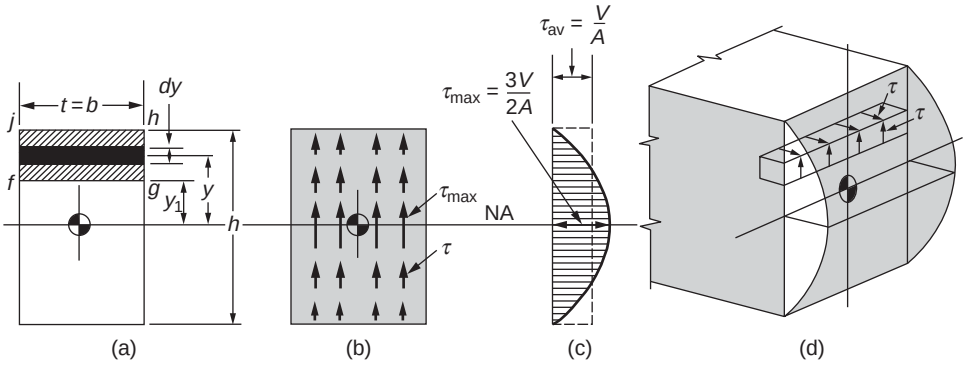

FIGURE 46.28 Shear stresses in a rectangular beam.

Since the shear-stress formula for beams is based on the flexure formula, all the limitations imposed on the flexure formula apply. The material is assumed to be elastic with the same elastic modulus in tension as in compression. The theory developed applies only to straight beams. Moreover, in certain cases such as a wide flange section, the shear-stress formula may not satisfy the requirement of a stress-free boundary condition. However, no appreciable error is involved by using Eq. (46.62) for thin-walled members, and the majority of beams belong to this group.

Shear Stresses in a Rectangular Beam

The cross-sectional area of a rectangular beam is shown in Fig. 46.28(a). A longitudinal cut through the beam at a distance y_1 from the neutral axis isolates the partial area *fghj* of the cross section. Here $t = b$ and the infinitesimal area of the cross section may be conveniently expressed as $b\,dy$. By applying Eq. (46.62), the horizontal shear stress is found at level y_1 of the beam. At the same cut, numerically equal vertical shear stresses act in the plane of the cross section ($\tau_{xy} = \tau_{yx}$):

$$\tau = \frac{VQ}{It} = \frac{V}{It}\int_{\substack{area\\fghj}} y\,dA = \int_{y1}^{h/2} by\,dy = \frac{V}{2I}\left[\left(\frac{h}{c}\right)^2 - y_1^2\right] \tag{46.63}$$

This equation shows that in a beam of rectangular cross section, both the horizontal and the vertical shear stresses vary parabolically. The maximum value of the shear stress is obtained when y_1 is equal to zero. In the plane of the cross section, Fig. 46.28(b), this is diagrammatically represented by τ_{max} at the neutral axis of the beam. At increasing distances from the neutral axis, the shear stresses gradually diminish. At the upper and lower boundaries of the beam, the shear stresses cease to exist as $y_1 = \pm h/2$. These values of the shear stresses at the various levels of the beam may be represented by the parabola shown in Fig. 46.28(c). An isometric view of the beam with horizontal and vertical shear stresses is shown in Fig. 46.28(d).

The maximum shear stress in a rectangular beam occurs at the neutral axis, and for this case, the general expression for τ_{max} may be simplified by setting $y_1 = 0$.

$$\tau_{max} = \frac{Vh^2}{8I} = \frac{Vh^2}{8bh^3/12} = \frac{3}{2}\frac{V}{bh} = \frac{3}{2}\frac{V}{A} \tag{46.64}$$

where V is the total shear and A is the entire cross-sectional area. Since beams of rectangular cross-sectional area are used frequently in practice, this equation is very useful. It is widely used in the design of wooden beams, since the shear strength of wood on planes parallel to the grain is small. Thus, although equal shear stresses exist on mutually perpendicular planes, wooden beams have a tendency to split

longitudinally along the neutral axis. Note that the maximum shear stress is 1½ times as great as the average shear stress V/A. Nevertheless, in the analysis of bolts and rivets, it is customary to determine their shear strengths by dividing the shear force V by the cross-sectional area A. Such practice is considered justified since the allowable and ultimate strengths are initially determined in this manner from tests.

Warpage of Plane Sections Due to Shear

A solution based on the mathematical theory of elasticity for a rectangular beam subjected simultaneously to bending and shear shows that plane sections perpendicular to the beam axis warp, i.e., they do not remain plane. This can also be concluded from Eq. (46.63). According to Hooke's law, shear strains must be associated with shear stresses. Therefore, the shear stresses given by Eq. (46.63) give rise to shear strains. According to this equation, the maximum shear stress, hence, maximum shear strain, occurs at $y = 0$; conversely, no shear strain takes place at $y = \pm h/2$. This behavior warps the initially plane sections through a beam, as shown qualitatively in Fig. 46.29, and contradicts the fundamental assumption of the simplified bending theory for pure flexure. However, based on rigorous analysis, warpage of the sections is known to be important only for very short members and is negligibly small for slender members. An examination of analytical results, as well as experimental measurements on beams, suggests that the assumption of "plane sections" is reasonable. It should also be noted that if shear force V along a beam is constant and the boundaries provide no restraint, the warping of all cross sections is the same. Therefore, the strain distribution caused by bending remains the same as in pure bending. Based on these considerations, a far-reaching conclusion can be made that the presence of shear at a section does not invalidate the expressions for bending stresses derived earlier.

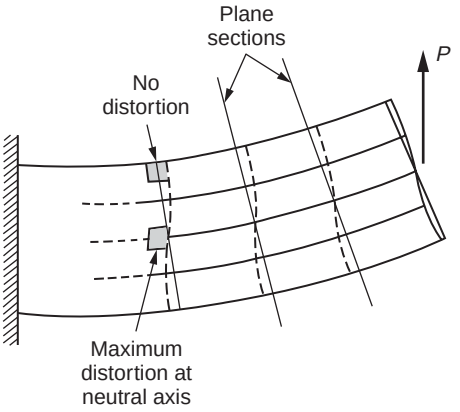

FIGURE 46.29 Shear distortions in a beam.

Shear Stresses in Beam Flanges

The shear-stress formula for beams is based on the flexure formula. Hence, all of the limitations imposed on the flexure formula apply. The material is assumed to be elastic with the same elastic modulus in tension as in compression. The theory developed applies only to straight beams. Moreover, there are additional limitations that are not present in the flexure formula.

Consider a section through the I beam shown in Fig. 46.30. The shear stresses computed for level 1-1 apply to the infinitesimal element *a*. The vertical shear stress is zero for this element. Likewise, no shear stresses exist on the top plane of the beam. This is as it should be, since the top surface of the beam is a free surface. In mathematical phraseology, this means that the conditions at the boundary are satisfied. For beams of rectangular cross section, the situation at the boundaries is correct. A different condition is found when the shear stresses determined for the I beam at level 2-2 are scrutinized. The shear stresses were found to be 570 psi for the elements, such as *b* or *c* shown in the figure. This requires matching horizontal shear stresses on the inner surfaces of the flanges. However, the latter surfaces must be free of the shear stresses because they are free boundaries of the beam. This leads to a contradiction that cannot be resolved by the methods of engineering mechanics of solids. The more advanced techniques

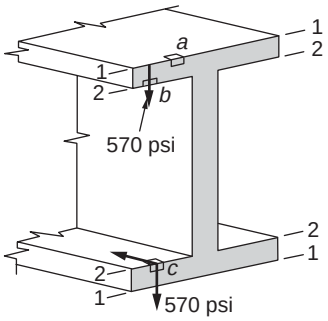

FIGURE 46.30 Boundary conditions are not satisfied at level 2-2.

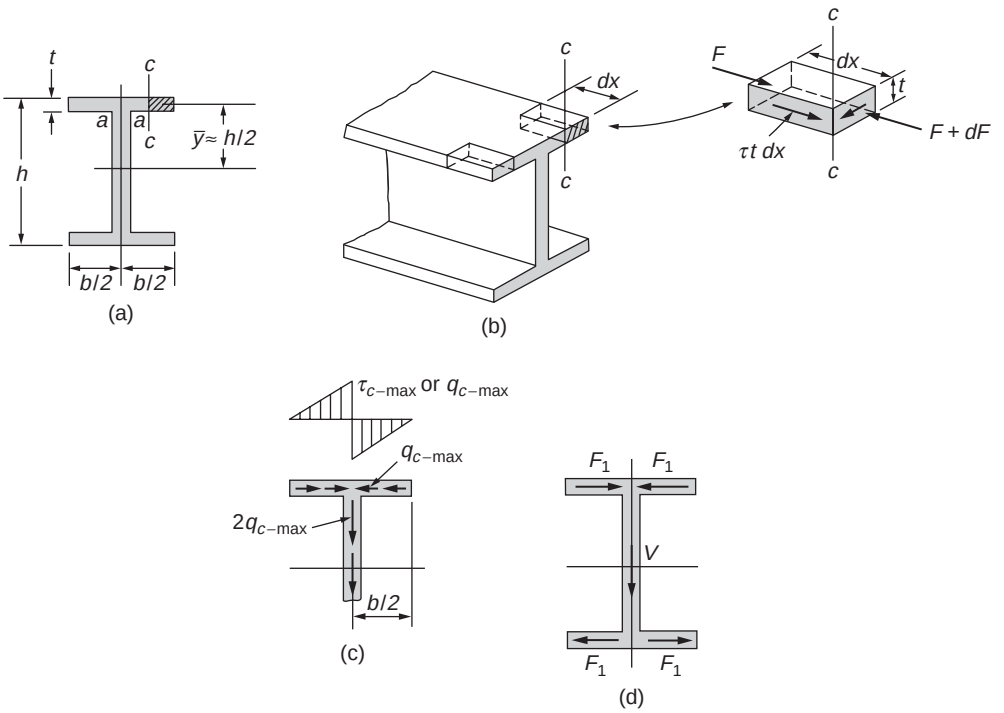

FIGURE 46.31 Shear forces in the flanges of an I beam.

of the mathematical theory of elasticity or three-dimensional finite-element analysis must be used to obtain an accurate solution.

Fortunately, the above defect of the shear-stress formula for beams is not serious. The vertical shear stresses in the flanges are small. The large shear stresses occur in the web and, for all practical purposes, are correctly given by Eq. (46.62). No appreciable error is involved by using the relations derived in this section for thin-walled members, and the majority of beams belong to this group. Moreover, as stated earlier, the solution for the shear stresses of a beam with a rectangular cross section is correct.

In an I beam, the shear stresses acting in a vertical longitudinal cut, as *c-c* in Fig. 46.31(a), act perpendicular to the plane of the paper. Their magnitude may be found by applying Eq. (46.62), and their sense follows by considering the bending moments at the adjoining sections through the beam. For example, if for the beam shown in Fig. 46.31(b) positive bending moments increase toward the reader, larger normal forces act on the near section. For the elements shown, $\tau t\,dx$ or $q\,dx$ must aid the smaller force acting on the partial area of the cross section. This fixes the sense of the shear stresses in the longitudinal cuts. However, numerically equal shear stresses act on the mutually perpendicular planes of an infinitesimal element, and the shear stresses on such planes either meet or part with their directional arrowheads at a corner. Hence, the sense of the shear stresses in the plane of the section also becomes known.

The magnitude of the shear stresses varies for the different vertical cuts. For example, if cut *c-c* in Fig. 46.31(a) is at the edge of the beam, the hatched area of the beam's cross section is zero. However, if the thickness of the flange is constant, and cut *c-c* is made progressively closer to the web, this area increases from zero at a linear rate. Moreover, as y remains constant for any such area, Q also increases linearly from zero toward the web. Therefore, since V and I are constant at any section through the beam, shear flow $q_c = VQ/I$ follows the same variation. If the thickness of the flange remains the same, the shear stress $\tau_c = VQ/It$ varies similarly. The same variation of q_c and τ_c applies on both sides of the axis of symmetry of the cross section. However, as may be seen from Fig. 46.31(b), these quantities in the plane of the cross section act in opposite directions on the two sides. The variation of these shear stresses or

shear flows is represented in Fig. 46.31(c), where for simplicity, it is assumed that the web has zero thickness.

In common with all stresses, the shear stresses shown in Fig. 46.31(c), when integrated over the area on which they act, are equivalent to a force. The magnitude of the horizontal force F_1 for one half of the flange, Fig. 46.31(d), is equal to the average shear stress multiplied by one half of the whole area of the flange, i.e.,

$$F_1 = \left(\frac{\tau_{c-\max}}{2}\right)\left(\frac{bt}{2}\right) \quad \text{or} \quad F_1 = \left(\frac{q_{c-\max}}{2}\right)\left(\frac{b}{2}\right) \tag{46.65}$$

If an I beam transmits a vertical shear, these horizontal forces act in the upper and lower flanges. However, because of the symmetry of the cross section, these equal forces occur in pairs and oppose each other, and cause no apparent external effect.

To determine the shear flow at the juncture of the flange and the web, cut *a-a* in Fig. 46.31(a), the whole area of the flange times y must be used in computing the value of Q. However, since in finding $q_{c\text{-max}}$, one half the flange area times the same y has already been used, the sum of the two horizontal shear flows coming in from opposite sides gives the vertical shear flow at cut *a-a*. Hence, figuratively speaking, the horizontal shear flows "turn through 90° and merge to become the vertical shear flow." Thus, the shear flows at the various horizontal cuts through the web may be determined in the manner explained in the preceding sections. Moreover, the resistance to the vertical shear V in thin-walled I beams is developed mainly in the web, as shown in Fig. 46.31(d). The sense of the shear stresses and shear flows in the web coincides with the direction of the shear V. Note that the vertical shear flow "splits" upon reaching the lower flange. This is represented in Fig. 46.31(d) by the two forces F_1 that are the result of the horizontal shear flows in the flanges.

The shear forces that act at a section of an I beam are shown in Fig. 46.31(d), and for equilibrium, the applied vertical forces must act through the centroid of the cross-sectional area to be coincident with V. If the forces are so applied, no torsion of the member will occur. This is true for all sections having cross-sectional areas with an axis of symmetry. To avoid torsion of such members, the applied forces must act in the plane of symmetry of the cross section and the axis of the beam. A beam with an unsymmetrical section will be discussed next.

Shear Center

The channel section shown in Fig. 46.32 does not have a vertical axis of symmetry. Thus with bending around the horizontal axis, there is a tendency for the channel to twist around some longitudinal axis. To prevent twisting and thus maintain the applicability of the flexure formula, the externally applied force P shown in Fig. 46.32(c) must be applied in such a manner as to balance the internal couple F_1h. This location is called the *shear center* or *center of twist* and is designated by the letter S. The shear center for any cross section lies on a longitudinal line parallel to the axis of the beam. Any transverse force

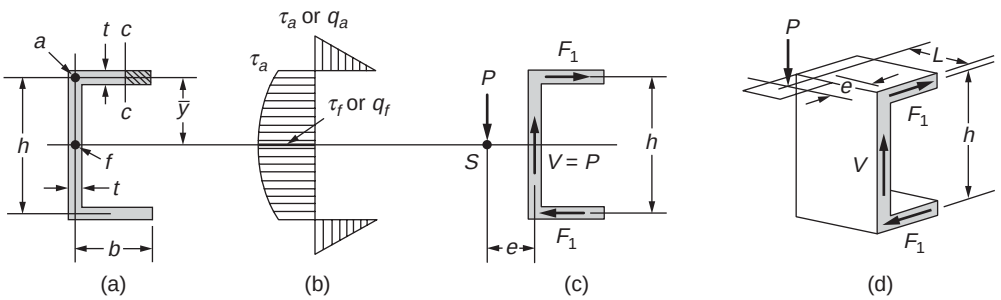

FIGURE 46.32 Deriving location of shear center for a channel.

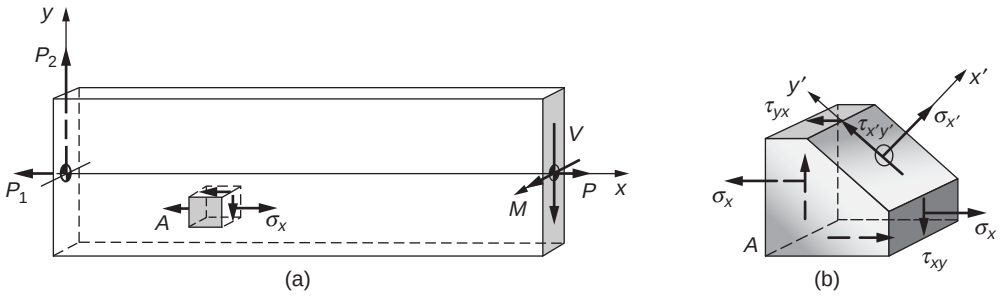

FIGURE 46.33 State of stress at a point on different planes.

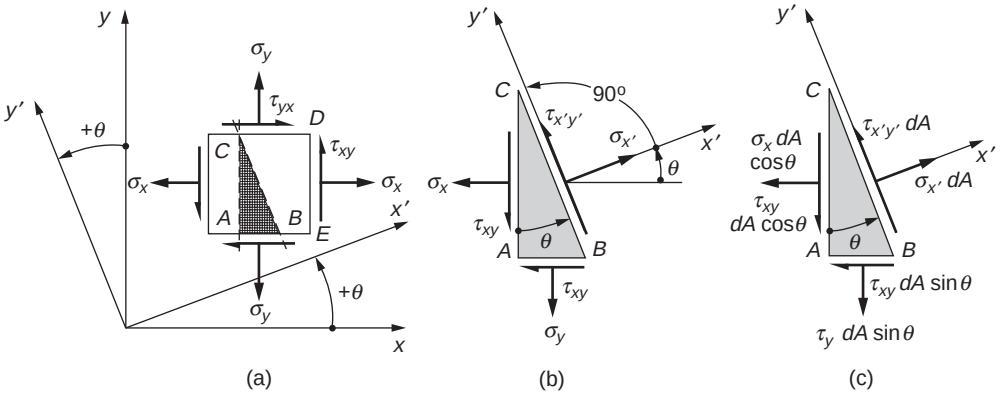

FIGURE 46.34 Derivation of stress transformation on an inclined plane.

applied through the shear center causes no torsion of the beam. For a channel section, the shear center location measured by e from the center of the web is equal to $b^2h^2t/4I$. For a symmetrical angle, the shear center is located at the intersection of the centerlines of its legs.

46.8 Transformation of Stress and Strain

Transformation of Stress

In stress analysis, a more general problem often arises, as illustrated in Fig. 46.33, in which element A is subjected to a normal stress σ_x, due to axial pull and bending, and simultaneously experiences a direct shear stress τ_{xy}. The combined normal stress with the shear stress requires a consideration of stresses on an inclined plane, such as shown by Fig. 46.33(b). Since an inclined plane may be chosen arbitrarily, the state of stress at a point can be described in an infinite number of ways, all of which are equivalent. The planes on which the normal or shear stresses reach their maximum intensity have a particularly significant effect on materials.

An infinitesimal element of unit thickness, as shown in Fig. 46.34(a), is used to describe the state of two-dimensional stress. To determine stresses on any inclined plane, the fundamental procedure involves isolating a wedge and using the equations of the equilibrium of forces. By multiplying the stresses shown in Fig. 46.34(b) by their respective areas, a diagram with the forces acting on the wedge is constructed, as in Fig. 46.34(c). Then, by applying the equations of static equilibrium to the forces acting on the wedge, the stresses $\sigma_{x'}$, $\sigma_{y'}$, and $\tau_{x'y'}$ are obtained:

$$\sigma_{x'} = \frac{\sigma_x + \sigma_y}{2} + \frac{\sigma_x - \sigma_y}{2}\cos 2\theta + \tau_{xy}\sin 2\theta \tag{46.66}$$

$$\sigma_{y'} = \frac{\sigma_x + \sigma_y}{2} - \frac{\sigma_z - \sigma_y}{2}\cos 2\theta - \tau_{xy}\sin 2\theta \tag{46.67}$$

$$\tau_{x'y'} = -\frac{\sigma_x - \sigma_y}{2}\sin 2\theta + \tau_{xy}\cos 2\theta \tag{46.68}$$

These equations are the equations of transformation of stress from one set of coordinates to another. The sign conventions assumed for positive stress and positive angle are depicted in Fig. 46.34(a).

By adding Eqs. (46.66) and (46.67), $\sigma_{x'} + \sigma_{y'} = \sigma_x + \sigma_y$, meaning that the sum of the normal stresses on any two mutually perpendicular planes remain the same, that is, *invariant*, regardless of the angle θ.

Principal Stresses

Interest often centers on the determination of the largest possible stress, as given by Eqs. (46.66) to (46.68), and the planes on which such stresses occur. To find the plane for a maximum or a minimum normal stress, Eq. (46.66) is differentiated with respect to θ and the derivative is set equal to zero. Hence,

$$\tan 2\theta_1 = \frac{\tau_{xy}}{\left(\sigma_x - \sigma_y\right)/2} \tag{46.69}$$

where the subscript of the angle is used to designate the angle that defines the plane of the maximum or minimum normal stress. If the location of planes on which no shear stresses act is wanted, Eq. (46.68) must be set equal to zero. This yields the same relation as that in Eq. (46.69). Therefore, an important conclusion is reached: on planes on which maximum or minimum normal stresses occur there are no shear stresses. These planes are called the *principal planes* of stress, and the stresses acting on these planes — the maximum and minimum normal stresses — are called the *principal stresses*.

Equation (46.69) has two roots that are 90° apart. One of these roots locates a plane on which the maximum normal stress acts; the other root locates the corresponding plane for the minimum normal stress. The magnitude of the principal stresses is obtained by substituting the values of the double angle given by Eq. (46.69) into Eq. (46.66). The expression for the maximum normal stress (denoted by σ_1) and the minimum normal stress (denoted by II_σ) becomes

$$\sigma_{1\text{ or }2} = \frac{\sigma_x + \sigma_y}{2} \pm \sqrt{\left(\frac{\sigma_x - \sigma_y}{2}\right)^2 + \tau_{xy}^2} \tag{46.70}$$

where the positive sign in front of the square root must be used to obtain σ_1 and the negative sign to obtain σ_2.

Maximum Shear Stress

Similarly, to locate the planes on which the maximum or the minimum shear stresses act, Eq. (46.68) must be differentiated with respect to and the derivative set equal to zero. Hence,

$$\tan 2\theta_2 = -\frac{\left(\sigma_x - \sigma_y\right)/2}{\tau_{xy}} \tag{46.71}$$

where the subscript 2 designates the plane on which the shear stress is a maximum or minimum. Again, the two planes defined by this equation are mutually perpendicular. Moreover, Eq. (46.71) is a negative reciprocal of Eq. (46.69). This means that the angles that locate the planes of maximum or minimum shear stress form angles of 45° with the planes of principal stresses. A substitution of the results of Eq. (46.71) into Eq. (46.68) gives the maximum and the minimum values of the shear stresses:

$$\tau_{\max \text{ or } \min} = \pm \sqrt{\left(\frac{\sigma_x - \sigma_y}{2}\right)^2 + \tau_{xy}^2} \tag{46.72}$$

Thus, the maximum shear stress differs from the minimum shear stress only in sign. From the physical point of view, these signs have no meaning, and for this reason, the largest shear stress regardless of sign will often be called the maximum shear stress. By substituting θ_2 into Eq. (46.66), the normal stresses σ' that act on the planes of the maximum shear stresses are

$$\sigma' = \frac{\sigma_x + \sigma_y}{2} \tag{46.73}$$

If σ_x and σ_y in Eq. (46.73) are the principal stresses, τ_{xy} is zero and Eq. (46.72) simplifies to

$$\tau_{\max} = \frac{\sigma_1 - \sigma_2}{2} \tag{46.74}$$

For pure shear, with the absence of normal stresses, the principal stresses are numerically equal to the shear stress, as displayed by Fig. 46.35.

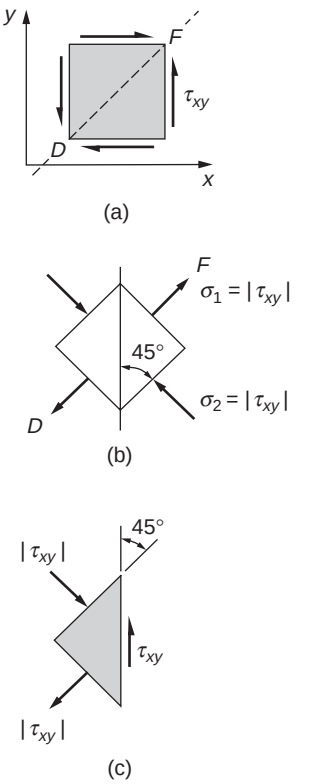

FIGURE 46.35 Equivalent representations for pure shear stress.

Mohr's Circle of Stress

The equations of stress transformation given by Eqs. (46.66), (46.67), and (46.68) may be presented graphically. They can be shown to represent a circle written in parametric form,

$$\left(\sigma_{x'} - a\right)^2 + \tau_{x'y'}^2 = b^2 \tag{46.75}$$

where the center of the circle C is at $(a, 0)$ and the circle radius is equal to b:

$$a = \frac{\sigma_x + \sigma_y}{2} \tag{46.76}$$

$$b = \sqrt{\left(\frac{\sigma_x - \sigma_y}{2}\right)^2 + \tau_{xy}^2} \tag{46.77}$$

In a given problem, σ_x, σ_y, and τ_{xy} are the three known stresses of the element. Hence, if a circle satisfying Eq. (46.75) is plotted, as shown in Fig. 46.36, the simultaneous values of a point (x, y) on this circle correspond to $\sigma_{x'}$ and $\tau_{x'y'}$ for a particular orientation of an inclined plane. The circle so constructed is called the *circle of stress* or *Mohr's circle of stress*.

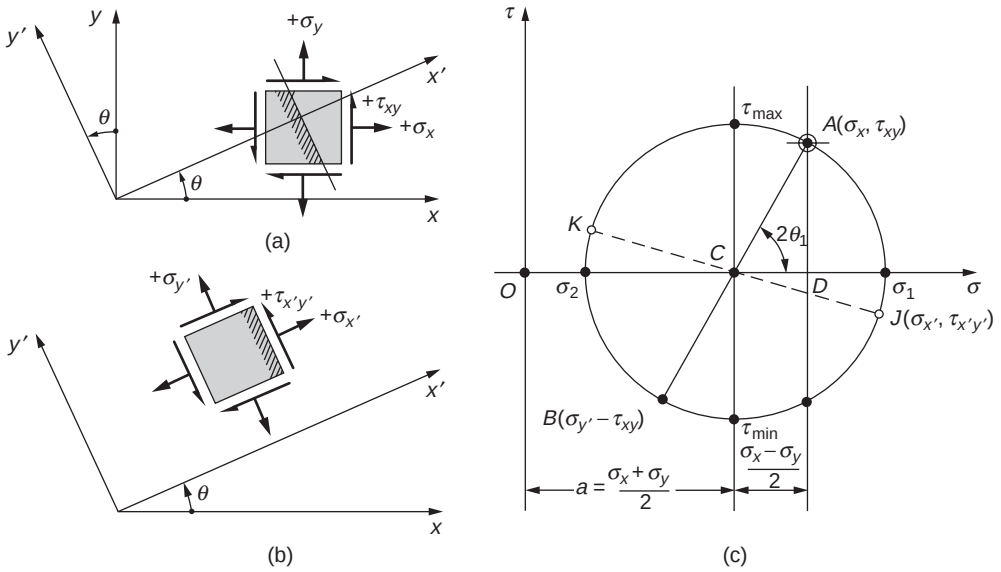

FIGURE 46.36 Mohr's circle of stress.

The coordinates for point *A* on the circle correspond to the stresses in Fig. 46.36(a) on the right face of the element. The coordinates for the conjugate point *B* correspond to the stresses on the upper face of the element. For any other orientation θ of an element, such as shown in Fig. 46.36(b), a pair of conjugate points J and K can always be found on the circle to give the corresponding stresses, as in Fig. 46.36(c). This may be easily accomplished by rotating the AB axis by a corresponding 2θ. The following important observations regarding the state of stress at a point can be made based on the Mohr's circle:

1. The largest possible normal stress is σ_1, and the smallest is σ_2. No shear stresses exist with these principal stresses.
2. The largest shear stress τ_{max} is numerically equal to the radius of the circle. A normal stress equal to $(\sigma_1 + \sigma_2)/2$ acts on each of the planes of maximum shear stress.
3. If $\sigma_1 = \sigma_2$, Mohr's circle degenerates into a point, and no shear stresses develop in the *xy* plane.
4. If $\sigma_x + \sigma_y = 0$, the center of Mohr's circle coincides with the origin of the $\sigma - t$ coordinates, and the state of pure shear exists.
5. The sum of the normal stresses on any two mutually perpendicular planes is invariant, that is, $\sigma_x + \sigma_y = \sigma_1 + \sigma_2 = \sigma_{x'} + \sigma_{y'} =$ constant.

Principal Stresses for a General State of Stress

Consider a general state of stress and define an infinitesimal tetrahedron, as shown in Fig. 46.37. The unknown stresses are sought on an arbitrary oblique plane *ABC* in the three-dimensional *xyz* coordinate system. A set of known stresses on the other three faces of the mutually perpendicular planes of the tetrahedron is given. These stresses are the same as those shown earlier in Fig. 46.2. A unit normal n to the oblique plane defines its orientation. This unit vector is identified by its direction cosines *l*, *m*, and *n*, as illustrated by Fig. 46.37(b). Further, if the infinitesimal area *ABC* is defined as *dA*, then the three areas of the tetrahedron along the coordinate axes are *dA l*, *dA m*, and *dA n*. Force equilibrium for the tetrahedron can now be written by multiplying the stresses given in Fig. 46.37 by the respective areas established. It will be assumed that only a normal stress σ_n (i.e., a principal stress) is acting on face *ABC*; then a system of linear homogeneous equations is obtained that has nontrivial solution if and only if the determinant of the coefficients of *l*, *m*, and *n* vanishes. Expansion of this determinant gives

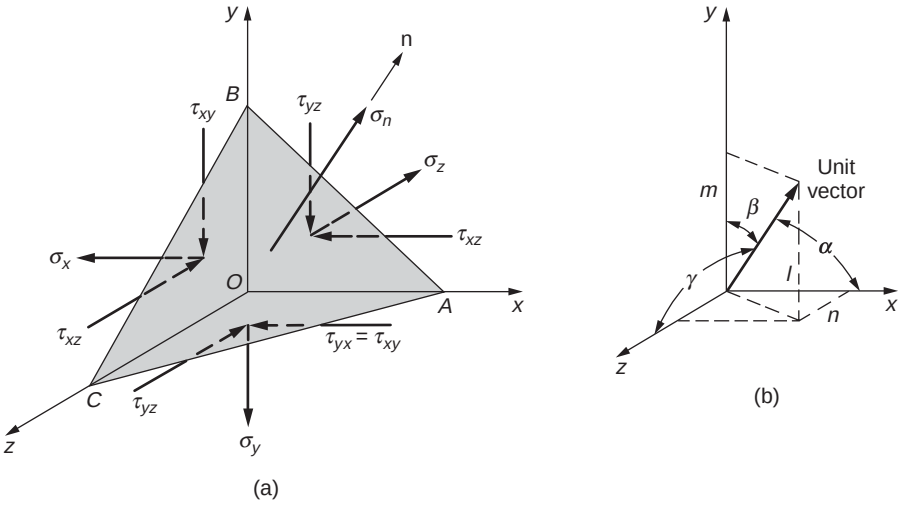

FIGURE 46.37 Tetrahedron for deriving a principal stress on an oblique plane.

$$\sigma_n^3 - I_\sigma \sigma_n^2 + II_\sigma \sigma_n - III_\sigma = 0 \tag{46.78}$$

where

$$I_\sigma = \sigma_x + \sigma_y + \sigma_z$$

$$II_\sigma = \left(\sigma_x\sigma_y + \sigma_y\sigma_z + \sigma_z\sigma_x\right) - \left(\tau_{xy}^2 + \tau_{yz}^2 + \tau_{zx}^2\right)$$

$$III_\sigma = \sigma_x\sigma_y\sigma_z + 2\tau_{xy}\tau_{yz}\tau_{xz} - \sigma_x\tau_{yz}^2 + \sigma_y\tau_{xz}^2 + \sigma_z\tau_{xy}^2$$

The constants I_σ, II_σ, and III_σ are invariant, since if the initial coordinate system is changed, thereby changing the three mutually perpendicular planes of the tetrahedron, the σ_n on the inclined plane must remain the same. In general, Eq. (46.78) has three real roots. These roots are the eigenvalues of the determinant and are the principal stresses of the problem.

Transformation of Strain

The transformation of normal and shear strain from one set of rotated axes to another (Fig. 46.38) is completely analogous to the transformation of normal and shear stresses presented earlier.

Fundamentally, this is because both stresses and strains are second-rank tensors and mathematically obey the same laws of transformation. One may then obtain equations of strain transformation from the equations of stress transformation by simply substituting the normal stress σ with the normal strain ε and the shear stress τ with shear strain γ. Hence, the basic expressions for strain transformation in a plane in an arbitrary direction defined by the x' axis are

$$\varepsilon_{x'} = \frac{\varepsilon_x + \varepsilon_y}{2} + \frac{\varepsilon_x - \varepsilon_y}{2}\cos 2\theta + \frac{\gamma_{xy}}{2}\sin 2\theta \tag{46.79}$$

$$\gamma_{x'y'} = -\left(\varepsilon_x - \varepsilon_y\right)\sin 2\theta + \gamma_{xy}\cos 2\theta \tag{46.80}$$

The sign convention adopted corresponds to the element distortions shown in Fig. 46.38(a) for positive strain. Likewise, Mohr's circle of strain can be constructed where every point on the circle gives two values: one for the normal strain, and the other for the shear strain divided by 2.

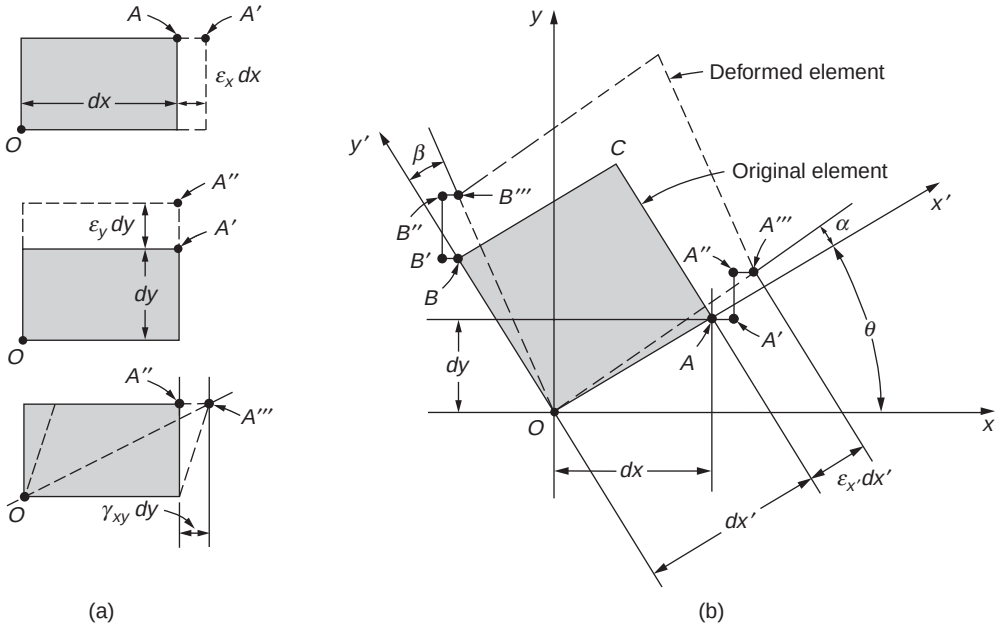

FIGURE 46.38 Exaggerated deformations of elements for deriving strains along new axes.

Yield and Fracture Criteria

Thus far the idealized mathematical procedures for determining the states of stress and strain, as well as their transformation to different coordinates, have been presented. However, it must be pointed out that the precise response of real materials to such stresses and strains defies accurate formulations. As yet, no comprehensive theory can provide accurate predictions of material behavior under the multitude of static, dynamic, impact, and cyclic loading, as well as temperature effects. Only the classical idealizations of yield and fracture criteria for materials are discussed in this section.

The *maximum shear-stress theory*, or simply the *maximum shear theory*, results from the observation that in a ductile material slip occurs during yielding along critically oriented planes. This suggests that the maximum shear stress plays the key role, and it is assumed that yielding of the material depends only on the maximum shear stress that is attained within an element. Therefore, whenever a certain critical value σ_n is reached, yielding in an element commences. For a given material, this value usually is set equal to the shear stress at yield σ_{yp} in simple tension or compression. Hence, according to Eq. (46.72), $t_{\max} = t_{cr} = \sigma_{yp}/2$. In applying this criterion to a biaxial plane stress problem, two different cases arise. In one case, if the signs of the principal stresses σ_1 and σ_2 are the same, the maximum shear stress is of the same magnitude, as would occur in a simple uniaxial stress. Therefore, the criteria corresponding to this case are

$$|\sigma_1| \le \sigma_{yp} \quad \text{and} \quad |\sigma_2| \le \sigma_{yp} \tag{46.81}$$

In the second case, the signs of σ_1 and σ_2 are opposite, and the maximum shear stress $t_{\max} = (|\sigma_1| + |\sigma_2|)/2$. Hence,

$$\left| \pm \frac{\sigma_1 - \sigma_2}{2} \right| \le \frac{\sigma_{yp}}{2} \tag{46.82}$$

A plot of Eqs. (46.81) and (46.82) is shown in Fig. 46.39. If a point defined by σ_2/σ_{yp} and σ_1/σ_{yp} falls on the hexagon shown, a material begins and continues to yield. No such stress points can lie outside

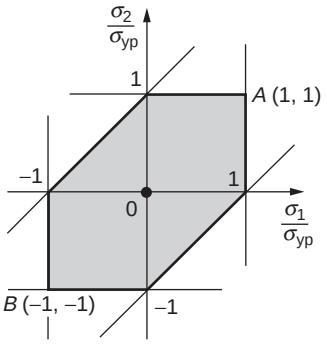

FIGURE 46.39 Yield criterion based on maximum shear stress.

the hexagon because one of the three yield criteria equations would be violated. The stress points falling within the hexagon indicate that a material behaves elastically. The derived yield criterion for perfectly plastic material is often referred to as the *Tresca yield condition* and is one of the widely used laws of plasticity.

Another widely accepted criterion of yielding for ductile isotropic materials is based on energy concepts. In this approach, the total elastic energy is divided into two parts: one associated with the volumetric changes of the material, and the other causing shear distortions. By equating the shear distortion energy at yield point in simple tension to that under combined stress, the yield criterion for combined stress is established.

Based on the concept of superposition, it is possible to consider the stress tensor of the three principal stresses — σ_1, σ_2, and σ_3 — to consist of two additive component tensors:

$$\begin{bmatrix} \sigma_1 & 0 & 0 \\ 0 & \sigma_2 & 0 \\ 0 & 0 & \sigma_3 \end{bmatrix} = \begin{bmatrix} \bar{\sigma} & 0 & 0 \\ 0 & \bar{\sigma} & 0 \\ 0 & 0 & \bar{\sigma} \end{bmatrix} + \begin{bmatrix} \sigma_1 - \bar{\sigma} & 0 & 0 \\ 0 & \sigma_2 - \bar{\sigma} & 0 \\ 0 & 0 & \sigma_3 - \bar{\sigma} \end{bmatrix} \tag{46.83}$$

where $\bar{\sigma} = (\sigma_1 + \sigma_2 + \sigma_3)/3$ is the "hydrostatic stress." The stresses associated with the first tensor component, which is called the *spherical stress tensor*, or alternatively the *dilatational stress tensor*, are the same in every possible direction. The second tensor component causes no volumetric changes, but instead distorts or deviates the element from its initial cubic shape. It is called the *deviatoric* or *distortional stress tensor*.

Extending the results from the section "Elastic Strain Energy for Uniaxial Stress," generalizing for three dimensions and expressing in terms of the principal stresses, the total strain energy per unit volume (i.e., strain density) can be found:

$$U_{total} = \frac{1}{2E}\left(\sigma_1^2 + \sigma_2^2 + \sigma_3^2\right) - \frac{\nu}{E}\left(\sigma_1\sigma_2 + \sigma_2\sigma_3 + \sigma_3\sigma_1\right) \tag{46.84}$$

The strain energy per unit volume due to the dilatational stress can be determined from this equation and expressed in terms of the principal stress. Thus,

$$U_{dilatation} = \frac{1-2\nu}{6E}\left(\sigma_1 + \sigma_2 + \sigma_3\right)^2 \tag{46.85}$$

By subtracting Eq. (46.85) from Eq. (46.84), simplifying and noting that $G = E/2(1 + \nu)$, one finds the distortion strain energy for combined stress:

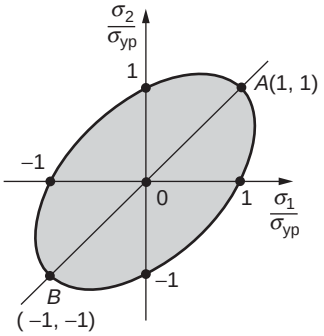

FIGURE 46.40 Yield criterion based on maximum distortion energy.

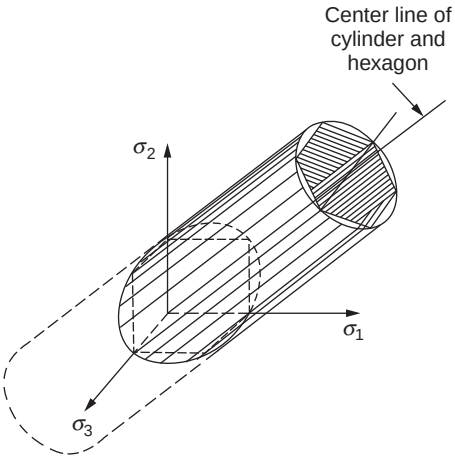

FIGURE 46.41 Yield surfaces for triaxial state of stress.

$$U_{distortion} = \frac{1}{12G}\left[(\sigma_1 - \sigma_2)^2 + (\sigma_2 - \sigma_3)^2 + (\sigma_3 - \sigma_1)^2\right] \tag{46.86}$$

According to the basic assumption of the distortion-energy theory, the expression of Eq. (46.86) must be equal to the maximum elastic distortion energy in simple tension, which is equal to $2\sigma_{yp}^2/12G$. After minor simplifications, one obtains the basic law for yielding of an ideally plastic material:

$$(\sigma_1 - \sigma_2)^2 + (\sigma_2 - \sigma_3)^2 + (\sigma_3 - \sigma_1)^2 = 2\sigma_{yp}^2 \tag{46.87}$$

The fundamental relation given by Eq. (46.87) is widely used for perfectly plastic material and is often referred to as the *Huber–Hencky–Mises*, or simply the *von Mises yield condition*.

For plane stress, $\sigma_3 = 0$, Eq. (46.87) is an equation of an ellipse, a plot of which is shown in Fig. 46.40. Any stress falling within the ellipse indicates that the material behaves elastically. Points on the ellipse indicate that the material is yielding.

In three-dimensional stress space, the yield surface becomes a cylinder with an axis having all three direction cosines equal to $1/\sqrt{3}$. Such a cylinder is shown in Fig. 46.41. The ellipse in Fig. 46.40 is simply the intersection of this cylinder with the $\sigma_1 - \sigma_2$ plane. It can be shown that the yield surface for the maximum shear stress criterion is a hexagon that fits into the tube, Fig. 46.41(b).

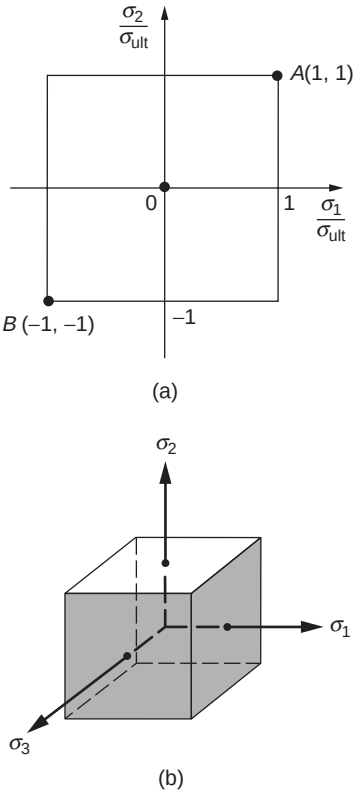

FIGURE 46.42 Fracture envelope based on maximum stress criterion.

The *maximum normal stress theory* or simply the *maximum stress theory* asserts that failure or fracture of a material occurs when the maximum normal stress at a point reaches a critical value regardless of the other stresses. Only the largest principal stress must be determined to apply this criterion. The critical value of stress $\sigma_{u/t}$ is usually determined in a tensile experiment. Experimental evidence indicates that this theory applies well to brittle materials in all ranges of stresses, providing that a tensile principal stress exists. Failure is characterized by separation fracture, or cleavage. The maximum stress theory can be interpreted on graphs, as shown in Fig. 46.42. Unlike the previous theories, the stress criterion gives a bounded surface of the stress space.

46.9 Stability of Equilibrium: Columns

Governing Differential Equation for Deflection

Figure 46.43 shows a deflected beam segment with point A' directly above its initial position A by a displacement v_A. The tangent to the elastic curve at the same point and a plane section with the centroid at A' rotate through an angle dv/dx. Therefore, assuming small angles, the displacement u of a material point at a distance y from the elastic curve is

$$u = -y\frac{dv}{dx} \tag{46.88}$$

Next, recall Eq. (46.22), which states that $\varepsilon_x = du/dx$. Therefore, from Eq. (46.88), $\varepsilon_x = -yd^2v/dx^2$. The same normal strain also can be found from Eqs. (46.26) and (46.48), yielding $\varepsilon_x = -My/EI$. On equating

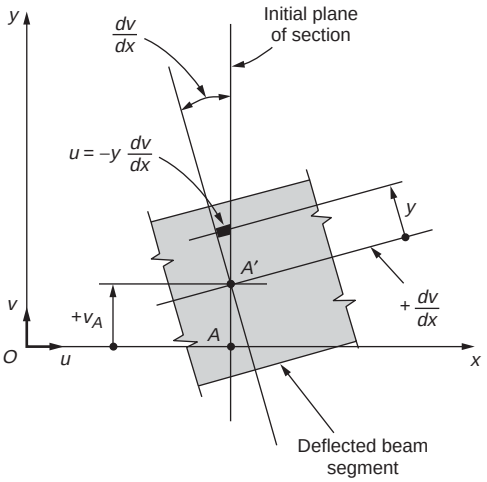

FIGURE 46.43 Longitudinal displacement in a beam due to rotation of a plane section.

the two alternative expressions for ε_x, one obtains the governing differential equation for small deflections of elastic beams as

$$\frac{d^2v}{dx^2} = \frac{M}{EI} \tag{46.89}$$

Buckling Theory for Columns

The procedures of stress and deformation analysis in a state of stable equilibrium were discussed in the preceding sections. But not all structural systems are necessarily stable. The phenomenon of structural instability occurs in numerous situations where compressive stresses are present. The consideration of material strength alone is not sufficient to predict the behavior of such members. Stability considerations are primary in some structural systems.

Consider the ideal perfectly straight column with pinned supports at both ends; see Fig. 46.44. The least force at which a buckled mode is possible is the *critical* or *Euler buckling load*. In a general case

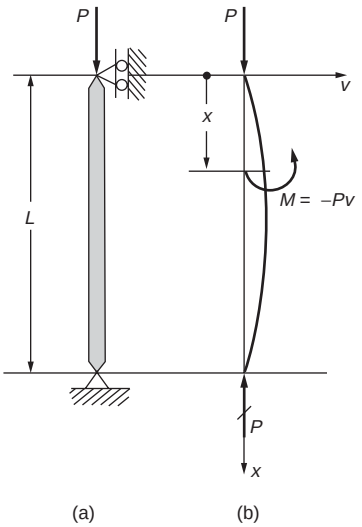

FIGURE 46.44 Column pinned at both ends.

where a compression member does not possess equal flexural rigidity in all directions, the significant flexural rigidity EI of a column depends on the minimum I, and at the critical load a column buckles either to one side or the other in the plane of the major axis.

In order to determine the critical load for this column, the compressed column is displaced as shown in Fig. 46.44. In this position, the bending moment is $-Pv$. By substituting this value of moment into Eq. (46.89), the differential equation for the elastic curve for the initially straight column becomes

$$\frac{d^2\nu}{dx^2} = \frac{M}{EI} = -\frac{P}{EI}\nu \tag{46.90}$$

Letting $\lambda^2 P/EI$ and transposing

$$\frac{d^2\nu}{dx^2} + \lambda^2\nu = 0 \tag{46.91}$$

This is an equation of the same form as the one for simple harmonic motion, and its solution is

$$v = A\sin\lambda x + Bcox\lambda x \tag{46.92}$$

where A and B are arbitrary constants that must be determined from the boundary conditions.

For Fig. 46.44 these conditions are $v\,(0) = 0$ and $v\,(L) = 0$. Hence, $B = 0$ and

$$A\sin\lambda L = 0 \tag{46.93}$$

This equation can be satisfied by taking $A = 0$. However, with A and B each equal to zero, this is a solution for a straight column, and is usually referred to as a trivial solution. An alternative solution is obtained by requiring the sine term in Eq. (46.92) to vanish. This occurs when λL equals $n\pi$, where n is an integer. Therefore, since λ was defined as $\sqrt{P/(EI)}$, the nth critical P_n that makes the deflected shape of the column possible follows from solving $\sqrt{P/(EI)}l = n\pi$. Hence,

$$P_n = \frac{n^2\pi^2 EI}{L^2} \tag{46.94}$$

which are the eigenvalues for this problem. However, since in stability problems only the least value of P_n is of importance, n must be taken as unity, and the critical or Euler load P_{cr} for an initially perfectly straight elastic column with pinned ends becomes

$$P_{cr} = \frac{\pi^2 EI}{L^2} \tag{46.95}$$

where E is the elastic modulus of the material, I is the least moment of inertia of the constant cross-sectional area of a column, and L is its length. This case of a column pinned at both ends is often referred to as the fundamental case.

According to Eq. (46.92), at the critical load, since $B = 0$, the equation of the buckled elastic curve is

$$v = A\sin\lambda x \tag{46.96}$$

This is the characteristic, or eigenfunction, of this problem, and since $\lambda = np/L$, n can assume any integer value. There are an infinite number of such functions. In this linearized solution, amplitude A of the buckling mode remains indeterminate. For the fundamental case $n = 1$, the elastic curve is a half-wave sine curve. This shape and the modes corresponding to $n = 2$ and 3 are shown in Fig. 46.45. The higher modes have no physical significance in buckling problems, since the least critical buckling load occurs at $n = 1$.

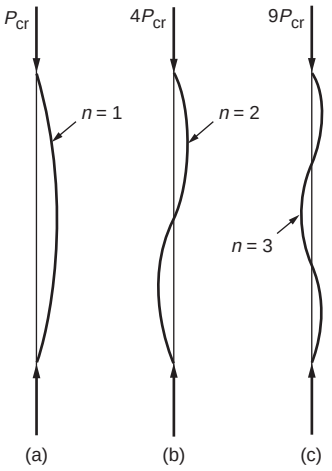

FIGURE 46.45 First three buck-lining modes for a column pinned at both ends.

It should be noted that the elastic modulus E was used for the derivation of the Euler formulas for columns; therefore, the formulas are applicable while the material behavior remains linearly elastic. To bring out this significant limitation, Eq. (46.94) is rewritten in a different form: by definition, $I = Ar^2$, where A is the cross-sectional area and r is its *radius of gyration*. Substitution of this relation into Eq. (46.94) gives

$$\sigma_{cr} = \frac{P'_{cr}}{A} = \frac{\pi^2 E}{\left(L/r\right)^2} \tag{46.97}$$

where the critical stress σ_{cr} for a column is the average stress over the cross-sectional area A of a column at the critical load P_{cr}. The ratio L/r of the column length to the least radius of gyration is called the column *slenderness ratio*. Note that σ_{cr} always decreases with increasing ratios of L/r. Since Eq. (46.97) is based on elastic behavior, σ_{cr} determined by this equation cannot exceed the proportional limit.

Euler Loads for Columns with Different End Restraints

The same procedure as that discussed before can be used to determine the critical axial loads for columns with different boundary conditions. The solutions of buckling problems are very sensitive to the end restraints. Some of these different cases of end restraint combinations are shown in Fig. 46.46. It can be shown that the buckling formulas for all these cases can be made to resemble the fundamental case, Eq. (46.95), provided that the effective column lengths are used, instead of the actual column length. The effective column length L_e for the fundamental case is L, but for a free-standing column it is $2L$. For a column fixed at both ends, the effective length is $L/2$, and for a column fixed at one end and pinned at the other, it is $0.7L$. For a general case, $L_e = KL$, where K is the *effective length factor*, which depends on the end restraints.

Generalized Euler Buckling Load Formulas

Beyond the proportional limit, it may be said that a column of different material has been created, since the stiffness of the material is no longer represented by the elastic modulus. At this point the material stiffness is given instantaneously by the tangent to the stress–strain curve, that is, by the tangent modulus E_t; see the section on constitutive relations. The column remains stable if its new flexural rigidity E_tI is sufficiently large and it can carry a higher load. Substitution of the tangent modulus E_t for the elastic

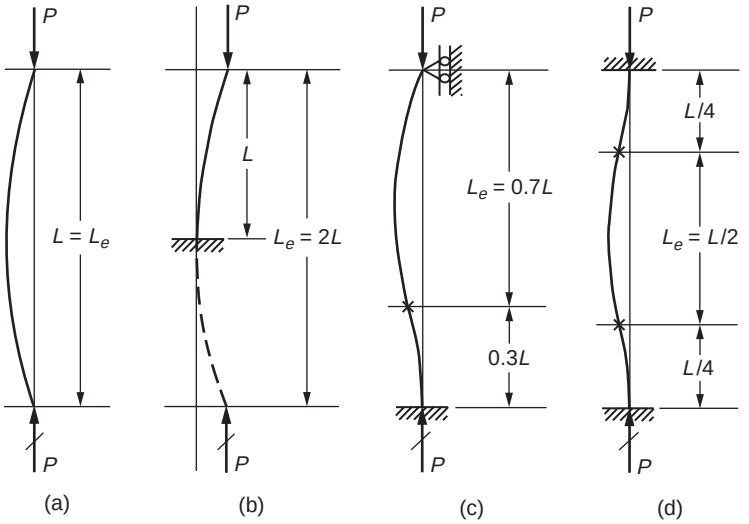

FIGURE 46.46 Effective lengths of columns with different restraints.

modulus E is the only modification necessary to make the elastic buckling formulas applicable in the inelastic range. Hence, the *generalized Euler buckling load formula*, or the *tangent modulus formula*, becomes

$$\sigma_{cr} = \frac{\pi^2 E_t}{\left(L/r\right)^2} \tag{46.98}$$

Eccentric Loads and the Secant Formula

Since no column is perfectly straight and the applied forces are not perfectly concentric, the behavior of real columns may be studied with some statistically determined imperfections or possible misalignments of the applied loads. To analyze the behavior of an eccentrically loaded column, consider the column shown in Fig. 46.47. The differential equation for the elastic curve is the same as that for a concentrically

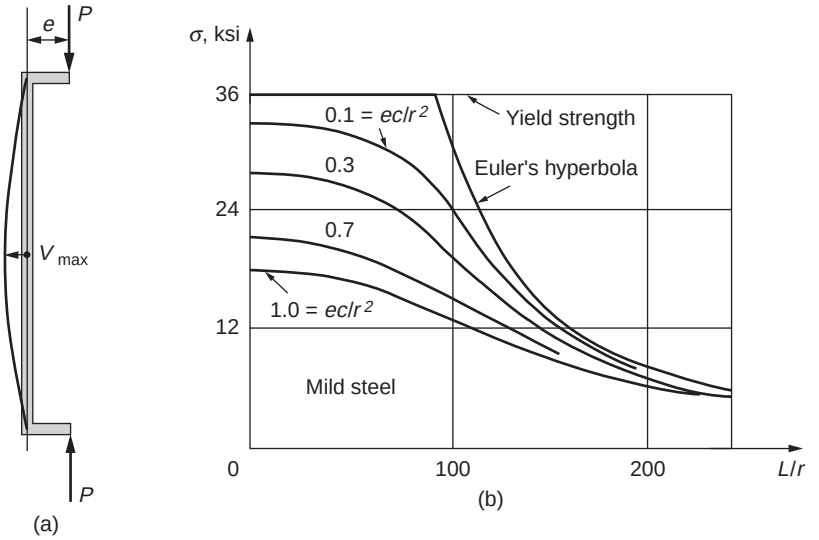

FIGURE 46.47 Results of analyses for different columns by the secant formula.

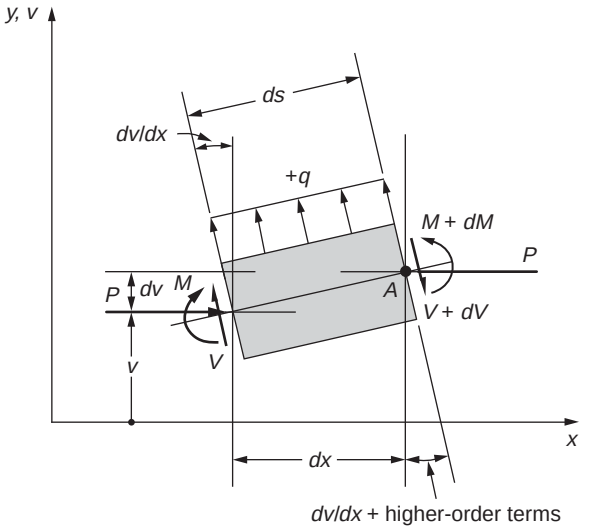

FIGURE 46.48 Beam-column element.

loaded column, derived earlier. However, the boundary conditions are now different. At the upper end, v is equal to the eccentricity e of the applied load. And given that the elastic curve has a vertical tangent at the midheight of the column, the equation for the elastic curve is obtained:

$$v = e\left(\frac{\sin \lambda L/2}{\cos \lambda L/2}\sin \lambda x + \cos \lambda x\right) \tag{46.99}$$

No indeterminacy of any constants appears in this equation, and the maximum deflection v_{max} can be found from it. This maximum occurs at $L/2$. Hence, $v_{max} = e \sec(\lambda L/2)$.

For the column shown in Fig. 46.47, the largest bending moment M is developed at the point of maximum deflection and numerically is equal to Pv_{max}. Therefore, the maximum compressive stress occurring in the column can be computed by superposition of the axial and bending stresses, that is, $(P/A) + (Mc/I)$, to give

$$\sigma_{max} = \frac{P}{A}\left(1 + \frac{ec}{r^2}\sec\frac{L}{r}\sqrt{\frac{P}{4EA}}\right) \tag{46.100}$$

This equation, because of the secant term, is known as the *secant formula* for columns. It applies to columns of any length, provided the maximum stress does not exceed the elastic limit.

Note that in Eq. (46.100), the relation between σ_{max} and P is not linear; σ_{max} increases faster than P. Therefore, the solutions for maximum stresses in columns caused by different axial forces cannot be superposed; instead, the forces must be superposed first, and then the stresses can be calculated. A plot of Eq. (46.100) is shown in Fig. 46.47. Note the large effect load eccentricity has on short columns and the negligible one it has on very slender columns. A condition of equal eccentricities of the applied forces in the same direction causes the largest deflection.

Differential Equations for Beam-Columns

As was the case in the preceding section, a member acted upon simultaneously by an axial force and transverse forces or moments causing bending is referred to as a *beam-column*. To obtain the governing differential equation, consider the beam-column element shown in Fig. 46.48. Applying the equilibrium equations and small deflection approximations, one obtains two equations:

$$\frac{dV}{dx} = q \tag{46.101}$$

and

$$V = \frac{dM}{dx} + P\frac{dv}{dx} \tag{46.102}$$

Therefore, the shear V, in addition to depending on the rate of change of moment M, as in beams, now also depends on the magnitude of the axial force and the slope of the elastic curve.

On substituting Eq. (46.102) into Eq. (46.101) and using the beam curvature–moment relation $d^2v/dx^2 = M/EI$, one obtains the two alternative governing differential equations for beam-columns:

$$\frac{d^2M}{dx^2} + \lambda^2 M = q \tag{46.103}$$

or

$$\frac{d^4v}{dx^4} + \lambda^2 \frac{d^2v}{dx^2} = \frac{q}{EI} \tag{46.104}$$

where, as before, $\lambda^2 = P/EI$.

Defining Terms

Constitutive relation — The relationship between stress and strain.

Elastic strain energy — The internal work (product of force and deformation) stored in an elastic body.

Elasticity — When unloaded, material responds by returning back along the loading path to its initial stress-free state of deformation.

Euler or **critical buckling load —** The least force at which a buckled mode is possible for an elastic material.

Hooke's law — The idealization of stress as being directly proportional to strain, that is, the stress–strain relationship is a straight line. The constant of proportionality E is called the elastic modulus, modulus of elasticity, or Young's modulus.

Inelasticity or **plasticity —** Material response characterized by a stress–strain diagram that is nonlinear and that retains a permanent strain on complete unloading.

Mechanics of materials — A branch of applied mechanics that deals with the behavior of various load-carrying members. It involves analytical methods for determining strength, stiffness, and stability.

Mohr's circle of stress — A graphical representation of stress transformation.

Poisson's ratio — For a body subjected to axial tension, the constant ratio of lateral strain to axial strain.

Principal stresses — For any general state of stress there exist three mutually perpendicular planes on which the shear stresses vanish. The normal stress components remaining are called principal stresses.

Stability — Stability refers to the ability of a load-carrying member to resist buckling under compressive loads.

Strain — Deformation per unit length. Normal or extensional strain is the change in length per unit of initial gage length. Shear strain is the change in initial right angle between any two imaginary planes in a body.

Stress concentration — Large stresses due to discontinuities that develop in a small portion of a member.

Stress — Intensity of force per unit area. Normal stress is the intensity of force perpendicular to or normal to the section at a point. Shear stress is the intensity of force parallel to the plane of the elementary area.

Transformation of stress and strain — The mathematical process for changing the components of the state of stress or strain given in one set of coordinate axes to any other set of rotated axes.

47.1 Fundamental Principles

The main purpose of *structural analysis* is to determine forces and deformations of the structure due to applied loads. *Structural design* involves form finding, determination of loadings, and proportioning of structural members and components in such a way that the assembled structure is capable of supporting the loads within the design limit states. An analytical model is an idealization of the actual structure. The structural model should relate the actual behavior to material properties, structural details, loading, and boundary conditions as accurately as is practicable.

Structures often appear in three-dimensional forms. For structures that have a regular layout and are rectangular in shape, subject to symmetric loads, it is possible to idealize them into two-dimensional frames arranged in orthogonal directions. A structure is said to be two-dimensional or planar if all the members lie in the same plane. *Joints* in a structure are those points where two or more members are connected. Beams are members subjected to loading acting transversely to their longitudinal axis and creating flexural bending only. *Ties* are members that are subjected to axial tension only, while struts (columns or posts) are members subjected to axial compression only. A *truss* is a structural system consisting of members that are designed to resist only axial forces. A structural system in which joints are capable of transferring end moments is called a *frame*. Members in this system are assumed to be capable of resisting bending moments, axial force, and shear force.

Boundary Conditions

A *hinge* or *pinned joint* does not allow translational movements (Fig. 47.1a). It is assumed to be frictionless and to allow rotation of a member with respect to the others. A *roller* permits the attached structural part to rotate freely with respect to the rigid surface and to translate freely in the direction parallel to the surface (Fig. 47.1b). Translational movement in any other direction is not allowed. A *fixed support* (Fig. 47.1c) does not allow rotation or translation in any direction. A *rotational spring* provides some

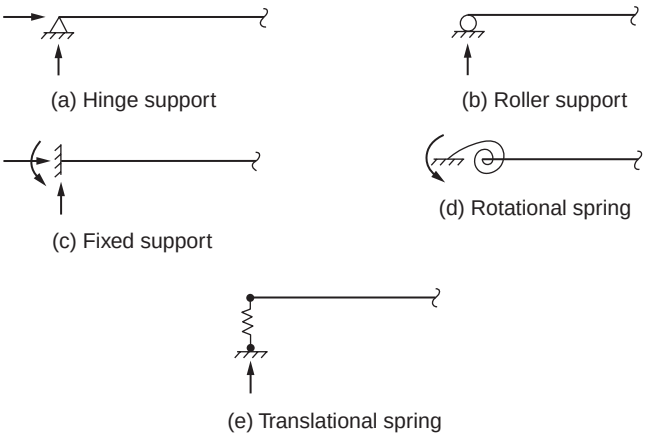

FIGURE 47.1 Various boundary conditions.

rotational restraint but does not provide any translational restraint (Fig. 47.1d). A *translational spring* can provide partial restraints along the direction of deformation (Fig. 47.1e).

Loads and Reactions

Loads that are of constant magnitude and remain in the original position are called *permanent loads*. They are also referred to as *dead loads*, which may include the self weight of the structure and other loads, such as walls, floors, roof, plumbing, and fixtures that are permanently attached to the structure. Loads that may change in position and magnitude are called *variable loads*. They are commonly referred to as live or imposed loads, which may include those caused by construction operations, wind, rain, earthquakes, snow, blasts, and temperature changes, in addition to those that are movable, such as furniture and warehouse materials.

Ponding loads are due to water or snow on a flat roof that accumulates faster than it runs off. *Wind loads* act as pressures on windward surfaces and pressures or suctions on leeward surfaces. *Impact loads* are caused by suddenly applied loads or by the vibration of moving or movable loads. They are usually taken as a fraction of the live loads. *Earthquake loads* are those forces caused by the acceleration of the ground surface during an earthquake.

A structure that is initially at rest and remains at rest when acted upon by applied loads is said to be in a state of *equilibrium*. The resultant of the external loads on the body and the supporting forces or reactions is zero. If a structure is to be in equilibrium under the action of a system of loads, it must satisfy the six static equilibrium equations:

$$\Sigma F_x = 0, \quad \Sigma F_y = 0, \quad \Sigma F_z = 0$$
$$\Sigma M_x = 0, \quad \Sigma M_y = 0, \quad \Sigma M_z = 0 \tag{47.1}$$

The summation in these equations is for all the components of the forces (F) and of the moments (M) about each of the three axes x, y, and z. If a structure is subjected to forces that lie in one plane, say x-y, the above equations are reduced to:

$$\Sigma F_x = 0, \quad \Sigma F_y = 0, \quad \Sigma M_z = 0 \tag{47.2}$$

Consider a beam under the action of the applied loads, as shown in Fig. 47.2a. The reaction at support B must act perpendicular to the surface on which the rollers are constrained to roll upon. The support

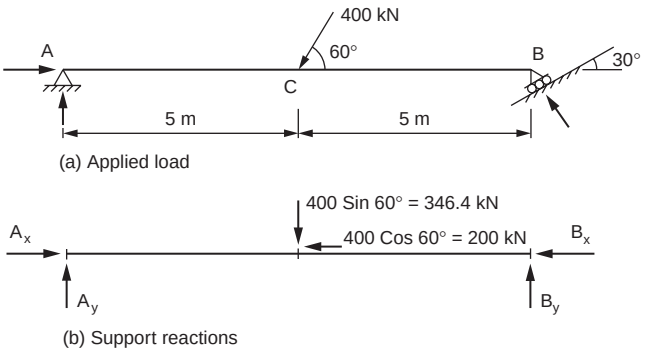

FIGURE 47.2 Beam in equilibrium.

reactions and the applied loads, which are resolved in vertical and horizontal directions, are shown in Fig. 47.2b.

From geometry, it can be calculated that $B_y = \sqrt{3}B_x$ 1. Equation (47.2) can be used to determine the magnitude of the support reactions. Taking moment about B gives

$$10A_y - 346.4 \times 5 = 0$$

from which

$$A_y = 173.2 \text{ kN}$$

Equating the sum of vertical forces, ΣF_y, to zero gives

$$173.2 + B_y - 346.4 = 0$$

and hence we get

$$B_y = 173.2 \text{ kN}$$

Therefore

$$B_x = B_y / \sqrt{3} = 100 \text{ kN}.$$

Equilibrium in the horizontal direction, $\Sigma F_x = 0$, gives

$$A_x - 200 - 100 = 0$$

and hence

$$A_x = 300 \text{ kN}$$

There are three unknown reaction components at a fixed end, two at a hinge, and one at a roller. If, for a particular structure, the total number of unknown reaction components equal the number of equations available, the unknowns may be calculated from the equilibrium equations, and the structure is then said to be *statically determinate externally*. Should the number of unknowns be greater than the number of equations available, the structure is *statically indeterminate externally*; if less, it is *unstable externally*. The ability of a structure to support adequately the loads applied to it is dependent not only on the number of reaction components but also on the arrangement of those components. It is possible for a structure to have as many or more reaction components than there are equations available and yet be unstable. This condition is referred to as *geometric instability*.

Principle of Superposition

The principle states that if the structural behavior is linearly elastic, the forces acting on a structure may be separated or divided into any convenient fashion and the structure analyzed for the separate cases. The final results can be obtained by adding up the individual results. This is applicable to the computation of structural responses such as moment, shear, deflection, etc.

However, there are two situations where the principle of superposition cannot be applied. The first case is associated with instances where the geometry of the structure is appreciably altered under load. The second case is in situations where the structure is composed of a material in which the stress is not linearly related to the strain.

47.2 Beams

One of the most common structural elements is a *beam*; it bends when subjected to loads acting transversely to its centroidal axis or sometimes by loads acting both transversely and parallel to this axis. The discussions given in the following subsections are limited to straight beams in which the centroidal axis is a straight line with a shear center coinciding with the centroid of the cross-section. It is also assumed that all the loads and reactions lie in a simple plane that also contains the centroidal axis of the flexural member and the principal axis of every cross-section. If these conditions are satisfied, the beam will simply bend in the plane of loading without twisting.

Relation between Load, Shear Force, and Bending Moment

Shear force at any transverse cross-section of a straight beam is the algebraic sum of the components acting transverse to the axis of the beam of all the loads and reactions applied to the portion of the beam on either side of the cross-section. *Bending moment* at any transverse cross-section of a straight beam is the algebraic sum of the moments, taken about an axis passing through the centroid of the cross-section. The axis about which the moments are taken is, of course, normal to the plane of loading.

When a beam is subjected to transverse loads, there exist certain relationships between load, shear force, and bending moment. Let us consider the beam shown in Fig. 47.3 subjected to some arbitrary loading, p. Let S and M be the shear and bending moment, respectively, for any point m at a distance x, which is measured from A, being positive when measured to the right. Corresponding values of the shear and bending moment at point n at a differential distance dx to the right of m are S + dS and M + dM, respectively. It can be shown, neglecting the second order quantities, that

$$p = \frac{dS}{dx} \tag{47.3}$$

and

$$S = \frac{dM}{dx} \tag{47.4}$$

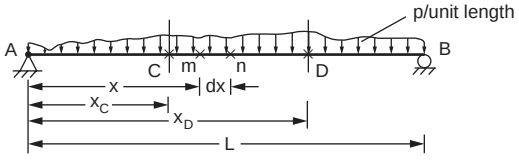

FIGURE 47.3 Beam under arbitrary loading.

Equation (47.3) shows that the rate of change of shear at any point is equal to the intensity of load applied to the beam at that point. Therefore, the difference in shear at two cross-sections C and D is

$$S_D - S_C = \int_{x_c}^{x_D} p\,dx \tag{47.5}$$

We can write this in the same way for moment as

$$M_D - M_C = \int_{x_C}^{x_D} S\,dx \tag{47.6}$$

Shear Force and Bending Moment Diagrams

In order to plot the shear force and bending moment diagrams, it is necessary to adopt a sign convention for these responses. A shear force is considered to be positive if it produces a clockwise moment about a point in the free body on which it acts. A negative shear force produces a counterclockwise moment about the point. The bending moment is taken as positive if it causes compression in the upper fibers of the beam and tension in the lower fiber. In other words, a sagging moment is positive and a hogging moment is negative. The construction of these diagrams is explained with an example given in Fig. 47.4.

Section E of the beam is in equilibrium under the action of applied loads and internal forces acting at E, as shown in Fig. 47.5. There must be an internal vertical force and internal bending moment to maintain equilibrium at section E. The vertical force or the moment can be obtained as the algebraic sum of all forces or the algebraic sum of the moment of all forces that lie on either side of section E.

The shear on a cross-section an infinitesimal distance to the right of point A is +55, and therefore the shear diagram rises abruptly from zero to +55 at this point. In portion AC, since there is no additional load, the shear remains +55 on any cross-section throughout this interval, and the diagram is a horizontal, as shown in Fig. 47.4. An infinitesimal distance to the left of C the shear is +55, but an infinitesimal

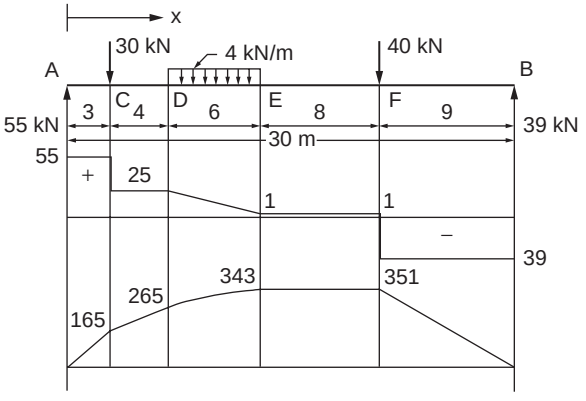

FIGURE 47.4 Bending moment and shear force diagrams.

FIGURE 47.5 Internal forces.

distance to the right of this point the concentrated load of magnitude 30 has caused the shear to be reduced to +25. Therefore, at point C, there is an abrupt change in the shear force from +55 to +25. In the same manner, the shear force diagram for portion CD of the beam remains a rectangle. In portion DE, the shear on any cross-section a distance x from point D is

$$S = 55 - 30 - 4x = 25 - 4x$$

which indicates that the shear diagram in this portion is a straight line decreasing from an ordinate of +25 at D to +1 at E. The remainder of the shear force diagram can easily be verified in the same way. It should be noted that, in effect, a concentrated load is assumed to be applied at a point, and hence, at such a point the ordinate to the shear diagram changes abruptly by an amount equal to the load.

In portion AC, the bending moment at a cross-section a distance x from point A is M = 55x. Therefore, the bending moment diagram starts at zero at A and increases along a straight line to an ordinate of +165 at point C. In portion CD, the bending moment at any point a distance x from C is M = 55(x + 3) – 30x. Hence, the bending moment diagram in this portion is a straight line increasing from 165 at C to 265 at D. In portion DE, the bending moment at any point a distance x from D is M = 55(x + 7) – 30(X + 4) – $4x^2/22$. Hence, the bending moment diagram in this portion is a curve with an ordinate of 265 at D and 343 at E. In an analogous manner, the remainder of the bending moment diagram can easily be constructed.

Bending moment and shear force diagrams for beams with simple boundary conditions and subject to some selected load cases are given in Fig. 47.6.

Fixed-End Beams

When the ends of a beam are held so firmly that they are not free to rotate under the action of applied loads, the beam is known as a built-in or fixed-end beam and it is statically indeterminate. The bending moment diagram for such a beam can be considered to consist of two parts viz. the free bending moment diagram obtained by treating the beam as if the ends are simply supported and the fixing moment diagram resulting from the restraints imposed at the ends of the beam. The solution of a fixed beam is greatly simplified by considering Mohr's principles, which state that:

1. The area of the fixing bending moment diagram is equal to that of the free bending moment diagram.
2. The centers of gravity of the two diagrams lie in the same vertical line, i.e., are equidistant from a given end of the beam.

The construction of the bending moment diagram for a fixed beam is explained with an example shown in Fig. 47.7. **P Q U T** is the free bending moment diagram, M_s, and **P Q R S** is the fixing moment diagram, M_i. The net bending moment diagram, M, is shaded. If A_s is the area of the free bending moment diagram and A_i the area of the fixing moment diagram, then from the first Mohr's principle we have $A_s = A_i$ and

$$\frac{1}{2} \times \frac{Wab}{L} \times L = \frac{1}{2}(M_A + M_B) \times L \tag{47.7}$$

$$M_A + M_B = \frac{Wab}{L}$$

From the second principle, equating the moment about A of A_s and A_i, we have

$$M_A + 2M_B = \frac{Wab}{L^3}\left(2a^2 + 3ab + b^2\right) \tag{47.8}$$

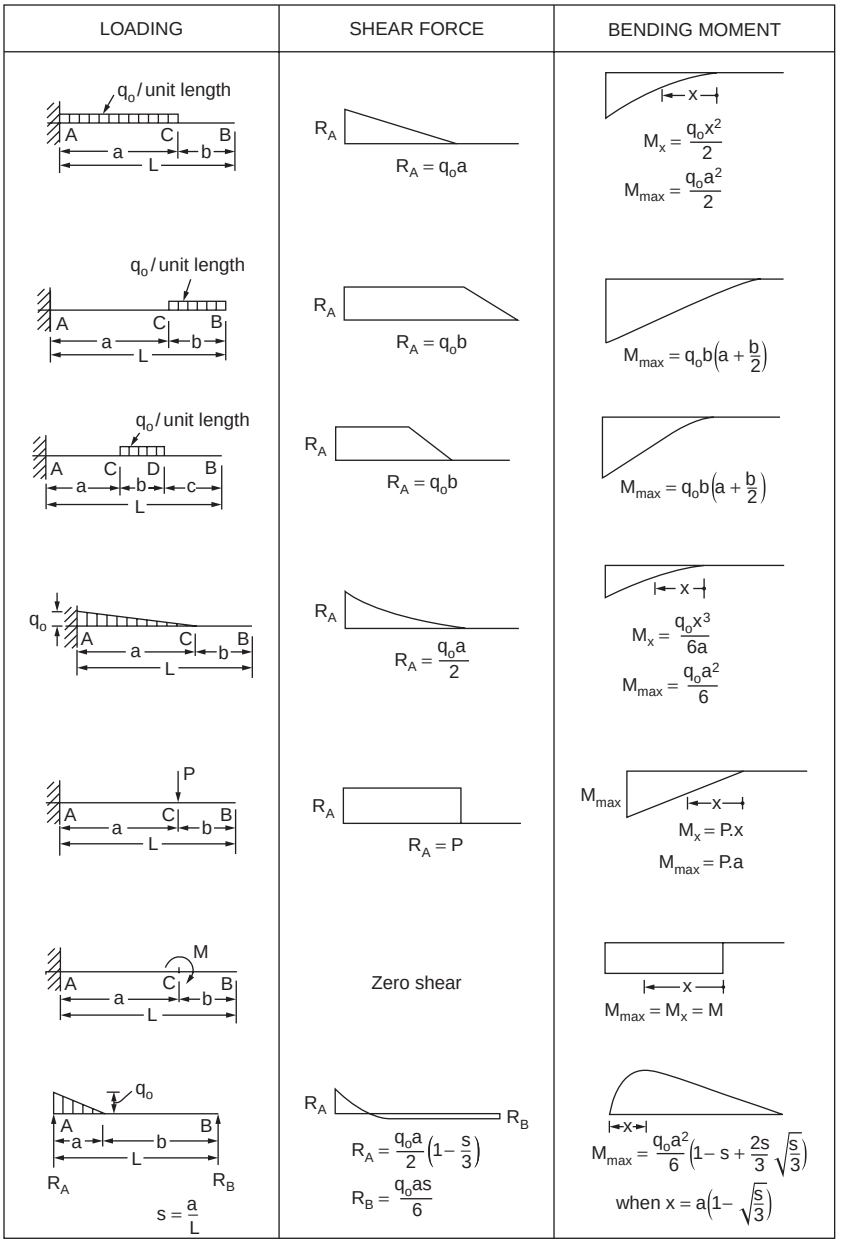

FIGURE 47.6 Shear force and bending moment diagrams for beams with simple boundary conditions subjected to selected loading cases.

Solving Eqs. (47.7) and (47.8) for M_A and M_B we get

$$M_A = \frac{Wab^2}{L^2}$$

$$M_B = \frac{Wa^2b}{L^2}$$

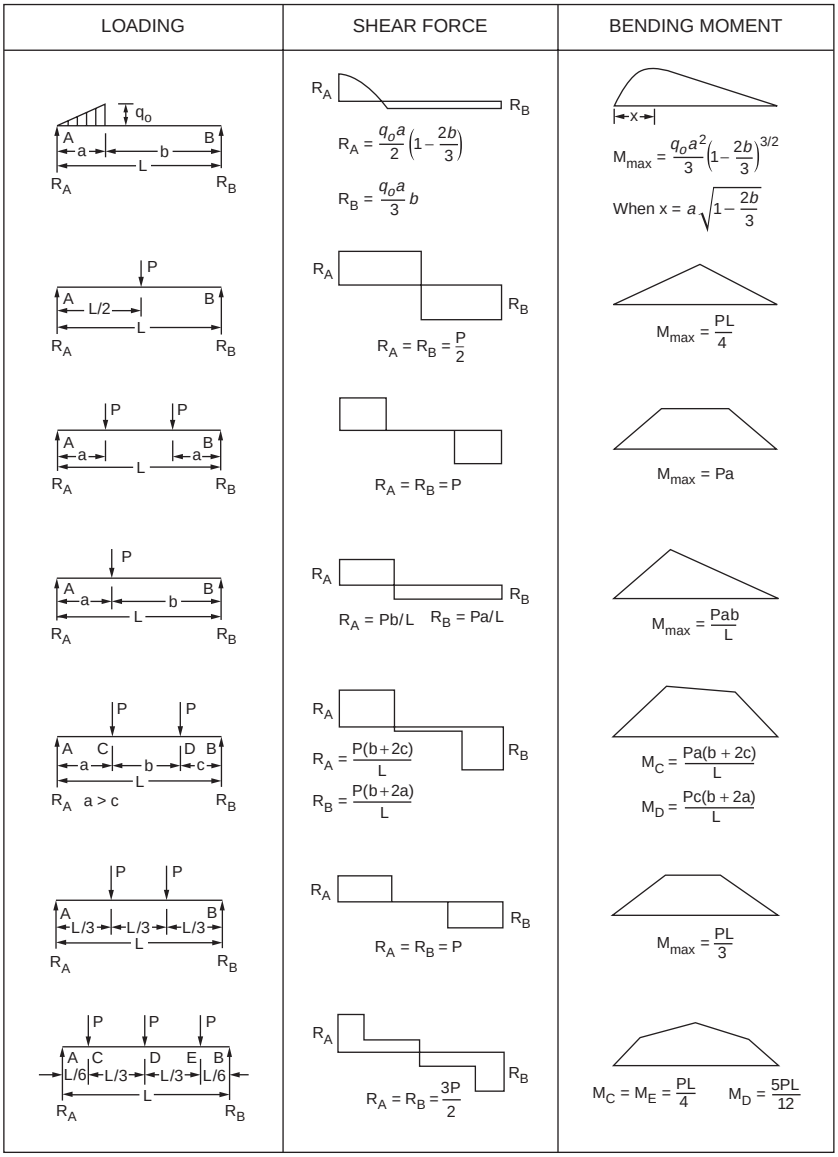

FIGURE 47.6 (continued).

Shear force can be determined once the bending moment is known. The shear force at the ends of the beam, i.e., at A and B, are

$$S_A = \frac{M_A - M_B}{L} + \frac{Wb}{L}$$

$$S_B = \frac{M_B - M_A}{L} + \frac{Wa}{L}$$

Bending moment and shear force diagrams for fixed-end beams subjected to some typical loading cases are shown in Fig. 47.8.

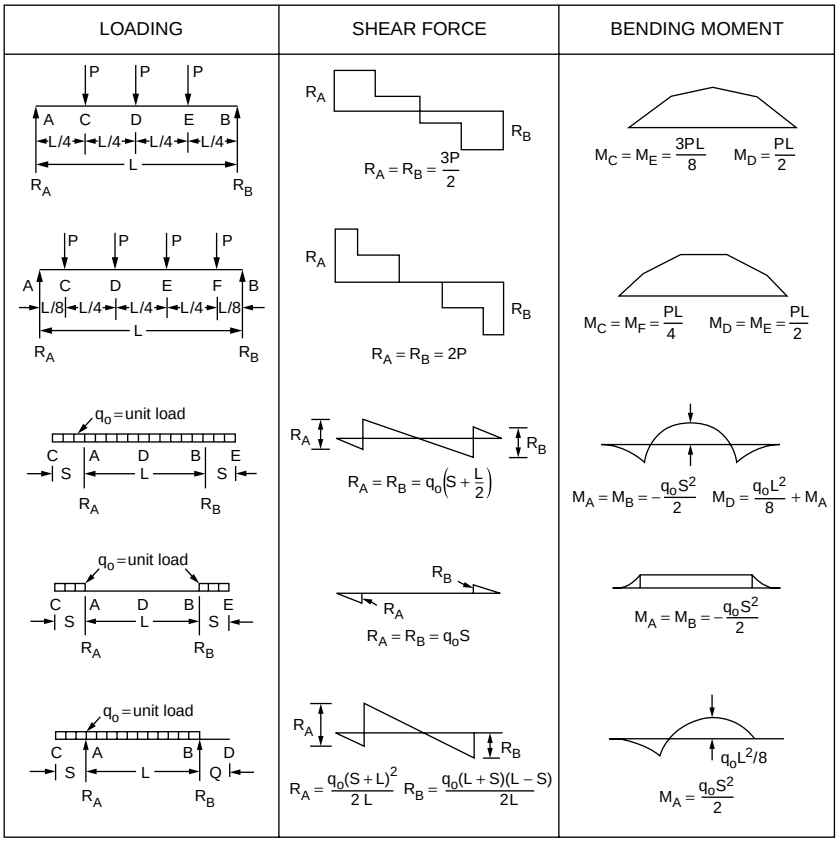

FIGURE 47.6 (continued).

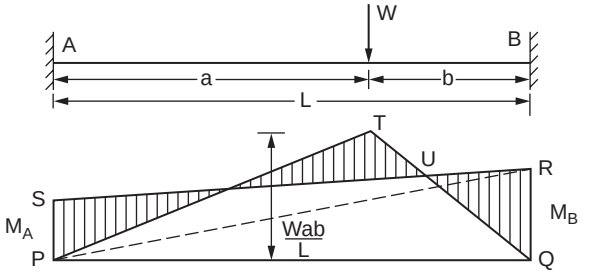

FIGURE 47.7 Fixed-end beam.

Continuous Beams

Continuous beams like fixed-end beams are statically indeterminate. Bending moments in these beams are functions of the geometry, moments of inertia, and modulus of elasticity of individual members, besides the load and span. They may be determined by Clapeyron's theorem of three moments, the moment distribution method, or the slope deflection method.

An example of a two-span continuous beam is solved by Clapeyron's theorem of three moments. The theorem is applied to two adjacent spans at a time, and the resulting equations in terms of unknown support moments are solved. The theorem states that

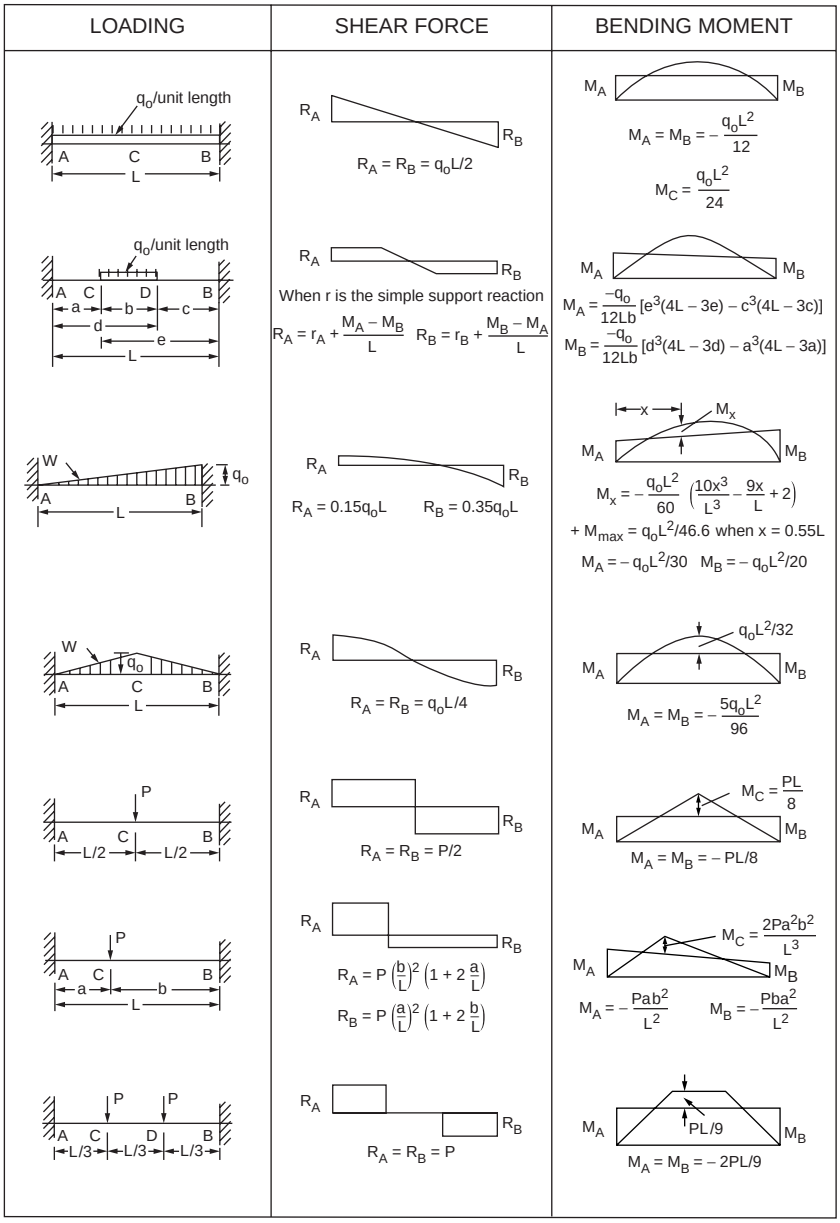

FIGURE 47.8 Shear force and bending moment diagrams for built-up beams subjected to typical loading cases.

$$M_AL_1 + 2M_B(L_1 + L_2) + M_CL_2 = 6\left(\frac{A_1x_1}{L_1} + \frac{A_2x_2}{L_2}\right) \tag{47.9}$$

in which M_A, M_B, and M_C are the hogging moment at supports A, B, and C, respectively, of two adjacent spans of length L_1 and L_2 (Fig. 47.9); A_1 and A_2 are the area of bending moment diagrams produced by the vertical loads on the simple spans AB and BC, respectively; x_1 is the centroid of A_1 from A; and x_2 is the distance of the centroid of A_2 from C. If the beam section is constant within a span but remains different for each of the spans Eq. (47.9) can be written as

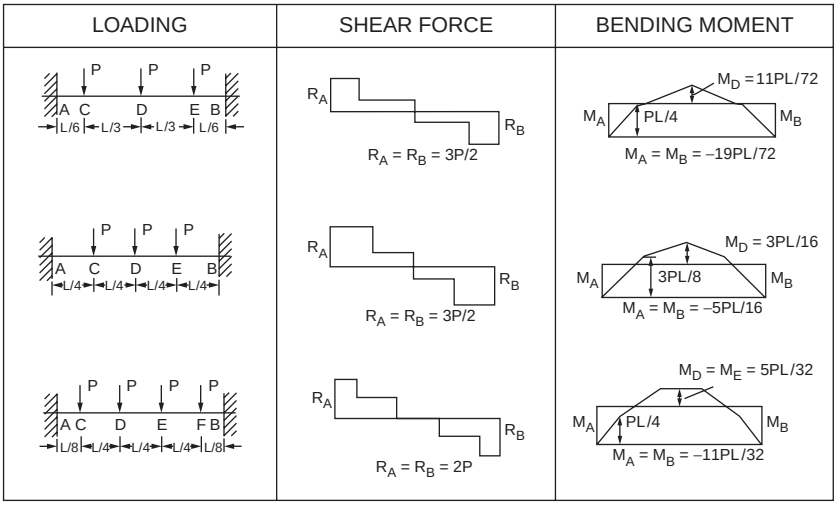

FIGURE 47.8 (continued).

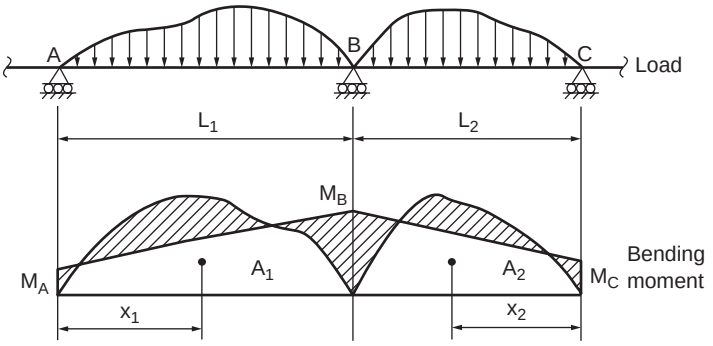

FIGURE 47.9 Continuous beams.

$$M_A \frac{L_1}{I_1} + 2M_B\left(\frac{L_1}{I_1} + \frac{L_2}{I_2}\right) + M_C \frac{L_2}{I_2} = 6\left(\frac{A_1 x_1}{L_1 I_1} + \frac{A_2 x_2}{L_2 I_2}\right) \tag{47.10}$$

in which I_1 and I_2 are the moments of inertia of the beam sections in spans L_1 and L_2, respectively.

Example 47.1

The example in Fig. 47.10 shows the application of this theorem.

For spans AC and BC

$$M_A \times 10 + 2M_C(10+10) + M_B \times 10 = 6\left[\frac{\frac{1}{2} \times 500 \times 10 \times 5}{10} + \frac{\frac{1}{2} \times 250 \times 10 \times 5}{10}\right]$$

Since the support at A is simply supported, $M_A = 0$. Therefore,

$$4M_C + M_B = 1250 \tag{47.11}$$

Considering an imaginary span BD on the right side of B and applying the theorem for spans CB and BD

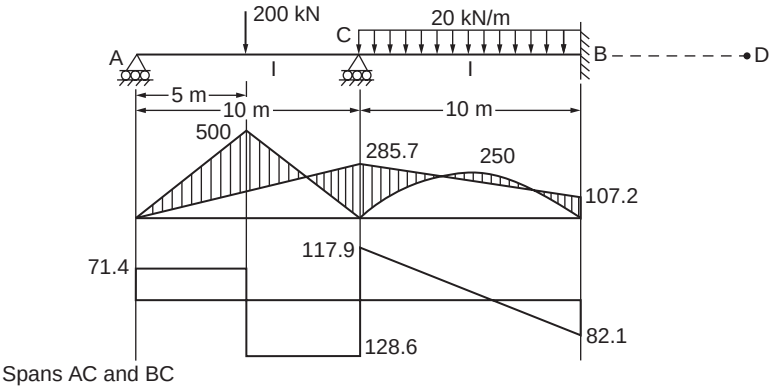

FIGURE 47.10 Example of a continuous beam.

$$M_C \times 10 + 2M_B(10) + M_D \times 10 = 6 \times \frac{\frac{2}{3} \times 10 \times 5}{10} \times 2$$
$$M_C + 2M_B = 500 \qquad (\because M_C - M_D) \tag{47.12}$$

Solving Eqs. (47.11) and (47.12) we get

$$M_B = 107.2 \text{ kNm}$$

$$M_C = 285.7 \text{ kNm}$$

Shear force at A is

$$S_A = \frac{M_A - M_C}{L} + 100 = -28.6 + 100 = 71.4\,\text{kN}$$

Shear force at C is

$$S_C = \left(\frac{M_C - M_A}{L} + 100\right) + \left(\frac{M_C - M_B}{L} + 100\right)$$
$$= (28.6 + 100) + (17.9 + 100) = 246.5\,\text{kN}$$

Shear force at B is

$$S_B = \left(\frac{M_B - M_C}{L} + 100\right)$$
$$= -17.9 + 100 = 82.1\,\text{kN}$$

The bending moment and shear force diagrams are shown in Fig. 47.10.

Beam Deflection

There are several methods for determining beam deflections: (1) moment area method, (2) conjugate beam method, (3) virtual work, and (4) Castigliano's second theorem, among others.

The elastic curve of a member is the shape the neutral axis takes when the member deflects under load. The inverse of the radius of curvature at any point of this curve is obtained as

$$\frac{1}{R} = \frac{M}{EI} \tag{47.13}$$

in which M is the bending moment at the point and EI the flexural rigidity of the beam section. Since the deflection is small, 1/R is approximately taken as d^2y/dx^2, and Eq. (47.13) may be rewritten as:

$$M = EI \frac{d^2y}{dx^2} \tag{47.14}$$

In Eq. (47.14), y is the deflection of the beam at distance x measured from the origin of coordinate. The change in slope in a distance dx can be expressed as M dx/EI, and hence the slope in a beam is obtained as

$$\theta_B - \theta_A = \int_A^B \frac{M}{EI} dx \tag{47.15}$$

Equation (47.15) may be stated: the change in slope between the tangents to the elastic curve at two points is equal to the area of the M/EI diagram between the two points.

Once the change in slope between tangents to the elastic curve is determined, the deflection can be obtained by integrating further the slope equation. In a distance dx the neutral axis changes in direction by an amount $d\theta$. The deflection of one point on the beam with respect to the tangent at another point due to this angle change is equal to $d\delta = x\, d\theta$, where x is the distance from the point at which deflection is desired to the particular differential distance.

To determine the total deflection from the tangent at one point, A, to the tangent at another point, B, on the beam, it is necessary to obtain a summation of the products of each $d\theta$ angle (from A to B) times the distance to the point where deflection is desired, or

$$\delta_B - \delta_A = \int_A^B \frac{Mx\, dx}{EI} \tag{47.16}$$

The deflection of a tangent to the elastic curve of a beam with respect to a tangent at another point is equal to the moment of M/EI diagram between the two points, taken about the point at which deflection is desired.

Moment Area Method

The moment area method is most conveniently used for determining slopes and deflections for beams in which the direction of the tangent to the elastic curve at one or more points is known, such as cantilever beams, where the tangent at the fixed end does not change in slope. The method is applied easily to beams loaded with concentrated loads, because the moment diagrams consist of straight lines. These diagrams can be broken down into single triangles and rectangles. Beams supporting uniform loads or uniformly varying loads may be handled by integration. Properties of some of the shapes of M/EI diagrams that designers usually come across are given in Fig. 47.11.

It should be understood that the slopes and deflections obtained using the moment area theorems are with respect to tangents to the elastic curve at the points being considered. The theorems do not directly give the slope or deflection at a point in the beam compared to the horizontal axis (except in one or two special cases); they give the change in slope of the elastic curve from one point to another or the deflection of the tangent at one point with respect to the tangent at another point. There are some special cases in which beams are subjected to several concentrated loads or the combined action of concentrated and uniformly distributed loads. In such cases it is advisable to separate the concentrated loads and uniformly

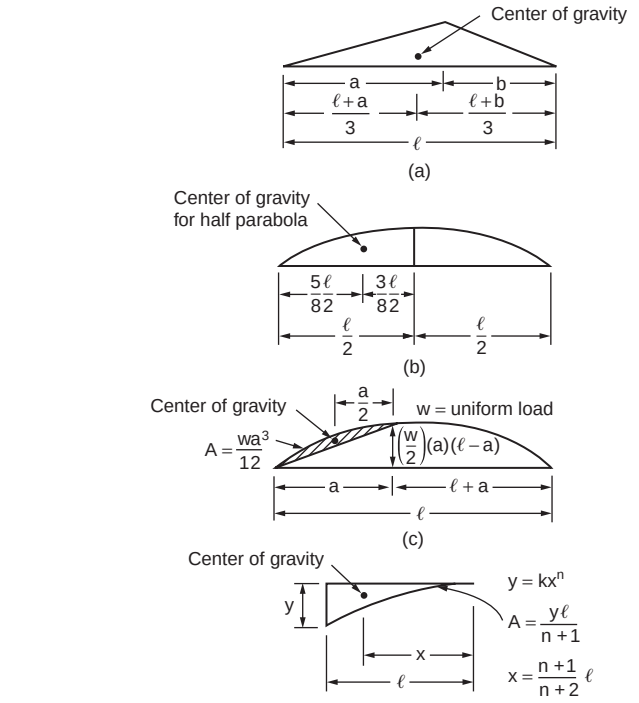

FIGURE 47.11 Typical M/EI diagram.

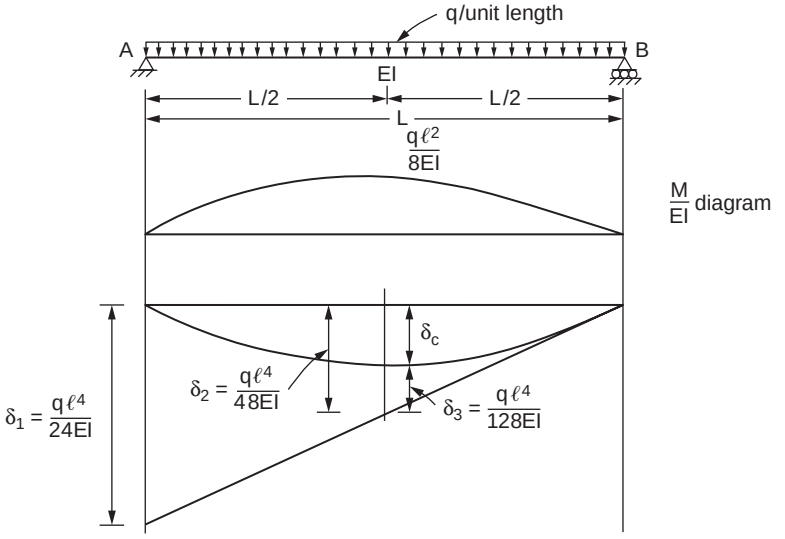

FIGURE 47.12 Deflection — simply supported beam under UDL.

distributed loads, and the moment area method can be applied separately to each of these loads. The final responses are obtained by the principle of superposition.

For example, consider a simply supported beam subjected to uniformly distributed load q, as shown in Fig. 47.12. The tangent to the elastic curve at each end of the beam is inclined. The deflection, δ_1, of the tangent at the left end from the tangent at the right end is found as $ql^4/24EI$. The distance from the original chord between the supports and the tangent at the right end, δ_2, can be computed as $ql^4/48EI$.

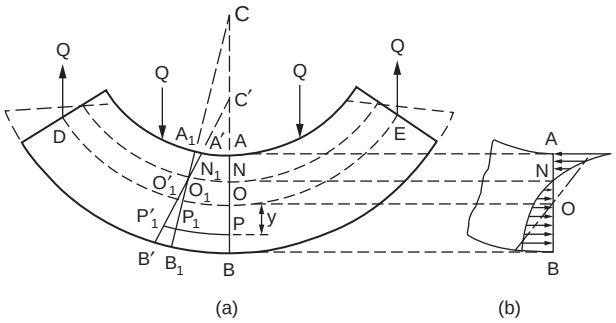

FIGURE 47.13 Bending of curved beams.

The deflection of a tangent at the center from a tangent at the right end, δ_3, is determined as $ql^4/128EI$. The difference between δ_2 and δ_3 gives the centerline deflection as (5/384) x (ql^4/EI).

Curved Beams

The beam formulas derived in the previous section are based on the assumption that the member to which bending moment is applied is initially straight. Many members, however, are curved before a bending moment is applied to them. Such members are called curved beams. In the following discussion all the conditions applicable to straight-beam formulas are assumed valid, except that the beam is initially curved.

Let the curved beam DOE shown in Fig. 47.13 be subjected to the load Q. The surface in which the fibers do not change in length is called the neutral surface. The total deformations of the fibers between two normal sections, such as AB and A_1B_1, are assumed to vary proportionally with the distances of the fibers from the neutral surface. The top fibers are compressed, while those at the bottom are stretched, i.e., the plane section before bending remains plane after bending.

In Fig. 47.13 the two lines AB and A_1B_1 are two normal sections of the beam before the loads are applied. The change in the length of any fiber between these two normal sections after bending is represented by the distance along the fiber between the lines A_1B_1 and $A'B'$; the neutral surface is represented by NN_1, and the stretch of fiber PP_1 is $P_1P'_1$, etc. For convenience, it will be assumed that line AB is a line of symmetry and does not change direction.

The total deformations of the fibers in the curved beam are proportional to the distances of the fibers from the neutral surface. However, the strains of the fibers are not proportional to these distances because the fibers are not of equal length. Within the elastic limit the stress on any fiber in the beam is proportional to the strain of the fiber, and hence the elastic stresses in the fibers of a curved beam are not proportional to the distances of the fibers from the neutral surface. The resisting moment in a curved beam, therefore, is not given by the expression $\sigma I/c$. Hence the neutral axis in a curved beam does not pass through the centroid of the section. The distribution of stress over the section and the relative position of the neutral axis are shown in Fig. 47.13b; if the beam were straight, the stress would be zero at the centroidal axis and would vary proportionally with the distance from the centroidal axis, as indicated by the dot–dash line in the figure. The stress on a normal section such as AB is called the circumferential stress.

Sign Conventions

The bending moment M is positive when it decreases the radius of curvature and negative when it increases the radius of curvature; y is positive when measured toward the convex side of the beam and negative when measured toward the concave side, that is, toward the center of curvature. With these sign conventions, σ is positive when it is a tensile stress.

Circumferential Stresses

Figure 47.14 shows a free-body diagram of the portion of the body on one side of the section; the equations of equilibrium are applied to the forces acting on this portion. The equations obtained are

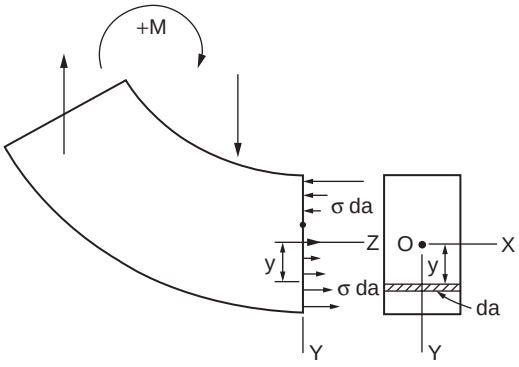

FIGURE 47.14 Free-body diagram of curved beam segment.

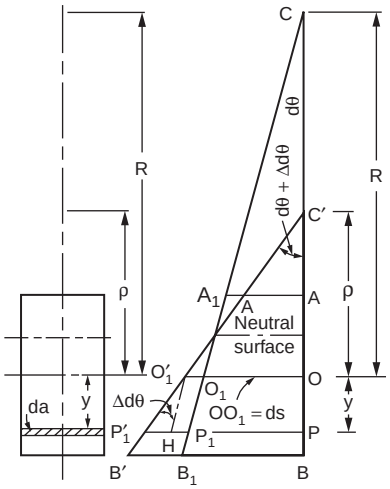

FIGURE 47.15 Curvature in a curved beam.

$$\Sigma F_z = 0 \quad \text{or} \quad \int \sigma da = 0 \tag{47.17}$$

$$\Sigma M_z = 0 \quad \text{or} \quad M = \int y\sigma da \tag{47.18}$$

Figure 47.15 represents the part ABB_1A_1 of Fig. 47.13a enlarged; the angle between the two sections AB and A_1B_1 is $d\theta$. The bending moment causes the plane A_1B_1 to rotate through an angle $\Delta d\theta$, thereby changing the angle this plane makes with the plane BAC from $d\theta$ to $(d\theta + \Delta d\theta)$; the center of curvature is changed from C to C′, and the distance of the centroidal axis from the center of curvature is changed from R to ρ. It should be noted that y, R, and ρ at any section are measured from the centroidal axis and not from the neutral axis.

It can be shown that the bending stress σ is given by the relation

$$\sigma = \frac{M}{aR}\left(1 + \frac{1}{Z}\frac{y}{R+y}\right) \tag{47.19}$$

in which

$$Z = -\frac{1}{a}\int \frac{y}{R+y}da$$

σ is the tensile or compressive (circumferential) stress at a point at distance y from the centroidal axis of a transverse section at which the bending moment is M; R is the distance from the centroidal axis of the section to the center of curvature of the central axis of the unstressed beam; a is the area of the cross-section; and Z is a property of the cross-section, the values of which can be obtained from the expressions for various areas given in Fig. 47.17. Detailed information can be obtained from Seely and Smith (1952).

Example 47.2

The bent bar shown in Fig. 47.16 is subjected to a load P = 1780 N. Calculate the circumferential stress at A and B, assuming that the elastic strength of the material is not exceeded.
We know from Eq. (47.19)

$$\sigma = \frac{P}{a} + \frac{M}{aR}\left(1 + \frac{1}{Z}\frac{y}{R+y}\right)$$

in which a = the area of rectangular section ($40 \times 12 = 480$ mm^2)
R = 40 mm
$y_A = -20$
$y_B = +20$
P = 1780 N
$M = -1780 \times 120 = -213{,}600$ N mm.

From Table 47.2.1, for rectangular section

$$Z = -1 + \frac{R}{h}\left[\log_e \frac{R+c}{R-c}\right]$$

$h = 40$ mm

$c = 20$ mm

Hence,

$$Z = -1 + \frac{40}{40}\left[\log_e \frac{40+20}{40-20}\right] = 0.0986$$

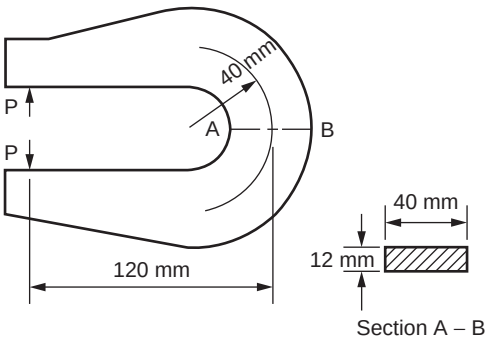

FIGURE 47.16 Bent bar.

	$Z = \frac{1}{4}\left(\frac{c}{R}\right)^2 + \frac{1}{8}\left(\frac{c}{R}\right)^4 + \frac{5}{64}\left(\frac{c}{R}\right)^6 + \frac{7}{128}\left(\frac{c}{R}\right)^8 + \cdots$ $Z = -1 + 2\left(\frac{R}{c}\right)^2 - 2\left(\frac{R}{c}\right)\sqrt{\left(\frac{R}{c}\right)^2 - 1}$
	$Z = \frac{1}{3}\left(\frac{c}{R}\right)^2 + \frac{1}{5}\left(\frac{c}{R}\right)^4 + \frac{1}{7}\left(\frac{c}{R}\right)^6 + \cdots$ $Z = -1 + \frac{R}{h}\left[\log_e\left(\frac{R + c}{R - c}\right)\right]$
	$Z = -1 + \frac{R}{ah}\left\{[b_1 h + (R + c_1)(b - b_1)]\log_e\left(\frac{R + c_1}{R - c_2}\right) - (b - b_1)h\right\}$ $Z = -1 + \frac{2R}{(b + b_1)h}\left\{\left[b_1 + \frac{b - b_1}{h}(R + c_1)\right]\log_e\left(\frac{R + c_1}{R - c_2}\right) - (b - b_1)\right\}$
	$Z = -1 + 2\frac{R}{h^2}\left[(R + c_1)\log_e\left(\frac{R + c_1}{R - c_2}\right) - h\right]$
	$Z = \frac{1}{4}\left(\frac{c}{R}\right)^2 + \frac{1}{8}\left(\frac{c}{R}\right)^4 + \frac{5}{64}\left(\frac{c}{R}\right)^6 + \frac{7}{128}\left(\frac{c}{R}\right)^8 + \cdots$ $Z = -1 + 2\left(\frac{R}{c}\right)^2 - 2\left(\frac{R}{c}\right)\sqrt{\left(\frac{R}{c}\right)^2 - 1}$

FIGURE 47.17 Analytical expressions for Z.

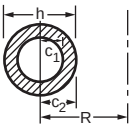
Therefore

$$\sigma_A = \frac{1780}{480} + \frac{-213600}{480 \times 40}\left(1 + \frac{1}{0.0986}\ \frac{-20}{40-20}\right) = 105.4\ \text{N/mm}^2\ \text{(tensile)}$$

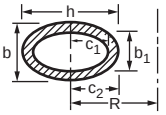
$$\sigma_B = \frac{1780}{480} + \frac{-213600}{480 \times 40}\left(1 + \frac{1}{0.0986}\ \frac{20}{40+20}\right) = -45\ \text{N/mm}^2\ \text{(compressive)}$$

47.3 Trusses

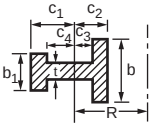
A structure that is composed of a number of members pin-connected at their ends to form a stable framework is called a truss. If all the members lie in a plane, it is a planar truss. It is generally assumed that loads and reactions are applied to the truss only at the joints. The centroidal axis of each member is straight, coincides with the line connecting the joint centers at each end of the member, and lies in a plane that also contains the lines of action of all the loads and reactions. Many truss structures are three-dimensional in nature. However, in many cases, such as bridge structures and simple roof systems, the three-dimensional framework can be subdivided into planar components for analysis as planar trusses



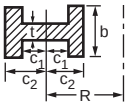
$$Z = -1 + \frac{2R}{c_2^2 - c_1^2}\left[\sqrt{R^2 - c_1^2} - \sqrt{R^2 - c_2^2}\right]$$

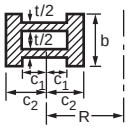


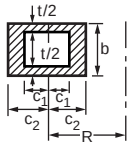
$$Z = -1 + \frac{1}{bc_2 - b_1c_1}\left\{bc_2\left[2\left(\frac{R}{c_2}\right)^2 - 2\left(\frac{R}{c_2}\right)\sqrt{\left(\frac{R}{c_2}\right)^2 - 1}\right]\right.$$
$$\left. - b_1c_1\left[2\left(\frac{R}{c_1}\right)^2 - 2\left(\frac{R}{c_1}\right)\sqrt{\left(\frac{R}{c_1}\right)^2 - 1}\right]\right\}$$



$$Z = -1 + \frac{R}{a}[b_1\log_e(R + c_1) + (t - b_1)\log_e(R + c_4)$$
$$+ (b - t)\log_e(R - c_3) - b\log_e(R - c_2)]$$





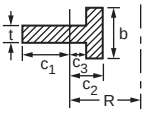


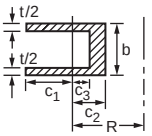
The value of Z for each of these three sections may be found from the expression above by making

$b_1 = b$, $c_2 = c_1$, and $c_3 = c_4$

$$Z = -1 + \frac{R}{a}\left[b\log_e\left(\frac{R + c_2}{R - c_2}\right) + (t - b)\log_e\left(\frac{R + c_1}{R - c_1}\right)\right]$$

$$\text{Area} = a = 2[(t - b)c_1 + bc_2]$$





In the expression for the unequal I given above make $c_4 = c_1$ and $b_1 = t$, then

$$Z = -1 + \frac{R}{a}[t\log_e(R + c_1) + (b - t)\log_e(R - c_3) - b\log_e(R - c_2)]$$

$$\text{Area} = a = tc_1 - (b - t)c_3 + bc_2$$

FIGURE 47.17 (continued).

without seriously compromising the accuracy of the results. Figure 47.18 shows some typical idealized planar truss structures.

There exists a relation between the number of members, m, the number of joints, j, and the reaction components, r. The expression is

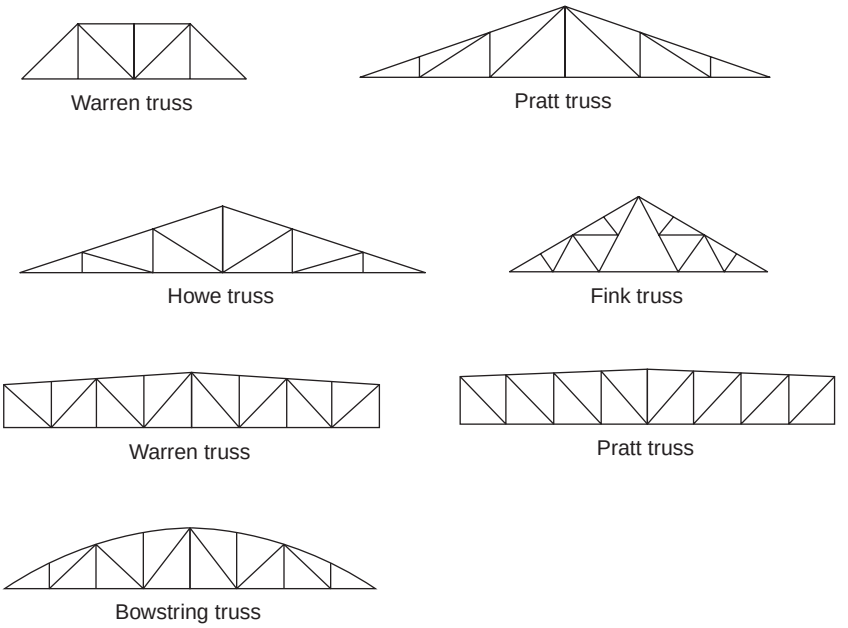


FIGURE 47.18 Typical planar trusses.

$$m = 2j - r \tag{47.20}$$

which must be satisfied if it is to be statically determinate internally. r is the least number of reaction components required for external stability. If m exceeds (2j – r), then the excess members are called redundant members, and the truss is said to be statically indeterminate.

For a statically determinate truss, member forces can be found by using the method of equilibrium. The process requires repeated use of free-body diagrams from which individual member forces are determined. The *method of joints* is a technique of truss analysis in which the member forces are determined by the sequential isolation of joints — the unknown member forces at one joint are solved and become known for the subsequent joints. The other method is known as *method of sections*, in which equilibrium of a part of the truss is considered.

Method of Joints

An imaginary section may be completely passed around a joint in a truss. The joint has become a free body in equilibrium under the forces applied to it. The equations $\Sigma H = 0$ and $\Sigma V = 0$ may be applied to the joint to determine the unknown forces in members meeting there. It is evident that no more than two unknowns can be determined at a joint with these two equations.

Example 47.3

A truss shown in Fig. 47.19 is symmetrically loaded and is sufficient to solve half the truss by considering joints 1–5. At joint 1, there are two unknown forces. Summation of the vertical components of all forces at joint 1 gives

$$135 - F_{12} \sin 45° = 0$$

which in turn gives the force in members 1 and 2, $F_{12} = 190$ kN (compressive). Similarly, summation of the horizontal components gives

$$F_{13} - F_{12} \cos 45° = 0$$

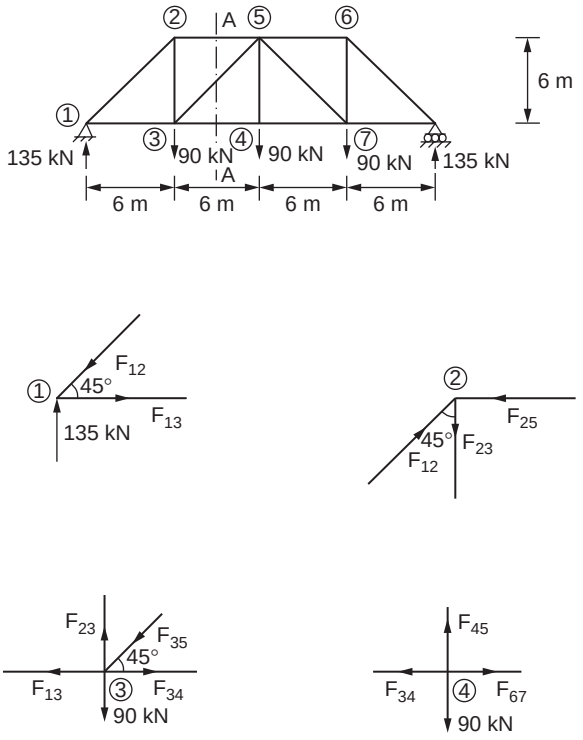

FIGURE 47.19 Example of the method of joints, planar truss.

Substituting for F_{12} gives the force in member 1–3 as

$$F_{13} = 135 \text{ kN (tensile)}$$

Now, joint 2 is cut completely, and it is found that there are two unknown forces F_{25} and F_{23}. Summation of the vertical components gives

$$F_{12} \cos 45° - F_{23} = 0$$

Therefore

$$F_{23} = 135 \text{ kN (tensile)}$$

Summation of the horizontal components gives

$$F_{12} \sin 45° - F_{25} = 0$$

and hence

$$F_{25} = 135 \text{ kN (compressive)}$$

After solving for joints 1 and 2, one proceeds to take a section around joint 3 at which there are now two unknown forces viz. F_{34} and F_{35}. Summation of the vertical components at joint 3 gives

$$F_{23} - F_{35} \sin 45° - 90 = 0$$

Substituting for F_{23}, one obtains $F_{35} = 63.6$ kN (compressive). Summing the horizontal components and substituting for F_{13} one gets

$$-135 - 45 + F_{34} = 0$$

Therefore,

$$F_{34} = 180 \text{ kN (tensile)}$$

The next joint involving two unknowns is joint 4. When we consider a section around it, the summation of the vertical components at joint 4 gives

$$F_{45} = 90 \text{ kN (tensile)}$$

Now, the forces in all the members on the left half of the truss are known, and by symmetry the forces in the remaining members can be determined. The forces in all the members of a truss can also be determined by using the method of sections.

Method of Sections

In this method, an imaginary cutting line called section is drawn through a stable and determinate truss. Thus, a section divides the truss into two separate parts. Since the entire truss is in equilibrium, any part of it must also be in equilibrium. Either of the two parts of the truss can be considered, and the three equations of equilibrium $\Sigma F_x = 0$, $\Sigma F_y = 0$, and $\Sigma M = 0$ can be applied to solve for member forces.

Example 47.3 above (Fig. 47.20) is once again considered. To calculate the force in members 3–5, F_{35}, section AA should be run to cut members 3–5 as shown in the figure. It is required only to consider the equilibrium of one of the two parts of the truss. In this case, the portion of the truss on the left of the section is considered. The left portion of the truss as shown in Fig. 47.20 is in equilibrium under the action of the forces viz. the external and internal forces. Considering the equilibrium of forces in the vertical direction, one can obtain

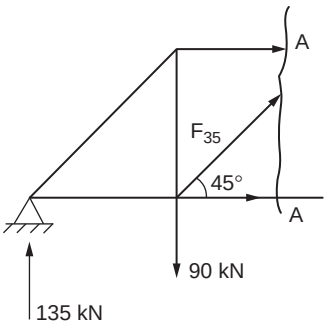

FIGURE 47.20 Example of the method of sections, planar truss.

$$135 - 90 + F_{35} \sin 45^\circ = 0$$

Therefore, F_{35} is obtained as

$$F_{35} = -45\sqrt{2} \text{ kN}$$

The negative sign indicates that the member force is compressive. The other member forces cut by the section can be obtained by considering the other equilibrium equations viz. $\Sigma M = 0$. More sections can be taken in the same way to solve for other member forces in the truss. The most important advantage of this method is that one can obtain the required member force without solving for the other member forces.

Compound Trusses

A compound truss is formed by interconnecting two or more simple trusses. Examples of compound trusses are shown in Fig. 47.21. A typical compound roof truss is shown in Fig. 47.21a in which two simple trusses are interconnected by means of a single member and a common joint. The compound truss shown in Fig. 47.21b is commonly used in bridge construction, and in this case, three members are used to interconnect two simple trusses at a common joint. There are three simple trusses interconnected at their common joints, as shown in Fig. 47.21c.

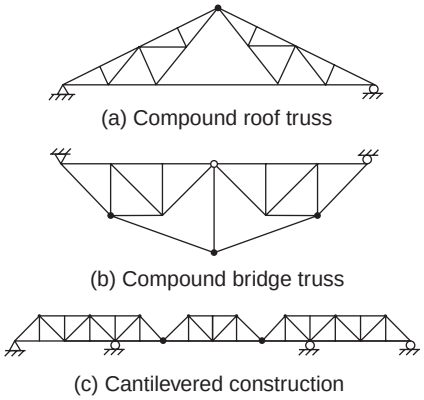

FIGURE 47.21 Compound truss.

The method of sections may be used to determine the member forces in the interconnecting members of compound trusses, similar to those shown in Fig. 47.21a and b. However, in the case of a cantilevered truss the middle simple truss is isolated as a free-body diagram to find its reactions. These reactions are reversed and applied to the interconnecting joints of the other two simple trusses. After the interconnecting forces between the simple trusses are found, the simple trusses are analyzed by the method of joints or the method of sections.

47.4 Frames

Frames are statically indeterminate in general; special methods are required for their analysis. Slope deflection and moment distribution methods are two such methods commonly employed. Slope deflection is a method that takes into account the flexural displacements such as rotations and deflections and involves solutions of simultaneous equations. Moment distribution, on the other hand, involves successive cycles of computation, each cycle drawing closer to the "exact" answers. The method is more labor intensive but yields accuracy equivalent to that obtained from the "exact" methods.

Slope Deflection Method

This method is a special case of the stiffness method of analysis. It is a convenient method for performing hand analysis of small structures.

Let us consider a prismatic frame member AB with undeformed position along the x axis deformed into configuration p, as shown in Fig. 47.22. Moments at the ends of frame members are expressed in terms of the rotations and deflections of the joints. It is assumed that the joints in a structure may rotate or deflect, but the angles between the members meeting at a joint remain unchanged. The positive axes, along with the positive member-end force components and displacement components, are shown in the figure.

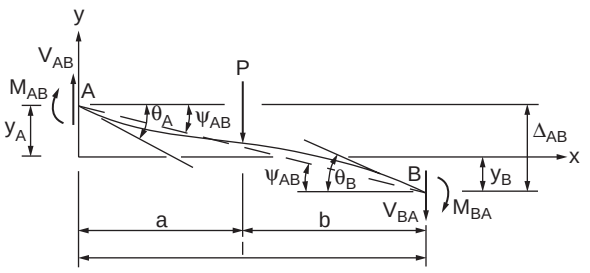

FIGURE 47.22 Deformed configuration of a beam.

The equations for end moments may be written as

$$M_{AB} = \frac{2EI}{\ell}\left(2\theta_A + \theta_B - 3\psi_{AB}\right) + M_{FAB}$$
$$M_{BA} = \frac{2EI}{\ell}\left(2\theta_B + \theta_A - 3\psi_{AB}\right) + M_{FBA} \tag{47.21}$$

in which M_{FAB} and M_{FBA} are fixed-end moments at supports A and B, respectively, due to the applied load. ψ_{AB} is the rotation as a result of the relative displacement between member ends A and B given as

$$\psi_{AB} = \frac{\Delta_{AB}}{1} = \frac{y_A + y_B}{1} \tag{47.22}$$

where Δ_{AB} is the relative deflection of the beam ends. y_A and y_B are the vertical displacements at ends A and B. Fixed-end moments for some loading cases may be obtained from Fig. 47.8. The slope deflection equations in Eq. (47.21) show that the moment at the end of a member is dependent on member properties EI, length l, and displacement quantities. The fixed-end moments reflect the transverse loading on the member.

Frame Analysis Using Slope Deflection Method

The slope deflection equations may be applied to statically indeterminate frames with or without side sway. A frame may be subjected to side sway if the loads, member properties, and dimensions of the frame are not symmetrical about the centerline. Application of the slope deflection method can be illustrated with the following example.

Example 47.4

Consider the frame shown in Fig. 47.23 subjected to side sway Δ to the right of the frame. Equation (47.21) can be applied to each of the members of the frame as follows:

Member AB:

$$M_{AB} = \frac{2EI}{6}\left(2\theta_A + \theta_B - \frac{3\Delta}{20}\right) + M_{FAB}$$
$$M_{BA} = \frac{2EI}{20}\left(2\theta_B + \theta_A - \frac{3\Delta}{20}\right) + M_{FBA}$$

$\theta_A = 0$, $\quad M_{FAB} = M_{FBA} = 0$

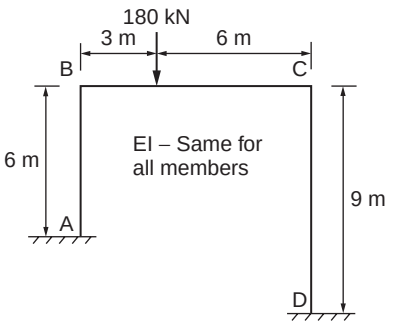

FIGURE 47.23 Example of the slope deflection method.

Hence

$$M_{AB} = \frac{2EI}{6}\left(\theta_B - 3\psi\right) \tag{47.23}$$

$$M_{BA} = \frac{2EI}{20}\left(2\theta_B - 3\psi\right) \tag{47.24}$$

in which

$$\psi = \frac{\Delta}{6}$$

Member BC:

$$M_{BC} = \frac{2EI}{9}\left(2\theta_B + \theta_C - 3 \times 0\right) + M_{FBC}$$

$$M_{CB} = \frac{2EI}{9}\left(2\theta_C + \theta_B - 3 \times 0\right) + M_{FCB}$$

$$M_{FBC} = -\frac{180 \times 3 \times 6^2}{9^2} = -240 \text{ ft-kips}$$

$$M_{FCB} = -\frac{180 \times 3^2 \times 6}{9^2} = 120 \text{ ft-kips}$$

Hence

$$M_{BC} = \frac{2EI}{9}\left(2\theta_B + \theta_C\right) - 240 \tag{47.25}$$

$$M_{CB} = \frac{2EI}{9}\left(2\theta_C + \theta_B\right) + 89 \tag{47.26}$$

Member CD:

$$M_{CD} = \frac{2EI}{9}\left(2\theta_C + \theta_D - \frac{3\Delta}{30}\right) + M_{FCD}$$

$$M_{DC} = \frac{2EI}{9}\left(2\theta_D + \theta_C - \frac{3\Delta}{30}\right) + M_{FDC}$$

$\theta_D = 0$, $\quad M_{FCD} = M_{FDC} = 0$

Hence

$$M_{CD} = \frac{2EI}{9}\left(2\theta_C - \frac{1}{3} \times 6\psi\right) = \frac{2EI}{9}\left(2\theta_C - 2\psi\right) \tag{47.27}$$

$$M_{DC} = \frac{2EI}{9}\left(\theta_C - \frac{1}{3} \times 6\psi\right) = \frac{2EI}{9}\left(\theta_C - 2\psi\right) \tag{47.28}$$

Considering moment equilibrium at joint B

$$\Sigma M_B = M_{BA} + M_{BC} = 0$$

Substituting for M_{BA} and M_{BC}, one obtains

$$\frac{EI}{9}\left(10\theta_B + 2\theta_C - 9\psi\right) = 240$$

or

$$110\theta_B + 2\theta_C - 9\psi = \frac{2160}{EI} \tag{47.29}$$

Considering moment equilibrium at joint C

$$\Sigma M_C = M_{CB} + M_{CD} = 0$$

Substituting for M_{CB} and M_{CD} we get

$$\frac{2EI}{9}\left(4\theta_C + \theta_B - 2\psi\right) = -120$$

or

$$\theta_B + 4\theta_C - 2\psi = -\frac{540}{EI} \tag{47.30}$$

For summation of base shears equal to zero, we have

$$\Sigma H = H_A + H_D = 0$$

or

$$\frac{M_{AB} + M_{BA}}{6} + \frac{M_{CD} + M_{DC}}{9} = 0$$

Substituting for M_{AB}, M_{BA}, M_{CD}, and M_{DC} and simplifying

$$2\theta_B + 12\theta_C - 70\psi = 0 \tag{47.31}$$

Solution of Eqs. (47.29) to (47.31) results in

$$\theta_B = \frac{342.7}{EI}$$

$$\theta_C = \frac{-169.1}{EI}$$

and

$$\psi = \frac{103.2}{EI} \tag{47.32}$$

Substituting for θ_B, θ_C, and ψ from Eq. (47.32) into Eqs. (47.23) to (47.28) we get

$$M_{AB} = 11.03 \text{ kNm}$$

$$M_{BA} = 125.3 \text{ kNm}$$

$$M_{BC} = -125.3 \text{ kNm}$$

$$M_{CB} = 121 \text{ kNm}$$

$$M_{CD} = -121 \text{ kNm}$$

$$M_{DC} = -83 \text{ kNm}$$

Moment Distribution Method

The moment distribution method involves successive cycles of computation, each cycle drawing closer to the "exact" answers. The calculations may be stopped after two or three cycles, giving a very good approximate analysis, or they may be carried out to whatever degree of accuracy is desired. Moment distribution remains the most important hand-calculation method for the analysis of continuous beams and frames, and it may be solely used for the analysis of small structures. Unlike the slope deflection method, this method does require the solution to simultaneous equations.

The terms constantly used in moment distribution are fixed-end moments, the unbalanced moment, distributed moments, and carryover moments. When all of the joints of a structure are clamped to prevent any joint rotation, the external loads produce certain moments at the ends of the members to which they are applied. These moments are referred to as *fixed-end moments*. Initially the joints in a structure are considered to be clamped. When the joint is released, it rotates if the sum of the fixed-end moments at the joint is not zero. The difference between zero and the actual sum of the end moments is the *unbalanced moment*. The unbalanced moment causes the joint to rotate. The rotation twists the ends of the members at the joint and changes their moments. In other words, rotation of the joint is resisted by the members, and resisting moments are built up in the members as they are twisted. Rotation continues until equilibrium is reached — when the resisting moments equal the unbalanced moment — at which time the sum of the moments at the joint is equal to zero. The moments developed in the members resisting rotation are the *distributed moments*. The distributed moments in the ends of the member cause moments in the other ends, which are assumed fixed; these are the *carryover moments*.

Sign Convention

The moments at the end of a member are assumed to be positive when they tend to rotate the member clockwise about the joint. This implies that the resisting moment of the joint would be counterclockwise. Accordingly, under a gravity loading condition the fixed-end moment at the left end is assumed as counterclockwise (–ve) and at the right end as clockwise (+ve).

Fixed-End Moments

Fixed-end moments for several cases of loading may be found in Fig. 47.8. Application of moment distribution may be explained with reference to a continuous beam example, as shown in Fig. 47.24. Fixed-end moments are computed for each of the three spans. At joint B the unbalanced moment is obtained and the clamp is removed. The joint rotates, thus distributing the unbalanced moment to the B ends of spans BA and BC in proportion to their distribution factors. The values of these distributed moments are carried over at one half rate to the other ends of the members. When equilibrium is reached,

		0.6	0.4		0.45	0.55	
–50	50	–150		150	–104		104
	60		40	–20.7	–25.3		
30		–10.4		20			–12.7
	+6.2		+4.2	–9.0	–11.0		
3.1		–4.5		2.1			–5.5
	+2.7		+1.8	–0.9	–1.2		
1.4		–0.5		0.9			–0.6
	+0.3		+0.2	–0.4	–0.5		
–15.5	119.2	–119.2		+142	–142		85.2

FIGURE 47.24 Example of a continuous beam by moment distribution.

joint B is clamped in its new rotated position and joint C is released afterwards. Joint C rotates under its unbalanced moment until it reaches equilibrium, the rotation causing distributed moments in the C ends of members CB and CD and their resulting carryover moments. Joint C is now clamped and joint B is released. This procedure is repeated again and again for joints B and C, the amount of unbalanced moment quickly diminishing, until the release of a joint causes negligible rotation. This process is called moment distribution.

The stiffness factors and distribution factors are computed as follows:

$$DF_{BA} = \frac{K_{BA}}{\sum K} = \frac{I/20}{I/20 + I/30} = 0.6$$

$$DF_{BC} = \frac{K_{BC}}{\sum K} = \frac{I/30}{I/20 + I/30} = 0.4$$

$$DF_{CB} = \frac{K_{CB}}{\sum K} = \frac{I/30}{I/30 + I/25} = 0.45$$

$$DF_{CD} = \frac{K_{CD}}{\sum K} = \frac{I/25}{II/30 + I/25} = 0.55$$

The fixed-end moments are

$$M_{FAB} = -50; \quad M_{FBC} = -150; \quad M_{FCD} = -104$$
$$M_{FBA} = 50; \quad M_{FCB} = 150; \quad M_{FDC} = 104$$

When a clockwise couple is applied near the end of a beam, a clockwise couple of half the magnitude is set up at the far end of the beam. The ratio of the moments at the far and near ends is defined as the *carryover factor,* 0.5 in the case of a straight prismatic member. The carryover factor was developed for carrying over to fixed ends, but it is applicable to simply supported ends, which must have final moments of zero. It can be shown that the beam simply supported at the far end is only three fourths as stiff as the one that is fixed. If the stiffness factors for end spans that are simply supported are modified by three fourths, the simple end is initially balanced to zero and no carryovers are made to the end afterward. This simplifies the moment distribution process significantly.

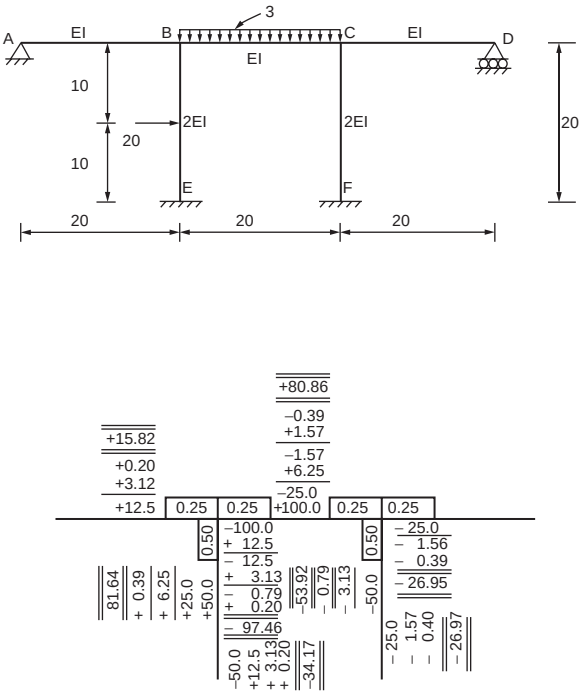

FIGURE 47.25 Example of a nonsway frame by moment distribution.

Moment Distribution for Frames

Moment distribution for frames without side sway is similar to that for continuous beams. The example shown in Fig. 47.25 illustrates the applications of moment distribution for a frame without side sway.

$$DF_{BA} = \frac{EI/20}{\frac{EI}{20} + \frac{EI}{20} + \frac{2EI}{20}} = 0.25$$

Similarly,

$$DF_{BE} = 0.5; \qquad DF_{BC} = 0.25$$
$$M_{FBC} = 0100; \qquad M_{FCB} = 100$$
$$M_{FBE} = 50; \qquad M_{FEB} = -50$$

Structural frames are usually subjected to side sway in one direction or the other, due to asymmetry of the structure and eccentricity of loading. The sway deflections affect the moments, resulting in an unbalanced moment. These moments could be obtained for the deflections computed and added to the originally distributed fixed-end moments. The sway moments are distributed to columns. Should a frame have columns all of the same length and the same stiffness, the side sway moments will be the same for each column. However, should the columns have differing lengths or stiffnesses, this will not be the case. The side sway moments should vary from column to column in proportion to their I/l^2 values.

The frame in Fig. 47.26 shows a frame subjected to sway. The process of obtaining the final moments is illustrated for this frame.

The frame sways to the right, and the side sway moment can be assumed in the ratio

$$\frac{400}{20^2} : \frac{300}{20^2} \quad \text{(or)} \quad 1 : 0.75$$

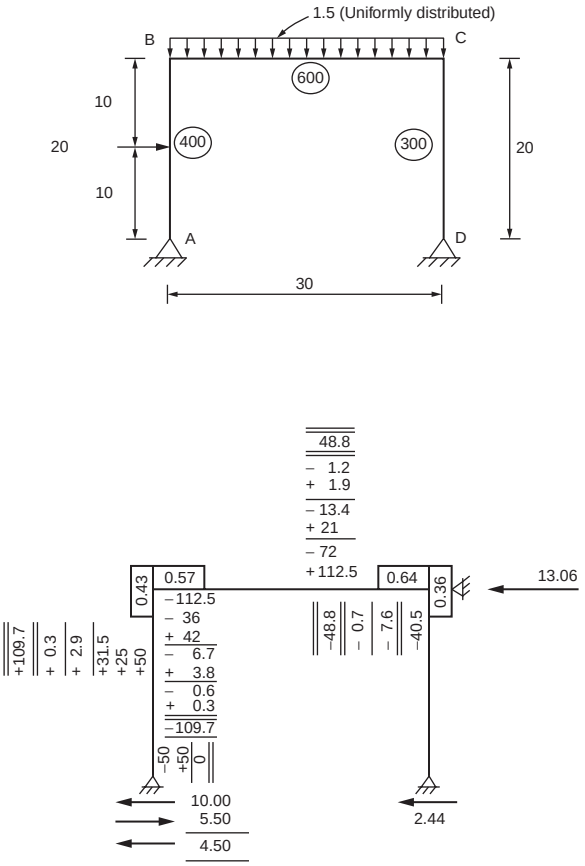

FIGURE 47.26 Example of a sway frame by moment distribution.

Final moments are obtained by adding distributed fixed-end moments and 13.06/2.99 times the distributed assumed side sway moments.

Method of Consistent Deformations

This method makes use of the principle of deformation compatibility to analyze indeterminate structures. It employs equations that relate the forces acting on the structure to the deformations of the structure. These relations are formed so that the deformations are expressed in terms of the forces, and the forces become the unknowns in the analysis.

Let us consider the beam shown in Fig. 47.27a. The first step, in this method, is to determine the degree of indeterminacy or the number of redundants that the structure possesses. As shown in the figure, the beam has three unknown reactions, R_A, R_C, and M_A. Since there are only two equations of equilibrium available for calculating the reactions, the beam is said to be indeterminate to the first degree. Restraints that can be removed without impairing the load-supporting capacity of the structure are referred to as *redundants*.

Once the number of redundants are known, the next step is to decide which reaction is to be removed in order to form a determinate structure. Any one of the reactions may be chosen to be the redundant, provided that a stable structure remains after the removal of that reaction. For example, let us take the reaction R_C as the redundant. The determinate structure obtained by removing this restraint is the cantilever beam shown in Fig. 47.27b. We denote the deflection at end C of this beam, due to P, by Δ_{CP}. The first subscript indicates that the deflection is measured at C, and the second subscript indicates that

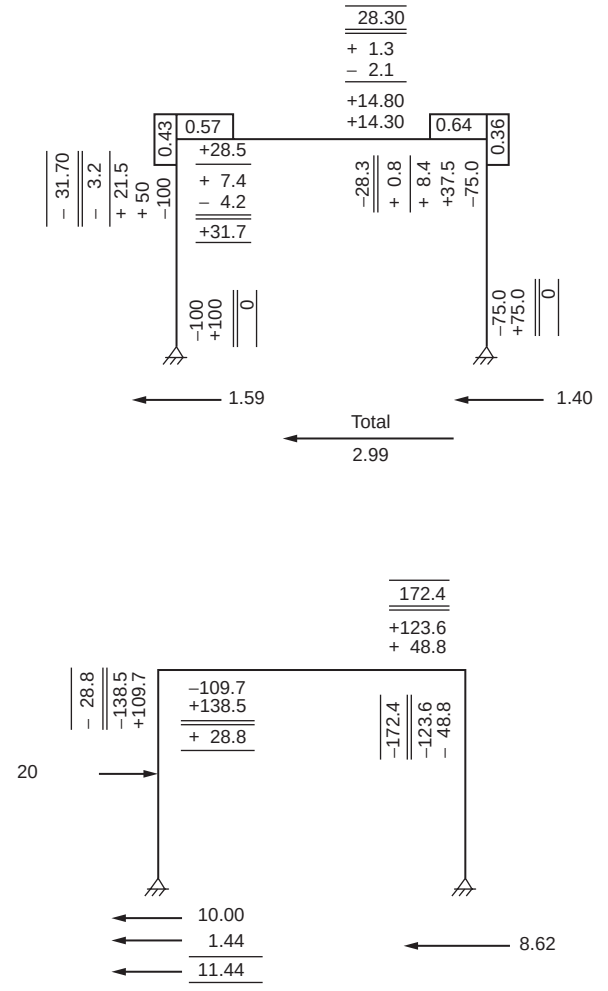

FIGURE 47.26 (continued).

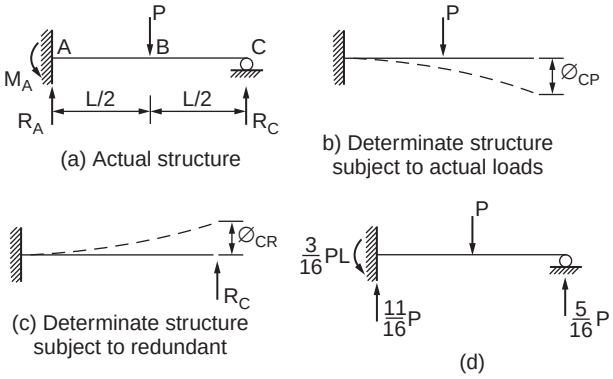

FIGURE 47.27 Beam with one redundant reaction.

the deflection is due to the applied load P. Using the moment area method, it can be shown that $\Delta_{CP} = 5PL^3/48EI$. The redundant R_C is then applied to the determinate cantilever beam, as shown in Fig. 47.27c. This gives rise to a deflection Δ_{CR} at point C, the magnitude of which can be shown to be $R_CL^3/3EI$.

In the actual indeterminate structure, which is subjected to the combined effects of the load P and the redundant R_C, the deflection at C is zero. Hence the algebraic sum of the deflection Δ_{CP} in Fig. 47.27b and the deflection Δ_{CR} in Fig. 47.27c must vanish. Assuming downward deflections to be positive, we write

$$\Delta_{CP} - \Delta_{CR} = 0 \tag{47.33}$$

or

$$\frac{5PL^3}{48EI} - \frac{R_C L^3}{3EI} = 0$$

from which

$$R_C = \frac{5}{16}P$$

Equation (47.33), which is used to solve for the redundant, is referred to as an equation of consistent deformations.

Once the redundant R_C has been evaluated, the remaining reactions can be determined by applying the equations of equilibrium to the structure in Fig. 47.27a. Thus $\Sigma F_y = 0$ leads to

$$R_A = P - \frac{5}{16}P = \frac{11}{16}P$$

and $\Sigma M_A = 0$ gives

$$M_A = \frac{PL}{2} - \frac{5}{16}PL = \frac{3}{16}PL$$

A free body of the beam, showing all the forces acting on it, is shown in Fig. 47.27d.

The steps involved in the method of consistent deformations follow:

1. The number of redundants in the structure are determined.
2. Enough redundants to form a determinate structure are removed.
3. The displacements that the applied loads cause in the determinate structure at the points where the redundants have been removed are calculated.
4. The displacements at these points in the determinate structure, due to the redundants, are obtained.
5. At each point where a redundant has been removed, the sum of the displacements calculated in steps 3 and 4 must be equal to the displacement that exists at that point in the actual indeterminate structure. The redundants are evaluated using these relationships.
6. Once the redundants are known, the remaining reactions are determined using the equations of equilibrium.

Structures with Several Redundants

The method of consistent deformations can be applied to structures with two or more redundants. For example, the beam in Fig. 47.28a is indeterminate to the second degree and has two redundant reactions. If the reactions at B and C are selected to be the redundants, then the determinate structure obtained by removing these supports is the cantilever beam, shown in Fig. 47.28b. To this determinate structure we apply separately the given load (Fig. 47.28c) and the redundants R_B and R_C, one at a time (Fig. 47.28d and e).

Since the deflections at B and C in the original beam are zero, the algebraic sum of the deflections in Fig. 47.28c, d, and e at these same points must also vanish. Thus

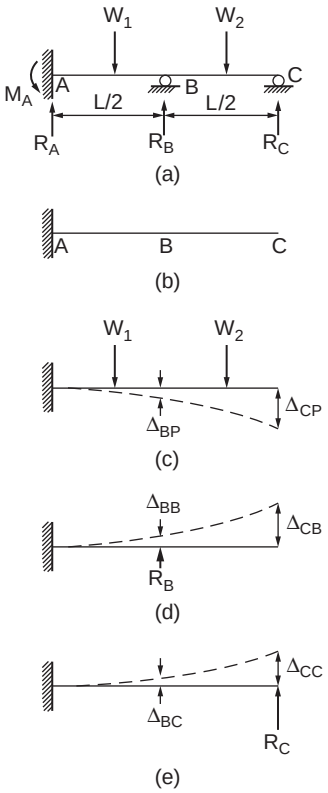

FIGURE 47.28 Beam with two redundant reactions.

$$\Delta_{BP} - \Delta_{BB} - \Delta_{BC} = 0$$
$$\Delta_{CP} - \Delta_{CB} - \Delta_{CC} = 0 \tag{47.34}$$

It is useful in the case of complex structures to write the equations of consistent deformations in the form

$$\Delta_{BP} - \delta_{BB}R_B - \delta_{BC}R_C = 0$$
$$\Delta_{CP} - \delta_{CB}R_B - \delta_{CC}R_C = 0 \tag{47.35}$$

in which δ_{BC}, for example, denotes the deflection at B due to a unit load at C in the direction of R_C. Solution of Eq. (47.35) gives the redundant reactions R_B and R_C.

Example 47.5

Determine the reactions for the beam shown in Fig. 47.29, and draw its shear force and bending moment diagrams.

It can be seen from the figure that there are three reactions viz. M_A, R_A, and R_C, one more than that required for a stable structure. The reaction R_C can be removed to make the structure determinate. We know that the deflection at support C of the beam is zero. One can determine the deflection δ_{CP} at C due to the applied load on the cantilever in Fig. 47.29b. In the same way the deflection δ_{CR} at C due to the redundant reaction on the cantilever (Fig. 47.29c) can be determined. The compatibility equation gives

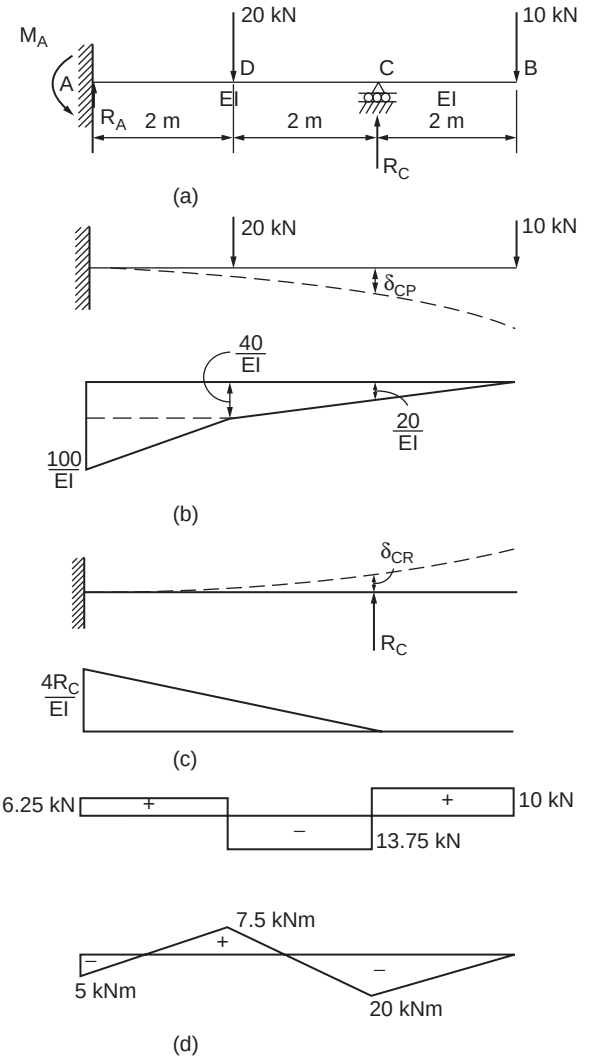

FIGURE 47.29 Example 47.5.

$$\delta_{CP} - \delta_{CR} = 0$$

By moment area method,

$$\delta_{CP} = \frac{20}{EI} \times 2 \times 1 + \frac{1}{2} \times \frac{20}{EI} \times 2 \times \frac{2}{3} \times 2 + \frac{40}{EI} \times 2 \times 3 + \frac{1}{2} \times \frac{60}{EI} \times 2 \times \left(\frac{2}{3} \times 2 + 2 \right) = \frac{1520}{3EI}$$

$$\delta_{CR} = \frac{1}{2} \times \frac{4R_C}{EI} \times 4 \times \frac{2}{3} \times 4 = \frac{64R_C}{3EI}$$

Substituting for δ_{CP} and δ_{CR} in the compatibility equation, one obtains,

$$\frac{1520}{3EI} - \frac{64R_C}{3EI} = 0$$

from which

$$R_C = 23.75 \text{ kN}\uparrow$$

By using statical equilibrium equations we get

$$R_A = 6.25 \text{ kN}\uparrow$$

and $M_A = 5$ kNm.

The shear force and bending moment diagrams are shown in Fig. 47.29d.

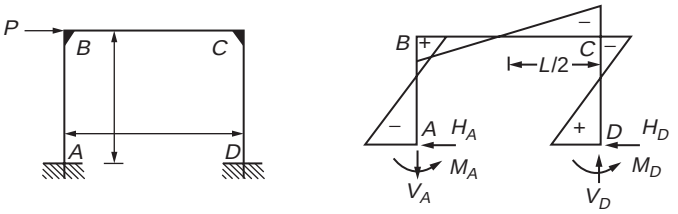
47.5 Plates

Bending of Thin Plates

A plate in which its thickness is small compared to the other dimensions is called a thin plate. The plane parallel to the faces of the plate and bisecting the thickness of the plate, in the undeformed state, is called the middle plane of the plate. When the deflection of the middle plane is small compared with the thickness, h, it can be assumed that

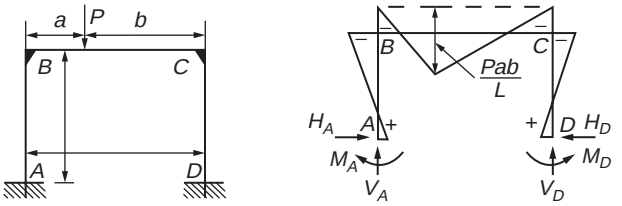
1. There is no deformation in the middle plane.
2. The normals of the middle plane before bending are deformed into the normals of the middle plane after bending.
3. The normal stresses in the direction transverse to the plate can be neglected.



$$M_A = -\frac{Ph}{2}\cdot\frac{3\alpha+1}{\beta_2} \qquad M_B = +\frac{Ph}{2}\cdot\frac{3\alpha}{\beta_2}$$

$$M_D = +\frac{Ph}{2}\cdot\frac{3\alpha+1}{\beta_2} \qquad M_C = -\frac{Ph}{2}\cdot\frac{3\alpha}{\beta_2}$$

$$H_A = -H_D = -\frac{P}{2} \qquad V_A = -V_D = -\frac{2M_B}{L}$$



$$M_A = \frac{Pab}{L}\left[\frac{1}{2\beta_1} - \frac{b-a}{2L\beta_2}\right] \qquad M_B = -\frac{Pab}{L}\left[\frac{1}{\beta_1} + \frac{b-a}{2L\beta_2}\right]$$

$$M_C = -\frac{Pab}{L}\left[\frac{1}{\beta_1} - \frac{b-a}{2L\beta_2}\right] \qquad M_D = \frac{Pab}{L}\left[\frac{1}{2\beta_1} + \frac{b-a}{2L\beta_2}\right]$$

$$V_A = \frac{Pb}{L}\left[1 + \frac{a(b-a)}{L^2\beta_2}\right] \qquad V_D = P - V_A$$

$$H_A = H_D = \frac{3Pab}{2Lh\beta_1}$$

FIGURE 47.30 (continued).

Based on these assumptions, all stress components can be expressed by deflection w of the plate. w is a function of the two coordinates (x, y) in the plane of the plate. This function has to satisfy a linear partial differential equation, which, together with the boundary conditions, completely defines w.

Figure 47.32a shows a plate element cut from a plate whose middle plane coincides with the xy plane. The middle plane of the plate subjected to a lateral load of intensity, q, is shown in Fig. 47.32b. It can be shown, by considering the equilibrium of the plate element, that the stress resultants are given as

$$M_X = -D\left(\frac{\partial^2 w}{\partial x^2} + \nu\frac{\partial^2 w}{\partial y^2}\right)$$

$$M_Y = -D\left(\frac{\partial^2 w}{\partial y^2} + \nu\frac{\partial^2 w}{\partial x^2}\right) \qquad (47.36)$$

FIGURE 47.31 (continued).

The governing equation for the plate is obtained as

$$\frac{\partial^4 w}{\partial x^4} + 2\frac{\partial^4 w}{\partial x^2 \partial y^2} + \frac{\partial^4 w}{\partial y^4} = \frac{q}{D} \tag{47.41}$$

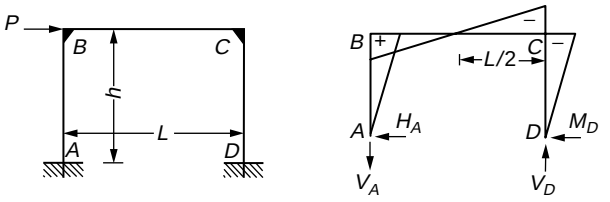
Any plate problem should satisfy the governing Eq. (47.41) and boundary conditions of the plate.

Boundary Conditions

There are three basic boundary conditions for plates. These are the clamped edge, simply supported edge, and free edge.

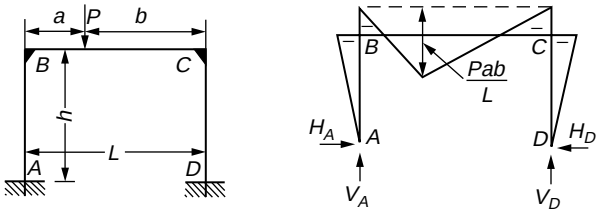
Clamped Edge

For this boundary condition, the edge is restrained such that the deflection and slope are zero along the edge. If we consider the edge x = a to be clamped, we have



$$M_B = -M_C = +\frac{Ph}{2}$$

$$V_A = -V_D = -\frac{Ph}{L} \qquad H_A = -H_D = -\frac{P}{2}$$



$$M_B = M_C = -\frac{Pab}{L} \cdot \frac{3}{2b}$$

$$V_A = \frac{Pb}{L} \qquad V_D = \frac{Pa}{L} \qquad H_A = H_D = -\frac{M_B}{h}$$

FIGURE 47.31 (continued).

$$\left(w\right)_{x=a} = 0; \quad \left(\frac{\partial w}{\partial x}\right)_{x=a} = 0 \tag{47.42}$$

Simply Supported Edge

If the edge x = a of the plate is simply supported, the deflection w along this edge must be zero. At the same time this edge can rotate freely with respect to the edge line. This means that

$$\left(w\right)_{x=a} = 0; \quad \left(\frac{\partial^2 w}{\partial x^2}\right)_{x=a} = 0 \tag{47.43}$$

Free Edge

If the edge x = a of the plate is entirely free, there are no bending and twisting moments and also vertical shearing forces. This can be written in terms of w, the deflection, as

$$\left(\frac{\partial^2 w}{\partial x^2} + \nu\frac{\partial^2 w}{\partial y^2}\right)_{x=a} = 0$$

$$\left(\frac{\partial^3 w}{\partial x^3} + (2-\nu)\frac{\partial^3 w}{\partial x\,\partial y^2}\right)_{x=a} = 0 \tag{47.44}$$

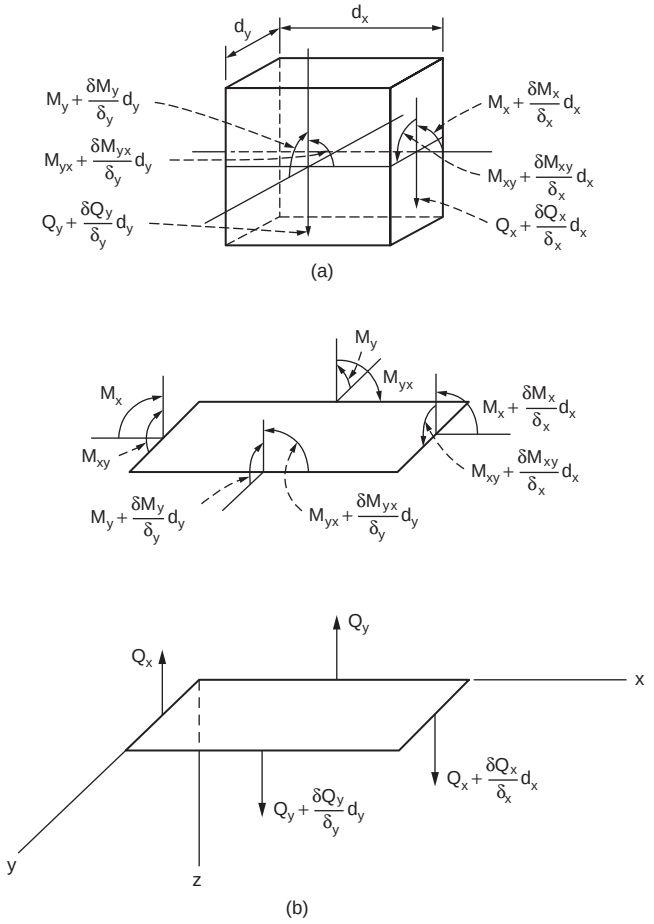


FIGURE 47.32 (a) Plate element. (b) Stress resultants.

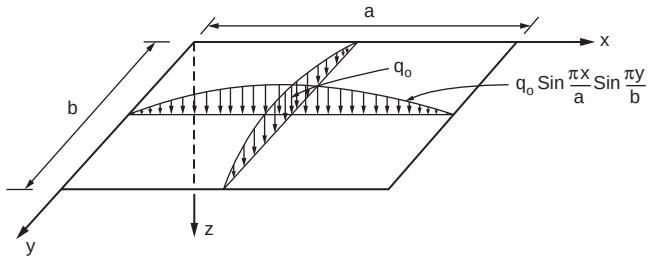

FIGURE 47.33 Rectangular plate under sinusoidal loading.

Bending of Rectangular Plates

The plate bending problem may be solved by referring to the differential Eq. (47.41). The solution, however, depends on the loading and boundary conditions. Consider a simply supported plate subjected to a sinusoidal loading, as shown in Fig. 47.33. The differential Eq. (47.41) in this case becomes

$$\frac{\partial^4 w}{\partial x^4} + 2\frac{\partial^4 w}{\partial x^2 \partial y^2} + \frac{\partial^4 w}{\partial y^4} = \frac{q_o}{D}\sin\frac{\pi x}{a}\sin\frac{\pi y}{b} \tag{47.45}$$

The boundary conditions for the simply supported edges are

$$\begin{aligned} w = 0, \quad \frac{\partial^2 w}{\partial x^2} = 0 \quad \text{for } x = 0 \text{ and } x = a \\ w = 0, \quad \frac{\partial^2 w}{\partial y^2} = 0 \quad \text{for } y = 0 \text{ and } y = b \end{aligned} \tag{47.46}$$

The deflection function becomes

$$w = w_0 \sin\frac{\pi x}{a} \sin\frac{\pi y}{b} \tag{47.47}$$

which satisfies all the boundary conditions in Eq. (47.46). w_0 must be chosen to satisfy Eq. (47.45). Substitution of Eq. (47.47) into Eq. (47.45) gives

$$\pi^4 \left(\frac{1}{a^2} + \frac{1}{b^2}\right)^2 w_0 = \frac{q_o}{D}$$

The deflection surface for the plate can, therefore, be found as

$$w = \frac{q_o}{\pi^4 D\left(\frac{1}{a^2} + \frac{1}{b^2}\right)} \sin\frac{\pi x}{a} \sin\frac{\pi y}{b} \tag{47.48}$$

Using Eqs. (47.48) and (47.36), we find expression for moments as

$$\begin{aligned} M_x &= \frac{q_o}{\pi^2\left(\frac{1}{a^2} + \frac{1}{b^2}\right)^2}\left(\frac{1}{a^2} + \frac{\nu}{b^2}\right) \sin\frac{\pi x}{a} \sin\frac{\pi y}{b} \\ M_y &= \frac{q_o}{\pi^2\left(\frac{1}{a^2} + \frac{1}{b^2}\right)^2}\left(\frac{\nu}{a^2} + \frac{1}{b^2}\right) \sin\frac{\pi x}{a} \sin\frac{\pi y}{b} \\ M_{xy} &= \frac{q_o(1-\nu)}{\pi^2\left(\frac{1}{a^2} + \frac{1}{b^2}\right)^2 ab} \cos\frac{\pi x}{a} \cos\frac{\pi y}{b} \end{aligned} \tag{47.49}$$

Maximum deflection and maximum bending moments that occur at the center of the plate can be written by substituting x = a/2 and y = b/2 in Eq. (47.49) as

$$\begin{aligned} w_{max} &= \frac{q_o}{\pi^4 D\left(\frac{1}{a^2} + \frac{1}{b^2}\right)^2} \\ (M_x)_{max} &= \frac{q_o}{\pi^2\left(\frac{1}{a^2} + \frac{1}{b^2}\right)^2}\left(\frac{1}{a^2} + \frac{\nu}{b^2}\right) \end{aligned} \tag{47.50}$$

$$\left(M_y\right)_{max} = \frac{q_o}{\pi^2\left(\frac{1}{a^2}+\frac{1}{b^2}\right)^2}\left(\frac{\nu}{a^2}+\frac{1}{b^2}\right)$$

If the plate is square, then a = b and Eq. (47.50) becomes

$$\begin{aligned} w_{max} &= \frac{q_o a^4}{4\pi^4 D} \\ \left(M_x\right)_{max} &= \left(M_y\right)_{max} = \frac{(1+\nu)}{4\pi^2} q_o a^2 \end{aligned} \tag{47.51}$$

If the simply supported rectangular plate is subjected to any kind of loading given by

$$q = q(x, y) \tag{47.52}$$

the function q(x, y) should be represented in the form of a double trigonometric series as

$$q(x,y) = \sum_{m=1}^{\infty}\sum_{n=1}^{\infty} q_{mn} \sin\frac{m\pi x}{a}\sin\frac{n\pi y}{b} \tag{47.53}$$

in which q_{mn} is given by

$$q_{mn} = \frac{4}{ab}\int_0^a\int_0^b q(x,y)\sin\frac{m\pi x}{a}\sin\frac{n\pi y}{b}dxdy \tag{47.54}$$

From Eqs. (47.45) and (47.52) to (47.54) we can obtain the expression for deflection as

$$w = \frac{1}{\pi^4 D}\sum_{m=1}^{\infty}\sum_{n=1}^{\infty}\frac{q_{mn}}{\left(\frac{m^2}{a^2}+\frac{n^2}{b^2}\right)^2}\sin\frac{m\pi x}{a}\sin\frac{n\pi y}{b} \tag{47.55}$$

If the applied load is uniformly distributed of intensity q_o, we have

$$q(x,y) = q_o$$

and from Eq. (47.54) we obtain

$$q_{mn} = \frac{4q_o}{ab}\int_0^a\int_0^b \sin\frac{m\pi x}{a}\sin\frac{n\pi y}{b}dxdy = \frac{16q_o}{\pi^2 mn} \tag{47.56}$$

in which m and n are odd integers. q_{mn} = 0 if m or n or both are even numbers. Finally, the deflection of a simply supported plate subjected to a uniformly distributed load can be expressed as

$$w = \frac{16q_o}{\pi^6 D}\sum_{m=1}^{\infty}\sum_{n=1}^{\infty}\frac{\sin\frac{m\pi x}{a}\sin\frac{n\pi y}{b}}{mn\left(\frac{m^2}{a^2}+\frac{n^2}{b^2}\right)^2} \tag{47.57}$$

where m = 1, 3, 5, …
n = 1, 3, 5. …

The maximum deflection occurs at the center. Its magnitude can be evaluated by substituting x = a/2 and y = b/2 in Eq. (47.57) as

$$w_{max} = \frac{16 q_o}{\pi^6 D} \sum_{m=1}^{\infty} \sum_{n=1}^{\infty} \frac{(-1)^{\frac{m+n}{2}} - 1}{mn\left(\frac{m^2}{a^2} + \frac{n^2}{b^2}\right)^2} \tag{47.58}$$

Equation (47.58) is a rapid converging series. A satisfactory approximation can be obtained by taking only the first term of the series; for example, in the case of a square plate,

$$w_{max} = \frac{4 q_o a^4}{\pi^6 D} = 0.00416 \frac{q_o a^4}{D}$$

Assuming ν = 0.3, the maximum deflection can be calculated as

$$w_{max} = 0.0454 \frac{q_o a^4}{E h^3}$$

The expressions for bending and twisting moments can be obtained by substituting Eq. (47.57) into Eq. (47.36). Figure 47.34 shows some loading cases and the corresponding loading functions.

If the opposite edges at x = 0 and x = a of a rectangular plate are simply supported, the solution taking the deflection function as

$$w = \sum_{m=1}^{\infty} Y_m \sin \frac{m\pi x}{a} \tag{47.59}$$

can be adopted. Equation (47.59) satisfies the boundary conditions w = 0 and $\partial^2 w/\partial x^2 = 0$ on the two simply supported edges. Y_m should be determined such that it satisfies the boundary conditions along the edges y = +b/–2 of the plate shown in Fig. 47.35 and also the equation of the deflection surface

$$\frac{\partial^4 w}{\partial x^4} + 2\frac{\partial^4 w}{\partial x^2 \partial y^2} + \frac{\partial^4 w}{\partial y^4} = \frac{q_o}{D} \tag{47.60}$$

q_o being the intensity of the uniformly distributed load.

The solution for Eq. (47.60) can be taken in the form

$$w = w_1 + w_2 \tag{47.61}$$

for a uniformly loaded simply supported plate. w_1 can be taken in the form

$$w_1 = \frac{q_o}{24D}\left(x^4 - 2ax^3 + a^3 x\right) \tag{47.62}$$

representing the deflection of a uniformly loaded strip parallel to the x axis. It satisfies Eq. (47.60) and also the boundary conditions along x = 0 and x = a.

The expression w_2 has to satisfy the equation

$$\frac{\partial^4 w_2}{\partial x^4} + 2\frac{\partial^4 w_2}{\partial x^2 \partial y^2} + \frac{\partial^4 w_2}{\partial y^4} = 0 \tag{47.63}$$

No.	Load $q(x,y)=\sum_m\sum_n q_{mn}\sin\frac{m\pi x}{a}\sin\frac{n\pi y}{b}$	Expansion Coefficients q_{mn}

6		$q_{mn}=\frac{4q_o}{\pi an}\sin\frac{m\pi\xi}{a}$ (m,n = 1, 2, 3, ...)

FIGURE 47.34 Typical loading on plates and loading functions.

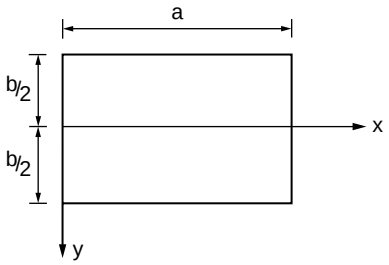

FIGURE 47.35 Rectangular plate.

and must be chosen such that Eq. (47.61) satisfies all boundary conditions of the plate. Taking w_2 in the form of series given in Eq. (47.59), it can be shown that the deflection surface takes the form

$$w = \frac{q_o}{24D}\left(x^4 - 2ax^3 + a^3x\right) + \frac{q_o a^4}{24D}\sum_{m=1}^{\infty}\left(A_m \cosh\frac{m\pi y}{a} + B_m \frac{m\pi y}{a}\sinh\frac{m\pi y}{a} + C_m \sinh\frac{m\pi y}{a} + D_m \frac{m\pi y}{a}\cosh\frac{m\pi y}{a}\right)\sin\frac{m\pi x}{a} \tag{47.64}$$

Observing that the deflection surface of the plate is symmetrical with respect to the x axis, only even functions of y are kept in Eq. (47.64); therefore, $C_m = D_m = 0$. The deflection surface takes the form

$$w = \frac{q_o}{24D}\left(x^4 - 2ax^3 + a^3x\right) + \frac{q_o a^4}{24D}\sum_{m=1}^{\infty}\left(A_m \cosh\frac{m\pi y}{a} + B_m \frac{m\pi y}{a}\sinh\frac{m\pi y}{a}\right)\sin\frac{m\pi x}{a} \tag{47.65}$$

Developing the expression in Eq. (47.62) into a trigonometric series, the deflection surface in Eq. (47.65) is written as

$$w = \frac{q_o a^4}{D}\sum_{m=1}^{\infty}\left(\frac{4}{\pi^5 m^5} + A_m \cosh\frac{m\pi y}{a} + B_m \frac{m\pi y}{a}\sin\frac{m\pi y}{a}\right)\sin\frac{m\pi x}{a} \tag{47.66}$$

Substituting Eq. (47.5.30) in the boundary conditions

$$w = 0, \qquad \frac{\partial^2 w}{\partial y^2} = 0 \tag{47.67}$$

one obtains the constants of integration A_m and B_m, and the expression for deflection may be written as

$$w = \frac{4q_o a^4}{\pi^5 D}\sum_{m=1,3,5\ldots}^{\infty}\frac{1}{m^5}\left(1 - \frac{\alpha_m \tanh\alpha_m + 2}{2\cosh\alpha_m}\cosh\frac{2\alpha_m y}{b} + \frac{\alpha_m}{2\cosh\alpha_m}\frac{2y}{b}\sinh\frac{2\alpha_m y}{b}\right)\sin\frac{m\pi x}{a} \tag{47.68}$$

in which $\alpha_m = m\pi b/2a$.

Maximum deflection occurs at the middle of the plate, x = a/2, y = 0, and is given by

$$w_{max} = \frac{4q_o a^4}{\pi^5 D}\sum_{m=1,3,5,\ldots}^{\infty}\frac{(-1)^{\frac{m-1}{2}}}{m^5}\left(1 - \frac{\alpha_m \tanh\alpha_m + 2}{2\cosh\alpha_m}\right) \tag{47.69}$$

The solutions of plates with arbitrary boundary conditions are complicated. It is possible to make some simplifying assumptions for plates with the same boundary conditions along two parallel edges in order to obtain the desired solution. Alternately, the energy method can be applied more efficiently to solve plates with complex boundary conditions. However, it should be noted that the accuracy of results depends on the deflection function chosen. These functions must be chosen so that they satisfy at least the kinematics boundary conditions.

Figure 47.36 gives formulas for deflection and bending moments of rectangular plates with typical boundary and loading conditions.

Case No.	Structural System and Static Loading	Deflection and Internal Forces

FIGURE 47.36 Typical loading and boundary conditions for rectangular plates.

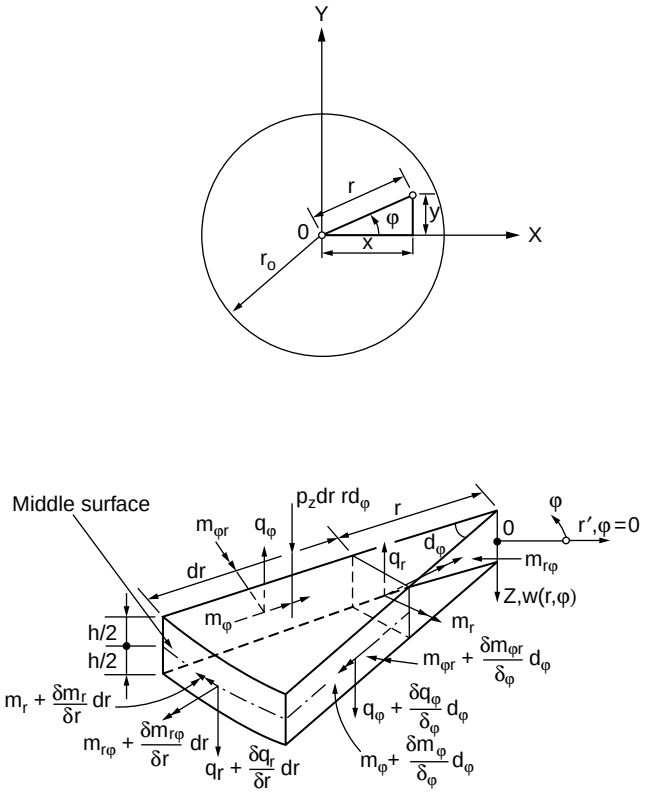

FIGURE 47.37 (a) Circular plate. (b) Stress resultants.

Bending of Circular Plates

In the case of a symmetrically loaded circular plate, the loading is distributed symmetrically about the axis perpendicular to the plate through its center. In such cases, the deflection surface to which the middle plane of the plate is bent will also be symmetrical. The solution of circular plates can be conveniently carried out by using polar coordinates.

Stress resultants in a circular plate element are shown in Fig. 47.37. The governing differential equation is expressed in polar coordinates as

$$\frac{1}{r}\frac{d}{dr}\left\{r\frac{d}{dr}\left[\frac{1}{r}\frac{d}{dr}\left(r\frac{dw}{dr}\right)\right]\right\} = \frac{q}{D} \tag{47.70}$$

in which q is the intensity of loading.

In the case of a uniformly loaded circular plate, Eq. (47.70) can be integrated successively and the deflection at any point at a distance r from the center can be expressed as

$$w = \frac{q_o r^4}{64D} + \frac{C_1 r^2}{4} + C_2 \log\frac{r}{a} + C_3 \tag{47.71}$$

in which q_o is the intensity of loading and a is the radius of the plate. C_1, C_2, and C_3 are constants of integration to be determined using the boundary conditions.

For a plate with clamped edges under uniformly distributed load q_o, the deflection surface reduces to

$$w = \frac{q_o}{64D}(a^2 - r^2)^2 \tag{47.72}$$

The maximum deflection occurs at the center, where r = 0, and is given by

$$w = \frac{q_o a^4}{64D} \tag{47.73}$$

Bending moments in the radial and tangential directions are respectively given by

$$\begin{aligned} M_r &= \frac{q_o}{16}\left[a^2(1+\nu) - r^2(3+\nu)\right] \\ M_t &= \frac{q_o}{16}\left[a^2(1+\nu) - r^2(1+3\nu)\right] \end{aligned} \tag{47.74}$$

The method of superposition can be applied in calculating the deflections for circular plates with simply supported edges. The expressions for deflection and bending moment are given as

$$\begin{aligned} w &= \frac{q_o(a^2 - r^2)}{64D}\left(\frac{5+\nu}{1+\nu}a^2 - r^2\right) \\ w_{max} &= \frac{5+\nu}{64(1+\nu)}\frac{q_o a^4}{D} \end{aligned} \tag{47.75}$$

$$\begin{aligned} M_r &= \frac{q_o}{16}(3+\nu)(a^2 - r^2) \\ M_t &= \frac{q_o}{16}\left[a^2(3+\nu) - r^2(1+3\nu)\right] \end{aligned} \tag{47.76}$$

This solution can be used to deal with plates with a circular hole at the center and subjected to concentric moment and shearing forces. Plates subjected to concentric loading and concentrated loading also can be solved by this method. More rigorous solutions are available to deal with irregular loading on circular plates. Once again, the energy method can be employed advantageously to solve circular plate problems. Figure 47.38 gives deflection and bending moment expressions for typical cases of loading and boundary conditions on circular plates.

Strain Energy of Simple Plates

The strain energy expression for a simple rectangular plate is given by

$$U = \frac{D}{2}\iint_{area}\left\{\left(\frac{\partial^2 w}{\partial x^2} + \frac{\partial^2 w}{\partial y^2}\right)^2 - 2(1-\nu)\left[\frac{\partial^2 w}{\partial x^2}\frac{\partial^2 w}{\partial y^2} - \left(\frac{\partial^2 w}{\partial x \partial y}\right)^2\right]\right\}dxdy \tag{47.77}$$

A suitable deflection function w(x, y) satisfying the boundary conditions of the given plate may be chosen. The strain energy, U, and the work done by the given load, q(x, y),

Case No.	Structural System and Static Loading	Deflection and Internal Forces
1		$w = \frac{q_o r_o^4}{64D(1+\nu)}[2(3+\nu)C_1 - (1+\nu)C_0]$ $m_r = \frac{q_o r_o^2}{16}(3+\nu)c_1$ $\quad \rho = \frac{r}{r_o}$ $m_\theta = \frac{q_o r_o^2}{16}[2(1-\nu) - (1+3\nu)C_1]$ $\quad C_o = 1-\rho^4$ $q_r = \frac{q_o r_o}{2}\rho$ $\quad C_1 = 1-\rho^2$
2		$w = \frac{q_o r_o^4}{14400D}B\frac{3(183+43\nu)}{1+\nu} - \frac{10(71+29\nu)}{1+\nu}\rho^2 + 225\rho^4 - 64\rho^5 F$ $(m_r)_{\rho=0} = (m_\varphi)_{\rho=0} = \frac{q_o r_o^4}{720}(71+29\nu);$ $(q_r)_{\rho=1} = -\frac{q_o r_o}{6}$ $\quad \rho = \frac{r}{r_o}$
3		$w = \frac{q_o r_o^4}{450D}B\frac{3(6+\nu)}{1+\nu} - \frac{5(4+\nu)}{1+\nu}\rho^2 + 2\rho^5 F$ $(m_r)_{\rho=0} = (m_\varphi)_{\rho=o} = \frac{q_o r_o^2}{45}(4+\nu);$ $(q_r)_{\rho=1} = -\frac{q_o r_o}{3}$ $\quad \rho = \frac{r}{r_o}$

FIGURE 47.38 Typical loading and boundary conditions for circular plates.

$$W = -\iint_{area} q(x,y)w(x,y)dxdy$$

can be calculated. The total potential energy is, therefore, given as V = U + W. Minimizing the total potential energy, the plate problem can be solved.

$$\left[\frac{\partial^2 w}{\partial x^2}\frac{\partial^2 w}{\partial y^2} - \left(\frac{\partial^2 w}{\partial x \partial y}\right)^2\right]$$

The term is known as the Gaussian curvature.

If the function w(x, y) = f(x)f(y) (product of a function of x only and a function of y only) and w = 0 at the boundary are assumed, then the integral of the Gaussian curvature over the entire plate equals zero. Under these conditions

$$U = \frac{D}{2}\iint_{area}\left(\frac{\partial^2 w}{\partial x^2} + \frac{\partial^2 w}{\partial y^2}\right)^2 dxdy$$

Case No.	Structural System and Static Loading	Deflection and Internal Forces
5		$w = \frac{Mr_o^2}{2D(1+\nu)C_1}$ $m_r = m_\varphi = M$ $q_r = 0$ $C_1 = 1 - \rho^2,\ \rho = \frac{r}{r_o}$
6		$w = \frac{q_o r_o^4}{64D}(1-\rho^2)^2$ $m_r = \frac{q_o r_o^2}{16}[1+\nu-(3+\nu)\rho^2]$ $m_\varphi = \frac{q_o r_o^2}{16}[1+\nu-(1+3\nu)\rho^2]$ $q_r = -\frac{q_o r_o}{2}\rho$ $\rho = \frac{r}{r_o}$
7		$w = \frac{q_o r_o^4}{14400D}(129 - 290\rho^2 + 225\rho^4 - 64\rho^5)$ $(m_r)_{\rho=0} = (m_\varphi)_{\rho=0} = \frac{29 q_o r_o^2}{720}(1+\nu)$ $(m_r)_{\rho=1} = (m_\varphi)_{\rho=1} = -\frac{7 q_o r_o^2}{120}$ $(q_r)_{\rho=1} = -\frac{q_o r_o}{6}$ $\rho = \frac{r}{r_o}$
8		$w = \frac{q_o r_o^4}{450D}(3 - 5\rho^2 + 2\rho^5)$ $m_r = \frac{q_o r_o^2}{45}[1+\nu-(4+\nu)\rho^3]$ $m_\varphi = \frac{q_o r_o^2}{45}[1+\nu-(1+4\nu)\rho^3]$ $q_r = -\frac{q_o r_o}{3}\rho^2$ $\rho = \frac{r}{r_o}$
9		$w = \frac{Pr_o^2}{16\pi D}(1-\rho^2+2\rho^2\ell n\,\rho)$ $m_r = -\frac{P}{4\pi}[1+(1+\nu)\ell n\,\rho]$ $m_\varphi = -\frac{P}{4\pi}[\nu+(1+\nu)\ell n\,\rho]$ $q_r = -\frac{P}{2\pi r_o \rho}$ $\rho = \frac{r}{r_o}$

FIGURE 47.38 (continued).

If polar coordinates instead of rectangular coordinates are used and axial symmetry of loading and deformation are assumed, the equation for strain energy, U, takes the form

$$U = \frac{D}{2}\int\int_{area}\left\{\left(\frac{\partial^2 w}{\partial r^2}+\frac{1}{r}\frac{\partial w}{\partial r}\right)^2 - \frac{2(1-\nu)}{r}\frac{\partial w}{\partial r}\frac{\partial^2 w}{\partial r^2}\right\} r\,dr\,d\theta \tag{47.78}$$

and the work done, W, is written as

$$W = -\int\int_{area} q w r\,dr\,d\theta \tag{47.79}$$

Detailed treatment of the plate theory can be found in Timoshenko and Woinowsky-Krieger (1959).

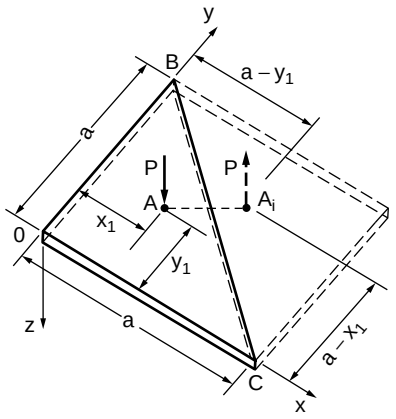

FIGURE 47.39 Isosceles triangular plate.

Plates of Various Shapes and Boundary Conditions

Simply Supported Isosceles Triangular Plate Subjected to a Concentrated Load

Plates of shapes other than a circle or rectangle are used in some situations. A rigorous solution of the deflection for a plate with a more complicated shape is likely to be very difficult. Consider, for example, the bending of an isosceles triangular plate with simply supported edges under concentrated load P acting at an arbitrary point (Fig. 47.39). A solution can be obtained for this plate by considering a mirror image of the plate, as shown in the figure. The deflection of OBC of the square plate is identical with that of a simply supported triangular plate OBC. The deflection owing to the force P can be written as

$$w_1 = \frac{4Pa^2}{\pi^4 D}\sum_{m=1}^{\infty}\sum_{n=1}^{\infty}\frac{\sin\left(m\pi x_1/a\right)\sin\left(n\pi y_1/a\right)}{\left(m^2+n^2\right)^2}\sin\frac{m\pi x}{a}\sin\frac{n\pi y}{a} \tag{47.80}$$

Upon substitution of –P for P, $(a - y_1)$ for x_1, and $(a - x_1)$ for y_1 in Eq. (47.80), we obtain the deflection due to the force –P at A_i:

$$w_2 = -\frac{4Pa^2}{\pi^4 D}\sum_{m=1}^{\infty}\sum_{n=1}^{\infty}(-1)^{m+n}\frac{\sin\left(m\pi x_1/a\right)\sin\left(n\pi y_1/a\right)}{\left(m^2+n^2\right)^2}\sin\frac{m\pi x}{a}\sin\frac{n\pi y}{a} \tag{47.81}$$

The deflection surface of the triangular plate is then

$$w = w_1 + w_2 \tag{47.82}$$

Equilateral Triangular Plates

The deflection surface of a simply supported plate loaded by uniform moment M_o along its boundary, and the surface of a uniformly loaded membrane, uniformly stretched over the same triangular boundary, are identical. The deflection surface for such a case can be obtained as

$$w = \frac{M_o}{4aD}\left[x^3 - 3xy^2 - a\left(x^2+y^2\right) + \frac{4}{27}a^3\right] \tag{47.83}$$

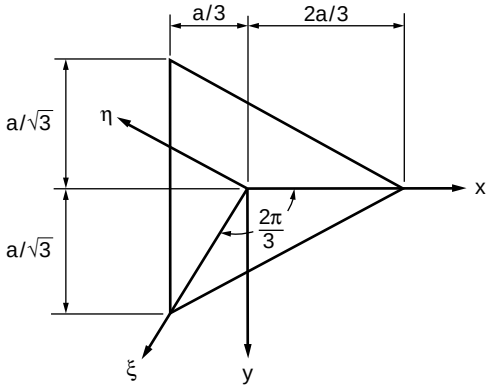

FIGURE 47.40 Equilateral triangular plate with coordinate axes.

If the simply supported plate is subjected to uniform load p_o, the deflection surface takes the form

$$w = \frac{p_o}{64aD}\left[x^3 - 3xy^2 - a\left(x^2 + y^2\right) + \frac{4}{27}a^3\right]\left(\frac{4}{9}a^2 - x^2 - y^2\right) \tag{47.84}$$

For the equilateral triangular plate (Fig. 47.40) subjected to a uniform load and supported at the corners, approximate solutions based on the assumption that the total bending moment along each side of the triangle vanishes were obtained by Vijakkhna et al. (1973), who derived the equation for the deflection surface as

$$w = \frac{qa^4}{144(1-\nu^2)D}\left[\frac{8}{27}(7+\nu)(2-\nu) - (7+\nu)(1-\nu)\left(\frac{x^2}{a} + \frac{y^2}{a^2}\right) - (5-\nu)(1+\nu)\left(\frac{x^3}{a^3} - 3\frac{xy^2}{a^3}\right) + \frac{9}{4}(1-\nu^2)\left(\frac{x^4}{a^4} + 2\frac{x^2y^2}{a^4} + \frac{y^4}{a^4}\right)\right] \tag{47.85}$$

The errors introduced by the approximate boundary condition, i.e., the assumption that the total bending moment along each side of the triangle vanishes, are not significant because the boundary condition's influence on the maximum deflection and stress resultants is small for practical design purposes. The value of the twisting moment on the edge at the corner given by this solution is found to be exact.

The details of the mathematical treatment may be found in Vijakkhna et al. (1973, p. 123–128).

Rectangular Plate Supported at Corners

Approximate solutions for rectangular plates supported at the corners and subjected to a uniformly distributed load were obtained by Lee and Ballesteros (1960). The approximate deflection surface is given as

$$w = \frac{qa^4}{48(1-\nu^2)D}\left[\left(10 + \nu - \nu^2\right)\left(1 + \frac{b^4}{a^4}\right) - 2(7\nu - 1)\frac{b^2}{a^2} + 2\left(\left(1 + 5\nu\right)\frac{b^2}{a^2} - \left(6 + \nu - \nu^2\right)\right)\frac{x}{a} + 2\left(\left(1 + 5\nu\right) - \left(6 + \nu - \nu^2\right)\frac{b^2}{a^2}\right)\frac{y^2}{a^2} + \left(2 + \nu - \nu^2\right)\frac{x^4 + y^4}{a^4} - 6(1+\nu)\frac{x^2y^2}{a^4}\right] \tag{47.86}$$

The details of the mathematical treatment may be found in Lee and Ballesteros (1960, p. 206–211).

Orthotropic Plates

Plates of anisotropic materials have important applications owing to their exceptionally high bending stiffness. A nonisotropic or anisotropic material displays direction-dependent properties. Simplest among them are those in which the material properties differ in two mutually perpendicular directions. A material so described is orthotropic, e.g., wood. A number of manufactured materials are approximated as orthotropic. Examples include corrugated and rolled metal sheets, fillers in sandwich plate construction, plywood, fiber reinforced composites, reinforced concrete, and gridwork. The latter consists of two systems of equally spaced parallel ribs (beams), mutually perpendicular and attached rigidly at the points of intersection.

The governing equation for orthotropic plates, similar to that of isotropic plates Eq. (47.86), takes the form

$$D_x \frac{\delta^4 w}{\delta x^4} + 2H \frac{\delta^4 w}{\delta x^2 \delta y^2} + D_y \frac{\delta^4 w}{\delta y^4} = q \tag{47.87}$$

in which

$$D_x = \frac{h^3 E_x}{12}, \quad D_y = \frac{h^3 E_y}{12}, \quad H = D_{xy} + 2G_{xy}, \quad D_{xy} = \frac{h^3 E_{xy}}{12}, \quad G_{xy} = \frac{h^3 G}{12}$$

The expressions for D_x, D_y, D_{xy}, and G_{xy} represent the flexural rigidities and the torsional rigidity of an orthotropic plate, respectively. E_x, E_y, and G are the orthotropic plate moduli. Practical considerations often lead to assumptions, with regard to material properties, resulting in approximate expressions for elastic constants. The accuracy of these approximations is generally the most significant factor in the orthotropic plate problem. Approximate rigidities for some cases that are commonly encountered in practice are given in Fig. 47.41.

General solution procedures applicable to the case of isotropic plates are equally applicable to orthotropic plates. Deflections and stress resultants can thus be obtained for orthotropic plates of different shapes with different support and loading conditions. These problems have been researched extensively, and solutions concerning plates of various shapes under different boundary and loading conditions may be found in the references viz. Tsai and Cheron (1968), Timoshenko and Woinowsky-Krieger (1959), Lee et al. (1971), and Shanmugam et al. (1988 and 1989).

47.6 Shells

Stress Resultants in Shell Element

A thin shell is defined as a shell with a relatively small thickness, compared with its other dimensions. The primary difference between a shell and a plate is that the former has a curvature in the unstressed state, whereas the latter is assumed to be initially flat. The presence of initial curvature is of little consequence as far as flexural behavior is concerned. The membrane behavior, however, is affected significantly by the curvature. Membrane action in a surface is caused by in-plane forces. These forces may be primary forces caused by applied edge loads or edge deformations, or they may be secondary forces resulting from flexural deformations.

In the case of the flat plates, secondary in-plane forces do not give rise to appreciable membrane action unless the bending deformations are large. Membrane action due to secondary forces is, therefore, neglected in small deflection theory. In the case of a shell which has an initial curvature, membrane action caused by secondary in-plane forces will be significant regardless of the magnitude of the bending deformations.

Geometry	Rigidities
A. Reinforced concrete slab with x and y directed reinforcement steel bars 	$D_x = \frac{E_c}{1-\nu_c^2}\left[I_{cx} + \left(\frac{E_s}{E_c} - 1\right) I_{sx}\right]$ $D_y = \frac{E_c}{1-\nu_c^2}\left[Icy + \left(\frac{E_s}{E_c} - 1\right) I_{sy}\right]$ $G_{xy} = \frac{1-\nu_c}{2}\sqrt{D_x D_y}$ $H = \sqrt{D_x D_y}$ $D_{xy} = \nu_c \sqrt{D_x D_y}$ ν_c : Poisson's ratio for concrete E_c, E_s : Elastic modulus of concrete and steel, respectively $I_{cx}(I_{sx})$, $I_{cy}(I_{sy})$: Moment of ineretia of the slab (steel bars) about neutral axis in the section x = constant and y = constant, respectively
B. Plate reinforced by equidistant stiffeners 	$D_x = H = \frac{Et^3}{12(1-\nu^2)}$ $D_y = \frac{Et^3}{12(1-\nu^2)} + \frac{E'I}{s}$ E, E′ : Elastic modulus of plating and stiffeners, respectively ν : Poisson's ratio of plating s : Spacing between centerlines of stiffeners I : Moment of inertia of the stiffener cross section with respect to midplane of plating
C. Plate reinforced by a set of equidistant ribs 	$D_x = \frac{Est^3}{12[s - h + h(t\,t_1)^3]}$ $D_y = \frac{EI}{s}$ $H = 2G'_{xy} + \frac{C}{s}$ $D_{xy} = 0$ C : Torsional rigidity of one rib I : Moment of inertia about neutral axis of a T-section of width s (shown as shaded) G'_{xy} : Torsional rigidity of the plating E : Elastic modulus of the plating
D. Corrugated plate 	$D_x = \frac{s}{\lambda}\frac{Et^3}{12(1-\nu^2)}$ $D_y = EI$, $H = \frac{\lambda}{a}\frac{Et^3}{12(1+\nu)}$ $D_{xy} = 0$ where $\lambda = s\left(1 + \frac{\pi^2 h^2}{4s^2}\right)$ $I = 0.5h^2 t\left[1 - \frac{0.81}{1 + 2.5(h/2s)^2}\right]$

FIGURE 47.41 Various orthotropic plates.

A plate is likened to a two-dimensional beam and resists transverse loads by two-dimensional bending and shear. A membrane is likened to a two-dimensional equivalent of the cable and resists loads through tensile stresses. Imagine a membrane with large deflections (Fig. 47.42a), reverse the load and the membrane, and we have the structural shell (Fig. 47.42b), provided that the shell is stable for the type of load shown. The membrane resists the load through tensile stresses, but the ideal thin shell must be capable of developing both tension and compression.

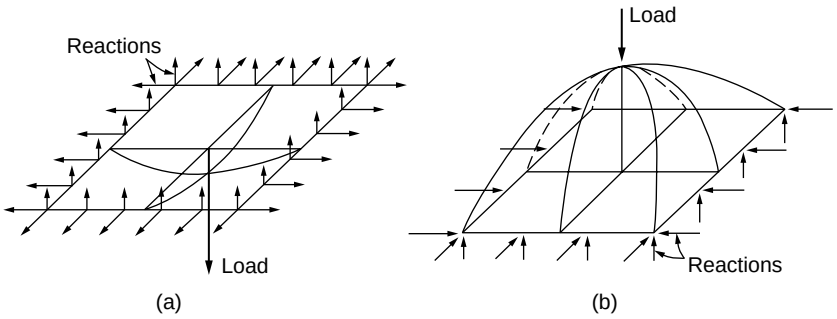

FIGURE 47.42

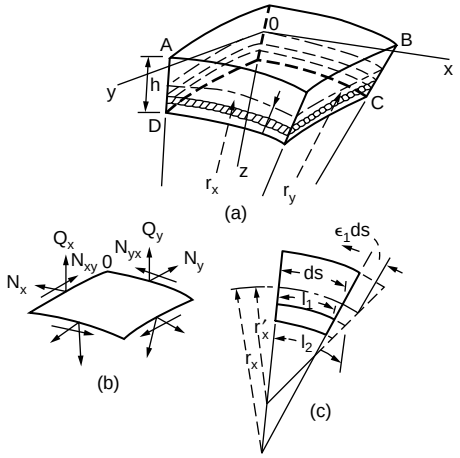

FIGURE 47.43 Shell element.

Consider an infinitely small shell element formed by two pairs of adjacent planes that are normal to the middle surface of the shell and contain its principal curvatures, as shown in Fig. 47.43a. The thickness of the shell is denoted as h. Coordinate axes x and y are taken tangent at o to the lines of principal curvature, and the axis z normal to the middle surface. r_x and r_y are the principal radii of curvature lying in the xz and yz planes, respectively. The resultant forces per unit length of the normal sections are given as

$$N_x = \int_{-h/2}^{h/2} \sigma_x \left(1 - \frac{z}{r_y}\right) dz, \quad N_y = \int_{-h/2}^{h/2} \sigma_y \left(1 - \frac{z}{r_x}\right) dz$$

$$N_{xy} = \int_{-h/2}^{h/2} \tau_{xy} \left(1 - \frac{z}{r_y}\right) dz, \quad N_{yx} = \int_{-h/2}^{h/2} \tau_{yx} \left(1 - \frac{z}{r_x}\right) dz \tag{47.88}$$

$$Q_x = \int_{-h/2}^{h/2} \tau_{xz} \left(1 - \frac{z}{r_y}\right) dz, \quad Q_y = \int_{-h/2}^{h/2} \tau_{yx} \left(1 - \frac{z}{r_x}\right) dz$$

The bending and twisting moments per unit length of the normal sections are given by

$$M_x = \int_{-h/2}^{h/2} \sigma_x Z\left(1-\frac{z}{r_y}\right)dz, \qquad M_y = \int_{-h/2}^{h/2} \sigma_y Z\left(1-\frac{z}{r_x}\right)dz$$
$$M_{xy} = -\int_{-h/2}^{h/2} \tau_{xy} Z\left(1-\frac{z}{r_y}\right)dz, \qquad M_{yx} = \int_{-h/2}^{h/2} \sigma_{yx} Z\left(1-\frac{z}{r_x}\right)dz \tag{47.89}$$

It is assumed, in bending of the shell, that linear elements such as AD and BC (Fig. 47.43), which are normal to the middle surface of the shell, remain straight and become normal to the deformed middle surface of the shell. If the conditions of a shell are such that bending can be neglected, the problem of stress analysis is greatly simplified, since the resultant moments (Eq. (47.89)) vanish along with shearing forces Q_x and Q_y in Eq. (47.88). Thus the only unknowns are N_x, N_y, and $N_{xy} = N_{yx}$; these are called membrane forces.

Shells of Revolution

Shells having the form of surfaces of revolution find extensive application in various kinds of containers, tanks, and domes. Consider an element of a shell cut by two adjacent meridians and two parallel circles, as shown in Fig. 47.44. There will be no shearing forces on the sides of the element because of the symmetry of loading. By considering the equilibrium in the direction of the tangent to the meridian and z, two equations of equilibrium are written, respectively, as

$$\frac{d}{d\varphi}\left(N_\varphi r_0\right) - N_\theta r_1 \cos\phi + Y r_1 r_0 = 0$$
$$N_\varphi r_0 + N_\theta r_1 \sin\varphi + Z r_1 r_0 = 0 \tag{47.90}$$

The forces N_θ and N_φ can be calculated from Eq. (47.90) if the radii r_0 and r_1 and the components Y and Z of the intensity of the external load are given.

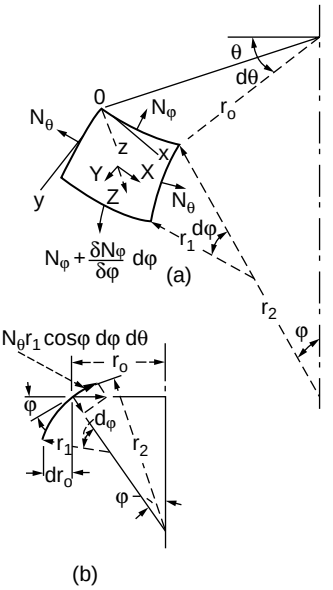

FIGURE 47.44 Element from shells of revolution — symmetrical loading.

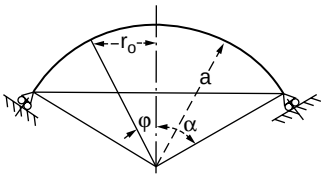

FIGURE 47.45 Spherical dome.

Spherical Dome

The spherical shell shown in Fig. 47.45 is assumed to be subjected to its own weight; the intensity of the self weight is assumed as a constant value, q_o, per unit area. Considering an element of the shell at an angle φ, the self weight of the portion of the shell above this element is obtained as

$$R = 2\pi \int_0^{\phi} a^2 q_0 \sin\varphi \, d\varphi$$

$$= 2\pi a^2 q_0 (1 - \cos\varphi)$$

Considering the equilibrium of the portion of the shell above the parallel circle, defined by the angle φ, we can write,

$$2\pi r_o N_\varphi \sin\varphi + R = 0 \tag{47.91}$$

Therefore,

$$N_\varphi = -\frac{aq_o(1-\cos\varphi)}{\sin^2\varphi} = -\frac{aq_o}{1+\cos\varphi}$$

We can write from Eq. (47.90)

$$\frac{N_\varphi}{r_1} + \frac{N_\theta}{r_2} = -Z \tag{47.92}$$

substituting for N_φ and z = R in Eq. (47.92)

$$N_\theta = -aq_o\left(\frac{1}{1+\cos\varphi} - \cos\varphi\right)$$

It is seen that the forces N_ϕ are always negative. There is thus a compression along the meridians that increases as the angle φ increases. The forces N_θ are also negative for small angles φ. The stresses as calculated above will represent the actual stresses in the shell with great accuracy if the supports are of such a type that the reactions are tangent to the meridians, as shown in Figure 47.45.

Conical Shells

If a force P is applied in the direction of the axis of the cone, as shown in Fig. 47.46, the stress distribution is symmetrical and we obtain

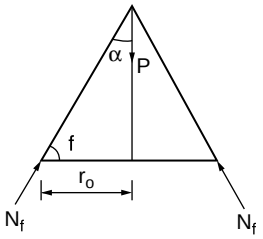

FIGURE 47.46 Conical shell.

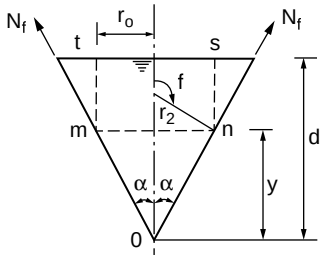

FIGURE 47.47 Inverted conical tank.

$$N_\phi = -\frac{P}{2\pi r_0 \cos\alpha}$$

By Eq. (47.92), one obtains $N_\theta = 0$.

In the case of a conical surface in which the lateral forces are symmetrically distributed, the membrane stresses can be obtained by using Eqs. (47.91) and (47.92). The curvature of the meridian in the case of a cone is zero, and hence $r_1 = \infty$; Eqs. (47.91) and (47.92) can therefore be written as

$$N_\phi = -\frac{R}{2\pi r_0 \sin\phi}$$

and

$$N_\theta = -r_2 Z = -\frac{Z r_0}{\sin\phi}$$

If the load distribution is given, N_ϕ and N_θ can be calculated independently.

For example, a conical tank filled with a liquid of specific weight γ is considered in Fig. 47.47. The pressure at any parallel circle mn is

$$p = -Z = \gamma(d - y)$$

For the tank, $\phi = \alpha + (\pi/2)$ and $r_0 = y\tan\alpha$. Therefore,

$$N_\theta = \frac{\gamma(d-y)y\tan\alpha}{\cos\alpha}$$

N_θ is maximum when $y = d/2$ and hence

$$(N_\theta)_{max} = \frac{\gamma d^2 \tan\alpha}{4\cos\alpha}$$

The term R in the expression for N_ϕ is equal to the weight of the liquid in the conical part mno, and the cylindrical part must be as shown in Fig. 47.46. Therefore,

$$R = -\left[\frac{1}{3}\pi y^3 \tan^2\alpha + \pi y^2 \tan^2\alpha(d-y)\right]\gamma$$

$$= -\pi\gamma y^2\left(d - \frac{2}{3}y\right)\tan^2\alpha$$

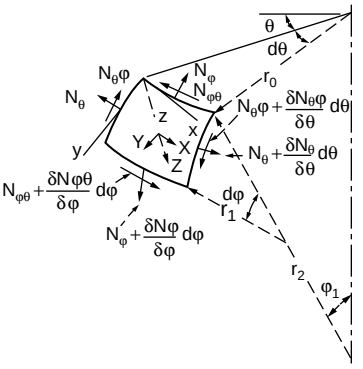

FIGURE 47.48 Element from shells of revolution — unsymmetrical loading.

Hence,

$$N_\phi = \frac{\gamma y\left(d-\frac{2}{3}y\right)\tan\alpha}{2\cos\alpha}$$

N_ϕ is maximum when $y = \frac{3}{4}d$ and

$$\left(N_\phi\right)_{max} = \frac{3}{16}\frac{d^2\gamma\tan\alpha}{\cos\alpha}$$

The horizontal component of N_ϕ is taken by the reinforcing ring provided along the upper edge of the tank. The vertical components constitute the reactions supporting the tank.

Shells of Revolution Subjected to Unsymmetrical Loading

Consider an element cut from a shell by two adjacent meridients and two parallel circles, as shown in Fig. 47.48. In general cases, shear forces $N_{\varphi\theta} = N_{\theta\varphi}$ and normal forces N_φ and N_θ will act on the sides of the element. Projecting the forces on the element in the y direction, we obtain the governing equation:

$$\frac{\partial}{\partial\varphi}\left(N_\varphi r_0\right)+\frac{\partial N_{\theta\varphi}}{\partial\theta}r_1 - N_\theta r_1\cos\varphi + Y r_1 r_0 = 0 \tag{47.93}$$

Similarly the forces in the x direction can be summed up to give

$$\frac{\partial}{\partial\varphi}\left(r_0 N_{\varphi\theta}\right)+\frac{\partial N_\theta}{\partial\theta}r_1 + N_{\theta\varphi} r_1\cos\varphi + X r_0 r_1 = 0 \tag{47.94}$$

Since the projection of shearing forces on the z axis vanishes, the third equation is the same as Eq. (47.92). The problem of determining membrane stresses under unsymmetrical loading reduces to solving Eqs. (47.92) to (47.94) for given values of the components X, Y, and Z of the intensity of the external load.

Cylindrical Shells

It is assumed that the generator of the shell is horizontal and parallel to the x axis. An element is cut from the shell by two adjacent generators and two cross sections perpendicular to the x axis, and its position is defined by the coordinate x and the angle φ. The forces acting on the sides of the element are shown in Fig. 47.49b.

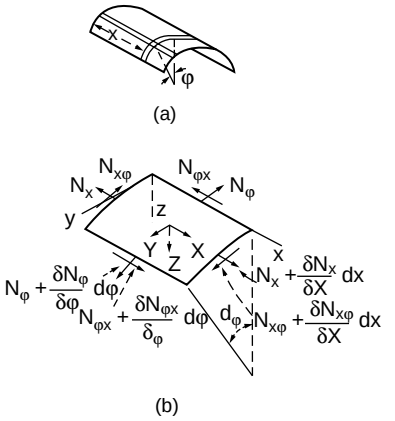

FIGURE 47.49 Membrane forces on a cylindrical shell element.

The components of the distributed load over the surface of the element are denoted as X, Y, and Z. Considering the equilibrium of the element and summing up the forces in the x direction, we obtain

$$\frac{\partial N_x}{\partial x} r d\varphi dx + \frac{\partial N_{\varphi x}}{\partial \varphi} d\varphi dx + X r d\varphi dx = 0$$

The corresponding equations of equilibrium in the y and z directions are given, respectively, as

$$\frac{\partial N_{x\varphi}}{\partial x} r d\varphi dx + \frac{\partial N_\varphi}{\partial \varphi} d\varphi dx + Y r d\varphi dx = 0$$

$$N_\varphi d\varphi dx + Z r d\varphi dx = 0$$

The three equations of equilibrium can be simplified and represented in the following form:

$$\begin{aligned} \frac{\partial N_x}{\partial x} + \frac{1}{r}\frac{\partial N_{x\varphi}}{\partial \varphi} &= -X \\ \frac{\partial N_{x\varphi}}{\partial x} + \frac{1}{r}\frac{\partial N_\varphi}{\partial \varphi} &= -Y \\ N_\varphi &= -Zr \end{aligned} \tag{47.95}$$

In each particular case we readily find the value of N_φ. Substituting this value in the second of the equations, we then obtain $N_{x\varphi}$ by integration. Using the value of $N_{x\varphi}$ thus obtained, we find N_x by integrating the first equation.

Symmetrically Loaded Circular Cylindrical Shells

To establish the equations required for the solution of a symmetrically loaded circular cylinder shell, we consider an element, as shown in Figs. 47.49a and 47.50. From symmetry, the membrane shearing forces $N_{x\varphi} = N_{\varphi x}$ vanish in this case; forces N_φ are constant along the circumference. From symmetry, only the forces Q_z do not vanish. Considering the moments acting on the element in Fig. 47.50, from symmetry it can be concluded that the twisting moments $M_{x\varphi} = M_{\varphi x}$ vanish and that the bending moments M_φ are constant along the circumference. Under such conditions of symmetry, three of the six equations of equilibrium of the element are identically satisfied. We have to consider only the equations, obtained by

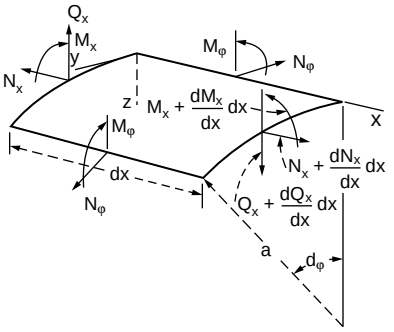

FIGURE 47.50 Stress resultants in a cylindrical shell element.

projecting the forces on the x and z axes and by taking the moment of the forces about the y axis. For example, consider a case in which external forces consist only of a pressure normal to the surface. The three equations of equilibrium are

$$\begin{aligned}
&\frac{dN}{dx}a\,dx\,d\varphi = 0\\
&\frac{dQ_x}{dx}a\,dx\,d\varphi + N_\varphi dx\,d\varphi + Za\,dx\,d\varphi = 0\\
&\frac{dM_x}{dx}a\,dx\,d\varphi - Q_x a\,dx\,d\varphi = 0
\end{aligned} \tag{47.96}$$

The first one indicates that the forces N_x are constant, and they are taken equal to zero in the further discussion. If they are different from zero, the deformation and stress corresponding to such constant forces can be easily calculated and superposed on stresses and deformations produced by lateral load. The remaining two equations are written in the simplified form:

$$\begin{aligned}
&\frac{dQ_x}{dx} + \frac{1}{a}N_\varphi = -Z\\
&\frac{dM_x}{dx} - Q_x = 0
\end{aligned} \tag{47.97}$$

These two equations contain three unknown quantities: N_φ, Q_x, and M_x. We need, therefore, to consider the displacements of points in the middle surface of the shell.

The component v of the displacement in the circumferential direction vanishes because of symmetry. Only the components u and w in the x and z directions, respectively, are to be considered. The expressions for the strain components then become

$$\varepsilon_x = \frac{du}{dx} \qquad \varepsilon_\varphi = -\frac{w}{a} \tag{47.98}$$

By Hooke's law, we obtain

$$\begin{aligned}
N_x &= \frac{Eh}{1-\nu^2}\left(\varepsilon_x + \nu\varepsilon_\varphi\right) = \frac{Eh}{1-\nu^2}\left(\frac{du}{dx} - \nu\frac{w}{a}\right) = 0\\
N_\varphi &= \frac{Eh}{1-\nu^2}\left(\varepsilon_\varphi + \nu\varepsilon_x\right) = \frac{Eh}{1-\nu^2}\left(-\frac{w}{a} + \nu\frac{du}{dx}\right) = 0
\end{aligned} \tag{47.99}$$

From the first of these equation it follows that

$$\frac{du}{dx} = \nu \frac{w}{a}$$

and the second equation gives

$$N_\varphi = -\frac{Ehw}{a} \tag{47.100}$$

Considering the bending moments, we conclude from symmetry that there is no change in curvature in the circumferential direction. The curvature in the x direction is equal to $-d^2w/dx^2$. Using the same equations as the ones for plates, we then obtain

$$\begin{aligned} M_\varphi &= \nu M_x \\ M_x &= -D\frac{d^2w}{dx^2} \end{aligned} \tag{47.101}$$

where

$$D = \frac{Eh^3}{12\left(1-\nu^2\right)}$$

is the flexural rigidity per unit length of the shell.

Eliminating Q_x from Eq. (47.97), we obtain

$$\frac{d^2M_x}{dx^2} + \frac{1}{a}N_\varphi = -Z$$

from which, by using Eqs. (47.100) and (47.101), we obtain

$$\frac{d^2}{dx^2}\left(D\frac{d^2w}{dx^2}\right) + \frac{Eh}{a^2}w = Z \tag{47.102}$$

All problems of symmetrical deformation of circular cylindrical shells thus reduce to the integration of Eq. (47.102).

The simplest application of this equation is obtained when the thickness of the shell is constant. Under such conditions Eq. (47.102) becomes

$$D\frac{d^4w}{dx^4} + \frac{Eh}{a^2}w = Z$$

using the notation

$$\beta^4 = \frac{Eh}{4a^2D} = \frac{3\left(1-\nu^2\right)}{a^2h^2} \tag{47.103}$$

Equation (47.103) can be represented in the simplified form

$$\frac{d^4w}{dx^4} + 4\beta^4 w = \frac{Z}{D} \tag{47.104}$$

The general solution of this equation is

$$w = e^{\beta x}\left(C_1 \cos\beta x + C_2 \sin\beta x\right) + e^{-\beta x}\left(C_3 \cos\beta x + C_4 \sin\beta x\right) + f(x) \tag{47.105}$$

Detailed treatment of the shell theory can be obtained from Timoshenko and Woinowsky-Krieger (1959) and Gould (1988).

47.7 Influence Lines

Bridges, industrial buildings with traveling cranes, and frames supporting conveyer belts are often subjected to moving loads. Each member of these structures must be designed for the most severe conditions that can possibly be developed in that member. Live loads should be placed at the positions where they will produce these severe conditions. The critical positions for placing live loads will not be the same for every member. On some occasions it is possible by inspection to determine where to place the loads to give the most critical forces, but on many other occasions it is necessary to resort to certain criteria to find the locations. The most useful of these methods is the influence lines.

An influence line for a particular response such as reaction, shear force, bending moment, and axial force is defined as a diagram, the ordinate to which at any point equals the value of that response attributable to a unit load acting at that point on the structure. Influence lines provide a systematic procedure for determining how the force in a given part of a structure varies as the applied load moves about on the structure. Influence lines of responses of statically determinate structures consist only of straight lines, whereas for statically indeterminate structures they consist of curves. They are primarily used to determine where to place live loads to cause maximum force and to compute the magnitude of those forces. The knowledge of influence lines helps to study the structural response under different moving load conditions.

Influence Lines for Shear in Simple Beams

Figure 47.51 shows influence lines for shear at two sections of a simply supported beam. It is assumed that positive shear occurs when the sum of the transverse forces to the left of a section is in the upward direction or when the sum of the forces to the right of the section is downward. A unit force is placed at various locations, and the shear forces at sections 1-1 and 2-2 are obtained for each position of the unit load. These values give the ordinate of influence line with which the influence line diagrams for shear force at sections 1-1 and 2-2 can be constructed. Note that the slope of the influence line for shear

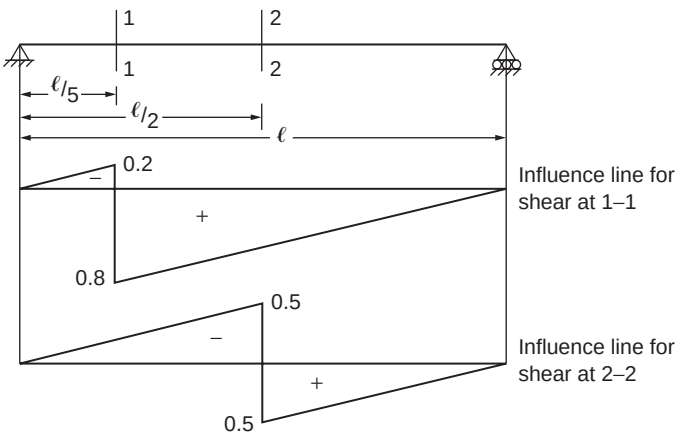

FIGURE 47.51 Influence line for shear force.

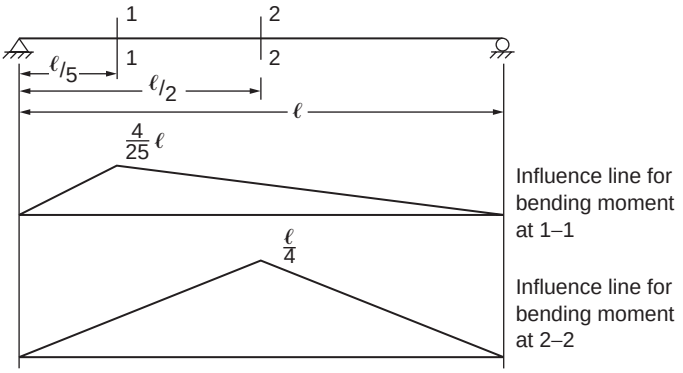

FIGURE 47.52 Influence line for bending moment.

on the left of the section is equal to the slope of the influence line on the right of the section. This information is useful in drawing shear force influence lines in other cases.

Influence Lines for Bending Moment in Simple Beams

Influence lines for bending moment at the same sections, 1-1 and 2-2, of the simple beam considered in Fig. 47.51 are plotted as shown in Fig. 47.52. For a section, when the sum of the moments of all the forces to the left is clockwise or when the sum to the right is counterclockwise, the moment is taken as positive. The values of bending moment at sections 1-1 and 2-2 are obtained for various positions of unit load and plotted as shown in the figure.

It should be understood that a shear or bending moment diagram shows the variation of shear or moment across an entire structure for loads fixed in one position. On the other hand, an influence line for shear or moment shows the variation of that response at one particular section in the structure caused by the movement of a unit load from one end of the structure to the other.

Influence lines can be used to obtain the value of a particular response for which they are drawn when the beam is subjected to any particular type of loading. If, for example, a uniform load of intensity q_o per unit length is acting over the entire length of the simple beam shown in Fig. 47.51, the shear force at section 1-1 is given by the product of the load intensity, q_o, and the net area under the influence line diagram. The net area is equal to 0.3, and the shear force at section 1-1 is therefore equal to 0.3 q_o. In the same way, the bending moment at the section can be found as the area of the corresponding influence line diagram times the intensity of loading, q_o. The bending moment at the section is equal to $0.08q_o l^2$.

Influence Lines for Trusses

Influence lines for support reactions and member forces may be constructed in the same manner as those for various beam functions. They are useful to determine the maximum load that can be applied to the truss. The unit load moves across the truss, and the ordinates for the responses under consideration may be computed for the load at each panel point. Member force, in most cases, does not need to be calculated for every panel point, because certain portions of influence lines can readily be seen to consist of straight lines for several panels. One method used for calculating the forces in a chord member of a truss is the method of sections, discussed earlier.

The truss shown in Fig. 47.53 is considered for illustrating the construction of influence lines for trusses.

The member forces in U_1U_2, L_1L_2, and U_1L_2 are determined by passing section 1-1 and considering the equilibrium of the free-body diagram of one of the truss segments. Unit load is placed at L_1 first, and the force in U_1U_2 is obtained by taking the moment about L_2 of all the forces acting on the right-hand segment of the truss and dividing the resulting moment by the lever arm (the perpendicular distance

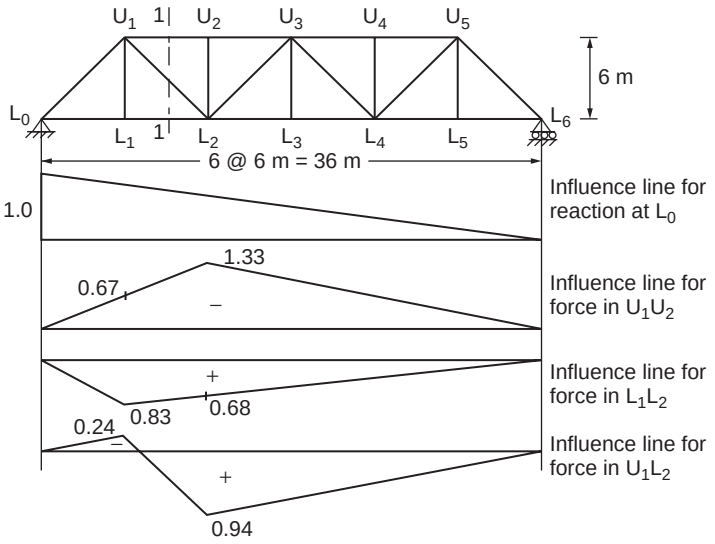

FIGURE 47.53 Influence line for truss.

of the force in U_1U_2 from L_2). The value thus obtained gives the ordinate of the influence diagram at L_1 in the truss. The ordinate at L_2, obtained similarly, represents the force in U_1U_2 for a unit load placed at L_2. The influence line can be completed with two other points, one at each of the supports. The force in the member L_1L_2 due to a unit load placed at L_1 and L_2 can be obtained in the same manner, and the corresponding influence line diagram can be completed. By considering the horizontal component of force in the diagonal of the panel, the influence line for force in U_1L_2 can be constructed. Figure 47.53 shows the respective influence diagram for member forces in U_1U_2, L_1L_2, and U_1L_2. Influence line ordinates for the force in a chord member of a "curved chord" truss may be determined by passing a vertical section through the panel and taking moments at the intersection of the diagonal and the other chord.

Qualitative Influence Lines

One of the most effective methods of obtaining influence lines is using Müller-Breslau's principle, which states that the ordinates of the influence line for any response in a structure are equal to those of the deflection curve obtained by releasing the restraint corresponding to this response and introducing a corresponding unit displacement in the remaining structure. In this way, the shape of the influence lines for both statically determinate and indeterminate structures can be easily obtained, especially for beams.

To draw the influence lines of a

1. support reaction, remove the support and introduce a unit displacement in the direction of the corresponding reaction to the remaining structure, as shown in Fig. 47.54, for a symmetrical overhang beam.
2. shear, make a cut at the section and introduce a unit relative translation (in the direction of positive shear) without relative rotation of the two ends at the section, as shown in Fig. 47.55.
3. bending moment, introduce a hinge at the section (releasing the bending moment) and apply bending (in the direction corresponding to the positive moment) to produce a unit relative rotation of the two beam ends at the hinged section, as shown in Fig. 47.56.

Influence Lines for Continuous Beams

Using Müller-Breslau's principle, the shape of the influence line of any response of a continuous beam can be sketched easily. One of the methods for beam deflection can then be used for determining the

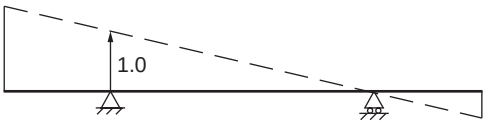

FIGURE 47.54 Influence line for support reaction.

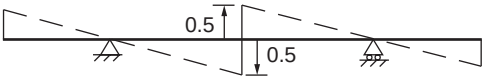

FIGURE 47.55 Influence line for midspan shear force.

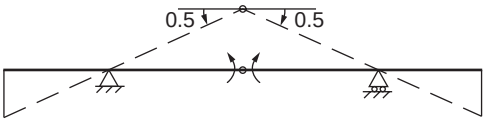

FIGURE 47.56 Influence line for midspan bending moment.

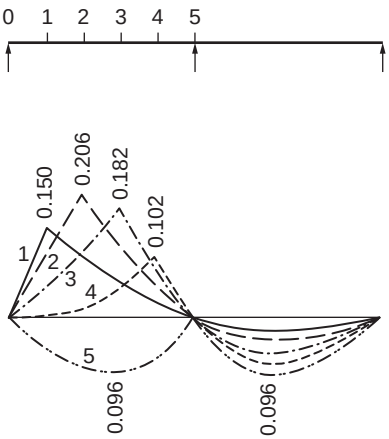

FIGURE 47.57 Influence line for bending moment — two-span beam.

ordinates of the influence line at critical points. Figures 47.57 to 47.59 show the influence lines of the bending moment at various points of two-, three-, and four-span continuous beams.

47.8 Energy Methods

Energy methods are a powerful tool in obtaining numerical solutions of statically indeterminate problems. The basic quantity required is the *strain energy*, or work stored due to deformations, of the structure.

Strain Energy Due to Uniaxial Stress

In an axially loaded bar with a constant cross section the applied load causes normal stress σ_y, as shown in Fig. 47.60. The tensile stress σ_y increases from zero to a value σ_y as the load is gradually applied. The

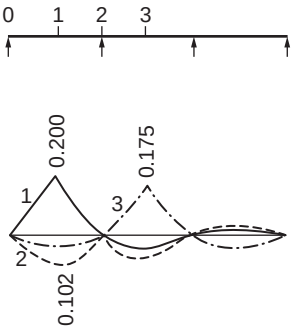

FIGURE 47.58 Influence line for bending moment — three-span beam.

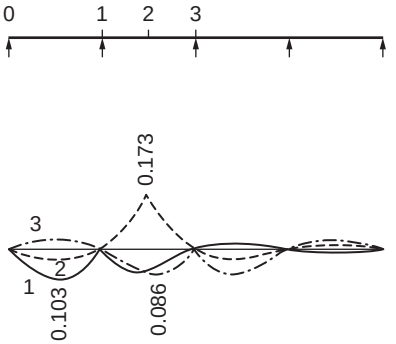

FIGURE 47.59 Influence line for bending moment — four-span beam.

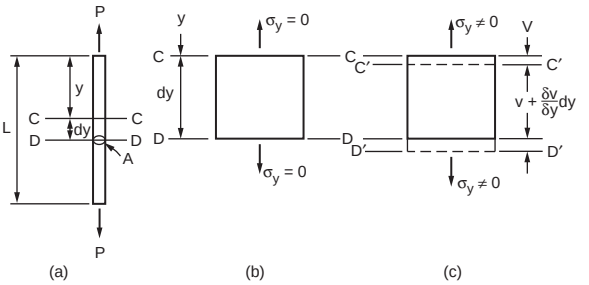

FIGURE 47.60 Axial loaded bar.

original, unstrained position of any section such as C-C will be displaced by an amount dv. A section D-D located a differential length below C-C will have been displaced by an amount $v + (\partial v/\partial y)dy$. As σ_y varies with the applied load, from zero to σ_y, the work done by the forces external to the element can be shown to be

$$dV = \frac{1}{2E}\sigma_y^2 A dy = \frac{1}{2}\sigma_y \varepsilon_y A dy \tag{47.106}$$

in which A = the area of cross section of the bar
ε_y = the strain in the direction of σ_y.

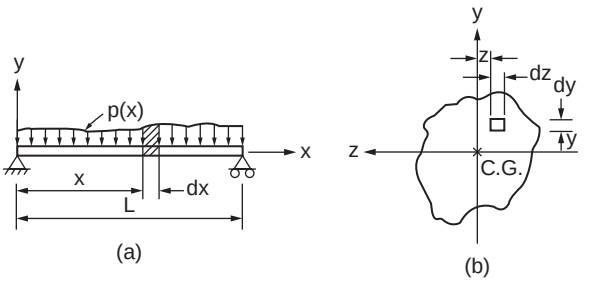

FIGURE 47.61 Beam under arbitrary bending load.

Strain Energy in Bending

It can be shown that the strain energy of a differential volume *dxdydz* stressed in tension or compression in the x direction only by a normal stress σ_x will be

$$dV = \frac{1}{2E}\sigma_x^2 dxdydz = \frac{1}{2}\sigma_x \varepsilon_x dxdydz \tag{47.107}$$

When σ_x is the bending stress given by $\sigma_x = My/I$ (see Fig. 47.61), then

$$dV = \frac{1}{2E}\frac{M^2 y^2}{I^2} dxdydz,$$

where I is the moment of inertia of the cross-sectional area about the neutral axis.

The total strain energy of bending of a beam is obtained as

$$V = \iiint_{volume} \frac{1}{2E}\frac{M^2}{I^2} y^2 \, dz\, dy\, dx$$

where

$$I = \iint_{area} y^2 \, dzdy$$

Therefore

$$V = \int_{length} \frac{M^2}{2EI} dx \tag{47.108}$$

Strain Energy in Shear

Figure 47.62 shows an element of volume *dxdydz* subjected to shear stress τ_{xy} and τ_{yx}. For static equilibrium, it can readily be shown that

$$\tau_{xy} = \tau_{yx}$$

The shear strain, γ, is defined as AB/AC. For small deformations, it follows that

$$\gamma_{xy} = \frac{AB}{AC}$$

Hence, the angle of deformation, γ_{xy}, is a measure of the shear strain. The strain energy for this differential volume is obtained as

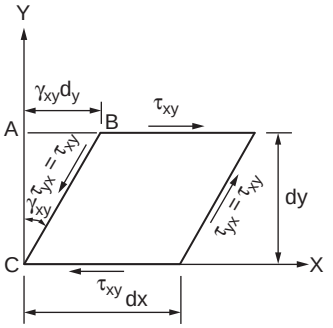

FIGURE 47.62 Shear loading.

$$dV = \frac{1}{2}(\tau_{xy}\,dzdx)\gamma_{xy}\,dy = \frac{1}{2}\tau_{xy}\gamma_{xy}\,dxdydz \tag{47.109}$$

Hooke's law for shear stress and strain is

$$\gamma_{xy} = \frac{\tau_{xy}}{G} \tag{47.110}$$

where G is the shear modulus of elasticity of the material. The expression for strain energy in shear reduces to

$$dV = \frac{1}{2G}\tau_{xy}^2\,dxdydz \tag{47.111}$$

The Energy Relations in Structural Analysis

The energy relations or laws, such as the law of conservation of energy, the theorem of virtual work, the theorem of minimum potential energy, and the theorem of complementary energy, are of fundamental importance in structural engineering and are used in various ways in structural analysis.

The Law of Conservation of Energy

The law of conservation of energy states that if a structure and the external loads acting on it are isolated so that these neither receive nor give out energy, then the total energy of this system remains constant.

A typical application of the law of conservation of energy can be made by referring to Fig. 47.63, which shows a cantilever beam of constant cross sections subjected to a concentrated load at its end. If only bending strain energy is considered,

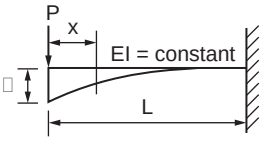

FIGURE 47.63 Cantilever beam.

$$\text{external work} = \text{internal work}$$

$$\frac{P\delta}{2} = \int_0^L \frac{M^2 dx}{2EI}$$

Substituting M = –Px and integrating along the length gives

$$\delta = \frac{PL^3}{3EI} \tag{47.112}$$

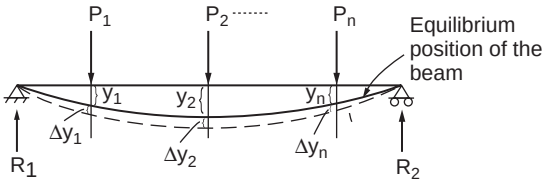

FIGURE 47.64 Equilibrium of a simple supported beam under loading.

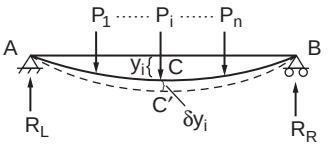

FIGURE 47.65 Simply supported beam under point loading.

The Theorem of Virtual Work

The theorem of virtual work can be derived by considering the beam shown in Fig. 47.64. The full curved line represents the equilibrium position of the beam under the given loads. Assume the beam to be given an additional small deformation consistent with the boundary conditions. This is called a virtual deformation and corresponds to increments of deflection $\Delta_{y1}, \Delta_{y2}, \ldots, \Delta_{yn}$ at loads $P_1, P_2, \ldots, P_n$, as shown by the dashed line.

The change in potential energy of the loads is given by

$$\Delta(\text{P.E.}) = \sum_{i=1}^{n} P_i \Delta_{y_i} \tag{47.113}$$

By the law of conservation of energy this must be equal to the internal strain energy stored in the beam. Hence, we may state the theorem of virtual work as: if a body in equilibrium under the action of a system of external loads is given any small (virtual) deformation, then the work done by the external loads during this deformation is equal to the increase in internal strain energy stored in the body.

The Theorem of Minimum Potential Energy

Let us consider the beam shown in Fig. 47.65. The beam is in equilibrium under the action of loads P_1, P_2, P_3, …, P_i, …, P_n. The curve ACB defines the equilibrium positions of the loads and reactions. Now apply by some means an additional small displacement to the curve so that it is defined by AC′B. Let y_i be the original equilibrium displacement of the curve beneath a particular load P_i. The additional small displacement is called δ_{yi}. The potential energy of the system while it is in the equilibrium configuration is found by comparing the potential energy of the beam and loads in equilibrium and in the undeflected position. If the change in potential energy of the loads is W and the strain energy of the beam is V, the total energy of the system is

$$U = W + V \tag{47.114}$$

If we neglect the second-order terms, then

$$\delta U = \delta(W + V) = 0 \tag{47.115}$$

The above is expressed as the principle or theorem of minimum potential energy, which can be stated as: if all displacements satisfy given boundary conditions, those that satisfy the equilibrium conditions make the potential energy a minimum.

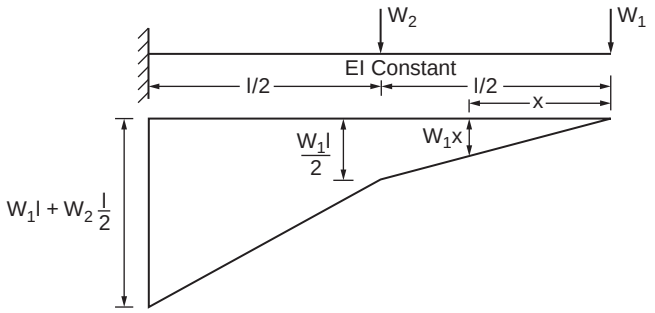

FIGURE 47.66 Example 47.6.

Castigliano's Theorem

This theorem applies only to structures stressed within the elastic limit, and all deformations must be linear homogeneous functions of the loads.

For a beam in equilibrium, as in Fig. 47.64, the total potential energy is

$$U = -\left[P_1 y_1 + P_2 y_2 + \ldots P_j y_j + \ldots P_n y_n\right] + V \tag{47.116}$$

For an elastic system, the strain energy, V, turns out to be one half the change in the potential energy of the loads.

$$V = \frac{1}{2}\sum_{i=1}^{i=n} P_i y_i \tag{47.117}$$

Castigliano's theorem results from studying the variation in the strain energy, V, produced by a differential change in one of the loads, say P_j.

If the load P_j is changed by a differential amount δP_j and if the deflections y are linear functions of the loads, then

$$\frac{\partial V}{\partial P_j} = \frac{1}{2}\sum_{i=1}^{i=n} P_i \frac{\partial y_i}{\partial P_j} + \frac{1}{2} y_j = y_j \tag{47.118}$$

Castigliano's theorem states that the partial derivatives of the total strain energy of any structure with respect to any one of the applied forces is equal to the displacement of the point of application of the force in the direction of the force.

To find the deflection of a point in a beam that is not the point of application of a concentrated load, one should apply a load P = 0 at that point and carry the term P into the strain energy equation. Finally, introduce the true value of P = 0 into the expression for the answer.

Example 47.6

Determination of the bending deflection at the free end of a cantilever, loaded as shown in Fig. 47.66, is required.

Solution:

$$V = \int_0^L \frac{M^2}{2EI} dx$$

$$\Delta = \frac{\partial V}{\partial W_1} = \int_0^L \frac{M}{EI}\frac{\partial M}{\partial W_1} dx$$

$$M = W_1 x \qquad 0 < x \frac{L}{2}$$

$$= W_1 x + W_2\left(x - \frac{\lambda}{2}\right) \qquad \frac{L}{2} < x < L$$

$$\Delta = \frac{1}{EI}\int_0^{\lambda/2} W_1 x \times x\,dx + \frac{1}{EI}\int_{\lambda/2}^{\lambda}\left[W_1 x + w_2\left(x - \frac{P}{2}\right)\right]x\,dx$$

$$= \frac{w_1\lambda^3}{24EI} + \frac{7W_1\lambda^3}{24EI} + \frac{5W_2\lambda^3}{48EI}$$

$$= \frac{W_1\lambda^3}{3EI} + \frac{5W_2\lambda^3}{48EI}$$

Castigliano's theorem can be applied to determine deflection of trusses as follows:

We know that the increment of strain energy for an axially loaded bar is given as

$$dV = \frac{1}{2E}\sigma_y^2 A\,dy$$

Substituting $\sigma_y = S/A$, where S is the axial load in the bar, and integrating over the length of the bar, the total strain energy of the bar is given as

$$V = \frac{S^2 L}{2AE} \tag{47.119}$$

The deflection component Δ_i of the point of application of a load P_i in the direction of P_i is given as

$$\Delta_i = \frac{\partial V}{\partial P_i} = \frac{\partial}{\partial P_i}\ \Sigma\frac{S^2 L}{2AE} = \Sigma\frac{S\dfrac{\partial S}{\partial P_i}L}{AE}$$

Example 47.7

Determine the vertical deflection at g of the truss subjected to three-point load, as shown in Fig. 47.67. Let us first replace the 20 load at g by P and carry out the calculations in terms of P. At the end, P will be replaced by the actual load of 20.

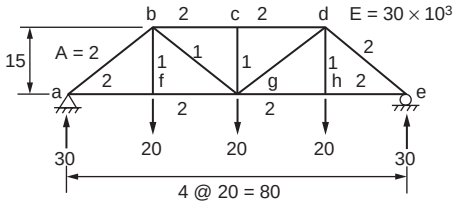

FIGURE 47.67 Example 47.7.

With P = 20,

$$\Delta_g = \Sigma \frac{S\frac{\delta S}{\delta P}L}{AE} = \frac{(2117 + 105 \times 20) \times 12}{30 \times 10^3} = 1.69$$

Unit Load Method

The unit load method is a versatile tool in the solution of deflections of both trusses and beams. Consider an elastic body in equilibrium under loads P_1, P_2, P_3, P_4, … P_n and a load p applied at point O, as shown in Fig. 47.68. By Castigliano's theorem, the component of the deflection of point O in the direction of the applied force p is

$$\delta_{o_p} = \frac{\partial V}{\partial p} \tag{47.120}$$

in which V is the strain energy of the body. It has been shown in Eq. (47.108) that the strain energy of a beam, neglecting shear effects, is given by

$$V = \int_O^L \frac{M^2}{2EI} dx$$

Also it was shown that if the elastic body is a truss, from Eq. (47.119)

$$V = \Sigma \frac{S^2 L}{2AE}$$

For a beam, therefore, from Eq. (47.120)

$$\delta_{o_p} = \int_L \frac{M\frac{\partial M}{\partial p}dx}{EI} \tag{47.121}$$

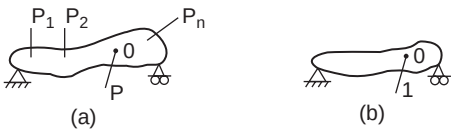

FIGURE 47.68 Elastic body in equilibrium under load.

and for a truss,

$$\delta_{o_p} = \Sigma \frac{S \dfrac{\partial S}{\partial p} L}{AE} \tag{47.122}$$

The bending moments M and the axial forces S are functions of the load p as well as of the loads P_1, P_2, … P_n. Let a unit load be applied at O on the elastic body and the corresponding moment be *m* if the body is a beam and the forces in the members of the body *u* if the body is a truss. For the body in Fig. 47.68 the moments M and the forces S due to the system of forces P_1, P_2, … P_n and p at O applied separately can be obtained by superposition as

$$M = M_p = pm \tag{47.123}$$

$$S = S_p + pu \tag{47.124}$$

in which M_p and S_p are, respectively, moments and forces produced by P_1, P_2, … P_n.

Then

$$\frac{\partial M}{\partial p} = m = \text{moments produced by a unit load at O} \tag{47.125}$$

$$\frac{\partial S}{\partial p} = u = \text{ stresses produced by a unit load at O} \tag{47.126}$$

Using Eqs. (47.125) and (47.126) in Eqs. (47.121) and (47.122), respectively,

$$\delta_{o_p} = \int_L \frac{Mm\,dx}{EI} \tag{47.127}$$

$$\delta_{o_p} = \Sigma \frac{SuL}{AE} \tag{47.128}$$

Example 47.8

Determine, using the unit load method, the deflection at C of a simple beam of constant cross section loaded as shown in Fig. 47.69a.

Solution:

The bending moment diagram for the beam due to the applied loading is shown in Fig. 47.69b. A unit load is applied at C, where it is required to determine the deflection, as shown in Fig. 47.69c; the corresponding bending moment diagram is shown in Fig. 47.69d. Now, using Eq. (47.127), we have

$$\delta_c = \int_o^L \frac{Mm\,dx}{EI}$$

$$= \frac{1}{EI}\int_o^{\frac{L}{4}} (Wx)\left(\frac{3}{4}x\right)dx + \frac{1}{EI}\int_{\frac{L}{4}}^{\frac{3L}{4}} \left(\frac{WL}{4}\right)\frac{1}{4}(L-x)dx$$

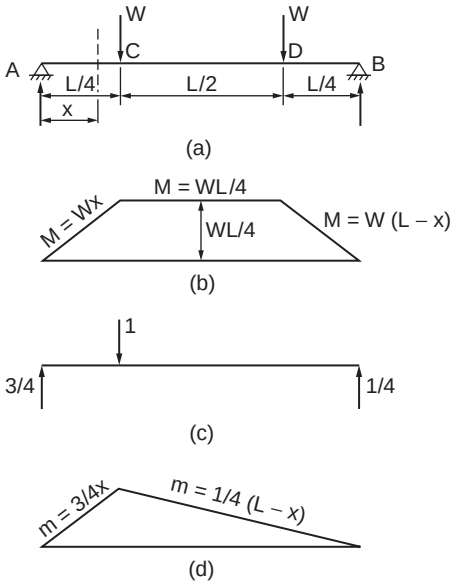

FIGURE 47.69 Example 47.8.

$$+\frac{1}{EI}\int_{\frac{3L}{4}}^{L} W(L-x)\frac{1}{4}(L-x)dx$$

$$=\frac{WL^3}{48EI}$$

Further details on energy methods in structural analysis may be found in Borg and Gennaro (1959).

47.9 Matrix Methods

In this method, a set of simultaneous equations that describe the load–deformation characteristics of the structure under consideration are formed. These equations are solved using the matrix algebra to obtain the load–deformation characteristics of discrete or finite elements into which the structure has been subdivided. The matrix method is ideally suited for performing structural analysis using a computer. In general, there are two approaches for structural analysis using the matrix analysis. The first is called the flexibility method, in which forces are used as independent variables, and the second is called the stiffness method, which employs deformations as the independent variables. The two methods are also called the force method and the displacement method, respectively.

Flexibility Method

In this method, the forces and displacements are related to one another by using stiffness influence coefficients. Let us consider, for example, a simple beam in which three concentrated loads, W_1, W_2, and W_3, are applied at sections 1, 2, and 3, respectively, as shown in Fig. 47.70. The deflection at section 1, Δ_1, can be expressed as

$$\Delta_1 = F_{11}W_1 + F_{12}W_2 + F_{13}W_3$$

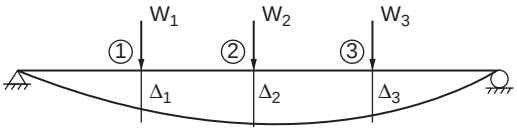

FIGURE 47.70 Simple beam under concentrated loads.

in which F_{11}, F_{12}, and F_{13} are called flexibility coefficients and are defined as the deflection at section 1 due to unit loads applied at sections 1, 2, and 3, respectively. Deflections at sections 2 and 3 are similarly given as

$$\Delta_2 = F_{21}W_1 + F_{22}W_2 + F_{23}W_3$$

and

$$\Delta_3 = F_{31}W_1 + F_{32}W_2 + F_{33}W_3 \tag{47.129}$$

These expressions are written in matrix form as

$$\begin{Bmatrix}\Delta_1\\ \Delta_2\\ \Delta_3\end{Bmatrix} = \begin{bmatrix}F_{11} & F_{12} & F_{13}\\ F_{21} & F_{22} & F_{23}\\ F_{31} & F_{32} & F_{33}\end{bmatrix}\begin{Bmatrix}W_1\\ W_2\\ W_3\end{Bmatrix}$$

or

$$\{\Delta\} = [F]\{W\} \tag{47.130}$$

Matrix [F] is called the flexibility matrix. It can be shown, by applying Maxwell's reciprocal theorem (Borg and Gennaro, 1959), that matrix [F] is a symmetric matrix.

Let us consider a cantilever beam loaded as shown in Fig. 47.71. The first column in the flexibility matrix can be generated by applying a unit vertical load at the free end of the cantilever, as shown in Fig. 47.71b, and making use of the moment area method. We get

$$F_{11} = \frac{8L^3}{3EI}, \quad F_{21} = \frac{2L^2}{EI}, \quad F_{31} = \frac{5L^3}{6EI}, \quad F_{41} = \frac{3L^2}{2EI}$$

Columns 2, 3, and 4 are similarly generated by applying unit moment at the free end and unit force and unit moment at the midspan, as shown in Figs. 47.71c to e, respectively. Combining the results, the flexibility matrix can be formed as

$$\begin{Bmatrix}\Delta_1\\ \Delta_2\\ \Delta_3\\ \Delta_4\end{Bmatrix} = \frac{1}{EI}\begin{bmatrix}\frac{8L^3}{3} & 2L^2 & \frac{5L^3}{6} & \frac{3L^2}{2}\\ 2L^2 & 2L & \frac{L^2}{2} & L\\ \frac{5L^3}{6} & \frac{L^2}{2} & \frac{L^3}{3} & \frac{L^2}{2}\\ \frac{3L^2}{2} & L & \frac{L^2}{2} & L\end{bmatrix}\begin{Bmatrix}W_1\\ W_2\\ W_3\\ W_4\end{Bmatrix} \tag{47.131}$$

For a given structure, it is necessary to subdivide the structure into several elements and to form the flexibility matrix for each of the elements. The flexibility matrix for the entire structure is then obtained by combining the flexibility matrices of the individual elements.

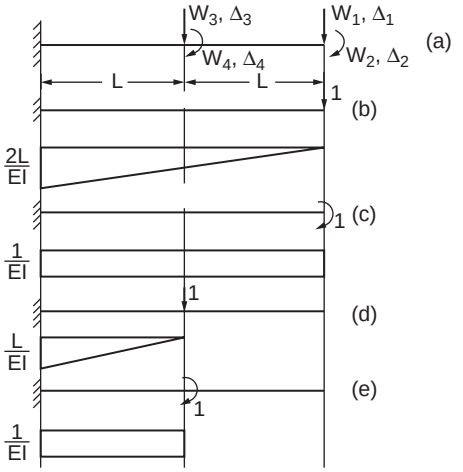

FIGURE 47.71 Cantilever beam.

The force transformation matrix relates what occurs in these elements to the behavior of the entire structure. Using the conditions of equilibrium, it relates the element forces to the structure forces. The principle of conservation of energy may be used to generate transformation matrices.

Stiffness Method

In this method, forces and deformations in a structure are related to one another by means of stiffness influence coefficients. Let us consider a simply supported beam subjected to end moments W_1 and W_2 applied at supports 1 and 2, respectively, and let the rotations be denoted as Δ_1 and Δ_2, as shown in Fig. 47.72. We can now write the expressions for end moments W_1 and W_2 as

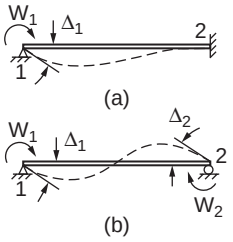

FIGURE 47.72 Simply supported beam.

$$\begin{aligned} W_1 &= K_{11}\Delta_1 + K_{12}\Delta_2 \\ W_2 &= K_{21}\Delta_1 + K_{22}\Delta_2 \end{aligned} \qquad (47.132)$$

in which K_{11} and K_{12} are called stiffness influence coefficients defined as moments at 1 due to unit rotation at 1 and 2, respectively. The above equations can be written in matrix form as

$$\begin{Bmatrix} W_1 \\ W_2 \end{Bmatrix} = \begin{bmatrix} K_{11} & K_{12} \\ K_{21} & K_{22} \end{bmatrix} \begin{Bmatrix} \Delta_2 \\ \Delta_2 \end{Bmatrix}$$

or

$$\{W\} = [K]\{\Delta\} \qquad (47.133)$$

Matrix [K] is referred to as the stiffness matrix. It can be shown that the flexibility matrix of a structure is the inverse of the stiffness matrix and vice versa. The stiffness matrix of the whole structure is formed out of the stiffness matrices of the individual elements that make up the structure.

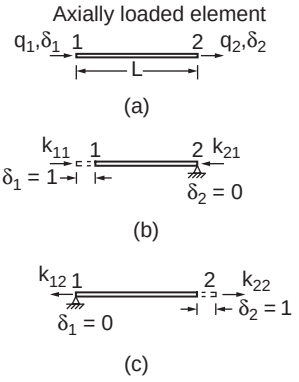

FIGURE 47.73 Axially loaded member.

Element Stiffness Matrix

Axially Loaded Member

Figure 47.73 shows an axially loaded member of a constant cross-sectional area with element forces q_1 and q_2 and displacements δ_1 and δ_2. They are shown in their respective positive directions. With unit displacement $\delta_1 = 1$ at node 1, as shown in Fig. 47.73, axial forces at nodes 1 and 2 are obtained as

$$K_{11} = \frac{EA}{L}, \quad K_{21} = -\frac{EA}{L}$$

In the same way, by setting $\delta_2 = 1$, as shown in Fig. 47.73, the corresponding forces are obtained as

$$K_{12} = -\frac{EA}{L}, \quad K_{22} = \frac{EA}{L}$$

The stiffness matrix is written as

$$\begin{Bmatrix} q_1 \\ q_2 \end{Bmatrix} = \begin{bmatrix} K_{11} & K_{12} \\ K_{21} & K_{22} \end{bmatrix} \begin{Bmatrix} \delta_1 \\ \delta_2 \end{Bmatrix}$$

or

$$\begin{Bmatrix} q_1 \\ q_2 \end{Bmatrix} = \frac{EA}{L} \begin{bmatrix} 1 & -1 \\ -1 & 1 \end{bmatrix} \begin{Bmatrix} \delta_1 \\ \delta_2 \end{Bmatrix} \tag{47.134}$$

Flexural Member

The stiffness matrix for the flexural element can be constructed by referring to Fig. 47.74. The forces and the corresponding displacements viz. the moments, shears, and corresponding rotations and translations at the ends of the member are defined in the figure. The matrix equation that relates these forces and displacements can be written in the form

$$\begin{bmatrix} q_1 \\ q_2 \\ q_3 \\ q_4 \end{bmatrix} = \begin{bmatrix} K_{11} & K_{12} & K_{13} & K_{14} \\ K_{21} & K_{22} & K_{23} & K_{24} \\ K_{31} & K_{32} & K_{33} & K_{34} \\ K_{41} & K_{42} & K_{43} & K_{44} \end{bmatrix} \begin{bmatrix} \delta_1 \\ \delta_2 \\ \delta_3 \\ \delta_4 \end{bmatrix}$$

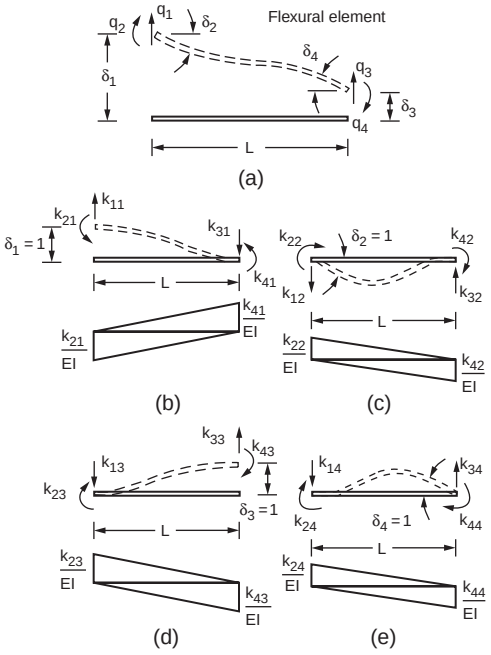

FIGURE 47.74 Beam element — stiffness matrix.

The terms in the first column consist of the element forces q_1 through q_4 that result from displacement $\delta_1 = 1$ when $\delta_2 = \delta_3 = \delta_4 = 0$. This means that a unit vertical displacement is imposed at the left end of the member, while translation at the right end and rotation at both ends are prevented, as shown in Fig. 47.74. The four member forces corresponding to this deformation can be obtained using the moment area method.

The change in slope between the two ends of the member is zero, and the area of the M/EI diagram between these points must therefore vanish. Hence

$$\frac{K_{41}L}{2EI} - \frac{K_{21}L}{2EI} = 0$$

and

$$K_{21} = K_{41} \tag{47.135}$$

The moment of the M/EI diagram about the left end of the member is equal to unity. Hence

$$\frac{K_{41}L}{2EI}\left(\frac{2L}{3}\right) - \frac{K_{21}L}{2EI}\left(\frac{L}{3}\right) = 1$$

and in view of Eq. (47.135),

$$K_{41} = K_{21} = \frac{6EI}{L^2}$$

Finally, moment equilibrium of the member about the right end leads to

$$K_{11} = \frac{K_{21} + K_{41}}{L} = \frac{12EI}{L^3}$$

and from equilibrium in the vertical direction we obtain

$$K_{31} = K_{11} = \frac{12EI}{L^3}$$

The forces act in the directions indicated in Fig. 47.74b. To obtain the correct signs, one must compare the forces with the positive directions defined in Fig. 47.74a. Thus

$$K_{11} = \frac{12EI}{L^3}, \quad K_{21} = -\frac{6EI}{L^2}, \quad K_{31} = -\frac{12EI}{L^3}, \quad K_{41} = \frac{6EI}{L^2}$$

The second column of the stiffness matrix is obtained by letting $\delta_2 = 1$ and setting the remaining three displacements equal to zero, as indicated in Fig. 47.74c. The area of the M/EI diagram between the ends of the member for this case is equal to unity, and hence

$$\frac{K_{22}L}{2EI} - \frac{K_{42}L}{2EI} = 1$$

The moment of the M/EI diagram about the left end is zero, so that

$$\frac{K_{22}L}{2EI}\left(\frac{L}{3}\right) - \frac{K_{42}L}{2EI}\left(\frac{2L}{3}\right) = 0$$

Therefore, one obtains

$$K_{22} = \frac{4EI}{L}, \quad K_{42} = \frac{2EI}{L}$$

From vertical equilibrium of the member,

$$K_{12} = K_{32}$$

and moment equilibrium about the right end of the member leads to

$$K_{12} = \frac{K_{22} - K_{42}}{L} = \frac{6EI}{L^2}$$

Comparison of the forces in Fig. 47.74c with the positive directions defined in Fig. 47.74a indicates that all the influence coefficients except k_{12} are positive. Thus

$$K_{12} = -\frac{6EI}{L^2}, \quad K_{22} = \frac{4EI}{L}, \quad K_{32} = \frac{6EI}{L^2}, \quad K_{42} = \frac{2EI}{L}$$

Using Figs. 47.74d and e, the influence coefficients for the third and fourth columns can be obtained. The results of these calculations lead to the following element stiffness matrix:

$$\begin{bmatrix} q_1 \\ q_2 \\ q_3 \\ q_4 \end{bmatrix} = \begin{bmatrix} \frac{12EI}{L^3} & -\frac{6EI}{L^2} & -\frac{12EI}{L^3} & -\frac{6EI}{L^2} \\ -\frac{6EI}{L^2} & \frac{4EI}{L} & \frac{6EI}{L^2} & \frac{2EI}{L} \\ -\frac{12EI}{L^3} & \frac{6EI}{L^2} & \frac{12EI}{L^3} & \frac{6EI}{L^2} \\ -\frac{6EI}{L^2} & \frac{2EI}{L} & \frac{6EI}{L^2} & \frac{4EI}{L} \end{bmatrix} \begin{bmatrix} \delta_1 \\ \delta_2 \\ \delta_3 \\ \delta_4 \end{bmatrix} \tag{47.136}$$

FIGURE 47.75 Beam element with axial force.

Note that Eq. (47.135) defines the element stiffness matrix for a flexural member with constant flexural rigidity EI.

If the axial load in a frame member is also considered, the general form of an element stiffness matrix for an element shown in Fig. 47.75 becomes

$$\begin{bmatrix} q_1 \\ q_2 \\ q_3 \\ q_4 \\ q_5 \\ q_6 \end{bmatrix} = \begin{bmatrix} \frac{EA}{L} & 0 & 0 & -\frac{EA}{L} & 0 & 0 \\ 0 & \frac{12EI}{L^3} & -\frac{6EI}{L^2} & 0 & -\frac{12EI}{L^3} & -\frac{6EI}{L^2} \\ 0 & -\frac{6EI}{L^2} & \frac{4EI}{L} & 0 & \frac{6EI}{L^2} & \frac{2EI}{L} \\ -\frac{EI}{L} & 0 & 0 & \frac{EI}{L} & 0 & 0 \\ 0 & -\frac{12EI}{L^3} & \frac{6EI}{L^2} & 0 & \frac{12EI}{L^3} & \frac{6EI}{L^2} \\ 0 & -\frac{6EI}{L^2} & \frac{2EI}{L} & 0 & \frac{6EI}{L^2} & \frac{4EI}{L} \end{bmatrix} \begin{bmatrix} \delta_1 \\ \delta_2 \\ \delta_3 \\ \delta_4 \\ \delta_5 \\ \delta_6 \end{bmatrix}$$

or

$$[q] = [k_c][\delta] \tag{47.137}$$

The member stiffness matrix can be written as

$$K = \begin{bmatrix} \frac{GJ}{L} & 0 & 0 & -\frac{GJ}{L} & 0 & 0 \\ 0 & \frac{12EI_z}{L^3} & \frac{6EI_z}{L^2} & 0 & -\frac{12EI_z}{L^3} & \frac{6EI_z}{L^2} \\ 0 & \frac{6EI_z}{L^2} & \frac{4EI_z}{L} & 0 & -\frac{6EI_z}{L^2} & \frac{2EI_z}{L} \\ -\frac{GJ}{L} & 0 & 0 & \frac{GJ}{L} & 0 & 0 \\ 0 & -\frac{12EI_z}{L^2} & -\frac{6EI_z}{L^2} & 0 & \frac{12EI_z}{L^3} & -\frac{6EI_z}{L^2} \\ 0 & \frac{6EI_z}{L^2} & \frac{2EI_z}{L} & 0 & -\frac{6EI_z}{L^2} & \frac{4EI_z}{L} \end{bmatrix} \tag{47.138}$$

Structure Stiffness Matrix

Equation (47.137) has been expressed in terms of the coordinate system of the individual members. In a structure consisting of many members there would be as many systems of coordinates as the number of members. Before the internal actions in the members of the structure can be related, all forces and deflections must be stated in terms of one single system of axes common to all — the global axes. The transformation from element to global coordinates is carried out separately for each element, and the resulting matrices are then combined to form the structure stiffness matrix. A separate transformation matrix [T] is written for each element, and a relation of the form

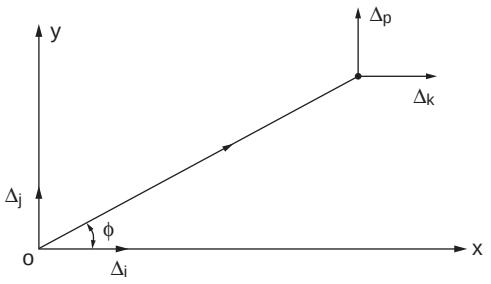

FIGURE 47.76 Grid member.

$$[\delta]_n = [T]_n [\Delta]_n \tag{47.139}$$

is written in which $[T]_n$ defines the matrix relating the element deformations of element n to the structure deformations at the ends of that particular element. The element and structure forces are related in the same way as the corresponding deformations as

$$[q]_n = [T]_n [W]_n \tag{47.140}$$

where $[q]_n$ contains the element forces for element n and $[W]_n$ contains the structure forces at the extremities of the element. The transformation matrix $[T]_n$ can be used to transform element n from its local coordinates to structure coordinates. We know, for an element n, that the force–deformation relation is given as

$$[q]_n = [k]_n [\delta]_n$$

Substituting for $[q]_n$ and $[\delta]_n$ from Eqs. (47.138) and (47.139), one obtains

$$[T]_n [W]_n = [k]_n [T]_n [\Delta]_n$$

or

$$\begin{aligned} [W]_n &= [T]_n^{-1} [k]_n [T]_n [\Delta]_n \\ &= [T]_n^{T} [k]_n [T]_n [\Delta]_n \\ &= [K]_n [\Delta]_n \\ [K]_n &= [T]_n^{T} [k]_n [T]_n \end{aligned} \tag{47.141}$$

$[K]_n$ is the stiffness matrix that transforms any element n from its local coordinate to structure coordinates. In this way, each element is transformed individually from element coordinate to structure coordinate, and the resulting matrices are combined to form the stiffness matrix for the entire structure.

For example, the member stiffness matrix $[K]_n$ in global coordinates for the truss member shown in Fig. 47.76 is given as

$$[K]_n = \frac{AE}{L} \begin{bmatrix} \lambda^2\mu & \lambda\mu & -\lambda^2 & -\lambda\mu \\ \lambda\mu & \mu^2 & -\lambda\mu & -\mu^2 \\ -\lambda^2 & -\lambda\mu & \lambda^2 & \lambda\mu \\ -\lambda\mu & -\mu^2 & \lambda\mu & \mu^2 \end{bmatrix} \begin{matrix} i \\ j \\ k \\ \ell \end{matrix} \tag{47.142}$$

in which $\lambda = \cos\phi$
$\mu = \sin\phi$.

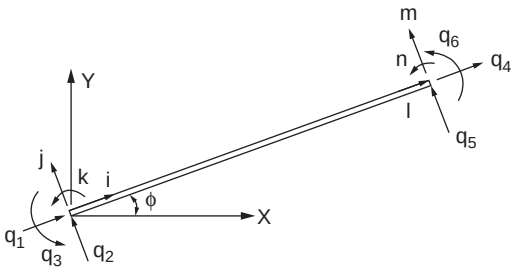

FIGURE 47.77 Flexural member in global coordinate.

To construct $[K]_n$ for a given member, it is necessary to have the values of λ and μ for the member. In addition, the structure coordinates i, j, k, and l at the extremities of the member must be known.

The member stiffness matrix $[K]_n$ in structural coordinates for the flexural member shown in Fig. 47.77 can be written as

$$[K]_n = \begin{bmatrix} \lambda^2\frac{AE}{L}+\mu^2\frac{12EI}{L^3} & & & & & \\ \mu\lambda\left(\frac{AE}{L}-\frac{12EI}{L^3}\right) & \mu^2\frac{AE}{L}+\lambda^2\frac{12EI}{L^3} & & \text{symmetric} & & \\ -\mu\left(\frac{6EI}{L^2}\right) & \lambda\frac{6EI_z}{L^2} & \frac{4EI}{L} & 0 & & \\ 0 & -\lambda^2\frac{AE}{L}-\mu^2\frac{12EI}{L^3} & \mu\lambda\left(\frac{AE}{L}-\frac{12EI}{L^3}\right) & \mu\left(\frac{6EI}{L^2}\right) & \lambda^2\frac{AE}{L}+\mu^2\frac{12EI}{L^3} & 0 \quad 0 \\ & -\mu\lambda\left(\frac{AE}{L}-\frac{12EI}{L^3}\right) & -\left(\mu^2\frac{AE}{L}+\lambda^2\frac{12EI}{L^3}\right) & -\lambda\left(\frac{6EI}{L^2}\right) & \mu\lambda\left(\frac{AE}{L}-\frac{12EI}{L^3}\right) & \left(\mu\frac{AE}{L}+\lambda^2\frac{12EI}{L^3}\right) \\ & \mu\frac{6EI_z}{L^2} & \lambda\frac{6EI_z}{L^2} & \frac{2EI}{L} & \mu\left(\frac{6EI}{L^2}\right) & -\lambda\frac{6EI}{L^2} \quad \frac{4EI}{L} \end{bmatrix} \tag{47.143}$$

where $\lambda = \cos\phi$ and $\mu = \sin\phi$.

Example 47.9

Determine the displacement at the loaded point of the truss shown in Fig. 47.78a. Both members have the same area of cross section: A = 3 and E = 30×10^3.

The details required to form the element stiffness matrix with reference to structure coordinates axes are listed below (see Fig. 47.78b):

Member	Length	ϕ	λ	μ	i	j	k	l
1	10	90°	0	1	1	2	3	4
2	18.9	32°	0.85	0.53	1	2	5	6

We now use these data in Eq. (47.142) to form $[K]_n$ for the two elements.

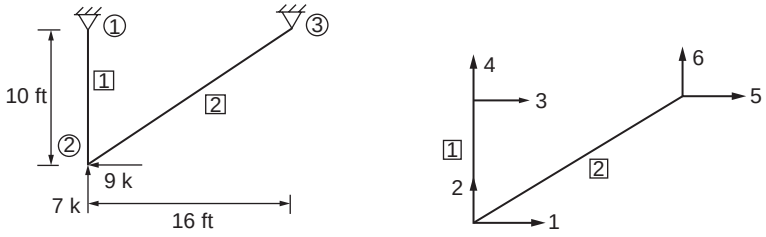

FIGURE 47.78 Example 47.9.

For member 1,

$$\frac{AE}{L} = \frac{3 \times 30 \times 10^3}{120} = 750$$

$$[K]_1 = \begin{array}{c|cccc|c} & 1 & 2 & 3 & 4 & \\ \hline & 0 & 0 & 0 & 0 & 1 \\ & 0 & 750 & 0 & -750 & 2 \\ & 0 & 0 & 0 & 0 & 3 \\ & 0 & -750 & 0 & 750 & 4 \end{array}$$

For member 2,

$$\frac{AE}{L} = \frac{3 \times 30 \times 10^3}{18.9 \times 12} = 397$$

$$[K]_2 = \begin{array}{c|cccc|c} & 1 & 2 & 5 & 6 & \\ \hline & 286 & 179 & -286 & -179 & 1 \\ & 179 & 111 & -179 & -111 & 2 \\ & -286 & -179 & 286 & 179 & 5 \\ & -179 & -111 & 179 & 111 & 6 \end{array}$$

Combining the element stiffness matrices $[K]_1$ and $[K]_2$, one obtains the structure stiffness matrix as follows:

$$\begin{bmatrix} W_1 \\ W_2 \\ W_3 \\ W_4 \\ W_5 \\ W_6 \end{bmatrix} = \begin{bmatrix} 286 & 179 & 0 & 0 & -286 & -179 \\ 179 & 861 & 0 & -750 & -179 & -111 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & -750 & 0 & 750 & 0 & 0 \\ -286 & -179 & 0 & 0 & 286 & 179 \\ -179 & -111 & 0 & 0 & 179 & 111 \end{bmatrix} \begin{bmatrix} \Delta_1 \\ \Delta_2 \\ \Delta_3 \\ \Delta_4 \\ \Delta_5 \\ \Delta_6 \end{bmatrix}$$

The stiffness matrix can now be subdivided to determine the unknowns. Let us consider Δ_1 and Δ_2, the deflections at joint 2, which can be determined in view of $\Delta_3 = \Delta_4 = \Delta_5 = \Delta_6 = 0$ as follows:

$$\begin{bmatrix} \Delta_1 \\ \Delta_2 \end{bmatrix} = \begin{bmatrix} 286 & 179 \\ 179 & 861 \end{bmatrix}^{-1} \begin{bmatrix} -9 \\ 7 \end{bmatrix}$$

or

$$\Delta_1 = 0.042$$

$$\Delta_2 = 0.0169$$

Example 47.10

A simple triangular frame is loaded at the tip by 20 units of force, as shown in Fig. 47.80. Assemble the structure stiffness matrix and determine the displacements at the loaded node.

Member	Length	A	I	ϕ	λ	μ
1	72	2.4	1037	0	1	0
2	101.8	3.4	2933	45°	0.707	0.707

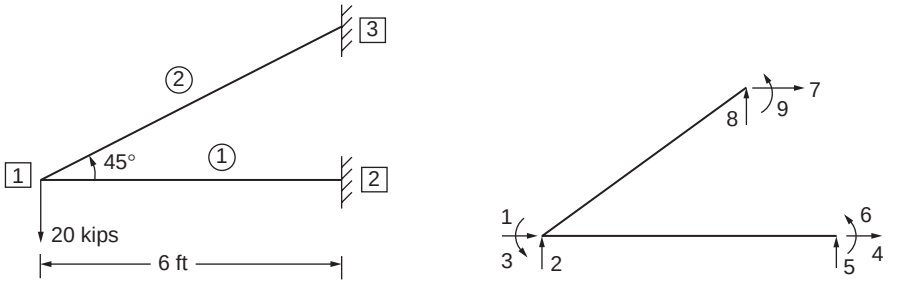

FIGURE 47.79 Example 47.10.

For members 1 and 2 the stiffness matrices in structure coordinates can be written by making use of Eq. (47.143):

$$[\mathrm{K}]_1 = 10^3 \times \begin{array}{c|cccccc} & 1 & 2 & 3 & 4 & 5 & 6 \\ \hline 1 & 1 & 0 & 0 & -1 & 0 & 0 \\ 2 & 0 & 1 & 36 & 0 & -1 & 36 \\ 3 & 0 & 36 & 1728 & 0 & -36 & 864 \\ 4 & -1 & 0 & 0 & 1 & 0 & 0 \\ 5 & 0 & -1 & -36 & 0 & 1 & -36 \\ 6 & 0 & 36 & 864 & 0 & -36 & 1728 \end{array}$$

and

$$[\mathrm{K}]_2 = 10^3 \times \begin{array}{c|cccccc} & 1 & 2 & 3 & 7 & 8 & 9 \\ \hline 1 & 1 & 0 & -36 & -1 & 0 & -36 \\ 2 & 0 & 1 & 36 & 0 & 1 & 36 \\ 3 & -36 & 36 & 3457 & 36 & -36 & 1728 \\ 7 & -1 & 0 & 36 & 1 & 0 & 36 \\ 8 & 0 & 1 & -36 & 0 & 1 & -36 \\ 9 & -36 & 36 & 1728 & 36 & -36 & 3457 \end{array}$$

Combining the element stiffness matrices $[\mathrm{K}]_1$ and $[\mathrm{K}]_2$, one obtains the structure stiffness matrix as follows:

$$[\mathrm{K}] = 10^3 \times \begin{array}{c|ccccccccc} & 1 & 2 & 3 & 4 & 5 & 6 & 7 & 8 & 9 \\ \hline 1 & 2 & 0 & -36 & -1 & 0 & 0 & -1 & 0 & -36 \\ 2 & 0 & 2 & 72 & 0 & -1 & 36 & 0 & 1 & 36 \\ 3 & -36 & 72 & 5185 & 0 & -36 & 864 & 36 & -36 & 1728 \\ 4 & -1 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 \\ 5 & 0 & -1 & -36 & 0 & 1 & -36 & 0 & 0 & 0 \\ 6 & 0 & 36 & 864 & 0 & -36 & 1728 & 0 & 0 & 0 \\ 7 & -1 & 0 & 36 & 0 & 0 & 0 & 1000 & 0 & 36 \\ 8 & 0 & 1 & -36 & 0 & 0 & 0 & 0 & 1 & -36 \\ 9 & -36 & 36 & 1728 & 0 & 0 & 0 & 36 & 36 & 3457 \end{array}$$

The deformations at joints 2 and 3 corresponding to Δ_5 to Δ_9 are zero, since joints 2 and 4 are restrained in all directions. Canceling the rows and columns corresponding to zero deformations in the structure stiffness matrix, one obtains the force–deformation relation for the structure:

$$\begin{bmatrix} F_1 \\ F_2 \\ F_3 \end{bmatrix} = \begin{bmatrix} 2 & 0 & -36 \\ 0 & 2 & 72 \\ -36 & 72 & 5185 \end{bmatrix} \times 10^3 \begin{bmatrix} \Delta_1 \\ \Delta_2 \\ \Delta_3 \end{bmatrix}$$

Substituting for the applied load $F_2 = -20$, the deformations are given as

$$\begin{bmatrix} \Delta_1 \\ \Delta_2 \\ \Delta_3 \end{bmatrix} = \begin{bmatrix} 2 & 0 & -36 \\ 0 & 2 & 72 \\ -36 & 72 & 5185 \end{bmatrix}^{-1} \times 10^3 \begin{bmatrix} 0 \\ -20 \\ 0 \end{bmatrix}$$

or

$$\begin{bmatrix} \Delta_1 \\ \Delta_2 \\ \Delta_3 \end{bmatrix} = \begin{bmatrix} 6.66 \\ -23.334 \\ 0.370 \end{bmatrix} \times 10^3$$

Loading between Nodes

The problems discussed so far have involved concentrated forces and moments applied only to nodes. But real structures are subjected to distributed or concentrated loading between nodes, as shown in Fig. 47.80. Loading may range from a few concentrated loads to an infinite variety of uniform or nonuniform distributed loads. The solution method of matrix analysis must be modified to account for such load cases.

One way to treat such loads in the matrix analysis is to insert artificial nodes, such as p and q, as shown in Fig. 47.80. The degrees of freedom corresponding to the additional nodes are added to the total structure, and the necessary additional equations are written by considering the requirements of equilibrium at these nodes. The internal member forces on each side of nodes p and q must equilibrate the external loads applied at these points. In the case of distributed loads, suitable nodes such as l, m, and n, shown in Fig. 47.80, are selected arbitrarily and the distributed loads are lumped as concentrated loads at these nodes. The degrees of freedom corresponding to the arbitrary and real nodes are treated as unknowns of the problem. There are different ways of obtaining equivalence between the lumped and the distributed loading. In all cases the lumped loads must be statically equivalent to the distributed loads they replace.

The method of introducing arbitrary nodes is not a very elegant procedure because the number of unknown degrees of freedom make the solution procedure laborious. The approach that is of the most general use with the displacement method is the one employing the related concepts of artificial joint restraint, fixed-end forces, and equivalent nodal loads.

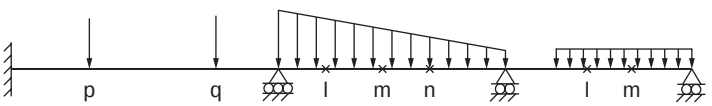

FIGURE 47.80 Loading between nodes.

Semirigid End Connection

A rigid connection holds unchanged the original angles between interesting members; a simple connection allows the member end to rotate freely; a semirigid connection possesses a moment resistance intermediate between those of the simple and rigid connections.

A simplified linear relationship between the moment M acting on the connection and the resulting connection rotation ψ in the direction of M is assumed, giving

$$M = R\frac{EI}{L}\psi \tag{47.144}$$

where EI and L are the flexural rigidity and length of the member, respectively. The nondimension quantity R, which is a measure of the degree of rigidity of the connection, is called the rigidity index. For a simple connection, R is zero; for a rigid connection, R is infinity. Considering the semirigidity of joints, the member flexibility matrix for flexure is derived as

$$\begin{bmatrix}\phi_1\\ \phi_2\end{bmatrix} = \frac{L}{EI}\begin{bmatrix}\frac{1}{3}+\frac{1}{R_1} & -\frac{1}{6}\\ -\frac{1}{6} & \frac{1}{3}+\frac{1}{R_2}\end{bmatrix}\begin{bmatrix}M_1\\ M_2\end{bmatrix} \tag{47.145}$$

or

$$[\phi] = [F][M] \tag{47.146}$$

where ϕ_1 and ϕ_2 are as shown in Fig. 47.81.

For convenience, two parameters are introduced as follows

$$p_1 = \frac{1}{1+\frac{3}{R_1}}$$

and

$$p_2 = \frac{1}{1+\frac{3}{R_2}}$$

where p_1 and p_2 are called the fixity factors. For hinged connections, both the fixity factors, p, and the rigidity index, R, are zero, but for rigid connections, the fixity factor is 1 and the rigidity index is infinity. Since the fixity factor can vary only from 0 to 1.0, it is more convenient to use in the analyses of structures with semirigid connections.

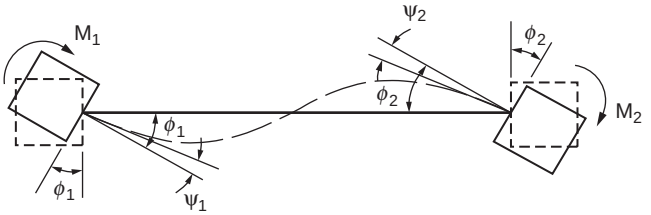

FIGURE 47.81 Flexural member with semirigid end connections.

Equation (47.145) can be rewritten to give

$$[F] = \frac{L}{EI}\begin{bmatrix} \frac{1}{3p_1} & -\frac{1}{6} \\ \frac{1}{6} & \frac{1}{3p_2} \end{bmatrix} \tag{47.147}$$

From Eq. (47.147), the modified member stiffness matrix [K] for a member with semirigid connections expresses the member end moments M_1 and M_2 in terms of the member end rotations ϕ_1 and ϕ_2 as

$$[K] = EI\begin{bmatrix} K_{11} & K_{12} \\ K_{21} & K_{22} \end{bmatrix} \tag{47.148a}$$

Expressions for K_{11}, $K_{12} = K_{21}$, and K_{22} may be obtained by inverting matrix [F], thus

$$K_{11} = \frac{12/p_1}{4/(p_1p_2) - 1} \tag{47.148b}$$

$$K_{12} = K_{21}\frac{6}{4(p_1p_2) - 1} \tag{47.148c}$$

$$K_{22} = \frac{12/p_1}{4/(p_1p_2) - 1} \tag{47.148d}$$

The modified member stiffness matrix [K], as expressed by Eq. (47.148a to d), will be needed in the stiffness method of analysis of frames in which there are semirigid member end connections.

47.10 Finite Element Method

For problems involving complex material properties and boundary conditions, numerical methods are employed to provide approximate but acceptable solutions. Of the many numerical methods developed before and after the advent of computers, the finite element method has proven to be a powerful tool. This method can be regarded as a natural extension of the matrix methods of structural analysis. It can accommodate complex and difficult problems such as nonhomogenity, nonlinear stress–strain behavior, and complicated boundary conditions. The finite element method is applicable to a wide range of boundary value problems in engineering, and it dates back to the mid-1950s with the pioneering work by Argyris (1960), Clough and Penzien (1993), and others. The method was applied first to the solution of plane stress problems and extended subsequently to the solution of plates, shells, and axisymmetric solids.

Basic Principle

The finite element method is based on the representation of a body or a structure by an assemblage of subdivisions called finite elements, as shown in Fig. 47.82. These elements are considered to be connected at nodes. Displacement functions are chosen to approximate the variation of displacements over each finite element. Polynomial functions are commonly employed to approximate these displacements. Equilibrium equations for each element are obtained by means of the principle of minimum potential energy. These equations are formulated for the entire body by combining the equations for the individual elements so that the continuity of displacements is preserved at the nodes. The resulting equations are solved satisfying the boundary conditions in order to obtain the unknown displacements.

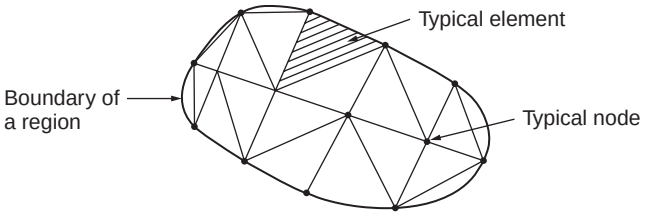

FIGURE 47.82 Assemblage of subdivisions.

The entire procedure of the finite element method involves the following steps:

1. The given body is subdivided into an equivalent system of finite elements.
2. A suitable displacement function is chosen.
3. The element stiffness matrix is derived using a variational principle of mechanics, such as the principle of minimum potential energy.
4. The global stiffness matrix for the entire body is formulated.
5. The algebraic equations thus obtained are solved to determine unknown displacements.
6. The element strains and stresses are computed from the nodal displacements.

Elastic Formulation

Figure 47.83 shows the state of stress in an elemental volume of a body under load. It is defined in terms of three normal stress components σ_x, σ_y, and σ_z and three shear stress components τ_{xy}, τ_{yz}, and τ_{zx}. The corresponding strain components are three normal strains ε_x, ε_y, and ε_z and three shear strains γ_{xy}, γ_{yz}, and γ_{zx}. These strain components are related to the displacement components u, v, and w at a point as follows:

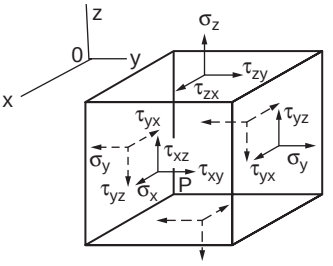

FIGURE 47.83 State of stress in an elemental volume.

$$\varepsilon_x = \frac{\partial u}{\partial x} \qquad \gamma_{xy} = \frac{\partial v}{\partial x} + \frac{\partial u}{\partial y}$$

$$\varepsilon_y = \frac{\partial v}{\partial y} \qquad \gamma_{yz} = \frac{\partial w}{\partial y} + \frac{\partial v}{\partial z} \tag{47.149}$$

$$\varepsilon_z = \frac{\partial w}{\partial z} \qquad \gamma_{zx} = \frac{\partial u}{\partial z} + \frac{\partial w}{\partial x}$$

The relations given in Eq. (47.149) are valid in the case of the body experiencing small deformations. If the body undergoes large or finite deformations, higher order terms must be retained.

The stress–strain equations for isotropic materials may be written in terms of Young's modulus and Poisson's ratio as

$$\sigma_x = \frac{E}{1-\nu^2}\left[\varepsilon_x + \nu\left(\varepsilon_y + \varepsilon_z\right)\right]$$

$$\sigma_y = \frac{E}{1-\nu^2}\left[\varepsilon_y + \nu\left(\varepsilon_z + \varepsilon_x\right)\right] \tag{47.150}$$

$$\sigma_z = \frac{E}{1-\nu^2}\left[\varepsilon_z + \nu\left(\varepsilon_x + \varepsilon_y\right)\right]$$

$$\tau_{xy} = G\gamma_{xy}, \quad \tau_{yz} = G\gamma_{yz}, \quad \tau_{zx} = G\gamma_{zx}$$

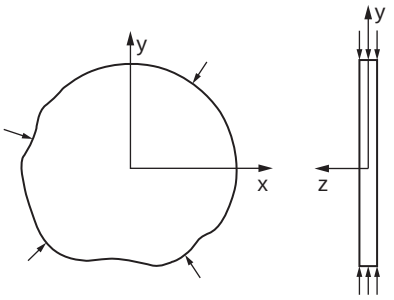

FIGURE 47.84 Plane stress problem.

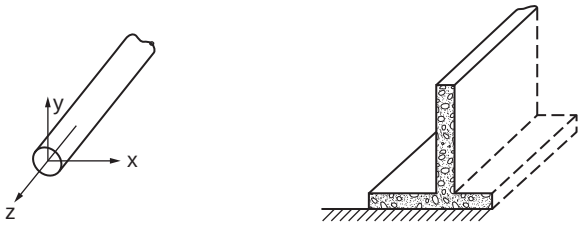

FIGURE 47.85 Practical examples of plane strain problems.

Plane Stress

When the elastic body is very thin and there are no loads applied in the direction parallel to the thickness, the state of stress in the body is said to be plane stress. A thin plate subjected to in-plane loading, as shown in Fig. 47.84, is an example of a plane stress problem. In this case, $\sigma_z = \tau_{yz} = \tau_{zx} = 0$ and the constitutive relation for an isotropic continuum is expressed as

$$\begin{bmatrix} \sigma_x \\ \sigma_y \\ \sigma_{xy} \end{bmatrix} = \frac{E}{1-\nu^2} \begin{bmatrix} 1 & \nu & 0 \\ \nu & 1 & 0 \\ 0 & 0 & \dfrac{1-\nu}{2} \end{bmatrix} \begin{bmatrix} \varepsilon_x \\ \varepsilon_y \\ \gamma_{xy} \end{bmatrix} \tag{47.151}$$

Plane Strain

The state of plane strain occurs in members that are not free to expand in the direction perpendicular to the plane of the applied loads. Examples of some plane strain problems are retaining walls, dams, long cylinders, tunnels, etc., as shown in Fig. 47.85. In these problems ε_z, γ_{yz}, and γ_{zx} will vanish and hence

$$\sigma_z = \nu(\sigma_x + \sigma_y)$$

The constitutive relations for an isotropic material is written as

$$\begin{bmatrix} \sigma_x \\ \sigma_y \\ \tau_{xy} \end{bmatrix} = \frac{E}{(1+\nu)(1-2\nu)} \begin{bmatrix} (1-\nu) & \nu & 0 \\ \nu & (1-\nu) & 0 \\ 0 & 0 & \dfrac{1-2\nu}{2} \end{bmatrix} \begin{bmatrix} \varepsilon_x \\ \varepsilon_y \\ \gamma_{xy} \end{bmatrix} \tag{47.152}$$

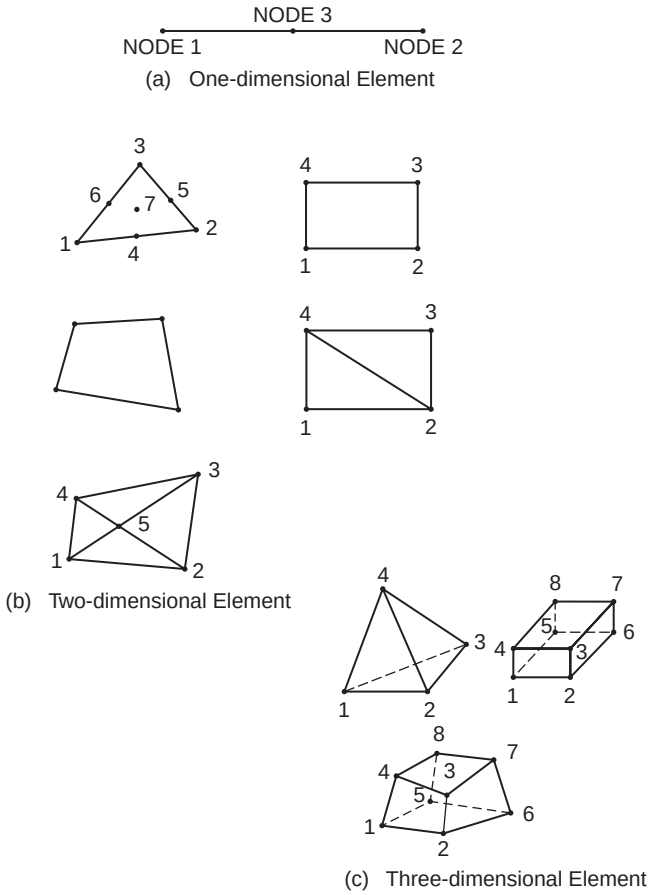

FIGURE 47.86 (a) One-dimensional element. (b) Two-dimensional element. (c) Three-dimensional element.

Choice of Element Shapes and Sizes

A finite element generally has a simple one-, two-, or three-dimensional configuration. The boundaries of elements are often straight lines, and the elements can be one-, two-, or three-dimensional, as shown in Fig. 47.86. While subdividing the continuum, one has to decide the number, shape, size, and configuration of the elements in such a way that the original body is simulated as closely as possible. Nodes must be located in locations where abrupt changes in geometry, loading, and material properties occur. A node must be placed at the point of application of a concentrated load because all loads are converted into equivalent nodal-point loads.

It is easy to subdivide a continuum into a completely regular one having the same shape and size. But problems encountered in practice do not involve regular shape; they may have regions of steep gradients of stresses. A finer subdivision may be necessary in regions where stress concentrations are expected in order to obtain a useful approximate solution. Typical examples of mesh selection are shown in Fig. 47.87.

Choice of Displacement Function

Selection of displacement function is the important step in the finite element analysis, since it determines the performance of the element in the analysis. Attention must be paid to select a displacement function that:

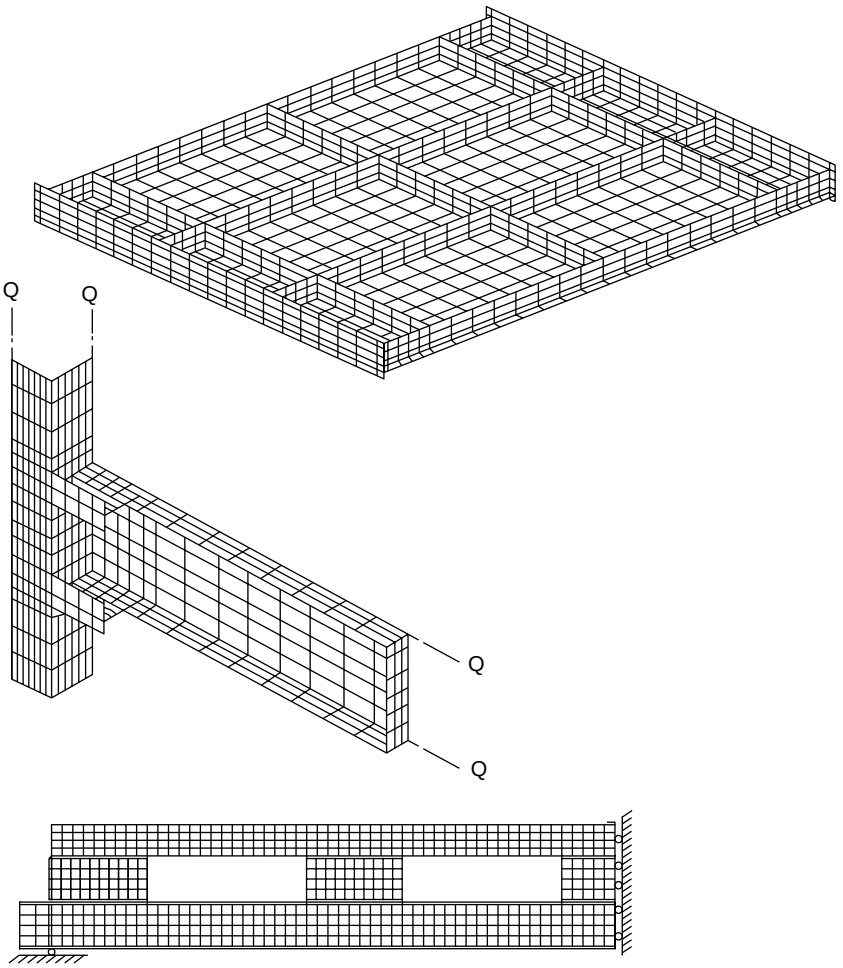

FIGURE 47.87 Typical examples of finite element mesh.

1. has the number of unknown constants as the total number of degrees of freedom of the element.
2. does not have any preferred directions.
3. allows the element to undergo rigid-body movement without any internal strain.
4. is able to represent states of constant stress or strain.
5. satisfies the compatibility of displacements along the boundaries with adjacent elements.

Elements that meet both 3 and 4 are known as *complete elements*.

A polynomial is the most common form of displacement function. Mathematics of polynomials are easy to handle in formulating the desired equations for various elements and convenient in digital computation. The degree of approximation is governed by the stage at which the function is truncated. Solutions closer to exact solutions can be obtained by including a greater number of terms. The polynomials are of the general form

$$w(x) = a_1 + a_2 x + a_3 x^2 + \ldots a_{n+1} x^n \tag{47.153}$$

The coefficient a's are known as *generalized displacement amplitudes*. The general polynomial form for a two-dimensional problem can be given as

$$u(x,y) = a_1 + a_2 x + a_3 y + a_4 x^2 + a_5 xy + a_6 y^2 + \ldots a_m y^n$$

$$v(x,y) = a_{m+1} + a_{m+2} + a_{m+3} y + a_{m+4} x^2 + a_{m+5} xy + a_{m+6} y^2 + \ldots + a_{2m} y^n$$

in which

$$m = \sum_{i=1}^{n+1} i \tag{47.154}$$

These polynomials can be truncated at any desired degree to give constant, linear, quadratic, or higher order functions. For example, a linear model in the case of a two-dimensional problem can be given as

$$\begin{aligned} u &= a_1 + a_2 x + a_3 y \\ v &= a_4 + a_5 x + a_6 y \end{aligned} \tag{47.155}$$

A quadratic function is given by

$$\begin{aligned} u &= a_1 + a_2 x + a_3 y + a_4 x^2 + a_5 xy + a_6 y^2 \\ v &= a_7 + a_8 x + a_9 y + a_{10} x^2 + a_{11} xy + a_{12} y^2 \end{aligned} \tag{47.156}$$

Pascal's triangle, shown below, can be used for the purpose of achieving isotropy, i.e., to avoid displacement shapes that change with a change in the local coordinate system.

					1						Constant
				x		y					Linear
			x^2		xy		y^2				Quadratic
		x^3		x^2y		xy^2		y^3			Cubic
	x^4		x^3y		x^2y^2		xy^3		y^4		Quantic
x^5		x^4y		x^3y^2		x^2y^3		xy^4		y^5	Quintic

Nodal Degrees of Freedom

The deformation of the finite element is specified completely by the nodal displacement, rotations, and/or strains, which are referred to as *degrees of freedom*. Convergence, geometric isotropy, and potential energy function are the factors that determine the minimum number of degrees of freedom necessary for a given element. Additional degrees of freedom beyond the minimum number may be included for any element by adding secondary external nodes, and such elements with additional degrees of freedom are called higher order elements. The elements with more additional degrees of freedom become more flexible.

Isoparametric Elements

The scope of finite element analysis is also measured by the variety of element geometries that can be constructed. Formulation of element stiffness equations requires the selection of displacement expressions with as many parameters as there are node point displacements. In practice, for planar conditions, only the four-sided (quadrilateral) element finds as wide an application as the triangular element. The simplest form of quadrilateral, the rectangle, has four node points and involves two displacement components at each point, for a total of eight degrees of freedom. In this case one would choose four-term expressions for both u and v displacement fields. If the description of the element is expanded to include nodes at the midpoints of the sides, an eight-term expression would be chosen for each displacement component.

The triangle and rectangle can approximate the curved boundaries only as a series of straight line segments. A closer approximation can be achieved by means of *isoparametric* coordinates. These are nondimensionalized curvilinear coordinates whose description is given by the same coefficients as are

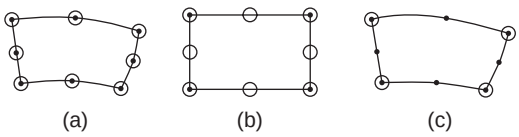

FIGURE 47.88 (a) Isoparametric element. (b) Subparametric element. (c) Superparametric element.

employed in the displacement expressions. The displacement expressions are chosen to ensure continuity across element interfaces and along supported boundaries, so that geometric continuity is ensured when the same forms of expressions are used as the basis of description of the element boundaries. The elements in which the geometry and displacements are described in terms of the same parameters and are of the same order are called *isoparametric elements.* The isoparametric concept enables one to formulate elements of any order that satisfy the completeness and compatibility requirements and that have isotropic displacement functions.

Isoparametric Families of Elements

Definitions and Justifications

For example, let u_i represent nodal displacements and x_i represent nodal x coordinates. The interpolation formulas are

$$u = \sum_{i=1}^{m} N_i u_i \qquad x = \sum_{i=1}^{n} N'_i x_i$$

where N_i and N are shape functions written in terms of the intrinsic coordinates. The value of u and the value of x at a point within the element are obtained in terms of nodal values of u_i and x_i from the above equations when the (intrinsic) coordinates of the internal point are given. Displacement components v and w in the y and z directions are treated in a similar manner.

The element is *isoparametric* if m = n, N_i = N, and the same nodal points are used to define both element geometry and element displacement (Fig. 47.88a); the element is *subparametric* if m > n, the order of N_i is larger than N'_i (Fig. 47.88b); the element is *superparametric* if m < n, the order of N_i is smaller than N'_i (Fig. 47.88c). The isoparametric elements can correctly display rigid-body and constant-strain modes.

Element Shape Functions

The finite element method is not restricted to the use of linear elements. Most finite element codes commercially available allow the user to select between elements with linear or quadratic interpolation functions. In the case of quadratic elements, fewer elements are needed to obtain the same degree of accuracy in the nodal values. Also, the two-dimensional quadratic elements can be shaped to model a curved boundary. Shape functions can be developed based on the following properties:

1. Each shape function has a value of 1 at its own node and is zero at each of the other nodes.
2. The shape functions for two-dimensional elements are zero along each side that the node does not touch.
3. Each shape function is a polynomial of the same degree as the interpolation equation. Shape functions for typical elements are given in Fig. 47.89a and b.

Formulation of Stiffness Matrix

It is possible to obtain all the strains and stresses within the element and to formulate the stiffness matrix and a consistent load matrix once the displacement function has been determined. This consistent load matrix represents the equivalent nodal forces that replace the action of external distributed loads.

Element name	Configuration	DOF	Shape functions
Two-node linear element		+	$N_i = \frac{1}{2}(1+\xi_0)$; $i = 1, 2$
Three-node parabolic element		+	$N_i = \frac{1}{2}\xi_0\,(1+\xi_0)$; $i = 1, 3$ $N_i = (1-\xi^2)$; $i = 2$
Four-node cubic element		+	$N_i = \frac{1}{16}(1+\xi_0)(9\xi^2-1)$ $i = 1, 4$ $N_i = \frac{9}{16}(1+9\xi_0)(1-\xi^2)$ $i = 2, 3$
Five-node quartic element		+	$N_i = \frac{1}{6}(1+\xi_0)\,\{4\xi_0(1-\xi^2)$ $+ 3\xi_0\}$ $i = 1, 5$ $N_i = 4\xi_0(1-\xi^2)(1+4\xi_0)$ $i = 2, 4$ $N_3 = (1-4\xi^2)(1-\xi^2)$

FIGURE 47.89 Shape functions for typical elements.

As an example, let us consider a linearly elastic element of any of the types shown in Fig. 47.90. The displacement function may be written in the form

$$\{f\} = [P]\{A\} \tag{47.157}$$

in which {f} may have two components {u, v} or simply be equal to w, [P] is a function of x and y only, and {A} is the vector of undetermined constants. If Eq. (47.157) is applied repeatedly to the nodes of the element one after the other, we obtain a set of equations of the form

$$\{D^*\} = [C]\{A\} \tag{47.158}$$

in which $\{D^*\}$ is the nodal parameters and [C] is the relevant nodal coordinates. The undetermined constants {A} can be expressed in terms of the nodal parameters $\{D^*\}$ as

$$\{A\} = [C]^{-1}\{D^*\} \tag{47.159}$$

Serial no.	Element name	Configuration	DOF	Shape functions
1	Four-node plane quadrilateral		u, v	$N_i = \frac{1}{4}(1 + \xi_0)(1 + \eta_0)$; i = 1, 2, 3, 4
2	Eight-node plane quadrilateral		u, v	$N_i = \frac{1}{4}(1 + \xi_0)(1 + \eta_0)(\xi_0 + \eta_0 - 1)$; i = 1, 3, 5, 7 $N_i = \frac{1}{2}(1 - \xi^2)(1 + \eta_0)$ i = 2,6 $N_i = \frac{1}{2}(1 - \eta^2)(1 + \xi_0)$ i = 4, 8
3	Twelve-node plane quadrilateral		u, v	$N_i = \frac{1}{32}(1 + \xi_0)(1 + \eta_0)(-10 + 9(\xi^2 + \eta^2))$ i = 1, 4, 7, 10 $N_i = \frac{9}{32}(1 + \xi_0)(1 + \eta^2)(1 + 9\eta_0)$ i = 5, 6, 11, 12 $N_i = \frac{9}{32}(1 + \eta_0)(1 - \xi^2)(1 + 9\xi_0)$ i = 2, 3, 8, 9

FIGURE 47.89 (continued).

Substituting Eq. (47.159) into (47.157)

$$\{f\} = [P][C]^{-1}\{D^*\} \tag{47.160}$$

Constructing the displacement function directly in terms of the nodal parameters, one obtains

$$\{f\} = [L]\{D^*\} \tag{47.161}$$

where [L] is a function of both (x, y) and $(x, y)_{i,j,m}$ given by

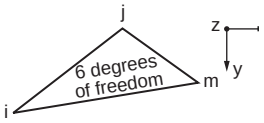
$$[L] = [P][C]^{-1} \tag{47.162}$$

Serial no.	Element name	Configuration	DOF	Shape functions
4	Six-node linear quadrilateral		u, v	$N_i = \frac{\xi_0}{4}(1+\xi_0)(1+\eta_0)$ i = 1, 3, 4, 6 $N_i = \frac{1}{2}(1-\xi^2)(1+\eta_0)$ i = 2, 5
5	Eight-node plane quadrilateral		u, v	$N_i = \frac{1}{32}(1+\xi_0)(-1+9\xi^2)$ $(1+\eta_0)$ i = 1, 4, 5, 8 $N_i = \frac{9}{32}(1-\xi^2)(1+9\xi_0)$ $(1+\eta_0)$ i = 2, 3, 6, 7
6	Seven-node plane quadrilateral		u, v	$N_1 = \frac{1}{4}(1-\xi)(1-\eta)$ $(1+\xi+\eta)$ $N_2 = \frac{1}{2}(1-\eta)(1-\xi^2)$ $N_3 = \frac{\xi}{4}(1+\xi)(1-\eta)$ $N_4 = \frac{\xi}{4}(1+\xi)(1+\eta)$ $N_5 = \frac{1}{2}(1+\eta)(1-\xi^2)$ $N_6 = -\frac{1}{4}(1-\xi)(1+\eta)$ $(1+\xi-\eta)$ $N_7 = \frac{1}{2}(1-\xi)(1-\eta^2)$

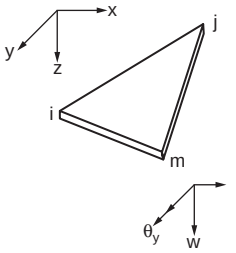
FIGURE 47.89 (continued).

The various components of strain can be obtained by appropriate differentiation of the displacement function. Thus,

$$\{\varepsilon\} = [B]\{D^*\} \tag{47.163}$$



(a)



(b)

FIGURE 47.90 Degrees of freedom: (a) triangular plane stress element, (b) triangular bending element.

[B] is derived by differentiating appropriately the elements of [L] with respect to x and y. The stresses $\{\sigma\}$ in a linearly elastic element are given by the product of the strain and a symmetrical elasticity matrix [E]. Thus,

$$\{\sigma\} = [E]\{\varepsilon\}$$

or

$$\{\sigma\} = [E][B]\{D^*\} \tag{47.164}$$

The stiffness and the consistent load matrices of an element can be obtained using the principle of minimum total potential energy. The potential energy of the external load in the deformed configuration of the element is written as

$$W = -\{D^*\}^T\{Q^*\} - \int_a \{f\}^T\{q\}da \tag{47.165}$$

In Eq. (47.165) $\{Q^*\}$ represents concentrated loads at nodes, and $\{q\}$ the distributed loads per unit area. Substituting for $\{f\}^T$ from Eq. (47.161), one obtains

$$W = -\{D^*\}^T\{Q^*\} - \{D^*\}^T\int_a [L]^T\{q\}da \tag{47.166}$$

Note that the integral is taken over the area a of the element. The strain energy of the element integrated over the entire volume v, is given as

$$U = \frac{1}{2}\int_v \{\varepsilon\}^T\{\sigma\}dv$$

Substituting for $\{\varepsilon\}$ and $\{\sigma\}$ from Eqs. (47.163) and (47.164), respectively,

$$U = \frac{1}{2}\{D^*\}^T\left(\int_v [B]^T[E][B]dv\right)\{D^*\} \tag{47.167}$$

The total potential energy of the element is

$$V = U + W$$

or

$$V = \frac{1}{2}\{D^*\}^T \left(\int_v [B]^T [E][B] dv \right) \{D^*\} - \{D^*\}^T \{Q^*\} - \{D^*\}^T \int_a [L]^T \{q\} da \tag{47.168}$$

Using the principle of minimum total potential energy, we obtain

$$\left(\int_v [B]^T [E][B] dv \right) \{D^*\} = \{Q^*\} + \int_a [L]^T \{q\} da$$

or

$$[K]\{D^*\} = \{F^*\} \tag{47.169}$$

where

$$[K] = \int_v [B]^T [E][B] dv \tag{47.170a}$$

and

$$\{F^*\} = \{Q^*\} + \int_a [L]^T \{q\} da \tag{47.170b}$$

Plates Subjected to In-Plane Forces

The simplest element available in two-dimensional stress analysis is the triangular element. The stiffness and consistent load matrices of such an element will now be obtained by applying the equation derived in the previous section.

Consider the triangular element shown in Fig. 47.90a. There are two degrees of freedom per node and a total of six degrees of freedom for the entire element. We can write

$$u = A_1 + A_2 x + A_3 y$$

and

$$v = A_4 + A_5 x + A_6 y$$

expressed as

$$\{f\} = \begin{Bmatrix} u \\ v \end{Bmatrix} = \begin{bmatrix} 1 & x & y & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & x & y \end{bmatrix} \begin{Bmatrix} A_1 \\ A_2 \\ A_3 \\ A_4 \\ A_5 \\ A_6 \end{Bmatrix} \tag{47.171}$$

or

$$\{f\} = [P]\{A\} \tag{47.172}$$

Once the displacement function is available, the strains for a plane problem are obtained from

$$\varepsilon_x = \frac{\partial u}{\partial x} \qquad \varepsilon_y = \frac{\partial v}{\partial y}$$

and

$$\gamma_{xy} = \frac{\partial u}{\partial y}\ \frac{\partial v}{\partial x}$$

Matrix [B], relating the strains to the nodal displacement $\{D^*\}$, is thus given as

$$[B] = \frac{1}{2\Delta}\begin{bmatrix} b_i & 0 & b_j & 0 & b_m & 0 \\ 0 & c_i & 0 & c_j & 0 & c_m \\ c_i & b_j & c_j & b_j & c_m & b_m \end{bmatrix} \tag{47.173}$$

b_i, c_i, etc. are constants related to the nodal coordinates only. The strains inside the element must all be constant and hence the name of the element.

For derivation of strain matrix, only isotropic material is considered. The plane stress and plane strain cases can be combined to give the following elasticity matrix, which relates the stresses to the strains:

$$[E] = \begin{bmatrix} C_1 & C_1C_2 & 0 \\ C_1C_2 & C_1 & 0 \\ 0 & 0 & C_{12} \end{bmatrix} \tag{47.174}$$

where

$$C_1 = \bar{E}/\left(1-\nu^2\right) \quad \text{and} \quad C_2 = \nu \quad \text{for plane stress}$$

and

$$C_1 = \frac{\bar{E}(1-\nu)}{(1+\nu)(1-2\nu)} \quad \text{and} \quad C_2 = \frac{\nu}{(1-\nu)} \quad \text{for plane stress}$$

and for both cases,

$$C_{12} = C_1\left(1-C_2\right)/2$$

and $\bar{E}$ is the modulus of elasticity.

The stiffness matrix can now be formulated according to Eq. (47.170a)

$$[E][B] = \frac{1}{2\Delta}\begin{bmatrix} C_1 & C_1C_2 & 0 \\ C_1C_2 & C_1 & 0 \\ 0 & 0 & C_{12} \end{bmatrix}\begin{bmatrix} b_i & 0 & b_j & 0 & b_m & 0 \\ 0 & c_i & 0 & c_j & 0 & c_m \\ c_i & b_i & c_j & b_j & c_m & b_m \end{bmatrix}$$

where Δ is the area of the element.

The stiffness matrix is given by Eq. (47.10.37a) as

$$[K] = \int_v [B]^T [E][B]\,dv$$

The stiffness matrix has been worked out algebraically to be

$$[K]=\frac{h}{4\Delta}\begin{bmatrix}
C_1b_i^2 & & & & & \\
+C_{12}c_i^2 & & & & & \\
C_1C_2b_ic_i & C_1c_i^2 & & & & \\
+C_{12}b_ic_i & +C_{12}b_i^2 & & \text{Symmetrical} & & \\
C_1b_ib_j & C_1C_2b_jc_i & C_1b_j^2 & & & \\
+C_{12}c_ic_j & +C_{12}b_ic_j & +C_{12}c_j^2 & & & \\
C_1C_2b_ic_j & C_1c_ic_j & C_1C_2b_jc_j & C_1c_j^2 & & \\
+C_{12}b_jc_i & +C_1b_ib_j & +C_{12}b_jc_j & +C_{12}b_j^2 & & \\
C_1b_ib_m & C_1C_2b_mc_i & C_1b_jb_m & C_1C_2b_mc_j & C_1b_m^2 & \\
+C_{12}c_ic_m & +C_{12}b_ic_m & +C_{12}c_jc_m & +C_{12}b_jc_m & +C_{12}c_m^2 & \\
C_1C_2b_ic_m & C_1c_ic_m & C_1C_2b_jc_m & C_1c_jc_m & C_1C_2b_mc_m & C_1c_m^2 \\
+C_{12}b_mc_i & +C_{12}b_ib_m & +C_{12}b_mc_j & +C_{12}b_jb_m & +C_{12}b_mc_m & +C_{12}b_m^2
\end{bmatrix}$$

Beam Element

The stiffness matrix for a beam element with two degrees of freedom (one deflection and one rotation) can be derived in the same manner as for other finite elements using Eq. (47.170a).

The beam element has two nodes, one at each end, and two degrees of freedom at each node, giving it a total of four degrees of freedom. The displacement function can be assumed as

$$f = w = A_1 + A_2x + A_3x^2 + A_4x^3$$

i.e.,

$$f=\begin{bmatrix}1 & x & x^2 & x^3\end{bmatrix}\begin{Bmatrix}A_1\\A_2\\A_3\\A_4\end{Bmatrix}$$

or

$$f=[P]\{A\}$$

With the origin of the x and y axis at the left-hand end of the beam, we can express the nodal displacement parameters as

$$D_1^* = (w)_{x=0} = A_1 + A_2(0) + A_3(0)^2 + A_4(0)^3$$

$$D_2^* = \left(\frac{dw}{dx}\right)_{x=0} = A_2 + 2A_3(0) + 3A_4(0)^2$$

$$D_3^* = (w)_{x=l} = A_1 + A_2(l) + A_3(l)^2 + A_4(l)^3$$

$$D_4^* = \left(\frac{dw}{dx}\right)_{x=l} = A_2 + 2A_3(l) + 3A_4(l)^2$$

or

$$\{D^*\} = [C]\{A\}$$

where

$$\{A\} = [C]^{-1}\{D^*\}$$

and

$$[C]^{-1} = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ \frac{-3}{I^2} & \frac{-2}{I} & \frac{3}{I^2} & \frac{-1}{I} \\ \frac{2}{I^3} & \frac{1}{I^2} & \frac{-2}{I^3} & \frac{1}{I^2} \end{bmatrix}$$

Using Eq. (47.177), we obtain

$$[L] = [P][C]^{-1} \tag{47.175}$$

or

$$[C]^{-1} = \left[\left(1 - \frac{3x^2}{I^2} + \frac{2x^3}{I^3}\right)\left|\left(x - \frac{2x^2}{I} + \frac{x^3}{I^2}\right)\right|\left(\frac{3x^2}{I^2} - \frac{2x^3}{I^3}\right)\left|\left(-\frac{x^2}{I} + \frac{x^3}{I^2}\right)\right.\right] \tag{47.176}$$

Neglecting shear deformation

$$\{\varepsilon\} = -\frac{d^2y}{dx^2}$$

Substituting Eq. (47.191) into Eq. (47.176) and the result into Eq. (47.192)

$$\{\varepsilon\} = \left[\left|\frac{6}{I^2} - \frac{12x}{I^3}\right|\frac{4}{I} - \frac{6x}{I^2}\left|-\frac{6}{I^2} + \frac{12x}{I^3}\right|\frac{2}{I} - \frac{6x}{I^2}\right]\{D^*\}$$

or

$$\{\varepsilon\} = [B]\{D^*\}$$

The moment–curvature relationship is given by

$$M = \bar{E}I\left(-\frac{d^2y}{dx^2}\right)$$

where

$\bar{E}$ is the modulus of elasticity,

or

$$\{\varepsilon\} = [B]\{D^*\}$$

We know that $\{\sigma\} = [E]\{\varepsilon\}$, so we have for the beam element

$$[E] = \bar{E}I$$

The stiffness matrix can now be obtained from Eq. (47.170a) written in the form

$$[K] = \int_0^1 [B]^T [d][B]dx$$

with the integration over the length of the beam. Substituting for [B] and [E], we obtain

$$[k] = \bar{E}I \int_0^1 \begin{bmatrix} \frac{36}{\lambda^4} - \frac{144x}{\lambda^5} + \frac{144x^2}{\lambda^6} & & \text{symmetrical} & \\ \frac{24}{\lambda^3} - \frac{84x}{\lambda^4} + \frac{72x^2}{\lambda^5} & \frac{16}{\lambda^2} - \frac{48x}{\lambda^3} + \frac{36x^2}{\lambda^4} & & \\ \frac{-36}{\lambda^4} + \frac{144x}{\lambda^5} - \frac{144x^2}{\lambda^6} & \frac{-24}{\lambda^3} + \frac{84x}{\lambda^4} - \frac{72x^2}{\lambda^5} & \frac{36}{\lambda^4} - \frac{144x}{\lambda^5} + \frac{144x^2}{\lambda^6} & \\ \frac{12}{\lambda^3} - \frac{60x}{\lambda^4} + \frac{72x^2}{\lambda^5} & \frac{8}{\lambda^2} - \frac{36x}{\lambda^3} + \frac{36x^2}{\lambda^4} & \frac{-12}{\lambda^3} + \frac{60x}{\lambda^4} - \frac{72x^2}{\lambda^5} & \frac{4}{\lambda^2} - \frac{24x}{\lambda^3} + \frac{36x^2}{\lambda^4} \end{bmatrix} dx$$

or

$$[K] = \bar{E}I \begin{bmatrix} \frac{12}{\lambda^3} & & \text{symmetrical} & \\ \frac{6}{\lambda^2} & \frac{4}{\lambda} & & \\ \frac{-12}{\lambda^3} & \frac{-6}{\lambda^2} & \frac{12}{\lambda^3} & \\ \frac{6}{\lambda^2} & \frac{2}{\lambda} & \frac{-6}{\lambda^2} & \frac{4}{\lambda} \end{bmatrix} \tag{47.178}$$

Plate Element

For the rectangular bending element shown in Fig. 47.91 with three degrees of freedom (one deflection and two rotations) at each node, the displacement function can be chosen as a polynomial with 12 undetermined constants:

$$\{f\} = w = A_1 + A_2x + A_3y + A_4x^2 + A_5xy + A_6y^2 + A_7x^3 + A_8x^2y + A_9xy^2 + A_{10}y^3 + A_{11}x^3y + A_{12}xy^3 \tag{47.179}$$

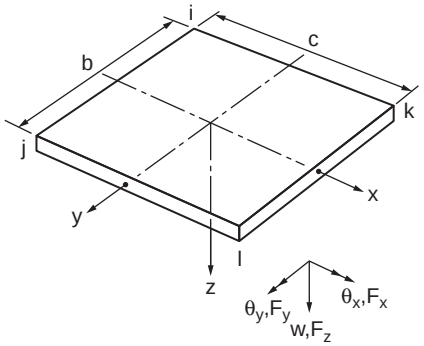


FIGURE 47.91 Rectangular bending element.

or

$$\{f\} = [P]\{A\}$$

The displacement parameter vector is defined as

$$\{D^*\} = \left\{ w_i, \theta_{xi}, \theta_{yi} \middle| w_j, \theta_{xj}, \theta_{yj} \middle| w_k, \theta_{xk}, \theta_{yk} \middle| w_\ell, \theta_{x\ell}, \theta_{y\ell} \right\}$$

where

$$\theta_x = \frac{\partial w}{\partial y} \quad \text{and} \quad \theta_y = -\frac{\partial w}{\partial x}$$

As in the case of beams, it is possible to derive from Eq. (47.179) a system of 12 equations relating $\{D^*\}$ to constants $\{A\}$. The last equation

$$w = \left[[L]_i \middle| [L]_j \middle| [L]_k \middle| [L]_\ell \right] \{D^*\} \tag{47.180}$$

The curvatures of the plate element at any point (x, y) are given by

$$\{\varepsilon\} = \begin{Bmatrix} \dfrac{-\partial^2 w}{\partial x^2} \\ \dfrac{-\partial^2 w}{\partial y^2} \\ \dfrac{2\partial^2 w}{\partial x \partial y} \end{Bmatrix}$$

By differentiating Eq. (47.180), we obtain

$$\{\varepsilon\} = \left[[B]_i \middle| [B]_j \middle| [B]_k \middle| [B]_l \right] \{D^*\} \tag{47.181}$$

or

$$\{\varepsilon\} = \sum_{r=i,j,k,l} [B]_r \{D^*\}_r \tag{47.182}$$

where

$$[B]_r = \begin{bmatrix} -\dfrac{\partial^2}{\partial x^2}[L]_r \\ \hline -\partial \dfrac{2}{\partial y^2}[L]_r \\ \hline 2\dfrac{\partial^2}{\partial x \partial y}[L]_r \end{bmatrix} \tag{47.183}$$

and

$$\{D^*\}_r = \{w_r, \theta_{xr}, \theta_{yr}\} \tag{47.184}$$

For an isotropic slab, the moment–curvature relationship is given by

$$\{\sigma\} = \{M_x \;\; M_y \;\; M_{xy}\} \tag{47.185}$$

$$[E] = N\begin{bmatrix} 1 & \nu & 0 \\ \nu & 1 & 0 \\ 0 & 0 & \dfrac{1-\nu}{2} \end{bmatrix} \tag{47.186}$$

and

$$N = \frac{\bar{E}h^3}{12(1-\nu^2)} \tag{47.187}$$

For orthotropic plates with the principal directions of orthotropy coinciding with the x and y axes, no additional difficulty is experienced. In this case we have

$$[E] = \begin{bmatrix} D_x & D_1 & 0 \\ D_1 & D_y & 0 \\ 0 & 0 & D_{xy} \end{bmatrix} \tag{47.188}$$

where D_x, D_1, D_y, and D_{xy} are the orthotropic constants used by Timoshenko and Woinowsky-Krieger (1959), and

$$\left.\begin{aligned} D_x &= \frac{E_x h^3}{12(1-\nu_x \nu_y)} \\ D_y &= \frac{E_y h^3}{12(1-\nu_x \nu_y)} \\ D_1 &= \frac{\nu_x E_y h^3}{12(1-\nu_x \nu_y)} = \frac{\nu_y E_x h^3}{12(1-\nu_x \nu_y)} \\ D_{xy} &= \frac{Gh^3}{12} \end{aligned}\right\} \tag{47.189}$$

where E_x, E_y, ν_x, ν_y, and G are the orthotropic material constants and h is the plate thickness.

Unlike the strain matrix for the plane stress triangle (see Eq. (47.173)), the stress and strain in the present element vary with x and y. In general we calculate the stresses (moments) at the four corners. These can be expressed in terms of the nodal displacements by Eq. (47.164), which, for an isotropic element, take the form

$$\begin{Bmatrix} \{\sigma\}_i \\ \{\sigma\}_j \\ \{\sigma\}_k \\ \{\sigma\}_r \end{Bmatrix} = \frac{N}{cb}\begin{bmatrix} 6p^{-1}+6\upsilon p & 4\nu c & -4b & -6\nu p & 2\nu c & 0 & -6p^{-1} & 0 & -2b & 0 & 0 & 0 \\ 6p+6\upsilon p^{-1} & 4c & -4\nu b & -6p & 2c & 0 & -6\nu p^{-1} & 0 & -2\nu p & 0 & 0 & 0 \\ -(1-\nu) & -(1-\nu)\mathbf{b} & (1-\nu)c & (1-\nu) & 0 & -(1-\nu)c & (1-\nu) & (1-\nu)b & 0 & -(1-\nu) & 0 & 0 \\ -6\nu p & -2\nu c & 0 & 6p^{-1}+6\upsilon p & -4\nu c & -4b & 0 & 0 & 0 & -6p^{-1} & 0 & -2b \\ -6p & -2c & 0 & 6p+6\upsilon p^{-1} & -4c & -4\nu b & 0 & 0 & 0 & -6\nu p^{-1} & 0 & -2\nu b \\ -(1-\boldsymbol{\nu}) & 0 & (1-\nu)c & (1-\nu) & -(1-\nu)b & (1-\nu) & 0 & 0 & -(1-\nu) & (1-\nu)b & 0 & 0 \\ -6p^{-1} & 0 & 2b & 0 & 0 & 0 & 6p^{-1}+6\upsilon p & 4\nu c & 4b & -6\nu p & 2\nu c & 0 \\ -6\nu p^{-1} & 0 & 2b & 0 & 0 & 0 & 6p+6\upsilon p^{-1} & 4c & 4\nu b & -6p & 2c & 0 \\ -(1-\nu) & -(1-\nu)b & 0 & (1-\nu) & 0 & 0 & (1-\nu) & (1-\nu)b & (1-\nu)c & -(1-\nu) & 0 & -(1-\nu)c \\ 0 & 0 & 0 & -6p^{-1} & 0 & 2b & -6\nu p & -2\nu c & 0 & 6p^{-1}+6\upsilon p & -4\nu c & 4b \\ 0 & 0 & 0 & -6\nu p^{-1} & 0 & 2\nu b & -6p & -2c & 0 & 6p+6\upsilon p^{-1} & -4c & 4\nu b \\ -(1-\nu) & 0 & \mathbf{0} & (1-\nu) & -(1-\nu)b & 0 & (1-\nu) & 0 & (1-\nu)c & -(1-\nu) & (1-\nu)b & -(1-\nu)c \end{bmatrix} \begin{Bmatrix} \{D'\}_i \\ \{D'\}_j \\ \{D'\}_k \\ \{D'\}_r \end{Bmatrix}\Sigma \tag{47.190}$$

The stiffness matrix corresponding to the 12 nodal coordinates can be calculated by

$$[K] = \int_{-b/2}^{b/2} \int_{-c/2}^{c/2} [B]^T [E][B]\,dx\,dy \tag{47.191}$$

For an isotropic element, this gives

$$[K^*] = \frac{N}{15cb}[T][\bar{k}][T] \tag{47.192}$$

where

$$[T] = \begin{bmatrix} [T_s] & \text{Submatrices not} \\ & [T_s] \text{ shown are} \\ & & [T_s] \text{ zero} \\ & & & [T_s] \end{bmatrix} \tag{47.193}$$

$$[T_s] = \begin{bmatrix} 1 & 0 & 0 \\ 0 & b & 0 \\ 0 & 0 & c \end{bmatrix} \tag{47.194}$$

and $[\bar{K}]$ is given by the matrix shown in Eq. (47.195).

(47.195)

$$[\bar{K}] = \begin{bmatrix}
\frac{60p^{-2}+60p^2}{-12\nu+42} & & & & & & & & & & & \\
--- & & & & & & & & & & & \\
\frac{30p^2+12\nu}{+3} & \frac{20p^2-4\nu}{+4} & & & & & & & & & & \\
--- & & & & & & & & & & & \\
-\left(\frac{30p^{-2}+12\nu}{+3}\right) & -15\nu & \frac{20p^{-2}-4\nu}{+4} & & & & \text{symmetrical} & & & & & \\
\frac{30p^{-2}-60p^2}{+12\nu-42} & \frac{-30p^2=3\nu}{-3} & \frac{-15p^{-2}+12\nu}{+3} & \frac{60p^{-2}+60p^2}{-12\nu+42} & & & & & & & & \\
--- & & & & & & & & & & & \\
\frac{30\mathbf{p}^2-3\nu}{+3} & \frac{10p^2+\nu}{-1} & 0 & -\left(\frac{30p^2+12\nu}{+3}\right) & \frac{20p^2-4\nu}{+4} & & & & & & & \\
--- & & & & & & & & & & & \\
\frac{-15p^{-2}+12\nu}{+3} & 0 & \frac{10p^{-2}+4\nu}{-4} & -\left(\frac{30p^{-2}+12\nu}{+3}\right) & 15\nu & \frac{20p^{-2}-4\nu}{+4} & & & & & & \\
--- & & & & & & & & & & & \\
\frac{-60p^{-2}+30p^2}{+12\nu-42} & \frac{15p^{-2}-12\nu}{-3} & \frac{30p^{-2}-3\mathbf{\nu}}{+3} & \frac{-30p^{-2}-30p^2}{-12\nu+42} & \frac{15p^{-2}+3\nu}{-3} & \frac{15p^{-2}+3\nu}{-3} & \frac{60p^{-2}+60p^2}{-12\nu+42} & & & & & \\
--- & & & & & & & & & & & \\
\frac{15p^{-2}-12\nu}{-3} & \frac{10p^2+4\nu}{-4} & 0 & \frac{15p^2-3\nu}{+3} & \frac{5p^2-\nu}{+1} & 0 & \frac{30p^2+12\nu}{+3} & \frac{20p^2-4\nu}{+4} & & & & \\
--- & & & & & & & & & & & \\
\frac{-30p^{-2}+3\nu}{-3} & 0 & \frac{10p^{-2}+\nu}{-3} & \frac{-15p^{-2}-3\nu}{+3} & 0 & \frac{5p^{-2}-\nu}{+1} & \frac{30p^{-2}+12\nu}{+3} & 15\nu & \frac{20p^{-2}-4\nu}{+4} & & & \\
--- & & & & & & & & & & & \\
\frac{-30p^{-2}+-30p^2}{-12\nu+42} & \frac{-15p^{-2}-3\nu}{+3} & \frac{15p^{-2}+3\nu}{-3} & \frac{-60p^{-2}+30p^2}{+12\nu-42} & \frac{-15p^{-2}+12\nu}{+\mathbf{3}} & \frac{30p^{-2}-3\nu}{+3} & \frac{30p^{-2}-60p^2}{+12\nu-42} & \frac{-30p^{-2}+3\nu}{-3} & \frac{15p^{-2}-12\nu}{-3} & \frac{60p^{-2}+60p^2}{-12\nu+42} & & \\
--- & & & & & & & & & & & \\
\frac{15p^{-2}-3\nu}{-3} & \frac{5p^{-2}-\nu}{+1} & 0 & \frac{-15p^{-2}+12\nu}{+3} & \frac{10p^{-2}+4\nu}{-4} & 0 & \frac{30p^2+3\nu}{+3} & \frac{10p^2+\nu}{-1} & 0 & -\left(\frac{30p^2+12\nu}{+3}\right) & \frac{20p^2-4\nu}{+4} & \\
--- & & & & & & & & & & & \\
\frac{-50p^{-2}-3\nu}{-3} & 0 & \frac{5p^{-2}-\nu}{+1} & \frac{-30p^{-2}+3\nu}{-3} & 0 & \frac{10p^{-2}+\nu}{-1} & \frac{15p^{-2}-12\nu}{-3} & 0 & \frac{10p^{-2}+4\nu}{-4} & \frac{30p^{-2}+12\nu}{+3} & -15\nu & \frac{20p^{-2}-4\nu}{+4}
\end{bmatrix} \Sigma$$

If the element is subjected to a uniform load in the z direction of intensity q, the consistent load vector becomes

$$\left[Q_q^*\right] = q \int_{-b/2}^{b/2} \int_{-c/2}^{c/2} [L]^T \, dx \, dy \tag{47.196}$$

where $\{Q_q^*\}$ is 12 forces corresponding to the nodal displacement parameters. Evaluating the integrals in this equation gives

$$\left\{Q_q^*\right\} = qcb \begin{Bmatrix} 1/4 \\ b/24 \\ -c/24 \\ \hline 1/4 \\ -b/24 \\ -c/24 \\ \hline 1/4 \\ b/24 \\ c/24 \\ \hline 1/4 \\ -b/24 \\ c/24 \end{Bmatrix} \tag{47.197}$$

More details on the finite element method can be found in Desai and Abel (1972) and Ghali and Neville (1978).

47.11 Inelastic Analysis

An Overall View

Inelastic analyses can be generalized into two main approaches. The first approach is known as *plastic hinge analysis*. This analysis assumes that structural elements remain elastic except at critical regions where plastic hinges are allowed to form. The second approach is known as *spread of plasticity analysis*. This analysis follows explicitly the gradual spread of yielding throughout the structure. Material yielding in the member is modeled by discretization of members into several line elements and subdivision of the cross sections into many "fibers." Although the spread of plasticity analysis can predict accurately the inelastic response of the structure, the plastic hinge analysis is considered to be computationally more efficient and less expensive to execute.

If the geometric nonlinear effect is not considered, the plastic hinge analysis predicts the maximum load of the structure corresponding to the formation of a plastic collapse mechanism (Chen and Sohal,

1995). First-order plastic analysis is finding considerable application in continuous beams and low-rise building frames where members are loaded primarily in flexure. For tall building frames and frames with slender columns subjected to side sway, the interaction between yielding and instability may lead to collapse prior to the formation of a plastic mechanism (SSRC, 1988). If an incremental analysis is carried out based on the updated deformed geometry of the structure, the analysis is termed *second order*. The need for a second-order analysis of steel frames is increasing in view of the modern codes and standards that give explicit permission for the engineer to compute load effects from a direct second-order analysis.

This section presents the virtual work principle to explain the fundamental theorems of plastic hinge analysis. Simple and approximate techniques of practical plastic analysis methods are then introduced. The concept of hinge-by-hinge analysis is presented. The more advanced topics, such as second-order elastic-plastic hinge, refined plastic hinge analysis, and spread of plasticity analysis, are covered in the Stability of Structures section.

Ductility

Plastic analysis is strictly applicable for materials that can undergo large deformation without fracture. Steel is one such material, with an idealized stress–strain curve, as shown in Fig. 47.92. When steel is subjected to tensile force, it will elongate elastically until the yield stress is reached. This is followed by an increase in strain without much increase in stress. Fracture will occur at very large deformation. This material idealization is generally known as *elastic-perfectly plastic* behavior. For a compact section, the attainment of initial yielding does not result in failure of a section. The compact section will have reserved plastic strength that depends on the shape of the cross-section. The capability of the material to deform under a constant load without decrease in strength is the *ductility* characteristic of the material.

Redistribution of Forces

The benefit of using a ductile material can be demonstrated from an example of a three-bar system, shown in Fig. 47.93. From the equilibrium condition of the system,

$$2T_1 + T_2 = P \tag{47.198}$$

Assuming the elastic stress–strain law, the displacement and force relationship of the bars may be written as:

$$\delta = \frac{T_1 L_1}{AE} = \frac{T_2 L_2}{AE} \tag{47.199}$$

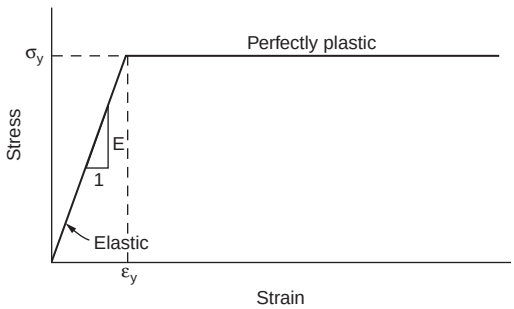

FIGURE 47.92 Idealized stress–strain curve.

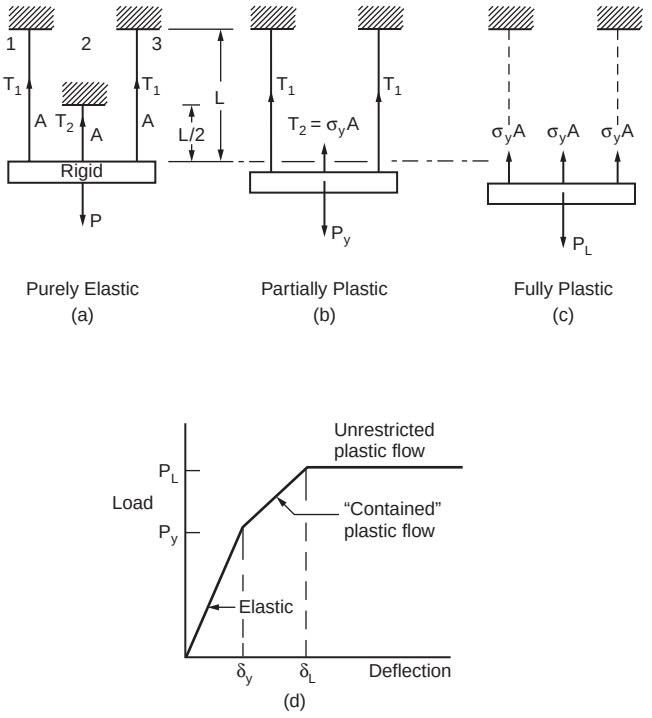

FIGURE 47.93 Force redistribution in a three-bar system: (a) elastic, (b) partially yielded, (c) fully plastic, (d) load-deflection curve.

Since $L_2 = L_1/2 = L/2$, Eq. (47.199) can be written as

$$T_1 = \frac{T_2}{2} \tag{47.200}$$

where T_1 and T_2 = the tensile forces in the rods
L_1 and L_2 = the lengths of the rods
A = the cross-section area
E = the elastic modulus.

Solving Eqs. (47.199) and (47.200) for T_2:

$$T_2 = \frac{P}{2} \tag{47.201}$$

The load at which the structure reaches the first yield (in Fig. 47.93b) is determined by letting $T_2 = \sigma_y A$. From Eq. (47.201),

$$P_y = 2T_2 = 2\sigma_y A \tag{47.202}$$

The corresponding displacement at first yield is

$$\delta_y = \varepsilon_y L = \frac{\sigma_y L}{2E} \tag{47.203}$$

After bar 2 is yielded, the system continues to take additional load until all the three bars reach their maximum strength of $\sigma_y A$, as shown in Fig. 47.93c. The plastic limit load of the system is thus written as

$$P_L = 3\sigma_y A \tag{47.204}$$

The process of successive yielding of bars in this system is known as inelastic redistribution of forces. The displacement at the incipient of collapse is

$$\delta_L = \varepsilon_y L = \frac{\sigma_y L}{E} \tag{47.205}$$

Figure 47.93d shows the load-displacement behavior of the system when subjected to increasing force. As load increases, bar 2 will reach its maximum strength first. As it yields, the force in the member remains constant, and additional loads on the system are taken by the less critical bars. The system will eventually fail when all three bars are fully yielded. This is based on an assumption that material strain hardening does not take place.

Concept of Plastic Hinge

A plastic hinge is said to form in a structural member when the cross-section is fully yielded. If material strain hardening is not considered in the analysis, a fully yielded cross-section can undergo indefinite rotation at a constant restraining plastic moment M_p.

Most of the plastic analyses assume that plastic hinges are concentrated at zero length plasticity. In reality, the yield zone is developed over a certain length, normally called the *plastic hinge length*, depending on the loading, boundary conditions, and geometry of the section. The hinge lengths of beams (ΔL) with different support and loading conditions are shown in Fig. 47.94a to c. Plastic hinges are developed first at the sections subjected to the greatest moment. The possible locations for plastic hinges to develop are at the points of concentrated loads, at the intersections of members involving a change in geometry, and at the point of zero shear for members under uniform distributed load.

Plastic Moment Capacity

A knowledge of full plastic moment capacity of a section is important in plastic analysis. It forms the basis for limit load analysis of the system. Plastic moment is the moment resistance of a fully yielded cross section. The cross-section must be fully compact in order to develop its plastic strength. The component plates of a section must not buckle prior to the attainment of full moment capacity.

The plastic moment capacity, M_p, of a cross-section depends on the material yield stress and the section geometry. The procedure for the calculation of M_p may be summarized in the following two steps:

1. The plastic neutral axis of a cross-section is located by considering equilibrium of forces normal to the cross section. Figure 47.95a shows a cross-section of arbitrary shape subjected to increasing moment. The plastic neutral axis is determined by equating the force in compression (C) to that in tension (T). If the entire cross-section is made of the same material, the plastic neutral axis can be determined by dividing the cross-sectional area into two equal parts. If the cross-section is made of more than one type of material, the plastic neutral axis must be determined by summing the normal force and letting the force equal zero.
2. The plastic moment capacity is determined by obtaining the moment generated by the tensile and compressive forces.

Consider an arbitrary section with area 2A and with one axis of symmetry of which the section is strengthened by a cover plate of area a, as shown in Fig. 47.95b. Further assume that the yield strengths of the original section and the cover plate are σ_{yo} and σ_{yc}, respectively. At the full plastic state, the total

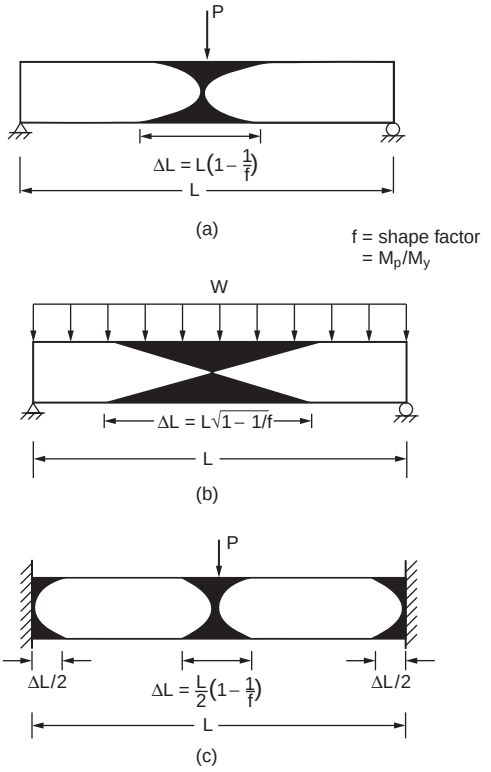

FIGURE 47.94 Hinge lengths of beams with different support and loading conditions.

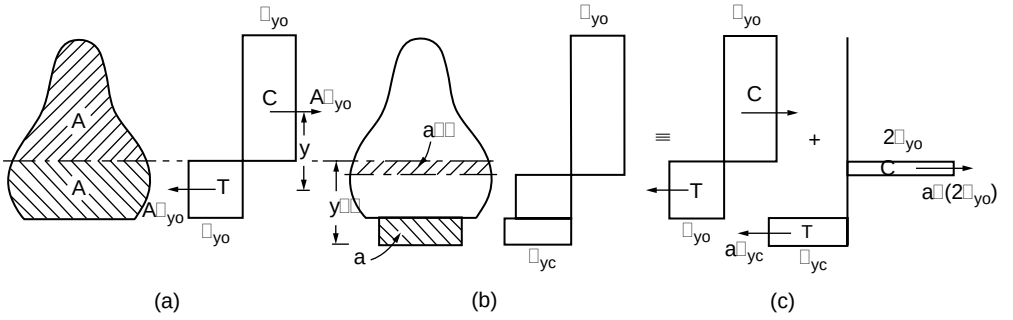

FIGURE 47.95 Cross-section of arbitrary shape subjected to bending.

axial force acting on the cover plate is $a\sigma_{yc}$. In order to maintain equilibrium of force in the axial direction, the plastic neutral axis must shift down from its original position by a′, i.e.,

$$a' = \frac{a\sigma_{yc}}{2\sigma_{yo}} \tag{47.206}$$

The resulting plastic capacity of the "built-up" section may be obtained by summing the full plastic moment of the original section and the moment contribution by the cover plate. The additional capacity is equal to the moment caused by the cover plate force $a\sigma_{yc}$ and a force due to the fictitious stress $2\sigma_{yo}$

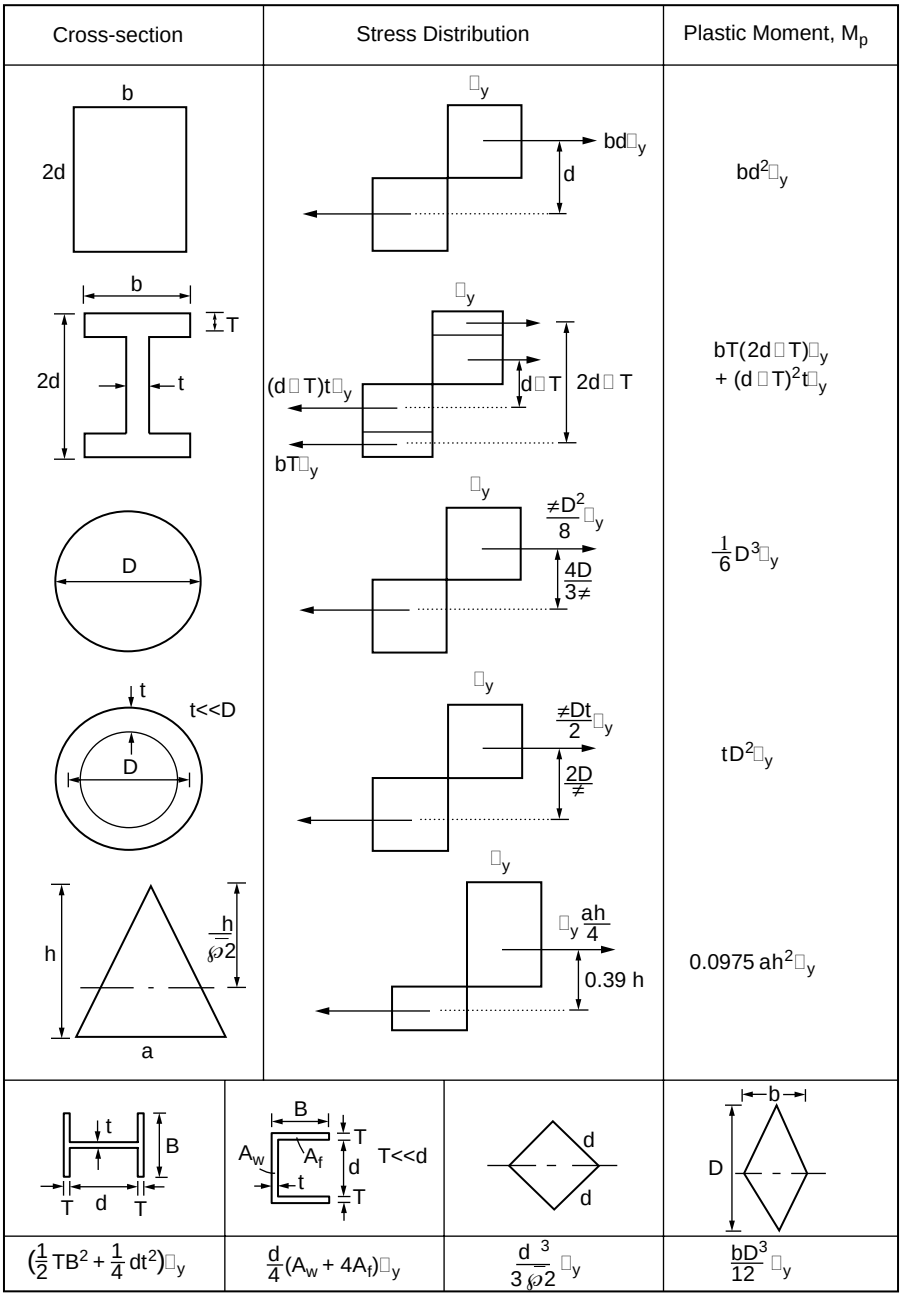

FIGURE 47.96 Plastic moment capacities of sections.

acting on the area a′, resulting from the shifting of the plastic neutral axis from the tension zone to the compression zone, as shown in Fig. 47.95c.

Figure 47.96 shows the computation of plastic moment capacity of several shapes of cross-sections. Based on the principle developed in this section, the plastic moment capacities of typical cross-sections may be generated. Additional information for sections subjected to combined bending, torsion, shear, and axial load can be found in Mrazik et al. (1987).

Theory of Plastic Analysis

There are two main assumptions for first-order plastic analysis:

1. The structure is made of ductile material that can undergo large deformations beyond elastic limit without fracture or buckling.
2. The deflections of the structure under loading are small so that second-order effects can be ignored.

An "exact" plastic analysis solution must satisfy three basic conditions. They are *equilibrium*, *mechanism,* and *plastic moment* conditions. The plastic analysis disregards the continuity condition as required by the elastic analysis of indeterminate structures. The formation of a plastic hinge in members leads to discontinuity of slope. If sufficient plastic hinges are formed to allow the structure to deform into a mechanism, this is a mechanism condition. Since plastic analysis utilizes the limit of resistance of a member's plastic strength, the plastic moment condition is required to ensure that the resistance of the cross-sections is not violated anywhere in the structure. Lastly, the equilibrium condition, which is the same condition to be satisfied in elastic analysis, requires that the sum of all applied forces and reactions be equal to zero and that all internal forces be self-balanced.

When all three conditions are satisfied, the resulting plastic analysis for the limiting load is the "correct" limit load. The collapse loads for simple structures such as beams and portal frames can be solved easily using a direct approach or through visualization of the formation of "correct" collapse mechanism. However, for more complex structures, the exact solution satisfying all three conditions may be difficult to predict. Thus, simple techniques using approximate methods of analysis are often used to assess these solutions. These techniques, named equilibrium and mechanism methods, will be discussed in the subsequent sections.

Principle of Virtual Work

The virtual work principle may be applied to relate a system of forces in equilibrium to a system of compatible displacements. For example, if a structure in equilibrium is given a set of small compatible displacement, then the work done by the external loads on these external displacements is equal to the work done by the internal forces on the internal deformation. In plastic analysis, internal deformations are assumed to be concentrated at plastic hinges. The virtual work equation for hinged structures can be written in explicit form as

$$\sum P_i \delta_j = \sum M_i \theta_j \tag{47.207}$$

where P_i is an external load and M_i is an internal moment at a hinge location. Both P_i and M_i constitute an equilibrium set, and they must be in equilibrium. δ_j is the displacement under point load P_i and in the direction of the load. θ_j is the plastic hinge rotation under the moment M_i. Both δ_j and θ_j constitute a displacement set, and they must be compatible with each other.

Lower Bound Theorem

For a given structure, if there exists any distribution of bending moments in the structure that satisfies both the equilibrium and plastic moment conditions, then the load factor, λ_L, computed from this moment diagram must be equal to or less than the collapse load factor, λ_c, of the structure. The lower bound theorem provides a safe estimate of the collapse limit load, i.e., $\lambda_L \le \lambda_L$.

Upper Bound Theorem

For a given structure subjected to a set of applied loads, a load factor, λ_u, computed based on an assumed collapse mechanism must be greater than or equal to the true collapse load factor, λ_c. The upper bound theorem, which uses only the mechanism condition, overestimates or equals the collapse limit load, i.e., $\lambda_u \ge \lambda_c$.

Uniqueness Theorem

A structure at collapse has to satisfy three conditions. First, a sufficient number of plastic hinges must be formed to turn the structure, or part of it, into a mechanism; this is called the mechanism condition. Second, the structure must be in equilibrium, i.e., the bending moment distribution must satisfy equilibrium with the applied loads. Finally, the bending moment at any cross-section must not exceed the full plastic value of that cross-section; this is called the plastic moment condition. The theorem simply implies that the collapse load factor, λ_c, obtained from the three basic conditions (mechanism, equilibrium, and plastic moment) has a unique value.

The proof of the three theorems can be found in Chen and Sohal (1995). A useful corollary of the lower bound theorem is that if at a load factor, λ, it is possible to find a bending moment diagram that satisfies both the equilibrium and moment conditions but not necessarily the mechanism condition, then the structure will not collapse at that load factor, unless the load happens to be the collapse load. A corollary of the upper bound theorem is that the true load factor at collapse is the smallest possible one that can be determined from a consideration of all possible mechanisms of collapse. This concept is very useful in finding the collapse load of the system from various combinations of mechanisms. From these, it can be seen that the lower bound theorem is based on the equilibrium approach, while the upper bound technique is based on the mechanism approach. These two alternative approaches to an exact solution, called the *equilibrium method* and the *mechanism method*, will be discussed in the following sections.

Equilibrium Method

The equilibrium method, which employs the lower bound theorem, is suitable for the analysis of continuous beams and frames in which the structural redundancies are not exceeding 2. The procedures of obtaining the equilibrium equations of a statically indeterminate structure and evaluating its plastic limit load are as follows:

To obtain the equilibrium equations of a statically indeterminate structure:

1. Select the redundant(s).
2. Free the redundants and draw a moment diagram for the determinate structure under the applied loads.
3. Draw a moment diagram for the structure due to the redundant forces.
4. Superimpose the moment diagrams in steps 2 and 3.
5. Obtain the maximum moment at critical sections of the structure utilizing the moment diagram in step 4.

To evaluate the plastic limit load of the structure:

6. Select value(s) of redundant(s) such that the plastic moment condition is not violated at any section in the structure.
7. Determine the load corresponding to the selected redundant(s).
8. Check for the formation of a mechanism. If a collapse mechanism condition is met, then the computed load is the exact plastic limit load. Otherwise, it is a lower bound solution.
9. Adjust the redundant(s) and repeat steps 6 to 9 until the exact plastic limit load is obtained.

Example 47.11: Continuous Beam

Figure 47.97a shows a two-span continuous beam that is analyzed using the equilibrium method. The plastic limit load of the beam is calculated based on the step-by-step procedure described in the previous section as follows:

1. Select the redundant force as M_1, which is the bending moment at the intermediate support, as shown in Fig. 47.97b.
2. Free the redundants and draw a moment diagram for the determinate structure under the applied loads, as shown in Fig. 47.97c.

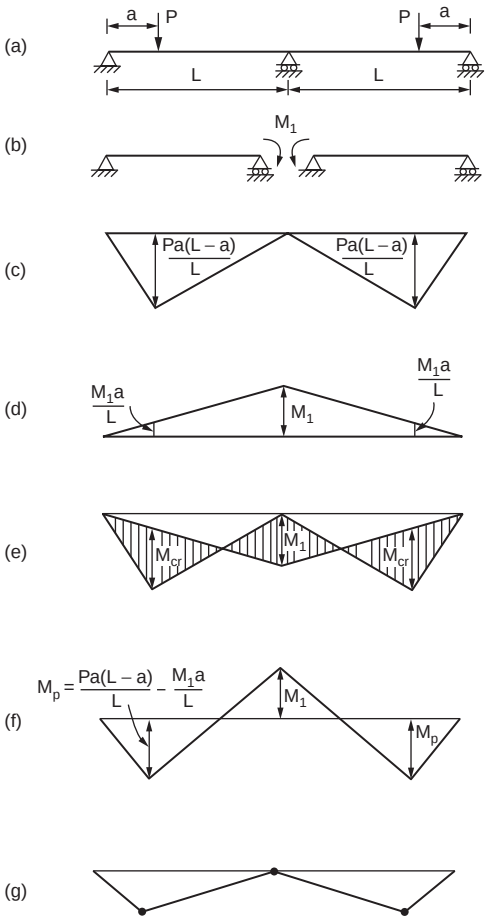

FIGURE 47.97 Analysis of a two-span continuous beam using equilibrium method.

3. Draw a moment diagram for the structure due to the redundant moment M_1, as shown in Fig. 47.97d.
4. Superimpose the moment diagrams in Fig. 47.97c and d, and the results are shown in Fig. 47.97e.

The moment diagram in Fig. 47.97e is redrawn on a single straight baseline. The critical moment in the beam is

$$M_{cr} = \frac{Pa(L-a)}{L} - \frac{M_1 a}{L} \tag{47.208}$$

The maximum moment at critical sections of the structure utilizing the moment diagram in Fig. 47.97e is obtained. By letting $M_{cr} = M_p$, the resulting moment distribution is shown in Fig. 47.97f.

A lower bound solution may be obtained by selecting a value of redundant moment M_1. For example, if $M_1 = 0$ is selected, the moment diagram is reduced to that shown in Fig. 47.97c. By equating the maximum moment in the diagram to the plastic moment, M_p, we have

$$M_{cr} = \frac{Pa(L-a)}{L} = M_p \tag{47.209}$$

which gives $P = P_1$ as

$$P_1 = \frac{M_p L}{a(L-a)} \tag{47.210}$$

The moment diagram in Fig. 47.97c shows a plastic hinge formed at each span. Since two plastic hinges in each span are required to form a plastic mechanism, the load P_1 is a lower bound solution. However, setting the redundant moment M_1 equal to the plastic moment M_p and letting the maximum moment in Fig. 47.97f equal the plastic moment, we have

$$M_{cr} = \frac{Pa(L-a)}{L} - \frac{M_p a}{L} = M_p \tag{47.211}$$

which gives $P = P_2$ as

$$P_2 = \frac{M_p(L+a)}{a(L-a)} \tag{47.212}$$

Since a sufficient number of plastic hinges has formed in the beams (Fig. 47.97g) to arrive at a collapse mechanism, the computed load, P_2, is the exact plastic limit load.

Example 47.12: Portal Frame

A pin-based rectangular frame is subjected to vertical load V and horizontal load H, as shown in Fig. 47.98a. All the members of the frame are made of the same section with moment capacity M_p. The objective is to determine the limit value of H if the frame's width-to-height ratio, L/h, is 1.0.

Procedure:

The frame has one degree of redundancy. The redundancy for this structure can be chosen as the horizontal reaction at E. Figure 47.98b and c show the resulting determinate frame loaded by the applied loads and redundant force. The moment diagrams corresponding to these two loading conditions are shown in Fig. 47.98d and e.

The horizontal reaction S should be chosen in such a manner that all three conditions — equilibrium, plastic moment, and mechanism — are satisfied. Formation of two plastic hinges is necessary to form a

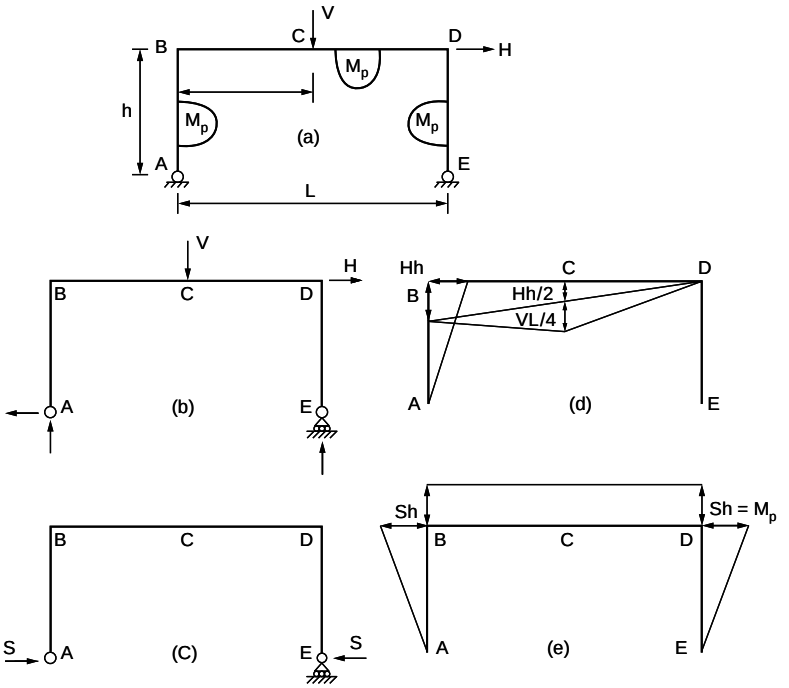

FIGURE 47.98 Analysis of portal frame using equilibrium method.

mechanism. The plastic hinges may be formed at B, C, and D. Assuming that a plastic hinge is formed at D, as shown in Fig. 47.98e, we have

$$S = \frac{M_p}{h} \tag{47.213}$$

Corresponding to this value of S, the moments at B and C can be expressed as

$$M_B = Hh - M_p \tag{47.214}$$

$$M_C = \frac{Hh}{2} + \frac{VL}{4} - M_p \tag{47.215}$$

The condition for the second plastic hinge to form at B is $|M_B| > |M_C|$. Form Eqs. (47.214) and (47.215) we have

$$Hh - M_p > \frac{Hh}{2} + \frac{VL}{4} - M_p \tag{47.216}$$

and

$$\frac{V}{H} < \frac{h}{L} \tag{47.217}$$

The condition for the second plastic hinge to form at C is $|M_C| > |M_B|$. Form Eqs. (47.214) and (47.215) we have

$$Hh - M_p < \frac{Hh}{2} + \frac{VL}{4} - M_p \tag{47.218}$$

and

$$\frac{V}{H} > \frac{h}{L} \tag{47.219}$$

For a particular combination of V, H, L, and h, the collapse load for H can be calculated.

When L/h = 1 and V/H = 1/3, we have

$$M_B = Hh - M_p \tag{47.220}$$

$$M_C = \frac{Hh}{2} + \frac{Hh}{12} - M_p = \frac{7}{12}Hh - M_p \tag{47.221}$$

Since $|M_B| > |M_C|$, the second plastic hinge will form at B, and the corresponding value for H is

$$H = \frac{2M_p}{h} \tag{47.222}$$

When L/h = 1 and V/H = 3, we have

$$M_B = Hh - M_p \tag{47.223}$$

$$M_C = \frac{Hh}{2} + \frac{3}{4}Hh - M_p = \frac{5}{4}Hh - M_p \tag{47.224}$$

Since $|M_C| > |M_B|$, the second plastic hinge will form at C, and the corresponding value for H is

$$H = \frac{1.6M_p}{h} \tag{47.225}$$

Mechanism Method

This method, which is based on the upper bound theorem, states that the load computed on the basis of an assumed failure mechanism is never less than the exact plastic limit load of a structure. Thus, it always predicts the upper bound solution of the collapse limit load. It can also be shown that the minimum upper bound is the limit load itself. The procedure of using the mechanism method has the following two steps:

1. Assume a failure mechanism and form the corresponding work equation from which an upper bound value of the plastic limit load can be estimated.
2. Write the equilibrium equations for the assumed mechanism and check the moments to see whether the plastic moment condition is met everywhere in the structure.

To obtain the true limit load using the mechanism method, it is necessary to determine every possible collapse mechanism, some of which are the combinations of a certain number of independent mechanisms. Once the independent mechanisms have been identified, a work equation may be established for each combination, and the corresponding collapse load is determined. The lowest load among those obtained by considering all the possible combinations of independent mechanisms is the correct plastic limit load.

Independent Mechanisms

The number of possible independent mechanisms, n, for a structure can be determined from the following equation:

$$n = N - R \tag{47.226}$$

where N is the number of critical sections at which plastic hinges might form and R is the degrees of redundancy of the structure.

Critical sections generally occur at the points of concentrated loads, at joints where two or more members are meeting at different angles, and at sections where there is an abrupt change in section geometries or properties. To determine the number of redundancies (R) of a structure, it is necessary to free sufficient supports or restraining forces in structural members so that the structure becomes an assembly of several determinate substructures.

Figure 47.99 shows two examples. The cuts that are made in each structure reduce the structural members to either cantilevers or simply supported beams. The fixed-end beam requires a shear force and a moment to restore continuity at the cut section, and thus R = 2. For the two-story frame, an axial force, shear, and moment are required at each cut section for full continuity, and thus R = 12.

Types of Mechanisms

Figure 47.100a shows a frame structure subjected to a set of loading. The frame may fail by different types of collapse mechanisms dependent on the magnitude of loading and the frame's configurations. The collapse mechanisms are:

1. *Beam*: possible mechanisms of this type are shown in Fig. 47.100b.
2. *Panel*: the collapse mode is associated with side sway, as shown in Fig. 47.100c.
3. *Gable*: the collapse mode is associated with the spreading of column tops with respect to the column bases, as shown in Fig. 47.100d.

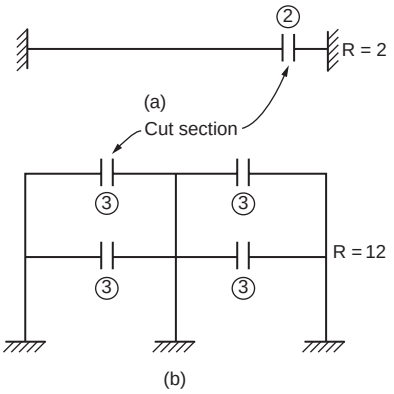

FIGURE 47.99 Number of redundants in: (a) a beam, (b) a frame.

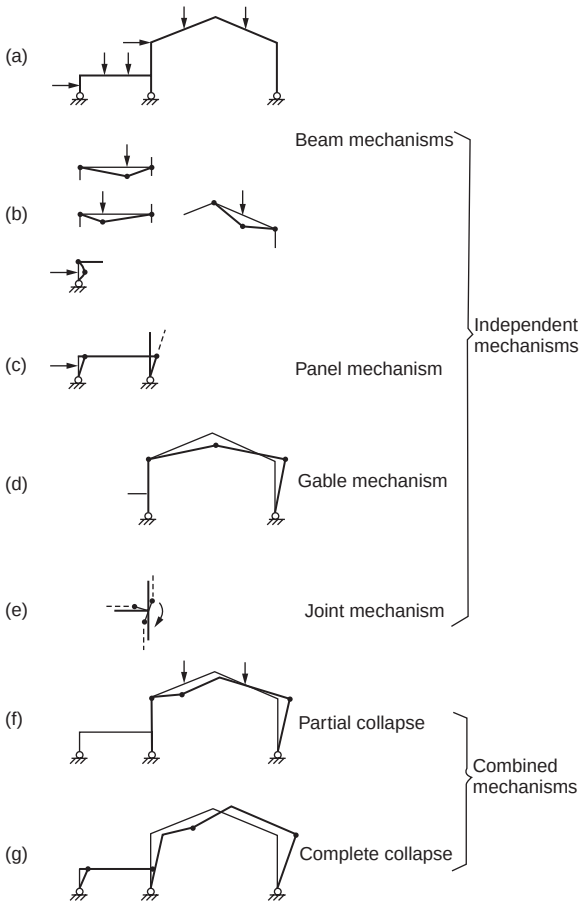

FIGURE 47.100 Typical plastic mechanisms.

4. *Joint*: the collapse mode is associated with the rotation of joints of which the adjoining members developed plastic hinges and deformed under an applied moment, as shown in Fig. 47.100e.
5. *Combined*: it can be a partial collapse mechanism, as shown in Fig. 47.100f, or it may be a complete collapse mechanism, as shown in Fig. 47.100g.

The principal rule for combining independent mechanisms is to obtain a lower value of collapse load. The combinations are selected in such a way that the external work becomes a maximum and the internal work becomes a minimum. Thus the work equation would require that the mechanism involve as many applied loads as possible and at the same time eliminate as many plastic hinges as possible. This procedure is illustrated in the following example.

Example 47.13: Rectangular Frame

A fixed-end rectangular frame has a uniform section with $M_p = 20$ and carries the load shown in Fig. 47.101. Determine the value of load ratio λ at collapse.

Solution:

Number of possible plastic hinges: $N = 5$
Number of redundancies: $R = 3$
Number of independent mechanisms: $N - R = 2$

The two independent mechanisms are shown in Fig. 47.101b and c, and the corresponding work equations are

Panel mechanism: $20\lambda = 4(20) = 80 \Rightarrow \lambda = 4$
Beam mechanism: $30\lambda = 4(20) = 80 \Rightarrow \lambda = 2.67$

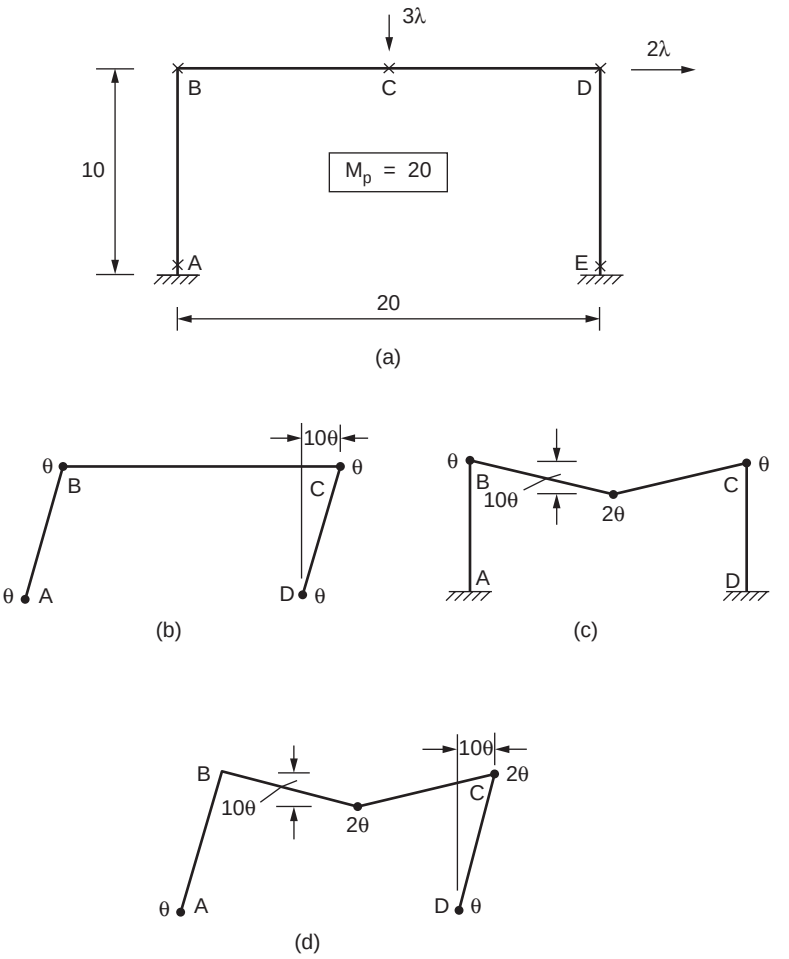

FIGURE 47.101 Collapse mechanisms of a fixed base portal frame.

The combined mechanisms are now examined to see whether they will produce a lower λ value. It is observed that only one combined mechanism is possible. The mechanism is shown in Fig. 47.101c and involves cancellation of the plastic hinge at B. The calculation of the limit load is described below:

Panel mechanism:	$20\lambda = 4(20)$
Beam mechanism:	$30\lambda = 4(20)$
Addition:	$50\lambda = 8(20)$
Cancel of plastic hinge:	$-2(20)$
Combined mechanism:	$50\lambda = 6(20) \Rightarrow \lambda = 2.4$

The combined mechanism results in a smaller value for λ, and no other possible mechanism can produce a lower load. Thus, $\lambda = 2.4$ is the collapse load.

Example 47.14: Frame Subjected to Distributed Load

When a frame is subjected to distributed loads, the maximum moment and hence the plastic hinge location is not known in advance. The exact location of the plastic hinge may be determined by writing the work equation in terms of the unknown distance and then maximizing the plastic moment by formal differentiation.

Consider the frame shown in Fig. 47.102a. The side sway collapse mode in Fig. 47.102b leads to the following work equation:

$$4M_p = 24(10\theta)$$

which gives

$$M_p = 60$$

The beam mechanism of Fig. 47.102c gives

$$4M_p\theta = \frac{1}{2}(10\theta)32$$

which gives

$$M_p = 40$$

In fact the correct mechanism is shown in Fig. 47.102d, in which the distance Z from the plastic hinge location is unknown. The work equation is

$$24(10\theta) + \frac{1}{2}(1.6)(20)(z\theta) = M_p\left(2 + 2\left(\frac{20}{20 - z}\right)\right)\theta$$

which gives

$$M_p = \frac{(240 + 16z)(20 - z)}{80 - 2z}$$

To maximize M_p, the derivative of M_p is set to zero, i.e.,

$$(80 - 2z)(80 - 32z) + (4800 + 80z - 16z^2)(2) = 0$$

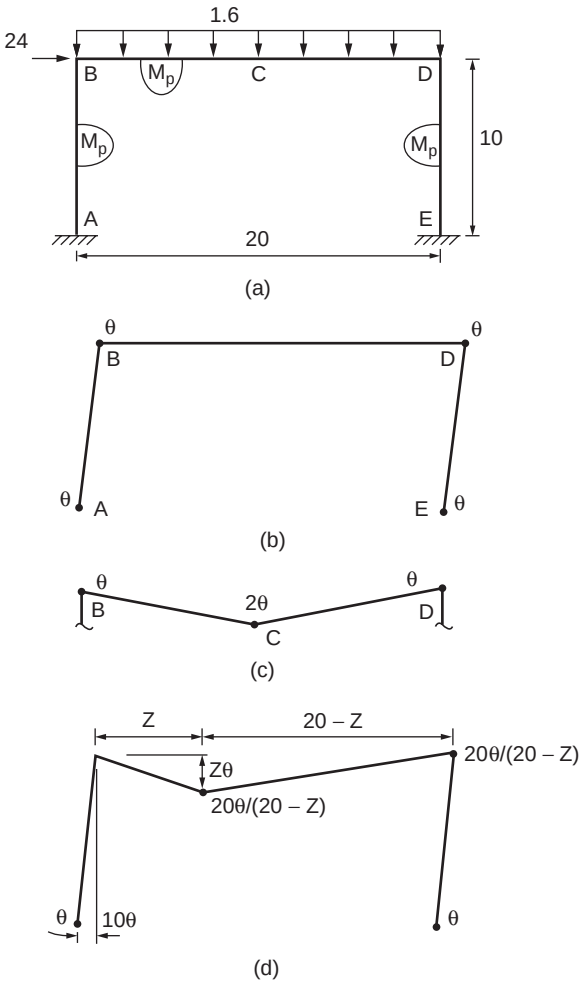

FIGURE 47.102 Portal frame subjected to a combined uniform distributed load and horizontal load.

which gives

$$z = 40 - \sqrt{1100} = 6.83$$

and

$$M_p = 69.34$$

In practice, uniform load is often approximated by applying several equivalent point loads to the member under consideration. Plastic hinges thus can be assumed to form only at the concentrated load points, and the calculations become simpler when the structural system is getting more complex.

Example 47.15: Gable Frame

The mechanism method is used to determine the plastic limit load of the gable frame shown in Fig. 47.103. The frame is composed of members with a plastic moment capacity of 270 kip-in. The column bases are fixed. The frame is loaded by a horizontal load H and vertical concentrated load V. A graph from which V and H cause the collapse of the frame is to be produced.

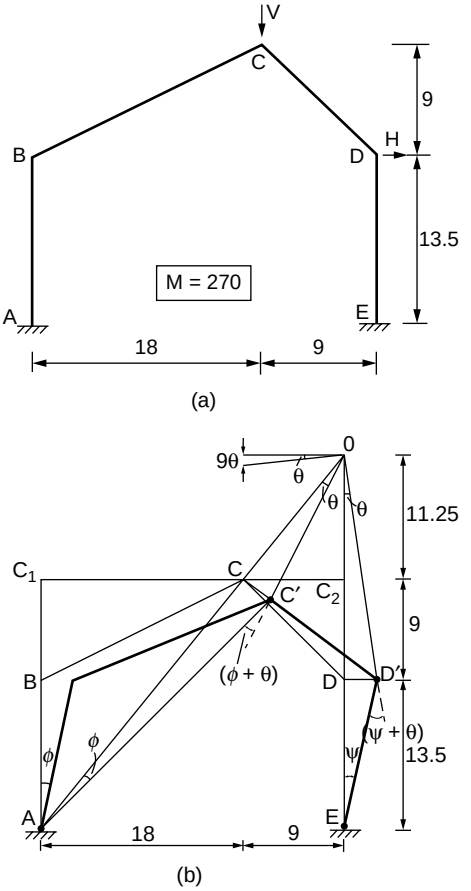

FIGURE 47.103 Collapse mechanisms of a fixed base gable frame.

Solution:

Consider the three modes of collapse as follows:

Mechanism 1: plastic hinges form at A, C, D, and E:

The mechanism is shown in Fig. 47.103b. The instantaneous center O for member CD is located at the intersection of AC and $_{E}$D extended. From similar triangles ACC1 and OCC2, we have

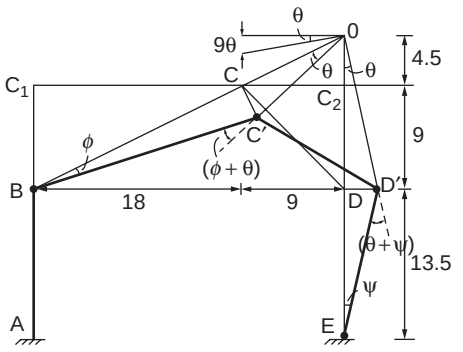
$$\frac{OC_2}{CC_2} = \frac{C_1A}{C_1C}$$

which gives

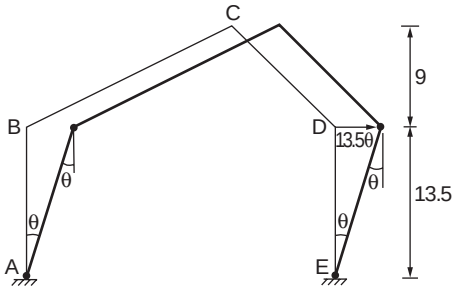
$$OC_2 = \frac{C_1A}{C_1C}CC_2 = \frac{22.5(9)}{18} = 11.25\text{ft}$$

From triangles ACC′ and CC′O, we have

$$AC(\phi) = OC(\theta)$$



(c)



(d)

FIGURE 47.103 (continued).

which gives

$$\phi = \frac{OC}{AC}\theta = \frac{CC_2}{C_1C}\theta = \frac{9}{8}\theta = \frac{1}{2}\theta$$

Similarly, from triangles ODD′ and EDD′, the rotation at E is given as

$$DE(\Psi) = OD(\theta)$$

which gives

$$\Psi = \frac{OD}{DE}\theta = 1.5\theta$$

From the hinge rotations and displacements, the work equation for this mechanism can be written as

$$V(9\theta) + H(13.5\Psi) = M_p\left[\phi + (\phi + \theta) + (\theta + \Psi) + \Psi\right]$$

Substituting values for ψ and ϕ and simplifying, we have

$$V + 2.25H = 180$$

Mechanism 2: mechanism with hinges at B, C, D, and E:
Figure 47.103c shows the mechanism in which the plastic hinge rotations and displacements at the load points can be expressed in terms of the rotation of member CD about the instantaneous center O.

From similar triangles BCC_1 and OCC_2, we have

$$\frac{OC_2}{CC_2} = \frac{BC_1}{C_1C}$$

which gives

$$OC_2 = \frac{BC_1}{C_1C} CC_2 = \frac{9}{18}(9) = 4.5$$

From triangles BCC′ and CC′O, we have

$$BC(\phi) = OC(\theta)$$

which gives

$$\phi = \frac{OC}{BC}\theta = \frac{OC_2}{BC_1}\theta = \frac{4.5}{9}\theta = \frac{1}{2}\theta$$

Similarly, from triangles ODD′ and EDD′, the rotation at E is given as

$$DE(\Psi) = OD(\theta)$$

which gives

$$\Psi = \frac{OD}{DE}\theta = \theta$$

The work equation for this mechanism can be written as

$$V(9\theta) + H(13.5\Psi) = M_p\left[\phi + (\phi + \theta) + (\theta + \Psi) + \Psi\right]$$

Substituting values of ψ and ϕ and simplifying, we have

$$V + 1.5H = 150$$

Mechanism 3: mechanism with hinges at A, B, D, and E:
The hinge rotations and displacements corresponding to this mechanism are shown in Fig. 47.103d. The rotation of all hinges is θ. The horizontal load moves by 13.5θ, but the horizontal load has no vertical displacement. The work equation becomes

$$H(13.5\theta) = M_p(\theta + \theta + \theta + \theta)$$

or

$$H = 80$$

The interaction equations corresponding to the three mechanisms are plotted in Fig. 47.104. By carrying out moment checks, it can be shown that mechanism 1 is valid for portion AB of the curve, mechanism 2 is valid for portion BC, and mechanism 3 is valid only when V = 0.

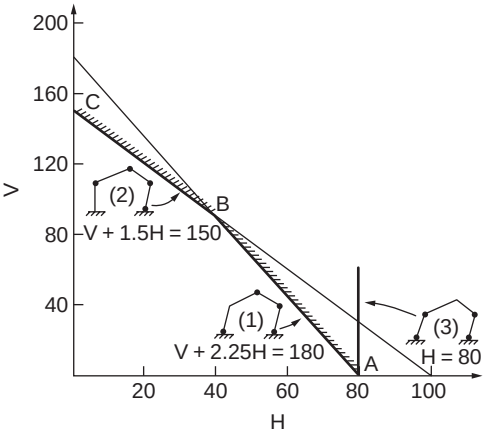


FIGURE 47.104 Vertical load and horizontal force interaction curve for collapse analysis of gable frame.

Analysis Aids for Gable Frames

Pin-Based Gable Frames

Figure 47.105a shows a pinned-end gable frame subjected to a uniform gravity load λwL and a horizontal load λ1H at the column top. The collapse mechanism is shown in Fig. 47.105b. The work equation is used to determine the plastic limit load. First, the instantaneous center of rotation O is determined by considering similar triangles,

$$\frac{OE}{CF} = \frac{L}{xL} \quad \text{and} \quad \frac{OE}{CF} = \frac{OE}{h_1 + 2xh_2} \tag{47.227}$$

and

$$OD = OE - h_1 = \frac{(1-x)h_1 + 2xh_2}{x} \tag{47.228}$$

From the horizontal displacement of D,

$$\theta h_1 = \phi OD \tag{47.229}$$

of which

$$\phi = \frac{x}{(1-x) + 2xk}\theta \tag{47.230}$$

where $k = h_2/h_1$. From the vertical displacement at C,

$$\beta = \frac{1-x}{(1-x) + 2xk}\theta \tag{47.231}$$

The work equation for the assumed mechanism is

$$\lambda_1 H h_1 \beta + \frac{\lambda w L^2}{2}(1-x)\phi = M_p(\beta + 2\phi + \theta) \tag{47.232}$$

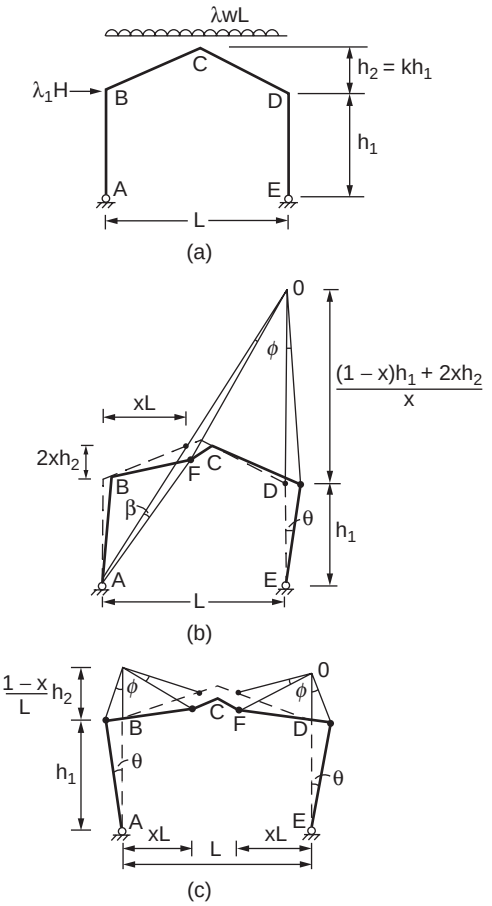

FIGURE 47.105 Pinned base gable frame subjected to a combined uniform distributed load and horizontal load.

which gives

$$M_p = \frac{(1-x)\lambda_1 H h_1 + (1-x)x\lambda wL^2/2}{2(1+kx)} \tag{47.233}$$

Differentiating M_p in Eq. (47.233) with respect to x and solving for x,

$$x = \frac{A-1}{k} \tag{47.234}$$

where

$$A = \sqrt{(1+k)(1-Uk)} \quad \text{and} \quad U = \frac{2\lambda_1 H h_1}{\lambda wL^2} \tag{47.235}$$

Substituting for x in the expression for M_p gives

$$M_p = \frac{\lambda wL^2}{8}\left[\frac{U(2+U)}{A^2 + 2A - Uk^2 + 1}\right] \tag{47.236}$$

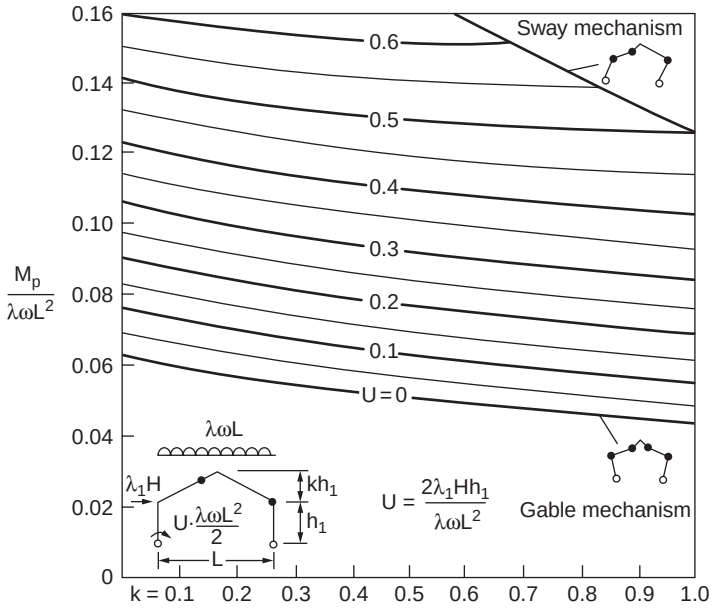

FIGURE 47.106 Analysis chart for pinned base gable frame.

In the absence of horizontal loading, the gable mechanism, as shown in Fig. 47.105c, is the failure mode. In this case, letting H = 0 and U = 0 gives (Horne, 1964):

$$M_p = \frac{\lambda w L^2}{8}\left[\frac{1}{1+k+\sqrt{1+k}}\right] \tag{47.237}$$

Equation (47.236) can be used to produce a chart, as shown in Fig. 47.106, by which the value of M_p can be determined rapidly by knowing the values of

$$k = \frac{h_2}{h_1} \quad \text{and} \quad U = \frac{2\lambda_1 H h_1}{\lambda w L^2} \tag{47.238}$$

Fixed-Base Gable Frames

A similar chart can be generated for fixed-base gable frames, as shown in Fig. 47.107. Thus, if the values of loading, λw and $\lambda_1 H$, and frame geometry, h_1, h_2, and L, are known, the parameters k and U can be evaluated and the corresponding value of $M_p/(\lambda w L^2)$ can be read directly from the appropriate chart. The required value of M_p is obtained by multiplying the value of $M_p/(\lambda w L^2)$ by $\lambda w L^2$.

Grillages

Grillage is a type of structure that consists of straight beams lying on the same plane, subjected to loads acting perpendicular to the plane. An example of such a structure is shown in Fig. 47.108. The grillage consists of two equal simply supported beams of span length 2L and full plastic moment M_p. The two beams are connected rigidly at their centers, where a concentrated load W is carried.

The collapse mechanism consists of four plastic hinges formed at the beams adjacent to the point load, as shown in Fig. 47.108. The work equation is

$$WL\theta = 4M_p\theta$$

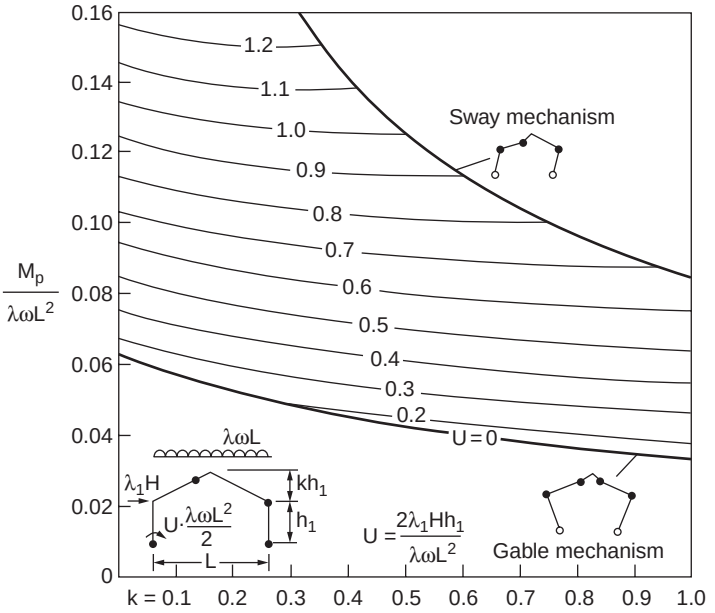

FIGURE 47.107 Analysis chart for fixed gable frame.

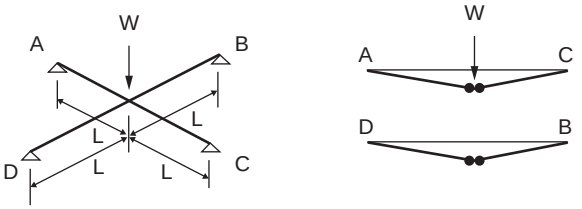

FIGURE 47.108 Two-beam grillage system.

of which the collapse load is

$$W = \frac{4M_p}{L}$$

Six-Beam Grillage

A grillage consisting of six beams of span length 4L each and full plastic moment M_p is shown in Fig. 47.109. A total load of 9W acts on the grillage, splitting into concentrated loads W at the nine nodes. Three collapse mechanisms are possible. Ignoring member twisting due to torsional forces, the work equations associated with the three collapse mechanisms are computed as follows:
Mechanism 1 (Fig. 47.110a):

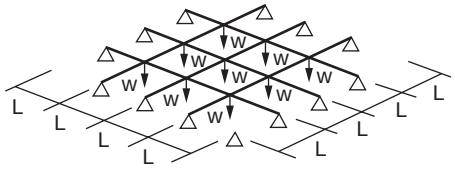

FIGURE 47.109 Six-beam grillage system.

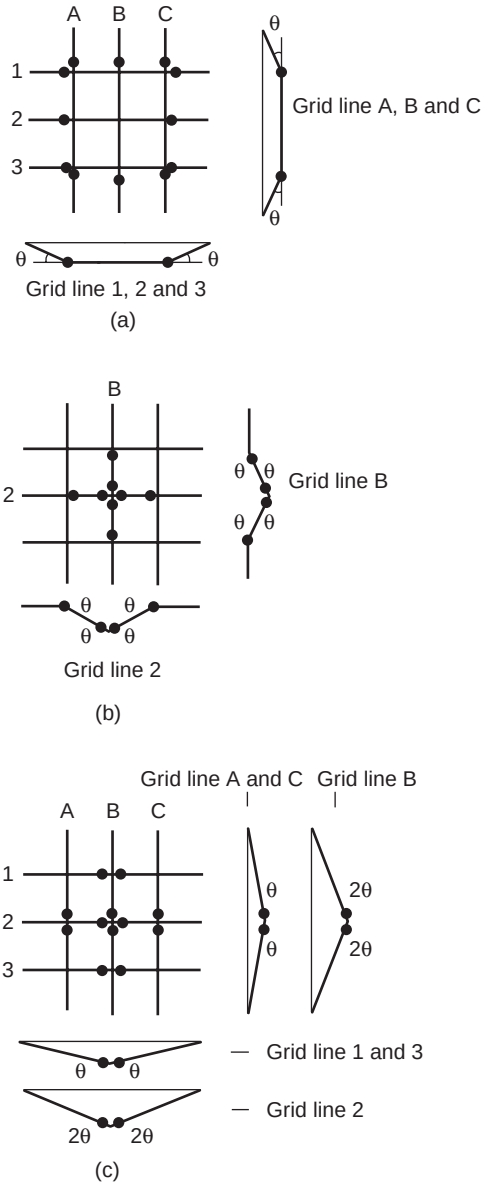

FIGURE 47.110 Six-beam grillage system: (a) mechanism 1, (b) mechanism 2, (c) mechanism 3.

Work equation:

$$9wL\theta = 12M_p\theta$$

of which

$$w = \frac{12}{9}\frac{M_p}{L} = \frac{4M_p}{3L}$$

Mechanism 2 (Fig. 47.110b):

Work equation:

$$wL\theta = 8M_p\theta$$

of which

$$w = \frac{8M_p}{L}$$

Mechanism 3 (Fig. 47.110c):

Work equation:

$$w2L2\theta + 4 \times w2L\theta = M_p(4\theta + 8\theta)$$

of which

$$w = \frac{M_p}{L}$$

The lowest upper bound load corresponds to mechanism 3. This can be confirmed by conducting a moment check to ensure that bending moments anywhere are not violating the plastic moment condition. Additional discussion of plastic analysis of grillages can be found in Baker and Heyman (1969) and Heyman (1971).

Vierendeel Girders

Figure 47.111 shows a simply supported girder in which all members are rigidly joined and have the same plastic moment M_p. It is assumed that axial loads in the members do not cause member instability. Two possible collapse mechanisms are considered, as shown in Fig. 47.111b to c.

The work equation for mechanism 1 is

$$W3\theta L = 20M_p\theta$$

so that

$$W = \frac{20M_p}{3L}$$

The work equation for mechanism 2 is

$$W3\theta L = 16M_p\theta$$

or

$$W = \frac{16M_p}{3L}$$

It can be easily proved that the collapse load associated with mechanism 2 is the correct limit load. This is done by constructing an equilibrium set of bending moments and checking that they are not violating the plastic moment condition.

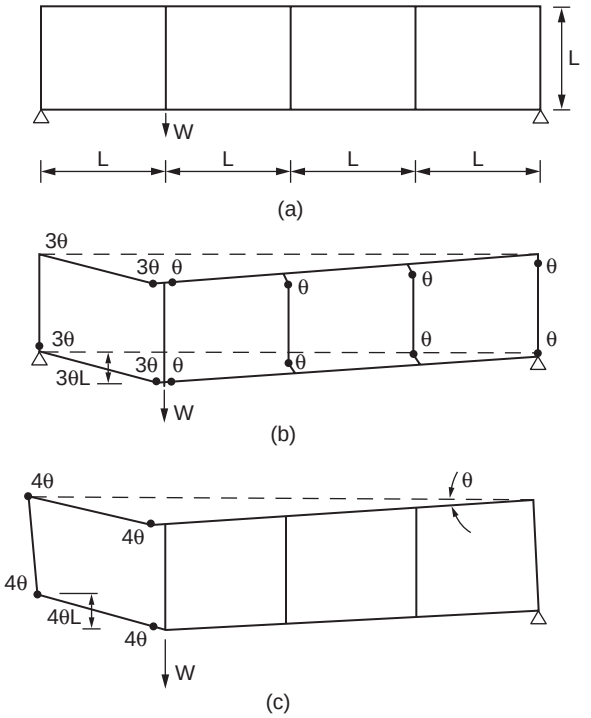

FIGURE 47.111 Collapse mechanism of a Vierendeel girder.

Hinge-by-Hinge Analysis

Instead of finding the collapse load of the frame, it may be useful to obtain information about the distribution and redistribution of forces prior to reaching the collapse load. Elastic-plastic hinge analysis (also known as hinge-by-hinge analysis) determines the order of plastic hinge formation, the load factor associated with each plastic hinge formation, and member forces in the frame between each hinge formation. Thus the state of the frame can be defined at any load factor rather than only at the state of collapse. This allows a more accurate determination of member forces at the design load level.

Educational and commercial software are now available for elastic-plastic hinge analysis (Chen and Sohal, 1995). The computations of deflections for simple beams and multistory frames can be done using the virtual work method (Chen and Sohal, 1995; ASCE, 1971; Beedle, 1958; Knudsen et al., 1953). The basic assumption of first-order elastic-plastic hinge analysis is that the deformations of the structure are insufficient to alter radically the equilibrium equations. This assumption ceases to be true for slender members and structures, and the method gives unsafe predictions of limit loads.

47.12 Stability of Structures

Stability Analysis Methods

Several stability analysis methods have been utilized in research and practice. Figure 47.112 shows schematic representations of the load-displacement results of a sway frame obtained from each type of analysis to be considered.

Elastic Buckling Analysis

The elastic buckling load is calculated by linear buckling or bifurcation (or eigenvalue) analysis. The buckling loads are obtained from the solutions of idealized elastic frames subjected to loads that do not

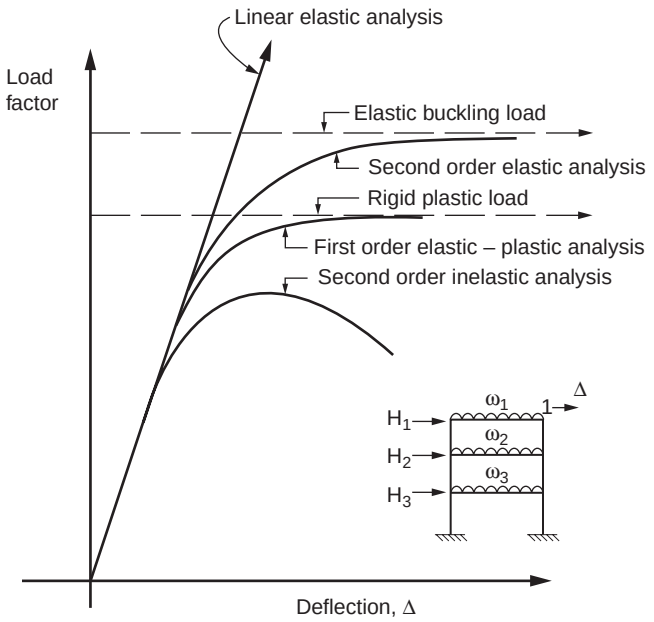

FIGURE 47.112 Catagorization of stability analysis methods.

produce direct bending in the structure. The only displacements that occur before buckling occurs are those in the directions of the applied loads. When buckling (bifurcation) occurs, the displacements increase without bound, assuming linearized theory of elasticity and small displacement, as shown by the horizontal straight line in Fig. 47.112. The load at which these displacements occur is known as the buckling load, commonly referred to as the bifurcation load. For structural models that actually exhibit a bifurcation from the primary load path, the elastic buckling load is the largest load that the model can sustain, at least within the vicinity of the bifurcation point, provided that the postbuckling path is in unstable equilibrium. If the secondary path is in stable equilibrium, the load can still increase beyond the critical load value.

Buckling analysis is a common tool for calculations of column effective lengths. The effective length factor of a column member can be calculated using the procedure described later. The buckling analysis provides useful indices of the stability behavior of structures; however, it does not predict actual behavior of all structures, but of idealized structures with gravity loads applied only at the joints.

Second-Order Elastic Analysis

The analysis is formulated based on the deformed configuration of the structure. When derived rigorously, a second-order analysis can include both the member curvature (P-δ) and the side sway (P-Δ) stability effects. The P-δ effect is associated with the influence of the axial force acting through the member displacement with respect to the rotated chord, whereas the P-Δ effect is the influence of the axial force acting through the relative side sway displacements of the member ends. A structural system will become stiffer when its members are subjected to tension. Conversely, the structure will become softer when its members are in compression. Such behavior can be illustrated by a simple model shown in Fig. 47.113. There is a clear advantage for a designer to take advantage of the stiffer behavior of tension structures. However, the detrimental effects associated with second-order deformations due to compression forces must be considered in designing structures subjected to predominant gravity loads.

Unlike the first-order analysis, in which solutions can be obtained in a rather simple and direct manner, the second-order analysis often requires an iterative procedure to obtain solutions. The load-displacement curve generated from a second-order elastic analysis will gradually approach the horizontal straight line, which represents the buckling load obtained from the elastic buckling analysis, as shown in Fig. 47.112.

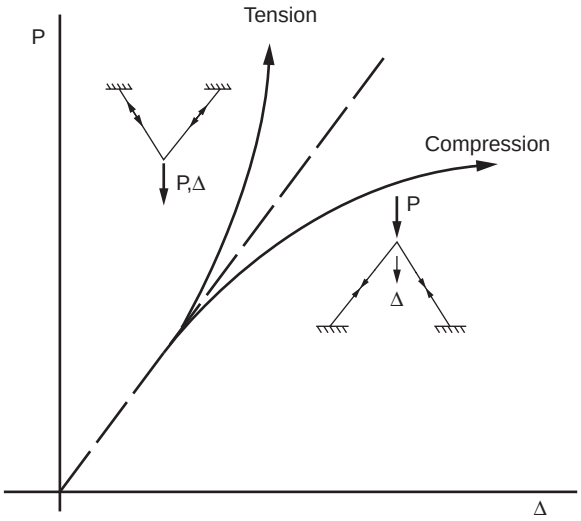

FIGURE 47.113 Behavior of frame in compression and tension.

Differences in the two limit loads may arise from the fact that the elastic stability limit is calculated for equilibrium based on the deformed configuration, whereas the elastic critical load is calculated as a bifurcation from equilibrium on the undeformed geometry of the frame.

The load-displacement response of many practical structures usually does not involve any bifurcation of the equilibrium path. In some cases, the second-order elastic incremental response may not have yielded any limit. See Chen and Lui (1987) for a basic discussion of these behavioral issues.

Recent works on second-order elastic analysis have been reported in Liew et al. (1991), White and Hajjar (1991), Chen and Lui (1991), and Chen and Toma (1994), among others. Second-order analysis programs that can take into consideration connection flexibility are also available (Chen et al., 1996; Chen and Kim, 1997; Faella et al., 2000).

Second-Order Inelastic Analysis

Second-order inelastic analysis refers to methods of analysis that can capture geometrical and material nonlinearities of the structures. The most rigorous inelastic analysis method is called spread-of-plasticity analysis. It involves discretization of a member into many line segments and the cross-section of each segment into a number of finite elements. Inelasticity is captured within the cross-sections and along the member length. The calculation of forces and deformations in the structure after yielding requires iterative trial-and-error processes because of the nonlinearity of the load–deformation response and the change in the cross section effective stiffness at inelastic regions associated with the increase in the applied loads and the change in structural geometry. Although most spread-of-plasticity analysis methods have been developed for planar analysis (White, 1985; Vogel, 1985), three-dimensional spread-of-plasticity techniques are also available involving various degrees of refinements (Clark, 1994; White, 1988; Wang, 1988; Chen and Atsuta, 1977; Jiang et al, 2002).

The simplest second-order inelastic analysis is the *elastic-plastic hinge* approach. The analysis assumes that the element remains elastic except at its ends, where zero-length plastic hinges are allowed to form. Plastic hinge analysis of planar frames can be found in Orbison (1982), Ziemian et al. (1992a, 1992b), White et al. (1993), Liew et al. (1993), Chen and Toma (1994), Chen and Sohal (1995), and Chen et al. (1996). Advanced analyses of three-dimensional frames are reported in Chen et al. (2000) and Liew et al. (2000). Second-order plastic hinge analysis allows efficient analysis of large-scale building frames. This is particularly true for structures in which the axial forces in the component members are small and the behavior is predominated by bending actions. Although elastic-plastic hinge approaches can provide essentially the same load-displacement predictions as second-order plastic-zone methods for many frame

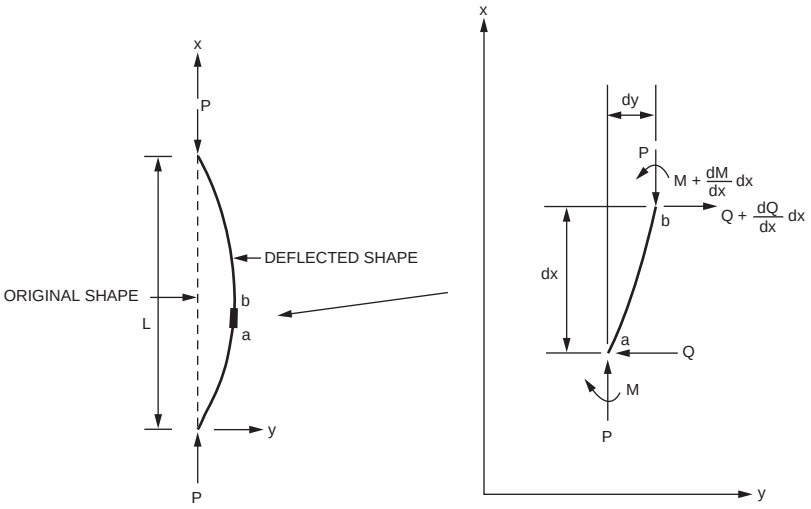

FIGURE 47.114 Stability equations of a column segment.

problems, they cannot be classified as advanced analysis for use in frame design. Some modifications to the elastic-plastic hinge are required to qualify the methods as advanced analysis; they are discussed later.

Figure 47.112 shows the load-displacement curve (a smooth curve with a descending branch) obtained from the second-order inelastic analysis. The computed limit load should be close to that obtained from the plastic-zone analysis.

Column Stability

Stability Equations

The stability equation of a column can be obtained by considering an infinitesimal deformed segment of the column, as shown in Fig. 47.114. Considering the moment equilibrium about point b, we obtain

$$Q\,dx + P\,dy + M - \left(M + \frac{dM}{dx}dx\right) = 0$$

or, upon simplification,

$$Q = \frac{dM}{dx} - P\frac{dy}{dx} \tag{47.239}$$

Summing the force horizontally, we can write

$$-Q + \left(Q + \frac{dQ}{dx}dx\right) = 0$$

or, upon simplification,

$$\frac{dQ}{dx} = 0 \tag{47.240}$$

Differentiating Eq. (47.239) with respect to x, we obtain

$$\frac{dQ}{dx} = \frac{d^2M}{dx^2} - P\frac{d^2y}{dx^2} \tag{47.241}$$

which, when compared with Eq. (47.240), gives

$$\frac{d^2M}{dx^2} - P\frac{d^2y}{dx^2} = 0 \tag{47.242}$$

Since moment $M = -EI(d^2y/dx^4)$, Eq. (47.242) can be written as

$$EI\frac{d^4y}{dx^4} + P\frac{d^2y}{dx^2} = 0 \tag{47.243}$$

or

$$y^{IV} + k^2y'' = 0 \tag{47.244}$$

Equation (47.244) is the general fourth-order differential equation that is valid for all support conditions. The general solution to this equation is

$$y = A\sin kx + B\cos kx + Cx + D \tag{47.245}$$

To determine the critical load, it is necessary to have four boundary conditions: two at each end of the column. In some cases, both geometric and force boundary conditions are required to eliminate the unknown coefficients (A, B, C, and D) in Eq. (47.245).

Column with Pinned Ends

For a column pinned at both ends, as shown in Fig. 47.115a, the four boundary conditions are:

$$y(x = 0) = 0, \quad M(x = 0) = 0 \tag{47.246}$$

$$y(x = L) = 0, \quad M(x = L) = 0 \tag{47.247}$$

Since $M = -EIy''$, the moment conditions can be written as

$$y''(0) = 0 \text{ and } y''(x = L) = 0 \tag{47.248}$$

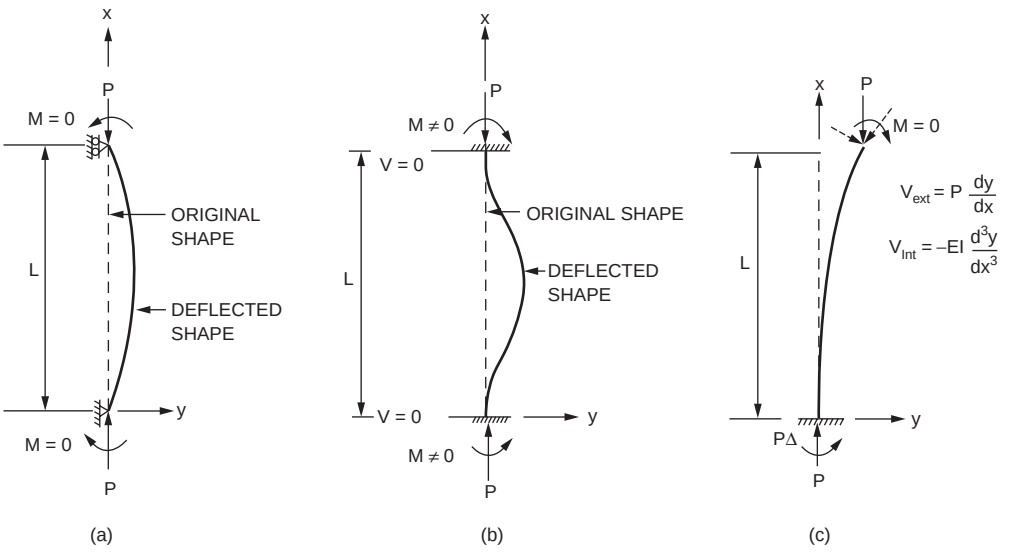

FIGURE 47.115 Column with: (a) pinned ends, (b) fixed ends, (c) fixed–free ends.

Using these conditions, we have

$$B = D = 0 \tag{47.249}$$

The deflection function (Eq. 47.245) reduces to

$$y = A\sin kx + Cx \tag{47.250}$$

Using the conditions $y(L) = y''(L) = 0$, Eq. (47.250) gives

$$A\sin kL + CL = 0 \tag{47.251}$$

and

$$-Ak^2 \sin kL = 0 \tag{47.252}$$

$$\begin{bmatrix} \sin kL & L \\ -k^2 \sin kL & 0 \end{bmatrix} \begin{bmatrix} A \\ C \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \end{bmatrix} \tag{47.253}$$

If A = C = 0, the solution is trivial. Therefore, to obtain a nontrivial solution, the determinant of the coefficient matrix of Eq. (47.253) must be zero, i.e.,

$$\det \begin{vmatrix} \sin kL & L \\ -k^2 \sin kL & 0 \end{vmatrix} = 0 \tag{47.254}$$

or

$$k^2 L \sin kL = 0 \tag{47.255}$$

Since k^2L cannot be zero, we must have

$$\sin kL = 0 \tag{47.256}$$

or

$$kL = n\pi, \; n = 1, \; 2, \; 3, \; \ldots \tag{47.257}$$

The lowest buckling load corresponds to the first mode obtained by setting n = 1:

$$P_{cr} = \frac{\pi^2 EI}{L^2} \tag{47.258}$$

Column with Fixed Ends

The four boundary conditions for a fixed-end column are (Fig. 47.115b):

$$y(x = 0) = y'(x = 0) = 0 \tag{47.259}$$

$$y(x = L) = y'''(x = L) = 0 \tag{47.260}$$

Using the first two boundary conditions, we obtain

$$D = -B, \quad C = -Ak \tag{47.261}$$

The deflection function (Eq. 47.245) becomes

$$y = A(\sin kx - kx) + B(\cos kx - 1) \tag{47.262}$$

Using the last two boundary conditions, we have

$$\begin{bmatrix} \sin kL - kL & \cos kL - 1 \\ \cos kL - 1 & -\sin kL \end{bmatrix} \begin{bmatrix} A \\ B \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \end{bmatrix} \tag{47.263}$$

For a nontrivial solution, we must have

$$\det \begin{bmatrix} \sin kL - kL & \cos kL - 1 \\ \cos kL - 1 & -\sin kL \end{bmatrix} = 0 \tag{47.264}$$

or, after expanding,

$$kL \sin kL + 2\cos kL - 2 = 0 \tag{47.265}$$

Using trigonometric identities $\sin kL = 2 \sin (kL/2) \cos (kL/2)$ and $\cos kL = 1 - 2 \sin^2 (kL/2)$, Eq. (47.265) can be written as

$$\sin \frac{kL}{2} \left(\frac{kL}{2} \cos \frac{kL}{2} - \sin \frac{kL}{2} \right) = 0 \tag{47.266}$$

The critical load for the symmetric buckling mode is $P_{cr} = 4\pi^2 EI/L^2$ by letting $\sin (kL/2) = 0$. The buckling load for the antisymmetric buckling mode is $P_{cr} = 80.8EI/L^2$ by letting the bracket term in Eq. (47.266) equal zero.

Column with One End Fixed and One End Free

The boundary conditions for a fixed–free column are (Fig. 47.115c):

$$y(x = 0) = y'(x = 0) = 0 \tag{47.267}$$

at the fixed end and

$$y''(x = L) = 0 \tag{47.268}$$

and at the free end. The moment $M = EIy''$ is equal to zero, and the shear force $V = -dM/dx = -EI'''$ is equal to Py', which is the transverse component of P acting at the free end of the column:

$$V = -EIy''' = Py' \tag{47.269}$$

It follows that the shear force condition at the free end has the form

$$y''' + k^2 y' = 0 \tag{47.270}$$

Using the boundary conditions at the fixed end, we have

$$B + D = 0, \text{ and } Ak + C = 0 \tag{47.271}$$

The boundary conditions at the free end give

$$A \sin kL + B \cos kL = 0, \text{ and } C = 0 \tag{47.272}$$

In matrix form, Eqs. (47.271) and (47.272) can be written as

$$\begin{bmatrix} 0 & 1 & 1 \\ k & 0 & 0 \\ \sin kL & \cos kL & 0 \end{bmatrix} \begin{bmatrix} A \\ B \\ C \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ 0 \end{bmatrix} \tag{47.273}$$

For a nontrivial solution, we must have

$$\det\begin{vmatrix} 0 & 1 & 1 \\ k & 0 & 0 \\ \sin kL & \cos kL & 0 \end{vmatrix} = 0 \tag{47.274}$$

The characteristic equation becomes

$$k \cos kL = 0 \tag{47.275}$$

Since k cannot be zero, we must have cos kL = 0 or

$$kL = \frac{n\pi}{2} \quad n = 1,3,5,... \tag{47.276}$$

The smallest root (n = 1) gives the lowest critical load of the column

$$P_{cr} = \frac{\pi^2 EI}{4L^2} \tag{47.277}$$

The boundary conditions for columns with various end conditions are summarized in Table 47.1.

TABLE 47.1 Boundary Conditions for Various End Conditions

End Conditions	Boundary Conditions
Pinned	$y = 0, \quad y'' = 0$
Fixed	$y = 0, \quad y'' = 0$
Guided	$y' = 0 \quad y''' = 0$
Free	$y'' = 0, \quad y''' + k^2 y' = 0$

Column Effective Length Factor

The effective length factor, K, of columns with different end boundary conditions can be obtained by equating the P_{cr} load obtained from the buckling analysis with the Euler load of a pinned-end column of effective length KL:

$$P_{cr} = \frac{\pi^2 EI}{(KL)^2}$$

The effective length factor can be obtained as

$$K = \sqrt{\frac{\pi^2 EI/L^2}{P_{cr}}} \tag{47.278}$$

The K factor is a factor that can be multiplied to the actual length of the end-restrained column to give the length of an equivalent pinned-end column whose buckling load is the same as that of the end-restrained column. Table 47.1 (AISC, 1993) summarizes the theoretical K factors for columns with different boundary conditions. Also shown in the table are the recommended K factors for design applications. The recommended values for design are equal to or higher than the theoretical values to account for semirigid effects of the connections used in practice.

Stability of Beam-Columns

Figure 47.116a shows a beam-column subjected to an axial compressive force P at the ends, a lateral load w along the entire length, and end moments M_A and M_B. The stability equation can be derived by considering the equilibrium of an infinitesimal element of length ds, as shown in Fig. 47.116b. The cross section forces S and H act in the vertical and horizontal directions.

TABLE 47.2 Comparison of Theoretical and Design K Factors

	(a)	(b)	(c)	(d)	(e)	(f)
Buckled shape of column is shown by dashed line						
Theoretical K value	0.5	0.7	1.0	1.0	2.0	2.0
Recommended design value when ideal conditions are approximated	0.65	0.80	1.2	1.0	2.10	2.0
End condition code		Rotation fixed and translation fixed Rotation free and translation fixed Rotation fixed and translation free Rotation free and translation free				

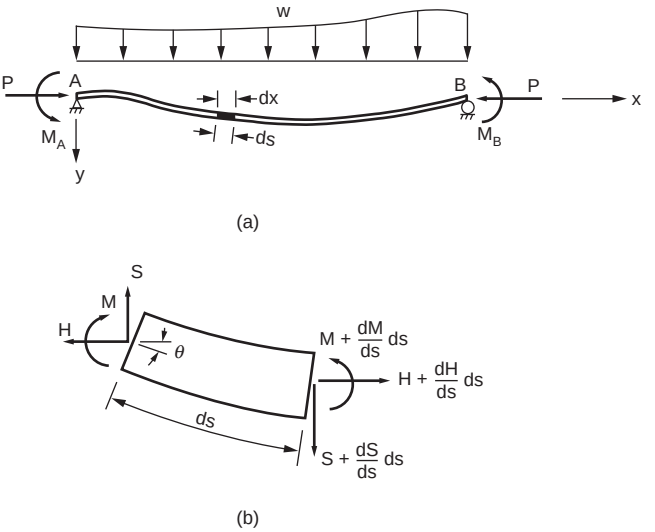

FIGURE 47.116 Basic differential equation of a beam-column.

Considering the equilibrium of forces,

Horizontal equilibrium:

$$H + \frac{dH}{ds} ds - H = 0 \tag{47.279}$$

Vertical equilibrium:

$$S + \frac{dS}{ds} ds - S + w\,ds = 0 \tag{47.280}$$

Moment equilibrium:

$$M + \frac{dM}{ds}ds - M - \left(S + \frac{dS}{ds} + S\right)\cos\theta\left(\frac{ds}{2}\right) + \left(H + \frac{dH}{ds}ds + H\right)\sin\theta\left(\frac{ds}{2}\right) = 0 \tag{47.281}$$

Since (dS/ds)ds and (dH/ds)ds are negligibly small compared to S and H, the above equilibrium equations can be reduced to

$$\frac{dH}{ds} = 0 \tag{47.282a}$$

$$\frac{dS}{ds} + w = 0 \tag{47.282b}$$

$$\frac{dM}{ds} - S\cos\theta + H\sin\theta = 0 \tag{47.282c}$$

For small deflections and neglecting shear deformations,

$$ds \cong dx, \quad \cos\theta \cong 1 \quad \sin\theta \cong \theta \cong \frac{dy}{dx} \tag{47.283}$$

where y is the lateral displacement of the member. Using the above approximations, Eq. (47.282) can be written as

$$\frac{dM}{dx} - S + H\frac{dy}{dx} = 0 \tag{47.284}$$

Differentiating Eq. (47.284) and substituting Eq. (47.283a and b) into the resulting equation, we have

$$\frac{d^2M}{dx^2} + w + H\frac{d^2y}{dx^2} = 0 \tag{47.285}$$

From elementary mechanics of materials, it can easily be shown that

$$M = -EI\frac{d^2y}{dx^2} \tag{47.286}$$

Upon substitution of Eq. (47.286) into Eq. (47.285) and realizing that H = –P, we obtain

$$EI\frac{d^4y}{dx^4} + P\frac{d^2y}{dx^2} = w \tag{47.287}$$

The general solution to this differential equation has the form

$$y = A\ \sin kx + B\ \cos kx + Cx + D + f(x) \tag{47.288}$$

where $k = \sqrt{P/EI}$ and f(x) is a particular solution satisfying the differential equation. The constants A, B, C, and D can be determined from the boundary conditions of the beam-column under investigation.

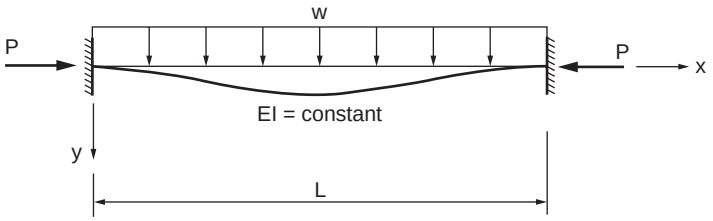

FIGURE 47.117 Beam-column subjects to uniform loading.

Beam-Column Subjected to Transverse Loading

Figure 47.117 shows a fixed-end beam-column with a uniformly distributed load w.

The general solution to Eq. (47.287) is

$$y = A \sin kx + B \cos x + Cx + D + \frac{w}{2EIk^2} x^2 \tag{47.289}$$

Using the boundary conditions

$$y_{x=0} = 0 \qquad y'_{x=0} = 0 \qquad y_{x=L} = 0 \qquad y'_{x=L} = 0 \tag{47.290}$$

in which a prime denotes differentiation with respect to x, it can be shown that

$$A = \frac{wL}{2EIk^3} \tag{47.291a}$$

$$B = \frac{wL}{2EIk^3 \tan(kL/2)} \tag{47.291b}$$

$$C = -\frac{wL}{2EIk^2} \tag{47.291c}$$

$$D = -\frac{wL}{2EIk^3 \tan(kL/2)} \tag{47.291d}$$

Upon substitution of these constants into Eq. (47.289), the deflection function can be written as

$$y = \frac{wL}{2EIk^3}\left[\sin kx + \frac{\cos kx}{\tan(kL/2)} - kx - \frac{1}{\tan(kL/2)} + \frac{kx^2}{L}\right] \tag{47.292}$$

The maximum moment for this beam-column occurs at the fixed ends and is equal to

$$M_{max} = -EIy''\big|_{x=0} = -EIy''\big|_{x=L} = -\frac{wL^2}{12}\left[\frac{3(\tan u - u)}{u^2 \tan u}\right] \tag{47.293}$$

where u = kL/2.

Since $wL^2/12$ is the maximum first-order moment at the fixed ends, the term in the bracket represents the theoretical moment amplification factor due to the P-δ effect.

TABLE 47.3 Theoretical and Design Moment Amplification Factor ($u = kL/2 = 1/2\sqrt{(PL^2/EI)}$)

Boundary Conditions	P_{cr}	Location of M_{max}	Moment Amplification Factor
Hinged-hinged	$\frac{\pi^2 EI}{L^2}$	Midspan	$\frac{2(\sec u - 1)}{u^2}$
Hinged-fixed	$\frac{\pi^2 EI}{(0.7L)^2}$	End	$\frac{2(\tan u - u)}{u^2(1/2u - 1/\tan 2u)}$
Fixed-fixed	$\frac{\pi^2 EI}{(0.5L)^2}$	End	$\frac{3(\tan u - u)}{u^2 \tan u}$
Hinged-hinged	$\frac{\pi^2 EI}{L^2}$	Midspan	$\frac{\tan u}{u}$
Hinged-fixed	$\frac{\pi^2 EI}{(0.7L)^2}$	End	$\frac{4u(1-\cos u)}{3u^2 \cos u(1/2u - 1/\tan 2u)}$
Fixed-fixed	$\frac{\pi^2 EI}{(0.5L)^2}$	Midspan and end	$\frac{2(1-\cos u)}{u \sin u}$

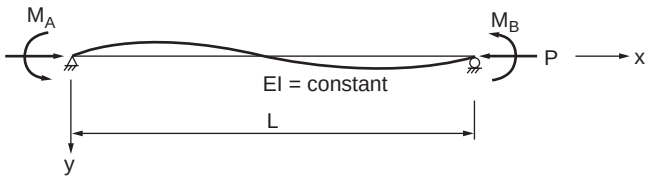

FIGURE 47.118 Beam-column subjects to end moments.

For beam-columns with other transverse loading and boundary conditions, a similar approach can be followed to determine the moment amplification factor. Table 47.3 summarizes the expressions for the theoretical and design moment amplification factors for some loading conditions (AISC, 1989).

Beam-Column Subjected to End Moments

Consider the beam-column shown in Fig. 47.118. The member is subjected to an axial force of P and end moments M_A and M_B. The differential equation for this beam-column can be obtained from Eq. (47.287) by setting w = 0:

$$EI\frac{d^4y}{dx^4} + P\frac{d^2y}{dx^2} = 0 \tag{47.294}$$

The general solution is

$$y = A\sin kx + B\cos kx + Cx + D \tag{47.295}$$

The constants A, B, C, and D are determined by enforcing the four boundary conditions:

$$y_{x=0} = 0, \quad y''_{x=0} = \frac{M_A}{EI} \quad y_{x=L} = 0 \quad y''_{x=L} = \frac{-M_B}{EI} \tag{47.296}$$

to give

$$A = \frac{M_A \cos kL + M_B}{EIk^2 \sin kL} \tag{47.297a}$$

$$B = -\frac{M_A}{EIk^2} \tag{47.297b}$$

$$C = -\left(\frac{M_A + M_B}{EIk^2 L}\right) \tag{47.297c}$$

$$D = \frac{M_A}{EIk^2} \tag{47.297d}$$

Substituting Eq. (47.297a to d) into the deflection function Eq. (47.295) and rearranging gives

$$y = \frac{1}{EIk}\left[\frac{\cos kL}{\sin kL}\sin kx - \cos kx - \frac{x}{L} + 1\right]M_A + \frac{1}{EIk^2}\left[\frac{1}{\sin kL}\sin kx - \frac{x}{L}\right]M_B \tag{47.298}$$

The maximum moment can be obtained by first locating its position by setting $dM/dx = 0$ and substituting the result into $M = -EIy''$ to give

$$M_{max} = \frac{\sqrt{\left(M_A^2 + 2M_A M_B \cos kL + M_B^2\right)}}{\sin kL} \tag{47.299}$$

Assuming that M_B is the larger of the two end moments, Eq. (47.299) can be expressed as

$$M_{max} = M_B\left[\frac{\sqrt{\left\{\left(M_A/M_B\right)^2 + 2\left(M_A/M_B\right)\cos kL + 1\right\}}}{\sin kL}\right] \tag{47.300}$$

Since M_B is the maximum first-order moment, the expression in brackets is therefore the theoretical moment amplification factor. In Eq. (47.300), the ratio (M_A/M_B) is positive if the member is bent in double (or reverse) curvature, and the ratio is negative if the member is bent in single curvature. A special case arises when the end moments are equal and opposite (i.e., $M_B = -M_A$). By setting $M_B = -M_A = M_0$ in Eq. (47.300), we have

$$M_{max} = M_0\left[\frac{\sqrt{\left\{2\left(1 - \cos kL\right)\right\}}}{\sin kL}\right] \tag{47.301}$$

For this special case, the maximum moment always occurs at midspan.

Slope Deflection Equations

The slope deflection equations of a beam-column can be derived by considering the beam-column shown in Fig. 47.118. The deflection function for this beam-column can be obtained from Eq. (47.298) in terms of M_A and M_B as:

$$y = \frac{1}{EIk^2}\left[\frac{\cos kL}{\sin kL}\sin kx - \cos kx - \frac{x}{L} + 1\right]M_A + \frac{1}{EIk^2}\left[\frac{1}{\sin kL}\sin kx - \frac{x}{L}\right]M_B \tag{47.302}$$

from which

$$y' = \frac{1}{EIk}\left[\frac{\cos kL}{\sin kL}\cos kx + \sin kx - \frac{1}{kL}\right]M_A + \frac{1}{EIk}\left[\frac{\cos kx}{\sin kL} - \frac{1}{kL}\right]M_B \tag{47.303}$$

The end rotations θ_A and θ_B can be obtained from Eq. (47.303) as

$$\begin{aligned}\theta_A = y'(x=0) &= \frac{1}{EIk}\left[\frac{\cos kL}{\sin kL} - \frac{1}{kL}\right]M_A + \frac{1}{EIk}\left[\frac{1}{\sin kL} - \frac{1}{kL}\right]M_B \\ &= \frac{L}{EI}\left[\frac{kL\cos kL - \sin kL}{(kL)^2 \sin kL}\right]M_A + \frac{L}{EI}\left[\frac{kL - \sin kL}{(kL)^2 \sin kL}\right]M_B\end{aligned} \tag{47.304}$$

and

$$\begin{aligned}\theta_B = y'(x=L) &= \frac{1}{EIk}\left[\frac{1}{\sin kL} - \frac{1}{kL}\right]M_A + \frac{1}{EIk}\left[\frac{\cos kL}{\sin kL} - \frac{1}{kL}\right]M_B \\ &= \frac{L}{EI}\left[\frac{kL - \sin kL}{(kL)^2 \sin kL}\right]M_A + \frac{L}{EI}\left[\frac{KL\cos kL - \sin kL}{(kL)^2 \sin kL}\right]M_B\end{aligned} \tag{47.305}$$

The moment rotation relationship can be obtained from Eqs. (47.304) and (47.305) by arranging M_A and M_B in terms of θ_A and θ_B as:

$$M_A = \frac{EI}{L}\left(s_{ii}\theta_A + s_{ij}\theta_B\right) \tag{47.306}$$

$$M_B = \frac{EI}{L}\left(s_{ji}\theta_A + s_{jj}\theta_B\right) \tag{47.307}$$

where

$$s_{ii} = s_{jj} = \frac{kL\sin kL - (kL)^2\cos kL}{2 - 2\cos kL - kL\sin kL} \tag{47.308}$$

$$s_{ij} = s_{ji} = \frac{(kL)^2 - kL\sin kL}{2 - 2\cos kL - kL\sin kL} \tag{47.309}$$

are referred to as the *stability functions*.

Equations (47.306) and (47.307) are the slope deflection equations for a beam-column that is not subjected to transverse loading and relative joint translation. It should be noted that when P approaches zero, $kL = \sqrt{(P/EI)}L$ approaches zero, and by using the L'Hospital's rule, it can be shown that $s_{ij} = 4$ and $s_{ij} = 2$. Values for s_{ii} and s_{ij} for various values of kL are plotted as shown in Fig. 47.119.

Equations (47.307) and (47.308) are valid if the following conditions are satisfied:

1. The beam is prismatic.
2. There is no relative joint displacement between the two ends of the member.
3. The member is continuous, i.e., there is no internal hinge or discontinuity in the member.
4. There is no in-span transverse loading on the member.
5. The axial force in the member is compressive.

If these conditions are not satisfied, some modifications to the slope deflection equations are necessary.

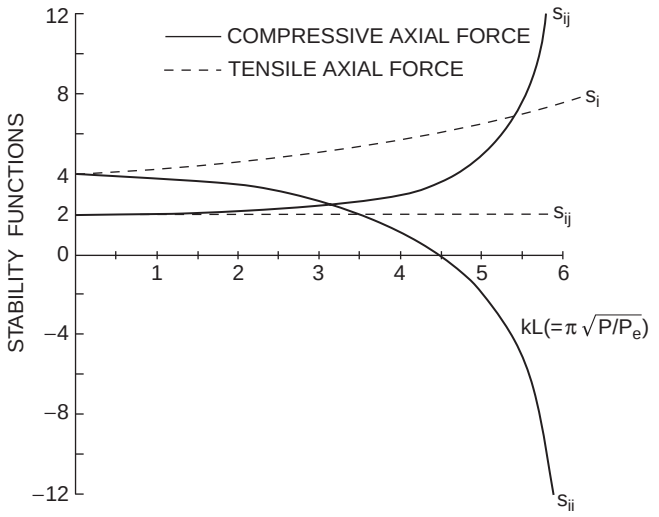

FIGURE 47.119 Plot of stability functions.

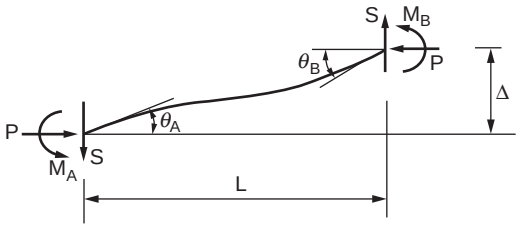

FIGURE 47.120 Beam-column subjects to end moments and side sway.

Member Subjected to Side Sway

If there is a relative joint translation, Δ, between the member ends, as shown in Fig. 47.120, the slope deflection equations are modified as

$$M_A = \frac{EI}{L}\left[s_{ii}\left(\theta_A - \frac{\Delta}{L}\right) + s_{ij}\left(\theta_B - \frac{\Delta}{L}\right)\right] = \frac{EI}{L}\left[s_{ii}\theta_A + s_{ij}\theta_B - (s_{ii} + s_{ij})\frac{\Delta}{L}\right] \tag{47.310}$$

$$M_B = \frac{EI}{L}\left[s_{ij}\left(\theta_A - \frac{\Delta}{L}\right) + s_{ii}\left(\theta_B - \frac{\Delta}{L}\right)\right] = \frac{EI}{L}\left[s_{ij}\theta_A + s_{ii}\theta_B - \left(s_{ii} + s_{ij}\right)\frac{\Delta}{L}\right] \tag{47.311}$$

Member with a Hinge at One End

If a hinge is present at the B end of the member, the end moment there is zero, i.e.,

$$M_B = \frac{EI}{L}\left(s_{ij}\theta_A + s_{ii}\theta_B\right) = 0 \tag{47.312}$$

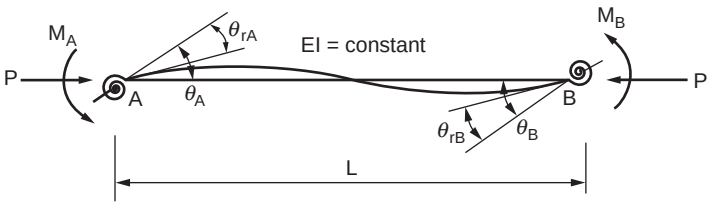

FIGURE 47.121 Beam column with end springs.

from which

$$\theta_B = -\frac{s_{ij}}{s_{ii}}\theta_A \tag{47.313}$$

Upon substituting Eq. (47.313) into Eq. (47.310), we have

$$M_A = \frac{EI}{L}\left(s_{ii} - \frac{s_{ij}^2}{s_{ii}}\right)\theta_A \tag{47.314}$$

If the member is hinged at the A end rather than at the B end, Eq. (47.314) is still valid, provided that the subscript A is changed to B.

Member with End Restraints

If the member ends are connected by two linear elastic springs, as in Fig. 47.121, with spring constants R_{kA} and R_{kB} at the A and B ends, respectively, the end rotations of the linear spring are M_A/R_{kA} and M_B/R_{kB}. If we denote the total end rotations at joints A and B by θ_A and θ_B, respectively, then the member end rotations, with respect to its chord, will be $\theta_A - M_A/R_{kA}$ and $\theta_B - M_B/R_{kB}$. As a result, the slope deflection equations are modified to

$$M_A = \frac{EI}{L}\left[s_{ii}\left(\theta_A - \frac{M_A}{R_{kA}}\right) + s_{ij}\left(\theta_B - \frac{M_B}{R_{kB}}\right)\right] \tag{47.315}$$

$$M_B = \frac{EI}{L}\left[s_{ij}\left(\theta_A - \frac{M_A}{R_{kA}}\right) + s_{jj}\left(\theta_B - \frac{M_B}{R_{kB}}\right)\right] \tag{47.316}$$

Solving Eqs. (47.315) and (47.316) simultaneously for M_A and M_B gives

$$M_A = \frac{EI}{LR^*}\left[\left(s_{ii} + \frac{EIs_{ii}^2}{LR_{kB}} - \frac{EIs_{ij}^2}{LR_{kB}}\right)\theta_A + s_{ij}\theta_B\right] \tag{47.317}$$

$$M_B = \frac{EI}{LR^*}\left[s_{ij}\theta_A + \left(s_{ii} + \frac{EIs_{ii}^2}{LR_{kA}} - \frac{EIs_{ij}^2}{LR_{kA}}\right)\theta_B\right] \tag{47.318}$$

where

$$R^* = \left(1 + \frac{EIs_{ii}}{LR_{kA}}\right)\left(1 + \frac{EIs_{ii}}{LR_{kB}}\right) - \left(\frac{EI}{L}\right)^2 \frac{s_{ij}^2}{R_{kA}R_{kB}} \tag{47.319}$$

In writing Eqs. (47.317) and (47.318), the equality $s_{jj} = s_{ii}$ has been used. Note that as R_{kA} and R_{kB} approach infinity, Eqs. (47.317) and (47.318) reduce to Eqs. (47.306) and (47.307), respectively.

Member with Transverse Loading

For members subjected to transverse loading, the slope deflection Eqs. (47.306) and (47.307) can be modified by adding an extra term for the fixed-end moment of the member.

$$M_A = \frac{EI}{L}\left(s_{ii}\theta_A + s_{ii}\theta_B\right) + M_{FA} \tag{47.320}$$

$$M_B = \frac{EI}{L}\left(s_{ij}\theta_A + s_{jj}\theta_B\right) + M_{FB} \tag{47.321}$$

Table 47.4 gives the expressions for the fixed-end moments of five commonly encountered cases of transverse loading. See Chen and Lui (1987, 1991) for more details.

Member with Tensile Axial Force

For members subjected to tensile force, Eqs. (47.306) and (47.307) can be used, provided that the stability functions are redefined as

$$s_{ii} = s_{jj} = \frac{(kL)^2 \cosh kL - kL \sinh kL}{2 - 2\cosh kL + kL \sinh kL} \tag{47.322}$$

$$s_{ij} = s_{ji} = \frac{kL \sinh kL - (kL)^2}{2 - 2\cosh kL + kL \sinh kL} \tag{47.323}$$

Member Bent in Single Curvature with $\theta_B = -\theta_A$

For the member bent in a single curvature in which $\theta_B = -\theta_A$, the slope deflection equations reduce to

$$M_A = \frac{EI}{L}\left(s_{ii} - s_{ij}\right)\theta_A \tag{47.324}$$

$$M_B = -M_A \tag{47.325}$$

Member Bent in Double Curvature with $\theta_B = \theta_A$

For the member bent in a double curvature such that $\theta_B = \theta_A$, the slope deflection equations become

$$M_A = \frac{EI}{L}\left(s_{ii} - s_{ij}\right)\theta_A \tag{47.326}$$

$$M_B = M_A \tag{47.327}$$

Second-Order Elastic Analysis

There are two methods to incorporate second-order effects, the stability function approach and the geometric stiffness (or finite element) approach. The stability function approach is based on the governing differential equations of the problem, as described above, whereas the stiffness approach is based on an assumed cubic polynomial variation of the transverse displacement along the element length. Therefore, the stability function approach is more exact in terms of representing the member stability behavior. However, the geometric stiffness approach is easier to implement for matrix analysis.

TABLE 47.4 Beam-Column Fixed-End Moments (Chen and Lui, 1991)

$$\left(u = kL/2 = \frac{L}{2}\sqrt{\frac{P}{EI}}\right)$$

Case	Fixed-End Moments
	$M_{FA} = \frac{QL}{8}\left[\frac{2(1-\cos u)}{u \sin u}\right]$ $M_{FB} = -M_{FA}$
	$M_{FA} = \frac{wL^2}{12}\left[\frac{3(\tan u - u)}{u^2 \tan u}\right]$ $M_{FB} = -M_{FA}$
	$M_{FA} = \frac{QL}{d}\left[\frac{2ub}{L}\cos 2u - 2u\cos\frac{2ub}{L} - \sin 2u + \sin\frac{2ua}{L} + \sin\frac{2ub}{L} + \frac{2ua}{L}\right]$ $M_{FB} = -\frac{QL}{d}\left[\frac{2ua}{L}\cos 2u - 2u\cos\frac{2ua}{L} - \sin 2u + \sin\frac{2ub}{L} + \sin\frac{2ua}{L} + \frac{2ub}{L}\right]$ where $d = 2u(2 - 2\cos 2u - 2u \sin 2u)$
	$M_{FA} = \frac{wL^2}{8u^2 e}\left[(2u\,\mathrm{cosec}\,2u - 1)\left(\frac{2ub}{L} - \sin\frac{2ub}{L}\right) + (\tan u)\left(1 - \cos\frac{2ub}{L} - \frac{2u^2b^2}{L^2}\right)\right]$ $M_{FB} = \frac{-wL^2}{8u^2 e}\left[(2u\cot 2u - 1)\left(\frac{2ub}{L} - \sin\frac{2ub}{L}\right) + (\tan u)\left(1 - \cos\frac{2ub}{L} + \frac{2u^2b^2}{L^2}\right) - 2u\left(1 - \cos\frac{2ub}{L}\right)\right]$ where $e = \tan u - u$
	$M_{FA} = \frac{M_o}{2e}\left[(2u\,\mathrm{cosec}\,2u - 1)\ \sin\frac{2ub}{L} - (\tan u)\left(1 - \cos\frac{2ub}{L}\right)\right]$ $M_{FB} = \frac{M}{2e}\left[(1 - 2u\cot 2u)\sin\frac{2ub}{L} - (\tan u)\left(1 + \cos\frac{2ub}{L}\right) + 2u\cos\frac{2ub}{L}\right]$ where $e = \tan u - u$

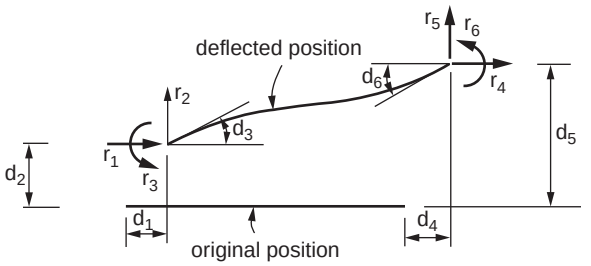

FIGURE 47.122 Nodal displacements and forces of a beam-column element.

For either of these approaches, the linearized element stiffness equations may be expressed in either incremental or total force and displacement forms as

$$[K]\{d\} + \{r_f\} = \{r\} \tag{47.328}$$

where [K] is the element stiffness matrix, $\{d\} = \{d_1, d_2, \ldots, d_6\}^T$ is the element nodal displacement vector, $\{r_f\} = \{r_{f1}, r_{f2}, \ldots, r_{f6}\}^T$ is the element fixed-end force vector due to the presence of in-span loading, and $\{r\} = \{r_1, r_2, \ldots, r_6\}^T$ is the nodal force vector, as shown in Fig. 47.122. If stability function approach is employed, the stiffness matrix of a two-dimensional beam-column element may be written as

$$[K] = \frac{EI}{L}\begin{bmatrix} \frac{A}{I} & 0 & 0 & -\frac{A}{I} & 0 & 0 \\ & \frac{2(S_{ii}+S_{ij})-(kL)^2}{L^2} & \frac{S_{ii}+S_{ij}}{L} & 0 & \frac{-2(S_{ii}+S_{ij})+(kL)^2}{L^2} & \frac{S_{ii}+S_{ij}}{L} \\ & & S_{ii} & 0 & \frac{-(S_{ii}+S_{ij})}{L} & S_{ij} \\ & & & \frac{A}{I} & 0 & 0 \\ & & & & \frac{2(S_{ii}+S_{ij})-(kL)^2}{L^2} & \frac{-(S_{ii}+S_{ij})}{L} \\ & & \text{sym.} & & & S_{ii} \end{bmatrix} \tag{47.329}$$

where S_{ii} and S_{ij} are the member stiffness coefficients obtained from the elastic beam-column stability functions (Chen and Lui, 1987). These coefficients may be expressed as

$$S_{ii} = \begin{cases} \dfrac{kL\sin(kL) - (kL)^2\cos(kL)}{2 - 2\cos(kL) - kL\sin(kL)} & \text{for } P < 0 \\ \dfrac{(kL)^2\cosh(kL) - kL\sinh(kL)}{2 - 2\cosh(kL) + kL\sinh(kL)} & \text{for } P > 0 \end{cases} \tag{47.330}$$

$$S_{ij} = \begin{cases} \dfrac{(kL)^2 - kL\sin(kL)}{2 - 2\cos(kL) - \rho\sin(kL)} & \text{for } P < 0 \\ \dfrac{kL\sinh(kL) - (kL)^2}{2 - 2\cosh(kL) + \rho\sinh(kL)} & \text{for } P > 0 \end{cases} \tag{47.331}$$

where $kL = L\sqrt{P/EI}$ and P is positive in compression and negative in tension.

The fixed-end force vector r_f is a 6×1 matrix that can be computed from the in-span loading in the beam-column. If curvature shortening is ignored, $r_{f1} = r_{f4} = 0$, $r_{f3} = M_{FA}$, and $r_{f6} = M_{FB}$. M_{FA} and M_{FB} can be obtained from Table 47.4 for different in-span loading conditions. r_{f2} and r_{f5} can be obtained from the equilibrium of forces.

If the axial force in the member is small, Eq. (47.329) can be simplified by ignoring the higher order terms of the power series expansion of the trigonometric functions. The resulting element stiffness matrix becomes:

$$[K] = \frac{EI}{L}\begin{bmatrix} \frac{A}{I} & 0 & 0 & -\frac{A}{I} & 0 & 0 \\ & \frac{12}{L^2} & \frac{6}{L} & 0 & \frac{-12}{L^2} & \frac{6}{L} \\ & & 4 & 0 & \frac{-6}{L} & 2 \\ & & & \frac{A}{I} & 0 & 0 \\ & & & & \frac{12}{L^2} & \frac{-6}{L} \\ & & \text{sym.} & & & 4 \end{bmatrix} + P\begin{bmatrix} 0 & 0 & 0 & 0 & 0 & 0 \\ & \frac{6}{5L} & \frac{1}{10} & 0 & \frac{-6}{5L} & \frac{1}{10} \\ & & \frac{2L}{15} & 0 & \frac{-1}{10} & \frac{-L}{30} \\ & & & 0 & 0 & 0 \\ & & & & \frac{6}{5L} & \frac{-1}{10} \\ & & \text{sym.} & & & \frac{2L}{15} \end{bmatrix} \quad (47.332)$$

The first term on the right is the first-order elastic stiffness matrix, and the second term is the geometric stiffness matrix, which accounts for the effect of axial force on the bending stiffness of the member. Detailed discussions on the limitation of the geometric stiffness approach versus the stability function approach are given in Liew et al. (2000).

Modifications to Account for Plastic Hinge Effects

There are two commonly used approaches for representing plastic hinge behavior in a second-order elastic-plastic hinge formulation (Chen et al., 1996). The most basic approach is to model the plastic hinge behavior as a "real" hinge for the purpose of calculating the element stiffness. The change in moment capacity due to the change in axial force can be accommodated directly in the numerical formulation. The change in moment is determined in the force recovery at each solution step such that, for continued plastic loading, the new force point is positioned at the strength surface at the current value of the axial force. A detailed description of these procedures is given by Chen and Lui (1991), Chen et al. (1996), and Lee and Basu (1989), among others.

Alternatively, the elastic-plastic hinge model may be formulated based on the "extending and contracting" plastic hinge model. The plastic hinge can rotate and extend or contract for plastic loading and axial force. The formulation can follow the force–space plasticity concept using the normality flow rule relative to the cross section surface strength (Chen and Han, 1988). Formal derivations of the beam-column element based on this approach have been presented by Porter and Powell (1971), Orbison et al. (1982), and Liew et al., (2000), among others.

Modification for End Connections

The moment rotation relationship of the beam-column with end connections at both ends can be expressed as (Eqs. (47.317) and (47.318)):

$$M_A = \frac{EI}{L}\left[s_{ii}^{*}\theta_A + s_{ij}^{*}\theta_B\right] \quad (47.333)$$

$$M_B = \frac{EI}{L}\left[s_{ij}^{*}\theta_A + s_{jj}^{*}\theta_B\right] \quad (47.334)$$

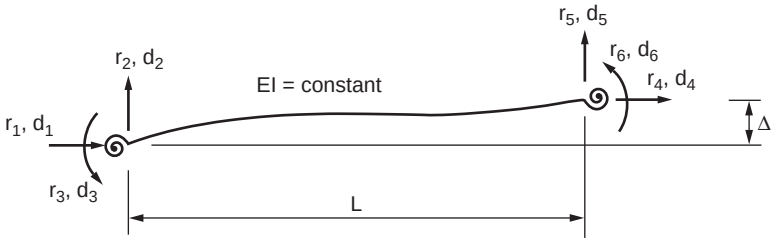

FIGURE 47.123 Nodal displacements and forces of a beam-column with end connections.

where

$$S_{ii}^{*} = \frac{S_{ii} + \frac{EIS_{ii}^{2}}{LR_{kB}} - \frac{EIS_{ij}^{2}}{LR_{kB}}}{\left[1 + \frac{EIS_{ii}}{LR_{kA}}\right]\left[1 + \frac{EIS_{jj}}{LR_{kB}}\right] - \left[\frac{EI}{L}\right]^{2}\frac{S_{ij}^{2}}{R_{kA}R_{kB}}} \tag{47.335}$$

$$S_{jj}^{*} = \frac{S_{ii} + \frac{EIS_{ii}^{2}}{LR_{kA}} - \frac{EIS_{ij}^{2}}{LR_{kA}}}{\left[1 + \frac{EIS_{ii}}{LR_{kA}}\right]\left[1 + \frac{EIS_{jj}}{LR_{kB}}\right] - \left[\frac{EI}{L}\right]^{2}\frac{S_{ij}^{2}}{R_{kA}R_{kB}}} \tag{47.336}$$

and

$$S_{ij}^{*} = \frac{S_{ij}}{\left[1 + \frac{EIS_{ii}}{LR_{kA}}\right]\left[1 + \frac{EIS_{jj}}{LR_{kB}}\right] - \left[\frac{EI}{L}\right]^{2}\frac{S_{ij}^{2}}{R_{kA}R_{kB}}} \tag{47.337}$$

The member stiffness relationship can be written in terms of six degrees of freedom — see the beam-column element shown in Fig. 47.123 — as

$$\begin{pmatrix} r_1 \\ r_2 \\ r_3 \\ r_4 \\ r_5 \\ r_6 \end{pmatrix} = \frac{EI}{L}\begin{bmatrix} \frac{A}{I} & 0 & 0 & -\frac{A}{I} & 0 & 0 \\ & \frac{S_{ii}^{*} + 2S_{ij}^{*} + S_{jj}^{*} - (kL)^{2}}{L^{2}} & \frac{S_{ii}^{*} + S_{ij}^{*}}{L} & 0 & \frac{-\left(S_{ii}^{*} + 2S_{ij}^{*} + S_{jj}^{*}\right) + (kL)^{2}}{L^{2}} & \frac{S_{ij}^{*} + S_{jj}^{*}}{L} \\ & & S_{ii}^{*} & 0 & \frac{-(S_{ii}^{*} + S_{ij}^{*})}{L} & S_{ij}^{*} \\ & & & \frac{A}{I} & 0 & 0 \\ & & & & \frac{S_{ii}^{*} + 2S_{ij}^{*} + S_{jj}^{*} - (kL)^{2}}{L^{2}} & \frac{-\left(S_{ij}^{*} + S_{jj}^{*}\right)}{L} \\ & & \text{sym.} & & & S_{jj}^{*} \end{bmatrix}\begin{pmatrix} d_1 \\ d_2 \\ d_3 \\ d_4 \\ d_5 \\ d_6 \end{pmatrix} \tag{47.338}$$

Second-Order Refined Plastic Hinge Analysis

The main limitation of the conventional elastic-plastic hinge approach is that it overpredicts the strength of columns that fail by inelastic flexural buckling. The key reason for this limitation is the modeling of

a member by a perfect elastic element between the plastic hinge locations. Furthermore, the elastic-plastic hinge model assumes that material behavior changes abruptly from the elastic state to the fully yielded state. The element under consideration exhibits a sudden stiffness reduction upon the formation of a plastic hinge. This approach, therefore, overestimates the stiffness of a member loaded into the inelastic range (Liew et al., 1993; White et al., 1991, 1993). This leads to further research and development of an alternative method called the *refined plastic hinge approach*. This approach is based on the following improvements to the elastic-plastic hinge model:

1. A column tangent modulus model E_t is used in place of the elastic modulus E to represent the distributed plasticity along the length of a member due to axial force effects. The member inelastic stiffness, represented by the member axial and bending rigidities E_tA and E_tI, is assumed to be the function of axial load only. In other words, E_tA and E_tI can be thought of as the properties of an effective core of the section, considering column action only. The tangent modulus captures the effect of early yielding in the cross-section due to residual stresses, which is believed to be the cause for the low strength of inelastic column buckling. The tangent modulus approach has been previously utilized by Orbison et al. (1982), Liew (1992), and White et al. (1993) to improve the accuracy of the elastic-plastic hinge approach for structures in which members are subjected to large axial forces.
2. Distributed plasticity effects associated with flexure are captured by gradually degrading the member stiffness at the plastic hinge locations as yielding progresses under an increasing load as the cross section strength is approached. Several models of this type have been proposed in recent literature based on extensions to the elastic-plastic hinge approach (Powell and Chen, 1986), as well as the tangent modulus inelastic hinge approach (Liew et al., 1993; White et al., 1993). The rationale of modeling stiffness degradation associated with both axial and flexural actions is that the tangent modulus model represents the column strength behavior in the limit of pure axial compression, and the plastic hinge stiffness degradation model represents the beam behavior in pure bending; thus the combined effects of these two approaches should also satisfy the cases in which the member is subjected to combined axial compression and bending.

It has been shown that with the above two improvements, the refined plastic hinge model can be used with sufficient accuracy to provide a quantitative assessment of a member's performance up to failure. Detailed descriptions of the method and discussion of the results generated by the method are given in White et al. (1993) and Chen et al. (1996). Significant work has been done to implement the refined plastic hinge methods for the design of three-dimensional real-size structures (Al-Bermani et al., 1995; Liew et al., 2000).

Second-Order Spread of Plasticity Analysis

Spread of plasticity analyses can be classified into two main types, namely three-dimensional shell element and two-dimensional beam-column approaches. In the three-dimensional spread of plasticity analysis, the structure is modeled using a large number of finite three-dimensional shell elements, and the elastic constitutive matrix, in the usual incremental stress–strain relations, is replaced by an elastic-plastic constitutive matrix once yielding is detected. This analysis approach typically requires numerical integration for the evaluation of the stiffness matrix. Based on a deformation theory of plasticity, the combined effects of normal and shear stresses may be accounted for. The three-dimensional spread-of-plasticity analysis is computational intensive and best suited for analyzing small-scale structures.

The second approach for plastic-zone analysis is based on use of the beam-column theory, in which the member is discretized into many beam-column segments, and the cross section of each segment is further subdivided into a number of fibers. Inelasticity is typically modeled by the consideration of normal stress only. When the computed stresses at the centroid of any fibers reach the uniaxial normal strength of the material, the fiber is considered yielded. Compatibility is treated by assuming that full continuity is retained throughout the volume of the structure in the same manner as for elastic range

calculations. Most of the plastic-zone analysis methods developed are meant for planar (two-dimensional) analysis (Chen and Toma, 1994; White, 1985; Vogel, 1985). Three-dimensional plastic-zone techniques are also available involving various degrees of refinements (White, 1988; Wang, 1988).

A plastic-zone analysis, which includes the spread of plasticity, residual stresses, initial geometric imperfections, and any other significant second-order behavioral effects, is often considered to be an exact analysis method. Therefore, when this type of analysis is employed, the checking of member interaction equations is not required. However, in reality, some significant behavioral effects, such as joint and connection performances, tend to defy precise numerical and analytical modeling. In such cases, a simpler method of analysis that adequately captures the inelastic behavior would be sufficient for engineering application. Second-order plastic hinge-based analysis is still the preferred method for advanced analysis of large-scale steel frames.

Three-Dimensional Frame Element

The two-dimensional beam-column formulation can be extended to a three-dimensional space frame element by including additional terms due to shear force, bending moment, and torsion. The following stiffness equation for a space frame element has been derived by Yang and Kuo (1994) by referring to Fig. 47.124:

$$\left[k_e\right]\{d\}+\left[k_g\right]\{d\}=\left\{{}^2f\right\}-\left\{{}^1f\right\} \tag{47.339}$$

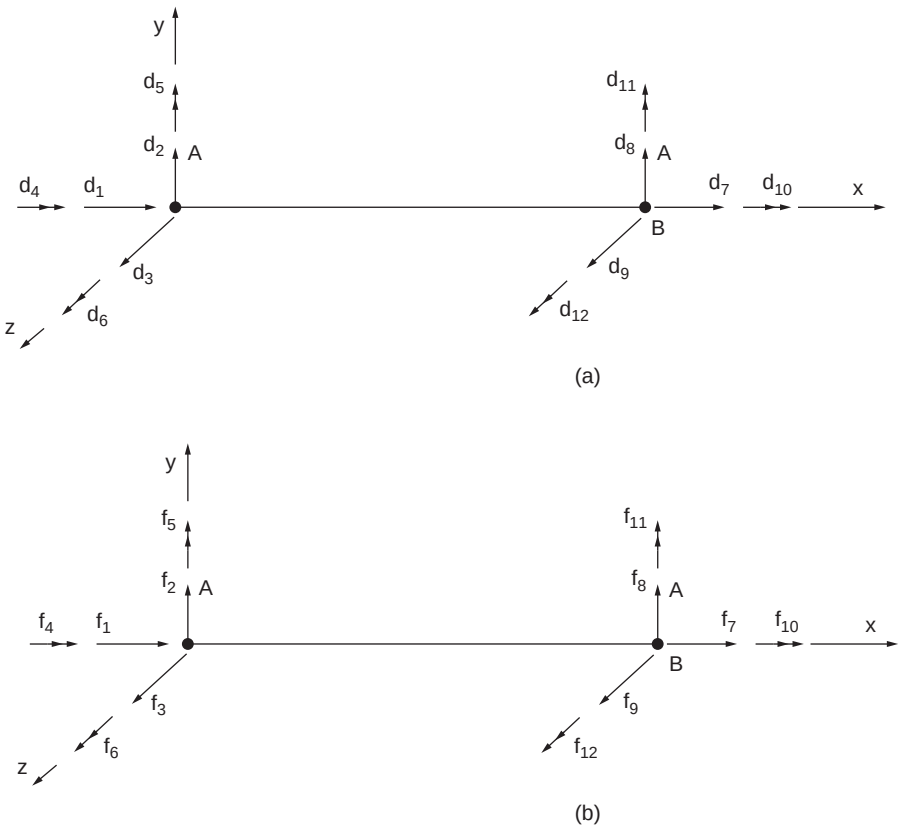

FIGURE 47.124 Three-dimensional frame element: (a) nodal degrees of freedom, (b) nodal forces.

where

$$\{d\}^T = \{d_1, d_2, \ldots, d_{12}\} \tag{47.340}$$

is the displacement vector, which consists of three translations and three rotations at each node, and

$$\{{}^i f\}^T = \{{}^i f_1, {}^i f_2, \ldots, {}^i f_{12}\} \quad i = 1, 2 \tag{47.341}$$

is the force vector, which consists of the corresponding nodal forces at configuration i = 1 or i = 2.

The physical interpretation of Eq. (47.339) is as follows: by increasing the nodal forces acting on the element from $\{^1f\}$ to $\{^2f\}$, further deformations $\{d\}$ may occur with the element, resulting in the motion of the element from a configuration associated with the forces $\{^1f\}$ to the new configuration associated with $\{^2f\}$. During this process of deformation, the increments in the nodal forces, i.e., $\{^2f\} - \{^1f\}$, will be resisted not only by the elastic actions generated by the elastic stiffness matrix $[k_e]$ but also by the forces induced by the change in geometry, as represented by the geometric stiffness matrix $[k_g]$.

The only assumption with the incremental stiffness equation is that the strains occurring with each incremental step should be small, so that the approximations implied by the incremental constitutive law are not violated.

The elastic stiffness matrix $[K_e]$ for the space frame element, which has a 12 x 12 dimension, can be derived as

$$[k] = \begin{bmatrix} [k_1] & [k_2] \\ [k_2]^T & [k_3] \end{bmatrix} \tag{47.342}$$

where the submatrices are

$$[k_1] = \begin{bmatrix} \frac{EA}{L} & 0 & 0 & 0 & 0 & 0 \\ 0 & \frac{12EI_z}{L^3} & 0 & 0 & 0 & \frac{6EI_z}{L^2} \\ 0 & 0 & \frac{12EI_y}{L^3} & 0 & -\frac{6EI_y}{L^2} & 0 \\ 0 & 0 & 0 & \frac{GJ}{L} & 0 & 0 \\ 0 & 0 & 0 & 0 & \frac{4EI_y}{L} & 0 \\ 0 & 0 & 0 & 0 & 0 & \frac{4EI_z}{L} \end{bmatrix} \tag{47.343}$$

$$[k_2] = \begin{bmatrix} -\frac{EA}{L} & 0 & 0 & 0 & 0 & 0 \\ 0 & -\frac{12EI_z}{L^3} & 0 & 0 & 0 & \frac{6EI_z}{L^2} \\ 0 & 0 & -\frac{12EI_y}{L^3} & 0 & -\frac{6EI_y}{L^2} & 0 \\ 0 & 0 & 0 & -\frac{GJ}{L} & 0 & 0 \\ 0 & 0 & \frac{6EI_y}{L^2} & 0 & \frac{2EI_y}{L} & 0 \\ 0 & -\frac{6EI_z}{L^2} & 0 & 0 & 0 & \frac{2EI_z}{L} \end{bmatrix} \tag{47.344}$$

$$[k_3] = \begin{bmatrix} \frac{EA}{L} & 0 & 0 & 0 & 0 & 0 \\ 0 & \frac{12EI_z}{L^3} & 0 & 0 & 0 & -\frac{6EI_z}{L^2} \\ 0 & 0 & \frac{12EI_y}{L^3} & 0 & \frac{6EI_y}{L^2} & 0 \\ 0 & 0 & 0 & \frac{GJ}{L} & 0 & 0 \\ 0 & 0 & 0 & 0 & \frac{4EI_y}{L} & 0 \\ 0 & 0 & 0 & 0 & 0 & \frac{4EI_z}{L} \end{bmatrix} \tag{47.345}$$

where I_x, I_y, and I_z = the moments of inertia about the x, y, and z axes
L = the member length
E = the modulus of elasticity
A = the cross-sectional area
G = the shear modulus
J = the torsional stiffness

The geometric stiffness matrix for a three-dimensional space frame element can be given as

$$[k_g] = \begin{bmatrix} a & 0 & 0 & 0 & -d & -e & -a & 0 & 0 & 0 & -n & -o \\ & b & 0 & d & g & k & 0 & -b & 0 & n & -g & k \\ & & c & e & h & g & 0 & 0 & -c & o & -h & -g \\ & & & f & i & l & 0 & -d & -e & -f & -i & -l \\ & & & & j & 0 & d & -g & h & -i & p & -q \\ & & & & & m & e & -k & -g & -l & q & r \\ & & & & & & a & 0 & 0 & 0 & n & o \\ & & & & & & & b & 0 & -n & g & -k \\ & & & & & & & & c & -o & h & g \\ & & & & & & & & & f & i & l \\ & \text{sym.} & & & & & & & & & j & o \\ & & & & & & & & & & & m \end{bmatrix} \tag{47.346}$$

where $a = -f_6 + f_{12}/L^2$; $b = 6f_7/5L$; $c = -f_5 + f_{11}/L^2$; $d = f_5/L$; $e = f_6/L$; $f = f_7J/AL$; $g = f_{10}/L$; $h = -f_7/10$; $i = f_6 + f_{12}/6$; $j = 2f_7L/15$; $k = -f_5 + f_{11}/6$; $l = f_{11}/L$; $m = f_{12}/L$; $n = -f_7L/30$; $o = -f_{10}/2$.

Further details can be obtained from Yang and Kuo (1994).

Buckling of Thin Plates

Rectangular Plates

The main difference between columns and plates is that quantities such as deflections and bending moments, which are functions of a single independent variable in columns, become functions of two independent variables in plates. Consequently, the behavior of plates is described by partial differential equations, whereas ordinary differential equations suffice for describing the behavior of columns. A main difference between column and plate buckling is that column buckling terminates the ability of the member to resist the axial load in columns; this is not true for plates. Upon reaching the critical load, the plate continues to resist the increasing axial force, and it does not fail until a load considerably in

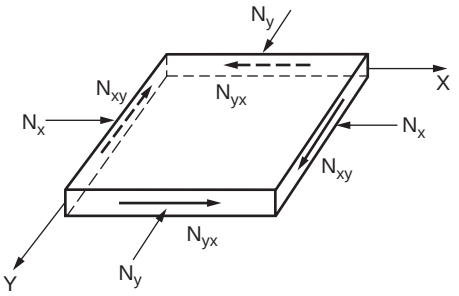

FIGURE 47.125 Plate subjected to in-plane forces.

excess of the elastic buckling load is reached. The critical load of a plate is, therefore, not its failure load. Instead, one must determine the load-carrying capacity of a plate by considering its postbuckling strength.

To determine the critical in-plane loading of a plate, a governing equation in terms of biaxial compressive forces N_x and N_y and constant shear force N_{xy}, as shown in Fig. 47.125, can be derived as

$$D\left(\frac{\delta^4 w}{\delta x^4}+2\frac{\delta^4 w}{\delta x^2\delta y^2}+\frac{\delta^4 w}{\delta y^4}\right)+N_x\frac{\delta^2 w}{\delta x^2}+N_y\frac{\delta^2 w}{\delta y^2}+2N_{xy}\frac{\delta^2 w}{\delta x\delta y}=0 \tag{47.347}$$

The critical load for uniaxial compression can be determined from the differential equation

$$D\left(\frac{\delta^4 w}{\delta x^4}+2\frac{\delta^4 w}{\delta x^2\delta y^2}+\frac{\delta^4 w}{\delta y^4}\right)+N_x\frac{\delta^2 w}{\delta x^2}=0 \tag{47.348}$$

which is obtained by setting $N_x = N_{xy} = 0$ in Eq. (47.347).

For example, in the case of a simply supported plate Eq. (47.348) can be solved to give

$$N_x=\frac{\pi^2 a^2 D}{m^2}\left(\frac{m^2}{a^2}+\frac{n^2}{b^2}\right)^2 \tag{47.349}$$

The critical value of N_x (i.e., the smallest value) can be obtained by taking n equal to 1. The physical meaning of this is that a plate buckles in such a way that there can be several half-waves in the direction of compression, but only one half-wave in the perpendicular direction. Thus, the expression for the critical value of the compressive force becomes

$$\left(N_x\right)_{cr}=\frac{\pi^2 D}{a^2}\left(m+\frac{1}{m}\frac{a^2}{b^2}\right)^2 \tag{47.350}$$

The first factor in this expression represents the Euler load for a strip of unit width and of length a. The second factor indicates in what proportion the stability of the continuous plate is greater than the stability of an isolated strip. The magnitude of this factor depends on the magnitude of the ratio a/b and also on the number m, which is the number of half-waves into which the plate buckles. If a is smaller than b, the second term in the parentheses of Eq. (47.350) is always smaller than the first, and the minimum value of the expression is obtained by taking m = 1, i.e., by assuming that the plate buckles in one half-wave. The critical value of N_x can be expressed as

$$N_{cr}=\frac{k\pi^2 D}{b^2} \tag{47.351}$$

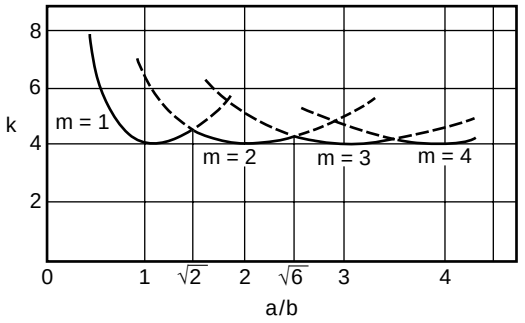

FIGURE 47.126 Buckling stress coefficients for unaxially compressed plate.

The factor k depends on the aspect ratio a/b of the plate and m. The variation of k with a/b for different values of m can be plotted as shown in Fig. 47.126. The critical value of N_x is the smallest value obtained for m = 1, and the corresponding value of k is 4.0. This formula is analogous to Euler's formula for the buckling of a column.

In the case where the normal forces N_x and N_y and the shearing forces N_{xy} are acting on the boundary of the plate, the same general method can be used. The critical stress for the case of a uniaxially compressed simply supported plate can be written as

$$\sigma_{cr} = 4\frac{\pi^2 E}{12\left(1-\nu^2\right)}\left(\frac{h}{b}\right)^2 \tag{47.352}$$

The critical stress values for different loading and support conditions can be expressed in the form

$$f_{cr} = k\frac{\pi^2 E}{12\left(1-\nu^2\right)}\left(\frac{h}{b}\right)^2 \tag{47.353}$$

Values of k for plates with several different boundary and loading conditions are given in Fig. 47.127.

Circular Plates

The critical value of the compressive forces N_r uniformly distributed around the edge of a circular plate of radius r_o, clamped along the edge (Fig. 47.128), can be determined by

$$r^2\frac{d^2\phi}{dr^2} + r\frac{d\phi}{dr} - \phi = -\frac{Qr^2}{D} \tag{47.354}$$

in which ϕ is the angle between the axis of revolution of the plate surface and any normal to the plate, r is the distance of any point measured from the center of the plate, and Q is the shearing force per unit of length. When there are no lateral forces acting on the plate, the solution of Eq. (47.5.60) involves a Bessel function of the first order of the first and second kind, and the resulting critical value of N_r is obtained as

$$\left(N_r\right)_{cr} = \frac{14.68D}{r_0^2} \tag{47.355}$$

The critical value of N_r for the plate when the edge is simply supported can be obtained in the same way as

$$\left(N_r\right)_{cr} = \frac{4.20D}{r_0^2} \tag{47.356}$$

$$f_{cr} = k \frac{\pi^2 E}{12(1-\mu^2)(w/t)^2}$$

Case	Boundary condition	Type of stress	Value of k for long plate
(a)		Compression	4.0
(b)		Compression	6.97
(c)		Compression	0.425
(d)		Compression	1.277
(e)		Compression	5.42
(f)		Shear	5.34
(g)		Shear	8.98
(h)		Bending	23.9
(i)		Bending	41.8

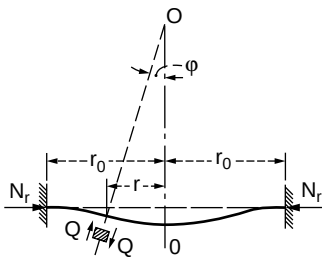

FIGURE 47.128 Circular plate under compressive loading.

Buckling of Shells

If a circular cylindrical shell is uniformly compressed in the axial direction, buckling symmetrical with respect to the axis of the cylinder (Fig. 47.129) may occur at a certain value of the compressive load. The critical value of the compressive force N_{cr} per unit length of the edge of the shell can be obtained by solving the differential equation

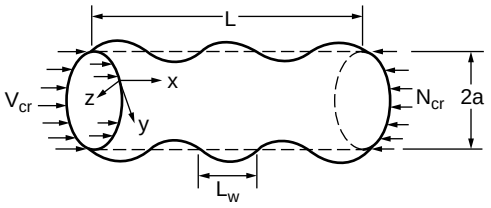

FIGURE 47.129 Buckling of a cylindrical shell.

$$D\frac{d^4w}{dx^4}+N\frac{d^2w}{dx^2}+Eh\frac{w}{a^2}=0 \tag{47.357}$$

in which a is the radius of the cylinder and h is the wall thickness.

Alternatively, the critical force per unit length may also be obtained by using the energy method. For a cylinder of length L, simply supported at both ends, one obtains

$$N_{cr}=D\left(\frac{m^2\pi^2}{L^2}+\frac{EhL^2}{Da^2m^2\pi^2}\right) \tag{47.358}$$

For each value of m there is a unique buckling mode shape and a unique buckling load. The lowest value is of greatest interest and is thus found by setting the derivative of N_{cr} with respect to L equal to zero for m = 1. With Poisson's ratio equal to 0.3, the buckling load is obtained as

$$N_{cr}=0.605\frac{Eh^2}{a} \tag{47.359}$$

It is possible for a cylindrical shell to be subjected to uniform external pressure or to the combined action of axial and uniform lateral pressure.

47.13 Dynamic Analysis

Equation of Motion

The essential physical properties of a linearly elastic structural system subjected to external dynamic loading are its mass, stiffness properties, and energy absorption capability or damping. The principle of dynamic analysis may be illustrated by considering a simple single-story structure, as shown in Fig. 47.130. The structure is subjected to a time-varying force f(t). k is the spring constant that relates the lateral story deflection x to the story shear force, and the dash pot relates the damping force to the velocity by a damping coefficient c. If the mass, m, is assumed to concentrate at the beam, the structure becomes a single-degree-of-freedom (SDOF) system. The equation of motion of the system may be written as

$$m\ddot{x}+c\dot{x}+kx=f(t) \tag{47.360}$$

Various solutions to Eq. (47.360) can give insight into the behavior of the structure under dynamic situations.

Free Vibration

In this case the system is set to motion and allowed to vibrate in the absence of applied force f(t). Letting f(t) = 0, Eq. (47.360) becomes

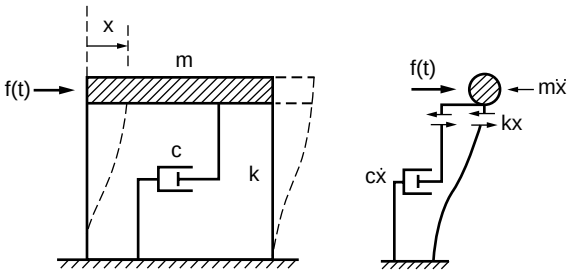

FIGURE 47.130 (a) One DOF structure. (b) Forces applied to structures.

$$m\ddot{x} + c\dot{x} + kx = 0 \tag{47.361}$$

Dividing Eq. (47.361) by the mass, m, we have

$$\ddot{x} + 2\xi\omega\dot{x} + \omega^2 x = 0 \tag{47.362}$$

where

$$2\xi\omega = \frac{c}{m} \quad \text{and} \quad \omega^2 = \frac{k}{m} \tag{47.363}$$

The solution to Eq. (47.362) depends on whether the vibration is damped or undamped.

Example 47.16: Undamped Free Vibration

In this case, c = 0, and the solution to the equation of motion may be written as

$$x = A\sin\omega t + B\cos\omega t \tag{47.364}$$

where $\omega = \sqrt{k/m}$ is the circular frequency. A and B are constants that can be determined by the initial boundary conditions. In the absence of external forces and damping, the system will vibrate indefinitely in a repeated cycle of vibration with an amplitude of

$$X = \sqrt{A^2 + B^2} \tag{47.365}$$

and a natural frequency of

$$f = \frac{\omega}{2\pi} \tag{47.366}$$

The corresponding natural period is

$$T = \frac{2\pi}{\omega} = \frac{1}{f} \tag{47.367}$$

The undamped free vibration motion, as described by Eq. (47.364), is shown in Fig. 47.131.

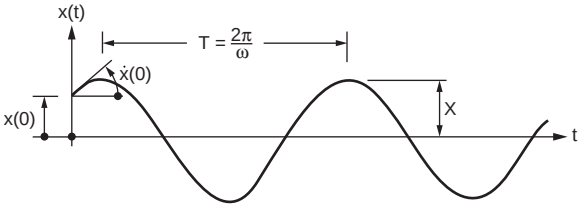

FIGURE 47.131 Response of undamped free vibration.

Example 47.17: Damped Free Vibration

If the system is not subjected to applied force and damping is presented, the corresponding solution becomes

$$x = A\exp(\lambda_1 t) + B\exp(\lambda_2 t) \tag{47.368}$$

where

$$\lambda_1 = \omega\left[-\xi + \sqrt{\xi^2 - 1}\right] \tag{47.369}$$

and

$$\lambda_2 = \omega\left[-\xi - \sqrt{\xi^2 - 1}\right] \tag{47.370}$$

The solution of Eq. (47.368) changes its form with the value of ξ, defined as

$$\xi = \frac{c}{2\sqrt{mk}} \tag{47.371}$$

If $\xi^2 < 1$, the equation of motion becomes

$$x = \exp(-\xi\omega t)(A\cos\omega_d t + B\sin\omega_d t) \tag{47.372}$$

where ξ_d is the damped angular frequency defined as

$$\omega_d = \sqrt{(1-\xi^2)\omega} \tag{47.373}$$

For most building structures ξ is very small (about 0.01), and therefore $\omega_d \approx \omega$. The system oscillates about the neutral position as the amplitude decays with time t. Figure 47.132 illustrates an example of such motion. The rate of decay is governed by the amount of damping present.

If the damping is large, then oscillation will be prevented. This happens when $\xi^2 > 1$; the behavior is referred to as *overdamped*. The motion of such behavior is shown in Fig. 47.133.

Damping with $\xi^2 = 1$ is called critical damping. This is the case where minimum damping is required to prevent oscillation, and the critical damping coefficient is given as

$$c_{cr} = 2\sqrt{km} \tag{47.374}$$

where k and m are the stiffness and mass of the system, respectively.

The degree of damping in the structure is often expressed as a proportion of the critical damping value. Referring to Eqs. (47.371) and (47.375), we have

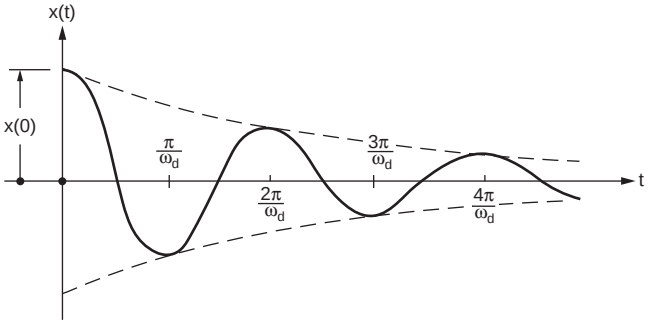

FIGURE 47.132 Response of damped free vibration.

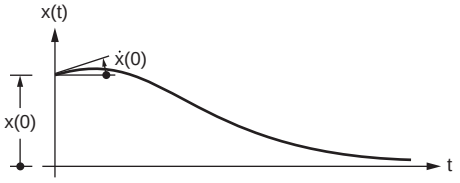

FIGURE 47.133 Response of free vibration with critical damping.

$$\xi = \frac{c}{c_{cr}} \tag{47.375}$$

ξ is called the critical damping ratio.

Forced Vibration

If a structure is subjected to a sinusoidal motion such as a ground acceleration of $\ddot{x} = F\sin\omega_f t$, it will oscillate, and after some time the motion of the structure will reach a steady state. For example, the equation of motion due to the ground acceleration (from Eq. (47.362)) is

$$\ddot{x} + 2\xi\omega\dot{x} + \omega^2 x = -F\sin\omega_f t \tag{47.376}$$

The solution to the above equation consists of two parts: the complimentary solution given by Eq. (47.364) and the particular solution. If the system is damped, oscillation corresponding to the complementary solution will decay with time. After some time the motion will reach a steady state, and the system will vibrate at a constant amplitude and frequency. This motion, which is called force vibration, is described by the particular solution expressed as

$$x = C_1\sin\omega_f t + C_2\cos\omega_f t \tag{47.377}$$

It can be observed that the steady force vibration occurs at the frequency of the excited force, ω_f, not at the natural frequency of the structure, ω.

Substituting Eq. (47.377) into (47.376), the displacement amplitude can be shown to be

$$X = -\frac{F}{\omega^2}\frac{1}{\sqrt{\left[\left\{1-\left(\frac{\omega_f}{\omega}\right)^2\right\}^2 + \left(\frac{2\xi\omega_f}{\omega}\right)^2\right]}} \tag{47.378}$$

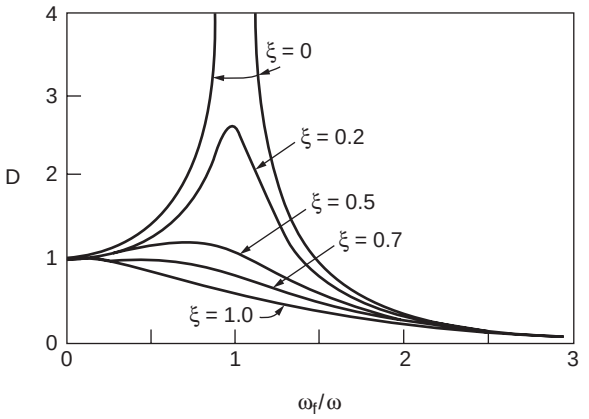

FIGURE 47.134 Vibration of dynamic amplification factor with frequency ratio.

The term $-F/\omega^2$ is the static displacement caused by the force due to the inertia force. The ratio of the response amplitude relative to the static displacement $-F/\omega^2$ is called the dynamic displacement amplification factor, D, given as

$$D = \frac{1}{\sqrt{\left[\left\{1-\left(\frac{\omega_f}{\omega}\right)^2\right\}^2 + \left(\frac{2\xi\omega_f}{\omega}\right)^2\right]}} \tag{47.379}$$

The variation of the magnification factor with the frequency ratio ω_f/ω and damping ratio ξ is shown in Fig. 47.134.

When the dynamic force is applied at a frequency much lower than the natural frequency of the system ($\omega_f/\omega \ll 1$), the response is quasistatic. The response is proportional to the stiffness of the structure, and the displacement amplitude is close to the static deflection.

When the force is applied at a frequency much higher than the natural frequency ($\omega_f/\omega \gg 1$), the response is proportional to the mass of the structure. The displacement amplitude is less than the static deflection ($D < 1$).

When the force is applied at a frequency close to the natural frequency, the displacement amplitude increases significantly. The condition at which $\omega_f/\omega = 1$ is known as resonance.

Similarly, the ratio of the acceleration response relative to the ground acceleration may be expressed as

$$D_a = \left|\frac{\ddot{x}+\ddot{x}_g}{\ddot{x}_g}\right| = \sqrt{\frac{1+\left(\frac{2\xi\omega_f}{\omega}\right)^2}{\left[\left\{1-\left(\frac{\omega_f}{\omega}\right)^2\right\}^2 + \left(\frac{2\xi\omega_f}{\omega}\right)^2\right]}} \tag{47.380}$$

D_a is called the dynamic acceleration magnification factor.

Response to Suddenly Applied Load

Consider the spring–mass damper system of which a load P_o is applied suddenly. The differential equation is given by

$$M\ddot{x} + c\dot{x} + kx = P_o \tag{47.381}$$

If the system is started at rest, the equation of motion is

$$x = \frac{P_o}{k}\left[1 - \exp\left(-\xi\omega t\right)\left\{\cos\omega_d t + \frac{\xi\omega}{\omega_d}\sin\omega_d t\right\}\right] \tag{47.382}$$

If the system is undamped, then $\xi = 0$ and $\omega_d = \omega$; we have

$$x = \frac{P_o}{k}\left[1 - \cos\omega_d t\right] \tag{47.383}$$

The maximum displacement is $2(P_o/k)$, corresponding to $\cos\omega_d t = -1$. Since P_o/k is the maximum static displacement, the dynamic amplification factor is 2. The presence of damping would naturally reduce the dynamic amplification factor and the force in the system.

Response to Time-Varying Loads

Some forces and ground motions that are encountered in practice are rather complex in nature. In general, numerical analysis is required to predict the response of such effects, and the finite element method is one of the most common techniques to be employed in solving such problems.

The evaluation of responses due to time-varying loads can be carried out using the piecewise exact method. In using this method, the loading history is divided into small time intervals. Between these points, it is assumed that the slope of the load curve remains constant. The entire load history is represented by a piecewise linear curve, and the error of this approach can be minimized by reducing the length of the time steps. A description of this procedure is given in Clough and Penzien (1993).

Other techniques employed include Fourier analysis of the forcing function, followed by solution for Fourier components in the frequency domain. For random forces, the random vibration theory and spectrum analysis may be used (Dowrick, 1988; Warburton, 1976).

Multiple Degree Systems

In multiple degree systems, an independent differential equation of motion can be written for each degree of freedom. The nodal equations of a multiple degree system consisting of n degrees of freedom may be written as

$$[m]\{\ddot{x}\} + [c]\{\dot{x}\} + [k]\{x\} = \{F(t)\} \tag{47.384}$$

where $[m]$ = a symmetrical n x n matrix of mass
$[c]$ = a symmetrical n x n matrix of damping coefficient
$\{F(t)\}$ = the force vector, which is zero in the case of free vibration

Consider a system under free vibration without damping; the general solution of Eq. (47.384) is assumed in the form of

$$\begin{Bmatrix} x_1 \\ x_2 \\ \vdots \\ x_n \end{Bmatrix} = \begin{bmatrix} \cos(\omega t - \phi) & 0 & 0 & 0 \\ 0 & \cos(\omega t - \phi) & 0 & 0 \\ \vdots & \vdots & \vdots & \vdots \\ 0 & 0 & 0 & \cos(\omega t - \phi) \end{bmatrix} \begin{Bmatrix} C_1 \\ C_2 \\ \vdots \\ C_n \end{Bmatrix} \tag{47.385}$$

where angular frequency ω and phase angle ϕ are common to all x's. In this assumed solution, ϕ and C_1, C_2, … C_n are the constants to be determined from the initial boundary conditions of the motion, and ω is a characteristic value (eigenvalue) of the system.

Substituting Eq. (47.385) into Eq. (47.384) yields

$$\begin{bmatrix} k_{11}-m_{11}\omega^2 & k_{12}-m_{12}\omega^2 & \cdots & k_{1n}-m_{1n}\omega^2 \\ k_{21}-m_{21}\omega^2 & k_{22}-m_{22}\omega^2 & \cdots & k_{2n}-m_{2n}\omega^2 \\ \vdots & \vdots & \vdots & \vdots \\ k_{n1}-m_{n1}\omega^2 & k_{n2}-m_{n2}\omega^2 & \cdots & k_{nn}-m_{nn}\omega^2 \end{bmatrix} \begin{Bmatrix} C_1 \\ C_2 \\ \vdots \\ C_n \end{Bmatrix} \cos(\omega t-\phi) = \begin{Bmatrix} 0 \\ 0 \\ \vdots \\ 0 \end{Bmatrix} \tag{47.386}$$

or

$$\left[[k]-\omega^2[m]\right]\{C\} = \{0\} \tag{47.387}$$

where [k] and [m] are the n × n matrices, ω^2 and $\cos(\omega t - \phi)$ are scalars, and {C} is the amplitude vector. For nontrivial solution, $\cos(\omega t - \phi) \neq 0$; thus solution to Eq. (47.387) requires the determinant of $[[k] - \omega^2[m]] = 0$. The expansion of the determinant yields a polynomial of n degree as a function of ω^2, the n roots of which are the eigenvalues $\omega_1, \omega_2, \ldots \omega_n$.

If the eigenvalue ω for a normal mode is substituted in Eq. (47.387), the amplitude vector {C} for that mode can be obtained. $\{C_1\}, \{C_2\}, \{C_3\}, \ldots \{C_n\}$ are therefore called eigenvectors, the absolute values that must be determined through initial boundary conditions. The resulting motion is a sum of n harmonic motions, each governed by the respective natural frequency ω, written as

$$\{x\} = \sum_{i=1}^{n} \{C_i\} \cos(\omega_i t - \phi_i) \tag{47.388}$$

Distributed Mass Systems

Although many structures may be approximated by lumped mass systems, in practice all structures are distributed mass systems consisting of an infinite number of particles. Consequently, if the motion is repetitive, the structure has an infinite number of natural frequency and mode shapes. The analysis of a distributed-parameter system is entirely equivalent to that of a discrete system once the mode shapes and frequencies have been determined, because in both cases the amplitudes of the modal response components are used as generalized coordinates in defining the response of the structure.

In principle an infinite number of these coordinates are available for a distributed-parameter system, but in practice only a few modes, usually those of lower frequencies, will provide significant contribute to the overall response. Thus the problem of a distributed-parameter system can be converted to a discrete system form in which only a limited number of modal coordinates is used to describe the response.

Flexural Vibration of Beams

The motion of the distributed mass system is best illustrated by a classical example of a uniform beam with of span length L, a flexural rigidity EI, and a self-weight of m per unit length, as shown in Fig. 47.135a. The beam is free to vibrate under its self-weight. From Fig. 47.135b, dynamic equilibrium of a small beam segment of length dx requires:

$$\frac{\partial V}{\partial x} dx = m dx \frac{\partial^2 y}{\partial t^2} \tag{47.389}$$

in which

$$\frac{\partial^2 y}{\partial x^2} = \frac{M}{EI} \tag{47.390}$$

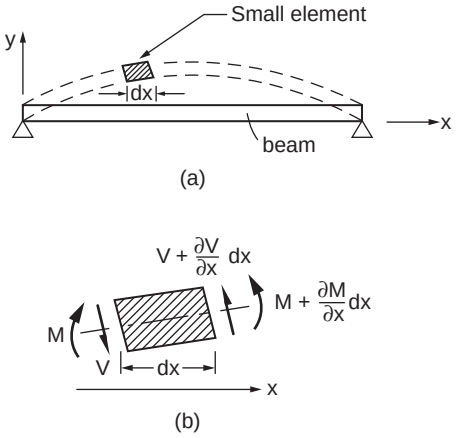

FIGURE 47.135 (a) Beam in flexural vibration. (b) Equilibrium of beam segment in vibration.

and

$$V = -\frac{\partial M}{\partial x}, \qquad \frac{\partial V}{\partial x} = -\frac{\partial^2 M}{\partial x^2} \tag{47.391}$$

Substituting these equations into Eq. (47.389) leads to the equation of motion of the flexural beam:

$$\frac{\partial^4 y}{\partial x^4} + \frac{m}{EI}\frac{\partial^2 y}{\partial t^2} = 0 \tag{47.392}$$

Equation (47.392) can be solved for beams with given sets of boundary conditions. The solution consists of a family of vibration modes with corresponding natural frequencies. Standard results are available in Table 47.5 to compute the natural frequencies of uniform flexural beams of different supporting conditions. Methods are also available for dynamic analysis of continuous beams (Clough and Penzien, 1993).

Shear Vibration of Beams

Beams can deform by flexure or shear. Flexural deformation normally dominates the deformation of slender beams. Shear deformation is important for short beams or in higher modes of slender beams. Table 47.6 gives the natural frequencies of uniform beams in shear, neglecting flexural deformation. The natural frequencies of these beams are inversely proportional to the beam length L rather than L^2, and the frequencies increase linearly with the mode number.

Combined Shear and Flexure

The transverse deformation of real beams is the sum of flexure and shear deformations. In general, numerical solutions are required to incorporate both the shear and flexural deformation in the prediction of the natural frequency of beams. For beams with comparable shear and flexural deformations, the following simplified formula may be used to estimate the beam's frequency:

$$\frac{1}{f^2} = \frac{1}{f_f^2} + \frac{1}{f_s^2} \tag{47.393}$$

where f is the fundamental frequency of the beam and f_f and f_s are the fundamental frequencies predicted by the flexure and shear beam theories, respectively (Rutenberg, 1975).

Natural Frequency of Multistory Building Frames

Tall building frames often deform more in the shear mode than in flexure. The fundamental frequencies of many multistory building frameworks can be approximated by (Housner and Brody, 1963; Rinne, 1952)

TABLE 47.6 Frequencies and Mode Shapes of Beams in Shear Vibration

$f_n = \frac{K_n}{2\pi}\sqrt{\frac{KG}{\rho L^2}}$ HZ	L = Length K = Shear coefficient (Cowper, 1966) G = Shear modulus = E/[2(1 + ν)] ρ = Mass density

$$f = \alpha\frac{\sqrt{B}}{H} \tag{47.394}$$

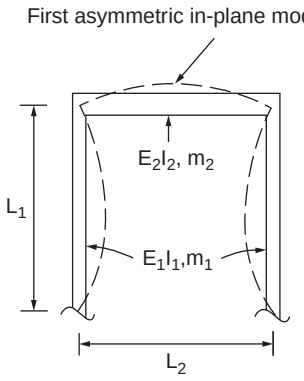
where α = approximately equal to 11 $\sqrt{m}$/sec
B = the building width in the direction of vibration
H = the building height

This empirical formula suggests that a shear beam model with f inversely proportional to H is more appropriate than a flexural beam for predicting natural frequencies of buildings.

Portal Frames

A portal frame consists of a cap beam rigidly connected to two vertical columns. The natural frequencies of portal frames vibrating in the fundamental asymmetric and symmetric modes are shown in Tables 47.7

TABLE 47.7 Fundamental Frequencies of Portal Frames in Asymmetrical Mode of Vibration



$$f = \frac{\lambda^2}{2\pi L_1^2}\left(\frac{E_1 I_1}{m_1}\right)^{1/2} \text{HZ}$$

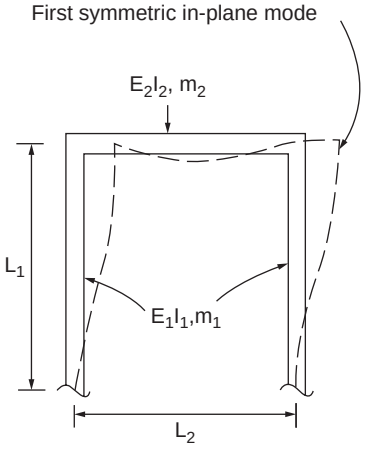
and 47.8, respectively. The beams in these frames are assumed to be uniform and sufficiently slender, so that shear and axial and torsional deformations can be neglected. The method of analysis of these frames is given in Yang and Sun (1973). The vibration is assumed to be in the plane of the frame, and the results are presented for portal frames with pinned and fixed bases.

If the beam is rigid and the columns are slender and uniform, but not necessarily identical, then the natural fundamental frequency of the frame can be approximated using the following formula (Robert, 1979):

TABLE 47.8 Fundamental Frequencies of Portal Frames in Symmetrical Mode of Vibration

First symmetric in-plane mode



$$f = \frac{\lambda^2}{2\pi L_1^2}\left(\frac{E_1 I_1}{m_1}\right)^{1/2} \text{HZ}$$

E = Modulus of elasticity

$$f = \frac{1}{2\pi}\left[\frac{12\sum E_i I_i}{L^3\left(M + 0.37\sum M_i\right)}\right]^{1/2} \text{Hz} \tag{47.395}$$

where M is the mass of the beam, M_i is the mass of the i-th column, and $E_i I_i$ is the flexural rigidity of the i-th column. The summation refers to the sum of all columns, and i must be greater or equal to 2. Additional results for frames with inclined members are discussed in Chang (1978).

Damping

Damping is found to increase with the increasing amplitude of vibration. It arises from the dissipation of energy during vibration. The mechanisms contributing to energy dissipation are material damping, friction at interfaces between components, and energy dissipation due to a foundation interacting with soil, among others. Material damping arises from the friction at bolted connections and frictional interaction between structural and nonstructural elements, such as partitions and cladding.

The amount of damping in a building can never be predicted precisely, and design values are generally derived based on dynamic measurements of structures of a corresponding type. Damping can be measured by the rate of decay of free vibration following an impact, spectral methods based on an analysis of the response to wind loading, and force excitation by a mechanical vibrator at varying frequencies to establish the shape of the steady-state resonance curve. However, these methods may not be easily carried out if several modes of vibration close in frequency are presented.

Table 47.8 gives values of modal damping that are appropriate for use when amplitudes are low. Higher values are appropriate at larger amplitudes where local yielding may develop, e.g., in seismic analysis.

Numerical Analysis

Many less complex dynamic problems can be solved without much difficulty by hand methods. For more complex problems, such as determination of natural frequencies of complex structures, calculation of response due to time-varying loads and response spectrum analysis to determine seismic forces may require numerical analysis. The finite element method has been shown to be a versatile technique for this purpose.

The global equations of an undamped force–vibration motion, in matrix form, may be written as

$$[M]\{\ddot{x}\} = [K]\{\dot{x}\} = \{F(t)\} \tag{47.396}$$

where

$$[K] = \sum_{i=1}^{n} [k_i] \qquad [M] = \sum_{i=1}^{n} [m_i] \qquad [F] = \sum_{i=1}^{n} [f_i] \tag{47.397}$$

are the global stiffness, mass, and force matrices, respectively. $[k_i]$, $[m_i]$, and $[f_i]$ are the stiffness, mass, and force of the i-th element, respectively. The elements are assembled using the direct stiffness method to obtain the global equations such that intermediate continuity of displacements is satisfied at common nodes, and in addition, interelement continuity of acceleration is also satisfied.

Equation (47.396) is the matrix equations discretized in space. To obtain solution of the equation, discretization in time is also necessary. The general method used is called direct integration. There are two methods for direct integration: *implicit* or *explicit*. The first, and simplest, is an explicit method known as the central difference method (Biggs, 1964). The second, more sophisticated but more versatile, is an implicit method known as the Newmark method (Newmark, 1959). Other integration methods are also available in Bathe (1982).

The natural frequencies are determined by solving Eq. (47.396) in the absence of force F(t) as

$$[M]\{\ddot{x}\} + [K]\{x\} = 0 \tag{47.398}$$

The standard solution for x(t) is given by the harmonic equation in time

$$\{x(t)\} = \{X\}e^{i\omega t} \tag{47.399}$$

where {X} is the part of the nodal displacement matrix called natural modes, which are assumed to be independent of time; i is the imaginary number; and ω is the natural frequency.

TABLE 47.9 Typical Structural Damping Values

Structural Type	Damping Value, ξ (%)
Unclad welded steel structures	0.3
Unclad bolted steel structures	0.5
Floor, composite and noncomposite	1.5–3.0
Clad buildings subjected to side sway	1

Differentiating Eq. (47.399) twice with respect to time, we have

$$\ddot{x}(t) = \{X\}\left(-\omega^2\right)e^{i\omega t} \tag{47.400}$$

Substituting of Eqs. (47.399) and (47.400) into Eq. (47.398) yields

$$e^{i\omega t}\left(\left[K\right] - \omega^2\left[M\right]\right)\{X\} = 0 \tag{47.401}$$

Since $e^{i\omega t}$ is not zero, we obtain

$$\left(\left[K\right] - \omega^2\left[M\right]\right)\{X\} = 0 \tag{47.402}$$

Equation (47.402) is a set of linear homogeneous equations in terms of displacement mode {X}. It has a nontrivial solution if the determinant of the coefficient matrix {X} is nonzero; that is

$$\left[K\right\} - \omega^2\left[M\right] = 0 \tag{47.403}$$

In general, Eq. (47.403) is a set of n algebraic equations, where n is the number of degrees of freedom associated with the problem.

48.1 Materials

Stress–Strain Behavior of Structural Steel

Structural steel is a construction material that possesses attributes such as *strength*, *stiffness*, *toughness*, and *ductility* that are desirable in modern constructions. Strength is the ability of a material to resist stresses. It is measured in terms of the material's yield strength F_y and ultimate or tensile strength F_u. Steel used in ordinary constructions normally has values of F_y and F_u that range from 36 to 50 ksi (248 to 345 MPa) and from 58 to 70 ksi (400 to 483 MPa), respectively, although higher strength steels are becoming more common. Stiffness is the ability of a material to resist deformation. It is measured in terms of the modulus of elasticity E and the modulus of rigidity G. With reference to Fig. 48.1, in which several uniaxial engineering stress–strain curves obtained from coupon tests for various grades of steels are shown, it is seen that the modulus of elasticity E does not vary appreciably for the different steel grades. Therefore, a value of 29,000 ksi (200 GPa) is often used for design. Toughness is the ability of a material to absorb energy before failure. It is measured as the area under the material's stress–strain curve. As shown in Fig. 48.1, most (especially the lower grade) steels possess high toughness that make them suitable for both static and seismic applications. Ductility is the ability of a material to undergo large inelastic (or plastic) deformation before failure. It is measured in terms of percent elongation or percent reduction in the area of the specimen tested in uniaxial tension. For steel, percent elongation ranges from around 10 to 40 for a 2-in. (5-cm)-gauge-length specimen. Ductility generally decreases with increasing steel strength. Ductility is a very important attribute of steel. The ability of structural steel to deform considerably before failure by fracture allows an indeterminate structure to undergo stress redistribution. Ductility also enhances the energy absorption characteristic of the structure, which is extremely important in seismic design.

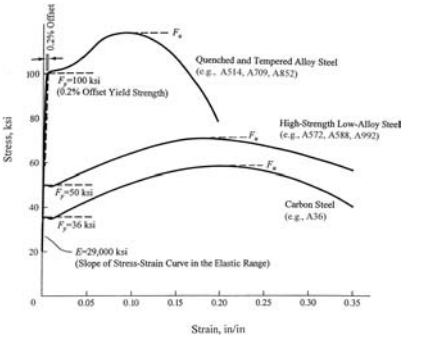

FIGURE 48.1 Uniaxial stress–strain behavior of steel.

Types of Steel

Structural steels used for construction are designated by the American Society of Testing and Materials (ASTM) (see table on page 48-3).

A summary of the specified minimum yield stresses F_y, the specified minimum tensile strengths F_u, and general uses for some commonly used steels is given in Table 48.1.

High-Performance Steel

High-performance steel (HPS) is a name given to a group of high-strength low-alloy (HSLA) steels that exhibit high strength, a higher yield-to-tensile-strength ratio, enhanced toughness, and improved weldability. Although research is still under way to develop and quantify the properties of a number of HPSs, one high-performance steel that is currently in use, especially for bridge construction, is HPS 70W. HPS 70W is a derivative of ASTM A709 grade 70W steel (see Table 48.1). Compared to ASTM A709 grade 70W, HPS 70W has improved mechanical properties and is more resistant to postweld cracking, even without preheating before welding.

Fireproofing of Steel

Although steel is an incombustible material, its strength (F_y, F_u) and stiffness (E) reduce quite noticeably at temperatures normally reached in fires when other materials in a building burn. Exposed steel members

ASTM Designation[a]	Steel Type
A36/A36M	Carbon structural steel
A131/A131M	Structural steel for ships
A242/A242M	High-strength low-alloy structural steel
A283/A283M	Low- and intermediate-tensile-strength carbon steel plates
A328/A328M	Steel sheet piling
A514/A514M	High-yield-strength, quenched and tempered alloy steel plate suitable for welding
A529/A529M	High-strength carbon–manganese steel of structural quality
A572/A572M	High-strength low-alloy columbium–vanadium steel
A573/A573M	Structural carbon steel plates of improved toughness
A588/A588M	High-strength low-alloy structural steel with 50-ksi (345-MPa) minimum yield point to 4 in. (100 mm) thick
A633/A633M	Normalized high-strength low-alloy structural steel plates
A656/A656M	Hot-rolled structural steel, high-strength low-alloy plate with improved formability
A678/A678M	Quenched and tempered carbon and high-strength low-alloy structural steel plates
A690/A690M	High-strength low-alloy steel H piles and sheet piling for use in marine environments
A709/A709M	Carbon and high-strength low-alloy structural steel shapes, plates, and bars and quenched and tempered alloy structural steel plates for bridges
A710/A710M	Age-hardening low-carbon nickel–copper–chromium–molybdenum–columbium alloy structural steel plates
A769/A769M	Carbon and high-strength electric resistance welded steel structural shapes
A786/A786M	Rolled steel floor plates
A808/A808M	High-strength low-alloy carbon–manganese–columbium–vanadium steel of structural quality with improved notch toughness
A827/A827M	Plates, carbon steel, for forging and similar applications
A829/A829M	Plates, alloy steel, structural quality
A830/A830M	Plates, carbon steel, structural quality, furnished to chemical composition requirements
A852/A852M	Quenched and tempered low-alloy structural steel plate with 70-ksi (485-MPa) minimum yield strength to 4 in. (100 mm) thick
A857/A857M	Steel sheet piling, cold formed, light gauge
A871/A871M	High-strength low alloy structural steel plate with atmospheric corrosion resistance
A913/A913M	High-strength low-alloy steel shapes of structural quality, produced by quenching and self-tempering (QST) process
A945/A945M	High-strength low-alloy structural steel plate with low carbon and restricted sulfur for improved weldability, formability, and toughness
A992/A992M	Steel for structural shapes (W sections) for use in building framing

[a] The letter M in the designations stands for metric.

that may be subjected to high temperature in a fire should be fireproofed to conform to the fire ratings set forth in city codes. Fire ratings are expressed in units of time (usually hours) beyond which the structural members under a standard ASTM specification (E119) fire test will fail under a specific set of criteria. Various approaches are available for fireproofing steel members. Steel members can be fireproofed by encasement in concrete if a minimum cover of 2 in. (5.1 mm) of concrete is provided. If the use of concrete is undesirable (because it adds weight to the structure), a lath and plaster (gypsum) ceiling placed underneath the structural members supporting the floor deck of an upper story can be used. In lieu of such a ceiling, spray-on materials such as mineral fibers, perlite, vermiculite, gypsum, etc. can also be used for fireproofing. Other means of fireproofing include placing steel members away from the source of heat, circulating liquid coolant inside box or tubular members, and the use of insulative paints. These special paints foam and expand when heated, thus forming a shield for the members [Rains, 1976]. For a more detailed discussion of structural steel design for fire protection, refer to the latest edition of AISI publication FS3, *Fire-Safe Structural Steel: A Design Guide*. Additional information on fire-resistant standards and fire protection can be found in the AISI booklets on *Fire Resistant Steel Frame Construction, Designing Fire Protection for Steel Columns*, and *Designing Fire Protection for Steel Trusses*, as well as in the *Uniform Building Code*.

TABLE 48.1 Steel Types and General Uses

ASTM Designation	F_y (ksi)[a]	F_u (ksi)[a]	Plate Thickness (in.)[b]	General Uses
A36/A36M	36	58–80	To 8	Riveted, bolted, and welded buildings and bridges
A529/A529M	42	60–85	To 0.5	Similar to A36; the higher yield stress for
	50	70–100	To 1.5	A529 steel allows for savings in weight; A529 supersedes A441
A572/A572M				
Grade 42	42	60	To 6	Grades 60 and 65 not suitable for welded
Grade 50	50	65	To 4	bridges
Grade 60	60	75	To 1.25	
Grade 65	65	80	To 1.25	
A242/A242M	42	63	1.5–5	Riveted, bolted, and welded buildings and
	46	67	0.75–1.5	bridges; used when weight savings and
	50	70	0.5–0.75	enhanced atmospheric corrosion resistance are desired; specific instructions must be provided for welding
A588/A588M	42	63	5–8	Similar to A242; atmospheric corrosion
	46	67	4–5	resistance is about four times that of A36
	50	70	To 4	steel
A709/A709M				Primarily for use in bridges
Grade 36	36	58–80	To 4	
Grade 50	50	65	To 4	
Grade 50W	50	70	To 4	
Grade 70W	70	90–110	To 4	
Grades 100 and 100W	90	100–130	2.5–4	
Grades 100 and 100W	100	110–130	To 2.5	
A852/A852M	70	90–110	To 4	Plates for welded and bolted construction where atmospheric corrosion resistance is desired
A514/A514M	90–100	100–130	2.5–6	Primarily for welded bridges; avoid use if
		110–130		ductility is important
A913/A913M	50–65	65 (max. $F_y/F_u = 0.85$)	To 4	Used for seismic applications
A992/A992M	50–65	65(max. $F_y/F_u = 0.85$)	To 4	Hot-rolled wide flange shapes for use in building frames

[a] 1 ksi = 6.895 MPa.
[b] 1in. = 25.4 mm.

Corrosion Protection of Steel

Atmospheric corrosion occurs when steel is exposed to a continuous supply of water and oxygen. The rate of corrosion can be reduced if a barrier is used to keep water and oxygen from contact with the surface of bare steel. Painting is a practical and cost-effective way to protect steel from corrosion. The Steel Structures Painting Council issues specifications for the surface preparation and painting of steel structures for corrosion protection of steel. In lieu of painting, the use of other coating materials such as epoxies or other mineral and polymeric compounds can be considered. The use of corrosion resistance steels such as ASTM A242, A588, or A606 steel or galvanized or stainless steel is another alternative. Corrosion-resistant steels such as A588 retard corrosion by the formation of a layer of deep reddish brown to black patina (an oxidized metallic film) on the steel surface after a few wetting–drying cycles, which usually take place within 1 to 3 years. Galvanized steel has a zinc coating. In addition to acting as a protective cover, zinc is anodic to steel. The steel, being cathodic, is therefore protected from corrosion. Stainless steel is more resistant to rusting and staining than ordinary steel, primarily because of the presence of chromium as an alloying element.

Structural Steel Shapes

Steel sections used for construction are available in a variety of shapes and sizes. In general, there are three procedures by which steel shapes can be formed: hot rolled, cold formed, and welded. All steel shapes must be manufactured to meet ASTM standards. Commonly used steel shapes include the wide flange (W) sections, the American Standard beam (S) sections, bearing pile (HP) sections, American Standard channel (C) sections, angle (L) sections, and tee (WT) sections, as well as bars, plates, pipes, and hollow structural sections (HSS). I sections that, by dimensions, can not be classified as W or S shapes are designated miscellaneous (M) sections, and C sections that, by dimensions, can not be classified as American Standard channels are designated miscellaneous channel (MC) sections.

Hot-rolled shapes are classified in accordance with their tensile property into five size groups by the American Society of Steel Construction (AISC). The groupings are given in the AISC manuals [AISC, 1989, 2001]. Groups 4 and 5 shapes and group 3 shapes with a flange thickness exceeding 1½ in. are generally used for application as *compression members*. When weldings are used, care must be exercised to minimize the possibility of cracking in regions at the vicinity of the welds by carefully reviewing the material specification and fabrication procedures of the pieces to be joined.

Structural Fasteners

Steel sections can be fastened together by rivets, bolts, and welds. Although rivets were used quite extensively in the past, their use in modern steel construction has become almost obsolete. Bolts have essentially replaced rivets as the primary means to connect nonwelded structural components.

Bolts

Four basic types of bolts are commonly in use. They are designated by ASTM as A307, A325, A490, and A449 [ASTM, 2001a, 2001b, 2001c, 2001d]. A307 bolts are called common, unfinished, machine, or rough bolts. They are made from low-carbon steel. Two grades (A and B) are available. They are available in diameters from 1/4 to 4 in. (6.4 to 102 mm) in 1/8-in. (3.2-mm) increments. They are used primarily for low-stress connections and for secondary members. A325 and A490 bolts are called high-strength bolts. A325 bolts are made from a heat-treated medium-carbon steel. They are available in two types: type 1, bolts made of medium-carbon steel; and type 3, bolts having atmospheric corrosion resistance and weathering characteristics comparable to those of A242 and A588 steel. A490 bolts are made from quenched and tempered alloy steel and thus have a higher strength than A325 bolts. Like A325 bolts, two types (types 1 and 3) are available. Both A325 and A490 bolts are available in diameters from 1/2 to 1½ in. (13 to 38 mm) in 1/8-in. (3.2-mm) increments. They are used for general construction purposes. A449 bolts are made from quenched and tempered steel. They are available in diameters from 1/4 to 3 in. (6.4 to 76 mm). Because A449 bolts are not produced to the same quality requirements or same heavy hex head and nut dimensions as A325 or A490 bolts, they are not to be used for slip critical connections. A449 bolts are used primarily when diameters over 1½ in. (38 mm) are needed. They are also used for anchor bolts and threaded rods.

High-strength bolts can be tightened to two conditions of tightness: snug tight and fully tight. Snug-tight conditions can be attained by a few impacts of an impact wrench or the full effort of a worker using an ordinary spud wrench. Snug-tight conditions must be clearly identified on the design drawing and are permitted in bearing-type connections where a slip is permitted or in tension or combined shear and tension applications where loosening or fatigue due to vibration or load fluctuations is not a design consideration. Bolts used in slip-critical conditions (i.e., conditions for which the integrity of the connected parts is dependent on the frictional force developed between the interfaces of the joint) and in conditions where the bolts are subjected to direct tension are required to be tightened to develop a pretension force equal to about 70% of the minimum tensile stress F_u of the material from which the bolts are made. This can be accomplished by using the turn-of-the-nut method, the calibrated wrench method, alternate design fasteners, or direct tension indicators [RCSC, 2000].

TABLE 48.2 Electrode Designations

Welding Processes	Electrode Designations	Remarks
Shielded metal arc welding (SMAW)	E60XX E70XX E80XX E100XX E110XX	The E denotes electrode; the first two digits indicate tensile strength in ksi[a]; the two X's represent numbers indicating the electrode use
Submerged arc welding (SAW)	F6X-EXXX F7X-EXXX F8X-EXXX F10X-EXXX F11X-EXXX	The F designates a granular flux material; the digit(s) following the F indicate the tensile strength in ksi (6 means 60 ksi, 10 means 100 ksi, etc.); the digit before the hyphen gives the Charpy V-notched impact strength; the E and the X's that follow represent numbers relating to the electrode use
Gas metal arc welding (GMAW)	ER70S-X ER80S ER100S ER110S	The digits following the letters ER represent the tensile strength of the electrode in ksi
Flux cored arc welding (FCAW)	E6XT-X E7XT-X E8XT E10XT E11XT	The digit(s) following the letter E represent the tensile strength of the electrode in ksi (6 means 60 ksi, 10 means 100 ksi, etc.)

[a] 1 ksi = 6.895 MPa.

Welds

Welding is a very effective means to connect two or more pieces of material together. The four most commonly used welding processes are *shielded metal arc welding* (SMAW), *submerged arc welding* (SAW), *gas metal arc welding* (GMAW), and *flux core arc welding* (FCAW) [AWS, 2000]. Welding can be done with or without filler materials, although most weldings used for construction utilize filler materials. The filler materials used in modern-day welding processes are electrodes. Table 48.2 summarizes the electrode designations used for the aforementioned four most commonly used welding processes. In general, the strength of the electrode used should equal or exceed the strength of the steel being welded [AWS, 2000].

Finished welds should be inspected to ensure their quality. Inspection should be performed by qualified welding inspectors. A number of inspection methods are available for weld inspections. They include visual methods; the use of liquid penetrants, magnetic particles, and ultrasonic equipment; and radiographic methods. Discussion of these and other welding inspection techniques can be found in the *Welding Handbook* [AWS, 1987].

Weldability of Steel

Weldability is the capacity of a material to be welded under a specific set of fabrication and design conditions and to perform as expected during its service life. Generally speaking, weldability is considered very good for low-carbon steel (carbon level, <0.15% by weight), good for mild steel (carbon level, 0.15 to 0.30%), fair for medium-carbon steel (carbon level, 0.30 to 0.50%), and questionable for high-carbon steel (carbon level, 0.50 to 1.00%). Because weldability normally decreases with increasing carbon content, special precautions such as preheating, controlling heat input, and postweld heat treating are normally required for steel with a carbon content reaching 0.30%. In addition to carbon content, the presence of other alloying elements will have an effect on weldability. In lieu of more accurate data, the table below can be used as a guide to determine the weldability of steel [Blodgett, undated].

Element	Range for Satisfactory Weldability (%)	Level Requiring Special Care (%)
Carbon	0.06–0.25	0.35
Manganese	0.35–0.80	1.40
Silicon	0.10 max.	0.30
Sulfur	0.035 max.	0.050
Phosphorus	0.030 max.	0.040

A quantitative approach to determine the weldability of steel is to calculate its *carbon equivalent value*. One definition of the carbon equivalent value C_{eq} is

$$C_{eq} = \text{Carbon} + \frac{(\text{Manganese} + \text{Silicon})}{6} + \frac{(\text{Copper} + \text{Nickel})}{15} + \frac{(\text{Chromium} + \text{Molybdenum} + \text{Vanadium} + \text{Columbium})}{5} \tag{48.1}$$

A steel is considered weldable if $C_{eq} \leq 0.50\%$ for steel in which the carbon content does not exceed 0.12%, and if $C_{eq} \leq 0.45\%$ for steel in which the carbon content exceeds 0.12%.

The above equation indicates that the presence of alloying elements decreases the weldability of steel. An example of high-alloy steels is stainless steel. There are three types of stainless steel: austenitic, martensitic, and ferritic. Austenitic stainless steel is the most weldable, but care must be exercised to prevent thermal distortion, because heat dissipation is only about one third as fast as it is in plain carbon steel. Martensitic steel is also weldable, but prone to cracking because of its high ability to harden. Preheating and the maintaining of an interpass temperature are often needed, especially when the carbon content is above 0.10%. Ferritic steel is weldable, but decreased ductility and toughness in the weld area can present a problem. Preheating and postweld annealing may be required to minimize these undesirable effects.

48.2 Design Philosophy and Design Formats

Design Philosophy

Structural design should be performed to satisfy the criteria for strength, serviceability, and economy. *Strength* pertains to the general integrity and safety of the structure under extreme load conditions. The structure is expected to withstand occasional overloads without severe distress and damage during its lifetime. *Serviceability* refers to the proper functioning of the structure as related to its appearance, maintainability, and durability under normal, or service load, conditions. Deflection, vibration, permanent deformation, cracking, and corrosion are some design considerations associated with serviceability. *Economy* is concerned with the overall material, construction, and labor costs required for the design, fabrication, erection, and maintenance processes of the structure.

Design Formats

At present, steel design in the U.S. can be performed in accordance with one of the following three formats:

Allowable stress design (ASD), which has been in use for decades for the steel design of buildings and bridges. It continues to enjoy popularity among structural engineers engaged in steel building design. In allowable stress (or working stress) design, member stresses computed under service (or working) loads are compared to some predesignated stresses called allowable stresses. The allowable stresses are often expressed as a function of the yield stress (F_y) or tensile stress (F_u) of

the material divided by a factor of safety. The factor of safety is introduced to account for the effects of overload, understrength, and approximations used in structural analysis. The general format for an allowable stress design has the form

$$\frac{R_n}{F.S.} \geq \sum_{i=1}^{m} Q_{ni} \tag{48.2}$$

where R_n = the nominal resistance of the structural component expressed in unit of stress (i.e., the allowable stress)
Q_{ni} = the service, or working, stresses computed from the applied working load of type i
$F.S.$ = the factor of safety, i is the load type (dead, live, wind, etc.)
m = the number of load type considered in the design

Plastic design (PD), which makes use of the fact that steel sections have reserved strength beyond the first yield condition. When a section is under flexure, yielding of the cross section occurs in a progressive manner, commencing with the fibers farthest away from the neutral axis and ending with the fibers nearest the neutral axis. This phenomenon of progressive yielding, referred to as *plastification*, means that the cross section does not fail at first yield. The additional moment that a cross section can carry in excess of the moment that corresponds to first yield varies, depending on the shape of the cross section. To quantify such reserved capacity, a quantity called the *shape factor*, defined as the ratio of the *plastic moment* (moment that causes the entire cross section to yield, resulting in the formation of a *plastic hinge*) to the *yield moment* (moment that causes yielding of the extreme fibers only) is used. The shape factor for hot-rolled I-shaped sections bent about the strong axes has a value of about 1.15. The value is about 1.50 when these sections are bent about their weak axes.

For an indeterminate structure, failure of the structure will not occur after the formation of a plastic hinge. After complete yielding of a cross section, force (or, more precisely, moment) redistribution will occur in which the unyielded portion of the structure continues to carry any additional loadings. Failure will occur only when enough cross sections have yielded, rendering the structure unstable, resulting in the formation of a *plastic collapse mechanism*.

In plastic design, the factor of safety is applied to the applied loads to obtain *factored loads*. A design is said to have satisfied the strength criterion if the load effects (i.e., forces, shears, and moments) computed using these factored loads do not exceed the nominal plastic strength of the structural component. Plastic design has the form

$$R_n \geq \gamma \sum_{i=1}^{m} Q_{ni} \tag{48.3}$$

where R_n = the nominal plastic strength of the member
Q_{ni} = the nominal load effect from loads of type i
γ = the load factor
i = the load type
m = the number of load types.

In steel building design, the load factor is given by the AISC specification as 1.7 if Q_n consists of dead and live gravity loads only, and as 1.3 if Q_n consists of dead and live gravity loads acting in conjunction with wind or earthquake loads.

Load and resistance factor design (LRFD) which is a probability-based limit state design procedure. A *limit state* is defined as a condition in which a structure or structural component becomes unsafe (i.e., a violation of the strength limit state) or unsuitable for its intended function (i.e., a violation of the serviceability limit state). In a limit state design, the structure or structural component is

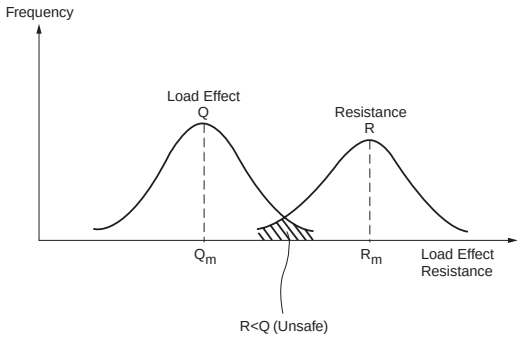

FIGURE 48.2 Frequency distribution of load effect and resistance.

designed in accordance to its limits of usefulness, which may be strength related or serviceability related. In developing the LRFD method, both load effects and resistance were treated as random variables. Their variabilities and uncertainties were represented by frequency distribution curves. A design is considered satisfactory according to the strength criterion if the resistance exceeds the load effects by a comfortable margin. The concept of safety is represented schematically in Fig. 48.2. Theoretically, the structure will not fail unless the load effect Q exceeds the resistance R, as shown by the shaded portion in the figure. The smaller this shaded area, the less likely that the structure will fail. In actual design, a *resistance factor* ϕ is applied to the nominal resistance of the structural component to account for any uncertainties associated with the determination of its strength, and a *load factor* γ is applied to each load type to account for the uncertainties and difficulties associated with determining its actual load magnitude. Different load factors are used for different load types to reflect the varying degree of uncertainties associated with the determination of load magnitudes. In general, a lower load factor is used for a load that is more predicable, and a higher load factor is used for a load that is less predicable. Mathematically, the LRFD format takes the form

$$\phi R_n \geq \sum_{i=1}^{m} \gamma_i Q_{ni} \tag{48.4}$$

where ϕR_n represents the *design* (or usable) *strength* and $\Sigma_i Q_{ni}$ represents the required strength or load effect for a given load combination. Table 48.3 shows examples of load combinations [ASCE, 1998] to be used on the right-hand side of Eq. (48.4). For a safe design, all load combinations should be investigated and the design based on the worst-case scenario.

48.3 Tension Members

Tension members are designed to resist tensile forces. Examples of tension members are hangers, truss members, and bracing members that are in tension. Cross sections that are used most often for tension members are solid and hollow circular rods, bundled bars and cables, rectangular plates, single and double angles, channels, WT and W sections, and a variety of built-up shapes.

Tension Member Design

Tension members are to be designed to preclude the following possible failure modes under normal load conditions: yielding in gross section, fracture in effective net section, block shear, shear rupture along a plane through the fasteners, bearing on fastener holes, and prying (for lap or hanger-type joints). In addition, the fasteners' strength must be adequate to prevent failure in the fasteners. Also, except for rods in tension, the slenderness of the tension member obtained by dividing the length of the member by its least radius of gyration should preferably not exceed 300.

TABLE 48.3 Load Factors and Load Combinations

$1.4D$
$1.2(D + F + T) + 1.6(L + H) + 0.5(L_r \text{ or } S \text{ or } R)$
$1.2D + 1.6(L_r \text{ or } S \text{ or } R) + (0.5L \text{ or } 0.8W)$
$1.2D + 1.3W + 0.5L + 0.5(L_r \text{ or } S \text{ or } R)$
$1.2D + 1.0E + 0.5L + 0.2S$
$0.9D + (1.3W \text{ or } 1.0E)$

where D = dead load
E = earthquake load
F = load due to fluids with well-defined pressures and maximum heights
H = load due to the weight and lateral pressure of soil and water in soil
L = live load
L_r = roof live load
R = rain load
S = snow load
T = self-straining force
W = wind load

Note: The load factor on L in the third, fourth, and fifth load combinations shown above shall equal 1.0 for garages, areas occupied as places of public assembly, and all areas where the live load is greater than 100 psf (4.79 kN/m^2).

Allowable Stress Design

The computed tensile stress f_t in a tension member shall not exceed the allowable stress for tension F_t, given by $0.60F_y$ for yielding on the gross area and by $0.50F_u$ for fracture on the effective net area. While the gross area is just the nominal cross-sectional area of the member, the *effective net area* is the smallest cross-sectional area accounting for the presence of fastener holes and the effect of *shear lag*. It is calculated using the equation

$$A_e = UA_n = U\left[A_g - \sum_{i=1}^{m} d_{ni}t_i + \sum_{j=1}^{k}\left(\frac{s^2}{4g}\right)_j t_j\right] \tag{48.5}$$

where U is a reduction coefficient given by [Munse and Chesson, 1963].

$$U = 1 - \frac{\bar{x}}{l} \le 0.90 \tag{48.6}$$

in which l is the length of the connection and $\bar{x}$ is the larger of the distance measured from the centroid of the cross section to the contact plane of the connected pieces or to the fastener lines. In the event that the cross section has two symmetrically located planes of connection, $\bar{x}$ is measured from the centroid of the nearest one half the area (Fig. 48.3). This reduction coefficient is introduced to account for the shear lag effect that arises when some component elements of the cross section in a joint are not connected, rendering the connection less effective in transmitting the applied load. The terms in brackets in Eq. (48.5) constitute the so-called net section A_n. The various terms are defined as follows:

A_g = gross cross-sectional area
d_n = nominal diameter of the hole (bolt cutout), taken as the nominal bolt diameter plus 1/8 in. (3.2 mm)
t = thickness of the component element
s = longitudinal center-to-center spacing (pitch) of any two consecutive fasteners in a chain of staggered holes
g = transverse center-to-center spacing (gauge) between two adjacent fastener gauge lines in a chain of staggered holes

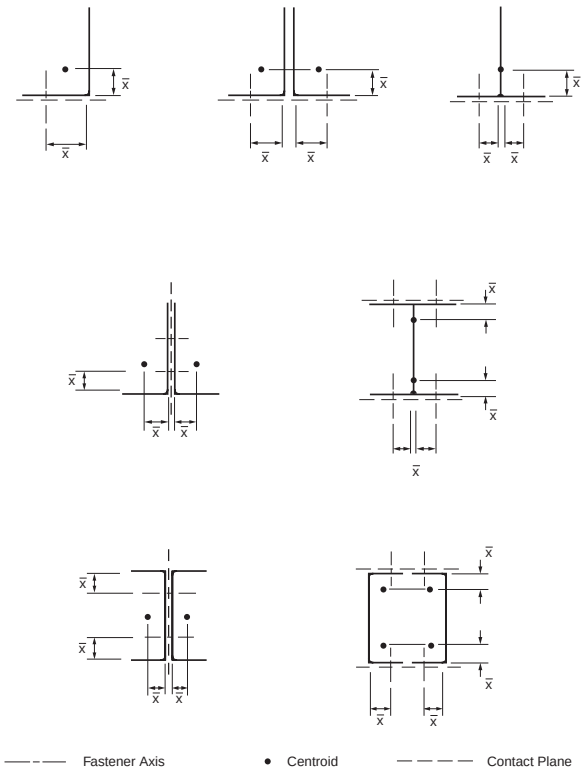

FIGURE 48.3 Definition of $\bar{x}$ for selected cross-sections.

The second term inside the brackets of Eq. (48.5) accounts for loss of material due to bolt cutouts; the summation is carried for all bolt cutouts lying on the failure line. The last term inside the brackets of Eq. (48.5) indirectly accounts for the effect of the existence of a combined stress state (tensile and shear) along an inclined failure path associated with staggered holes. The summation is carried for all staggered paths along the failure line. This term vanishes if the holes are not staggered. Normally, it is necessary to investigate different failure paths that may occur in a connection; the critical failure path is the one giving the smallest value for A_e.

To prevent block shear failure and shear rupture, the allowable strengths for block shear and shear rupture are specified as follows:

Block shear:

$$R_{BS} = 0.30\, A_v F_u + 0.50\, A_t F_u \tag{48.7}$$

Shear rupture:

$$F_v = 0.30 F_u \tag{48.8}$$

where A_v = the net area in shear
A_t = the net area in tension
F_u = the specificed mininum tensile strength.

The tension member should also be designed to possess adequate thickness, and the fasteners should be placed within a specific range of spacings and edge distances to prevent failure due to bearing or prying action (see Section 48.11).

Load and Resistance Factor Design

According to the LRFD specification [AISC, 1999], tension members designed to resist a factored axial force of P_u calculated using the load combinations shown in Table 48.3 must satisfy the condition of

$$\phi_t P_n \geq P_u \tag{48.9}$$

The design strength $\phi_t P_n$ is evaluated as follows:

Yielding in gross section:

$$\phi_t P_n = 0.90\left[F_y A_g\right] \tag{48.10}$$

where 0.90 = the resistance factor for tension
F_y = the specified minimum yield stress of the material
A_g = the gross cross-sectional area of the member.

Fracture in effective net section:

$$\phi_t P_n = 0.75\left[F_u A_e\right] \tag{48.11}$$

where 0.75 = the resistance factor for fracture in tension
F_u = the specified minimum tensile strength
A_e = the effective net area given in Eq. (48.5).

Block shear: if $F_u A_{nt} \geq 0.6 F_u A_{nv}$ (i.e., shear yield–tension fracture),

$$\phi_t P_n = 0.75\left[0.60 F_y A_{gv} + F_u A_{nt}\right] \leq 0.75\left[0.6 F_u A_{nv} + F_u A_{nt}\right] \tag{48.12a}$$

and if $F_u A_{nt} < 0.6 F_u A_{nv}$ (i.e., shear fracture–tension yield),

$$\phi_t P_n = 0.75\left[0.60 F_u A_{nv} + F_y A_{gt}\right] \leq 0.75\left[0.60 F_u A_{nv} + F_u A_{nt}\right] \tag{48.12b}$$

where 0.75 = the resistance factor for block shear
F_y and F_u = the specified minimum yield stress and tensile strength, respectively
A_{gv} = the gross shear area
A_{nt} = the net tension area
A_{nv} = the net shear area
A_{gt} = the gross tension area.

Example 48.1

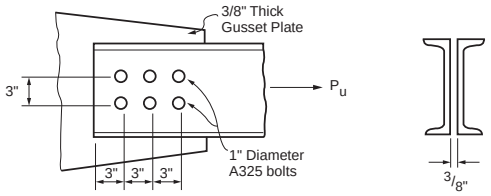
Using LRFD, select a double-channel tension member, shown in Fig. 48.4a, to carry a dead load D of 40 kips and a live load L of 100 kips. The member is 15 feet long. Six 1-in.-diameter A325 bolts in standard-size holes are used to connect the member to a 3/8-in. gusset plate. Use A36 steel (F_y = 36 ksi, F_u = 58 ksi) for all the connected parts.

Load combinations:
From Table 48.3, the applicable load combinations are:

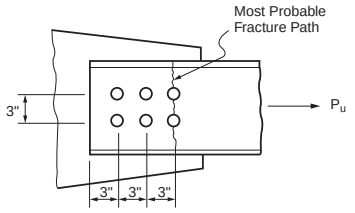
$$1.4D = 1.4(40) = 56 \text{ kips}$$

$$1.2D + 1.6L = 1.2(40) + 1.6(100) = 208 \text{ kips}$$

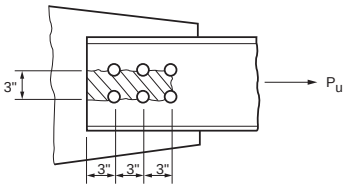
The design of the tension member is to be based on the larger of the two, i.e., 208 kips, and so *each* channel is expected to carry 104 kips.



(a) A Double Channel Tension Member



(b) Fracture Failure



(c) Block Shear Failure

FIGURE 48.4 Design of a double-channel tension member (1 in. = 25.4 mm).

Yielding in gross section:
Using Eqs. (48.9) and (48.10), the gross area required to prevent cross section yielding is

$$0.90\left[F_y A_g\right] \geq P_u$$

$$0.90\left[(36)(A_g)\right] \geq 104 \text{ kips}$$

$$(A_g)_{r'eqd} \geq 3.21 \text{ in}^2$$

From the section properties table contained in the AISC-LRFD manual, one can select the following trial sections: C8x11.5 (A_g = 3.38 in.^{2}), C9x13.4 (A_g = 3.94 in.^{2}), or C8x13.75 (A_g = 4.04 in.^{2}).

Check for the limit state of fracture on the effective net area:
The above sections are checked for the limiting state of fracture in the following table:

Section	A_g (in.^{2})	t_{gw} (in.)	$\bar{x}$ (in.)	U[a]	A_e[b] (in.^{2})	$\phi_t P_n$ (kips)
C8x11.5	3.38	0.220	0.571	0.90	2.6	113.1
C9x13.4	3.94	0.233	0.601	0.90	3.07	133.5
C8x13.75	4.04	0.303	0.553	0.90	3.02	131.4

[a]Eq. (48.6).
[b]Eq. (48.5), Fig. 48.4b.

From the last column of the above table, it can be seen that fracture is not a problem for any of the trial section.

Check for the limit state of block shear:
Figure 48.4c shows a possible block shear failure mode. To avoid block shear failure, the required strength of P_u = 104 kips should not exceed the design strength, $\phi_t P_n$, calculated using Eq. (48.12a) or (48.12b), whichever is applicable.

For the C8x11.5 section:

$$A_{gv} = 2(9)(0.220) = 3.96 \text{ in}^2$$

$$A_{nv} = A_{gv} - 5(1 + 1/8)(0.220) = 2.72 \text{ in}^2$$

$$A_{gt} = (3)(0.220) = 0.66 \text{ in}^2$$

$$A_{nt} = A_{gt} - 1(1 + 1/8)(0.220) = 0.41 \text{ in}^2$$

Substituting the above into Eq. (48.12b), since [$F_u A_{nt}$ = 23.8 kips] is smaller than [$0.6F_u A_{nv}$ = 94.7 kips], we obtain $\phi_t P_n$ = 88.8 kips, which is less than P_u = 104 kips. The C8x11.5 section is therefore not adequate. Significant increase in block shear strength is not expected from the C9x13.4 section because its web thickness t_w is just slightly over that of the C8x11.5 section. As a result, we shall check the adequacy of the C8x13.75 section instead.

For the C8x13.75 section:

$$A_{gv} = 2(9)(0.303) = 5.45 \text{ in}^2$$

$$A_{nv} = A_{gv} - 5(1 + 1/8)(0.303) = 3.75 \text{ in}^2$$

$$A_{gt} = (3)(0.303) = 0.91 \text{ in}^2$$

$$A_{nt} = A_{gt} - 1(1 + 1/8)(0.303) = 0.57 \text{ in}^2$$

Substituting the above into Eq. (48.12b), since [$F_u A_{nt}$ = 33.1 kips] is smaller than [$0.6F_u A_{nv}$ = 130.5 kips], we obtain $\phi_t P_n$ = 122 kips, which exceeds the required strength P_u of 104 kips. Therefore, block shear will not be a problem for the C8x13.75 section.

Check for the limiting slenderness ratio:
Using the parallel axis theorem, the least radius of gyration of the double-channel cross section is calculated to be 0.96 in. Therefore, L/r = (15 ft)(12 in./ft)/0.96 in. = 187.5, which is less than the recommended maximum value of 300.

Check for the adequacy of the connection:
An example of the calculations is shown in Section 48.11.

Longitudinal spacing of connectors:
According to Section J3.5 of the LRFD specification, the maximum spacing of connectors in built-up tension members shall not exceed:

- 24 times the thickness of the thinner plate or 12 in. (305 mm) for painted members or unpainted members not subject to corrosion
- 14 times the thickness of the thinner plate or 7 in. (180 mm) for unpainted members of weathering steel subject to atmospheric corrosion

Assuming the first condition applies, a spacing of 6 inches is to be used.

Use 2C8x13.75 connected intermittently at 6-in. intervals.

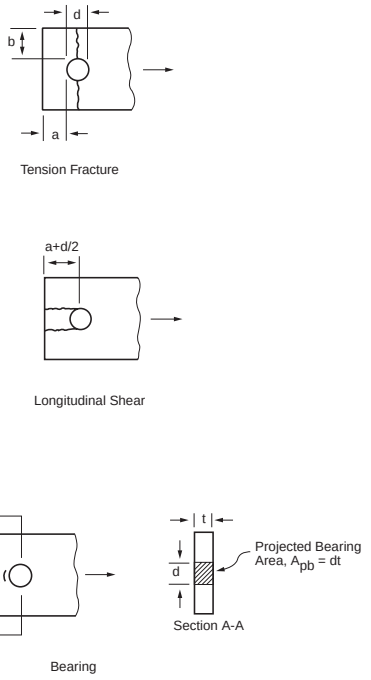


FIGURE 48.5 Failure modes of pin-connected members.

Pin-Connected Members

Pin-connected members shall be designed to preclude the following failure modes: (1) tension yielding in the gross section, (2) tension fracture on the effective net area, (3) longitudinal shear on the effective area, and (4) bearing on the projected pin area (Fig. 48.5).

Allowable Stress Design

The allowable stresses for tension yield, tension fracture, and shear rupture are $0.60F_y$, $0.45F_y$, and $0.30F_u$, respectively. The allowable stresses for bearing are given in Section 48.11.

Load and Resistance Factor Design

The design tensile strength $\phi_t P_n$ for pin-connected members is given as follows:

Tension on gross area: see Eq. (48.10).

Tension on effective net area:

$$\phi_t P_n = 0.75 \left[2\, t\, b_{eff}\ F_u\right] \tag{48.13}$$

Shear on effective area:

$$\phi_{sf} P_n = 0.75 \left[0.6\, A_{sf}\ F_u\right] \tag{48.14}$$

Bearing on projected pin area: see Section 48.11.

The terms in Fig. 48.5 and the above equations are defined as follows:

a = shortest distance from edge of the pin hole to the edge of the member measured in the direction of the force

A_{pb} = projected bearing area = dt

A_{sf} = $2t(a + d/2)$
b_{eff} = $2t$ + 0.63 in. (or $2t$ +16 mm), but not more than the actual distance from the edge of the hole to the edge of the part measured in the direction normal to the applied force
d = pin diameter
t = plate thickness

Threaded Rods

Allowable Stress Design

Threaded rods under tension are treated as bolts subject to tension in allowable stress design. These allowable stresses are given in the Section 48.11.

Load and Resistance Factor Design

Threaded rods designed as tension members shall have a gross area A_b given by

$$A_b \geq \frac{P_u}{\phi\, 0.75\, F_u} \tag{48.15}$$

where A_b = the gross area of the rod computed using a diameter measured to the outer extremity of the thread
P_u = the factored tensile load
ϕ = the resistance factor given as 0.75
P_u = the specified minimum tensile strength.

48.4 Compression Members

Members under compression can fail by yielding, inelastic buckling, or elastic buckling, depending on the slenderness ratio of the members. Members with low slenderness ratios tend to fail by yielding, while members with high slenderness ratios tend to fail by elastic buckling. Most compression members used in construction have intermediate slenderness ratios, so the predominant mode of failure is inelastic buckling. Overall member buckling can occur in one of three different modes: flexural, torsional, and flexural–torsional. Flexural buckling occurs in members with doubly symmetric or doubly antisymmetric cross sections (e.g., I or Z sections) and in members with singly symmetric sections (e.g., channel, tee, equal-legged angle, and double angle sections) when such sections are buckled about an axis that is *perpendicular* to the axis of symmetry. Torsional buckling occurs in members with doubly symmetric sections such as cruciform or built-up shapes with very thin walls. Flexural–torsional buckling occurs in members with singly symmetric cross sections (e.g., channel, tee, equal-legged angle, and double-angle sections) when such sections are buckled about the axis of symmetry and in members with unsymmetric cross sections (e.g., unequal-legged L). Normally, torsional buckling of symmetric shapes is not particularly important in the design of hot-rolled compression members. Either it does not govern or its buckling strength does not differ significantly from the corresponding weak-axis flexural buckling strengths. However, torsional buckling may become important for open sections with relatively thin component plates. It should be noted that for a given cross-sectional area, a closed section is much stiffer torsionally than an open section. Therefore, if torsional deformation is of concern, a closed section should be used. Regardless of the mode of buckling, the governing effective slenderness ratio (Kl/r) of the compression member preferably should not exceed 200.

In addition to the slenderness ratio and cross-sectional shape, the behavior of compression members is affected by the relative thickness of the component elements that constitute the cross section. The relative thickness of a component element is quantified by the width–thickness ratio (b/t) of the element. The width–thickness ratios of some selected steel shapes are shown in Fig. 48.6. If the width–thickness ratio falls within a limiting value (denoted by the LRFD Specification [AISC, 1999] as λ_r) as shown in Table 48.4, the section will not experience local buckling prior to overall buckling of the member.

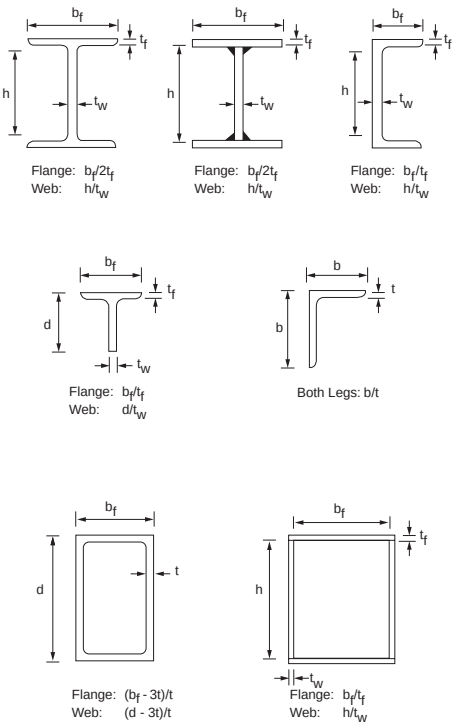

FIGURE 48.6 Definition of width–thickness ratio of selected cross sections.

TABLE 48.4 Limiting Width–Thickness Ratios for Compression Elements under Pure Compression

Component Element	Width–Thickness Ratio	Limiting Value, λ_r
Flanges of I-shaped sections; plates projecting from compression elements; outstanding legs of pairs of angles in continuous contact; flanges of channels	b/t	$0.56\sqrt{E/F_y}$
Flanges of square and rectangular box and hollow structural sections of uniform thickness; flange cover plates and diaphragm plates between lines of fasteners or welds	b/t	$1.40\sqrt{E/F_y}$
Unsupported width of cover plates perforated with a succession of access holes	b/t	$1.86\sqrt{E/F_y}$
Legs of single-angle struts; legs of double-angle struts with separators; unstiffened elements (i.e., elements supported along one edge)	b/t	$0.45\sqrt{E/F_y}$
Flanges projecting from built-up members	b/t	$0.64\sqrt{E/(F_y/k_c)}$
Stems of tees	d/t	$0.75\sqrt{E/F_y}$
All other uniformly compressed stiffened elements (i.e., elements supported along two edges)	b/t h/t_w [a]	$1.49\sqrt{E/F_y}$
Circular hollow sections	D/t [b]	$0.11E/F_y$

[a] h = web depth, t_w = web thickness.
[b] D = outside diameter, t = wall thickness.
[c] E = modulus of elasticity, F_y = specified minimum yield stress, $k_c = 4/\sqrt{(h/t_w)}$; $0.35 \le k_c \le 0.763$ for I-shaped sections, and $k_c = 0.763$ for other sections.

However, if the width–thickness ratio exceeds this limiting width–thickness value, consideration of local buckling in the design of the compression member is required.

To facilitate the design of compression members, column tables for W, tee, double-angle, square and rectangular tubular, and circular pipe sections are available in the AISC manuals for both allowable stress design [AISC, 1989] and load and resistance factor design [AISC, 2001].

Compression Member Design

Allowable Stress Design

The computed compressive stress f_a in a compression member shall not exceed its allowable value given by

$$F_a = \begin{cases} \dfrac{\left[1 - \dfrac{(Kl/r)^2}{2C_c^2}\right] F_y}{\dfrac{5}{3} + \dfrac{3(Kl/r)}{8C_c} - \dfrac{(Kl/r)^3}{8C_c^3}}, & \text{if } Kl/r \le C_c \\ \dfrac{12\pi^2 E}{23\,(Kl/r)^2}, & \text{if } Kl/r > C_c \end{cases} \tag{48.16}$$

where Kl/r = the slenderness ratio
K = the effective length factor of the compression member in the plane of buckling
l = the unbraced member length in the plane of buckling
r = the radius of gyration of the cross section about the axis of buckling
E = the modulus of elasticity
$C_c = \sqrt{(2\pi^2 E/F_y)}$ is the slenderness ratio that demarcates inelastic from elastic member buckling. Kl/r should be evaluated for both buckling axes, and the larger value should be used in Eq. (48.16) to compute F_a.

The first of Eq. (48.16) is the allowable stress for inelastic buckling; the second is the allowable stress for elastic buckling. In ASD, no distinction is made between flexural, torsional, and flexural–torsional buckling.

Load and Resistance Design

Compression members are to be designed so that the design compressive strength $\phi_c P_n$ will exceed the required compressive strength P_u. $\phi_c P_n$ is to be calculated as follows for the different types of overall buckling modes:

Flexural buckling (with a width–thickness ratio of $\le \lambda_r$):

$$\phi_c P_n = \begin{cases} 0.85\left[A_g\left(0.658^{\lambda_c^2}\right)F_y\right], & \text{if } \lambda_c \le 1.5 \\ 0.85\left[A_g\left(\dfrac{0.877}{\lambda_c^2}\right)F_y\right], & \text{if } \lambda_c > 1.5 \end{cases} \tag{48.17}$$

where $\lambda_c = (KL/r\pi)\sqrt{(F_y/E)}$ is the slenderness parameter
A_g = the gross cross-sectional area
F_y = the specified minimum yield stress
E = the modulus of elasticity
K = the effective length factor

l = the unbraced member length in the plane of buckling
r = the radius of gyration of the cross section about the axis of buckling

The first of Eq. (48.17) is the design strength for inelastic buckling; the second is the design strength for elastic buckling. The slenderness parameter $\lambda_c = 1.5$ demarcates inelastic from elastic behavior.

Torsional buckling (with a width–thickness ratio of $\leq \lambda_r$):
$\phi_c P_n$ is to be calculated from Eq. (48.17), but with λ_c replaced by λ_e given by

$$\lambda_e = \sqrt{\frac{F_y}{F_e}} \tag{48.18}$$

where

$$F_e = \left[\frac{\pi^2 E\, C_w}{(K_z L)^2} + GJ\right] \frac{1}{I_x + I_y} \tag{48.19}$$

in which C_w = the warping constant
G = the shear modulus, which equals 11,200 ksi (77,200 MPa)
I_x and I_y = the moments of inertia about the major and minor principal axes, respectively
J = the torsional constant
K_z = the effective length factor for torsional buckling

The warping constant C_w and the torsional constant J are tabulated for various steel shapes in the AISC-LRFD manual [AISC, 2001]. Equations for calculating approximate values for these constants for some commonly used steel shapes are shown in Table 48.5.

Flexural–torsional buckling (with a width–thickness ratio of $\leq \lambda_r$):
Same as for torsional buckling, except F_e is now given by:

For singly symmetric sections:

$$F_e = \frac{F_{es} + F_{ez}}{2H}\left[1 - \sqrt{1 - \frac{4\, F_{es}\, F_{ez}\, H}{(F_{es} + F_{ez})^2}}\right] \tag{48.20}$$

where $F_{es} = F_{ex}$ if the x axis is the axis of symmetry of the cross section, or $= F_{ey}$ if the y axis is the axis of symmetry of the cross section
$F_{ex} = \pi^2 E/(Kl/r)_x^2$; $F_{ey} = \pi^2 E/(Kl/r)_x^2$
$H = 1 - (x_o^2 + y_o^2)/r_o^2$, in which K_x and K_y are the effective length factors for buckling about the x and y axes, respectively
l = the unbraced member length in the plane of buckling
r_x and r_y = the radii of gyration about the x and y axes, respectively
x_o and y_o = the shear center coordinates with respect to the centroid (Fig. 48.7), $r_o^2 = x_o^2 + y_o^2 + r_x^2 + r_y^2$.

Numerical values for r_o and H are given for hot-rolled W, channel, tee, single-angle, and double-angle sections in the AISC-LRFD manual [AISC, 2001].

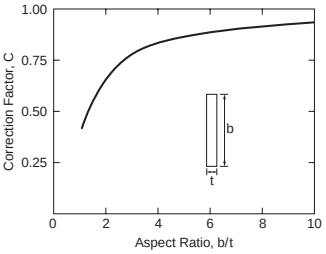
For unsymmetric sections:
F_e is to be solved from the cubic equation

$$(F_e - F_{ex})(F_e - F_{ey})(F_e - F_{ez}) - F_e^2 (F_e - F_{ey})\left(\frac{x_o}{r_o}\right)^2 - F_e^2 (F_e - F_{ex})\left(\frac{y_o}{r_o}\right)^2 = 0 \tag{48.21}$$

The terms in the above equations are defined the same as in Eq. (48.20).

TABLE 48.5 Approximate Equations for C_w and J

Structural Shape	Warping Constant, C_w	Torsional Constant, J
I	$h'^2 I_c I_t/(I_c+I_t)$	$\sum C_i(b_i t_i^3/3)$[a]
C	$(b' - 3E_o)h'^2 b'^2 t_f/6 + E_o^2 I_x$	
	where	b_i/t_i C_i
		1.00 0.423
	$E_o = b'^2\, t_f/(2b't_f + h't_w/3)$	1.20 0.500
T	$(b_f^3\, t_f^3/4 + h''^3 t_w^3)/36$	1.50 0.588
	($\approx$0 for small t)	1.75 0.642
L	$(l_1^3 t_1^3 + l_2^3 t_2^3)/36$	2.00 0.687
	($\approx$0 for small t)	2.50 0.747
		3.00 0.789
		4.00 0.843
		5.00 0.873
		6.00 0.894
		8.00 0.921
		10.00 0.936
		∞ 1.000



Note:

b' = distance measured from toe of flange to centerline of web
h' = distance between centerlines of flanges
h'' = distance from centerline of flange to tip of stem
l_1, l_2 = length of the legs of the angle
t_1, t_2 = thickness of the legs of the angle
b_f = flange width
t_f = average thickness of flange
t_w = thickness of web
I_c = moment of inertia of compression flange taken about the axis of the web
I_t = moment of inertia of tension flange taken about the axis of the web
I_x = moment of inertia of the cross section taken about the major principal axis

[a] b_i = width of component element i, t_i = thickness of component element i, C_i = correction factor for component element i.

Local buckling (with a width–thickness ratio of $\geq \lambda_r$):

Local buckling in the component element of the cross section is accounted for in design by introducing a reduction factor Q in Eq. (48.17) as follows:

$$\phi_c P_n = \begin{cases} 0.85\left[A_g Q\left(0.658^{Q\lambda^2}\right)F_y\right], & \text{if } \lambda\sqrt{Q} \leq 1.5 \\ 0.85\left[A_g\left(\dfrac{0.877}{\lambda^2}\right)F_y\right], & \text{if } \lambda\sqrt{Q} > 1.5 \end{cases} \tag{48.22}$$

where $\lambda = \lambda_c$ for flexural buckling and $\lambda = \lambda_e$ for flexural–torsional buckling.

The Q factor is given by

$$Q = Q_s Q_a \tag{48.23}$$

where Q_s = the reduction factor for unstiffened compression elements of the cross section (see Table 48.6)
Q_a = the reduction factor for stiffened compression elements of the cross section (see Table 48.7).

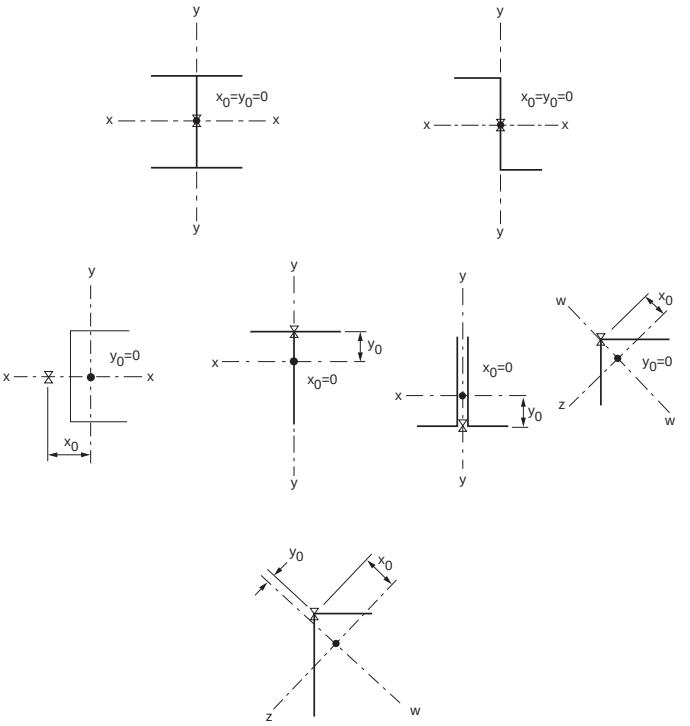


FIGURE 48.7 Location of shear center for selected cross sections.

TABLE 48.6 Formulas for Q_s

Structural Element	Range of b/t	Q_s
Single angles	$0.45\sqrt{(E/F_y)} < b/t < 0.91\sqrt{(E/F_y)}$ $b/t \geq 0.91\sqrt{(E/F_y)}$	$1.340 - 0.76(b/t)\sqrt{(F_y/E)}$ $0.53E/[F_y(b/t)^2]$
Flanges, angles, and plates projecting from columns or other compression members	$0.56\sqrt{(E/F_y)} < b/t < 1.03\sqrt{(E/F_y)}$ $b/t \geq 1.03\sqrt{(E/F_y)}$	$1.415 - 0.74(b/t)\sqrt{(F_y/E)}$ $0.69E/[F_y(b/t)^2]$
Flanges, angles, and plates projecting from built-up columns or other compression members	$0.64\sqrt{(E/(F_y/k_c))} < b/t < 1.17\sqrt{[(E/(F_y/k_c)]}$ $b/t \geq 1.17\sqrt{[E/(F_y/k_c)]}$	$1.415 - 0.65(b/t)\sqrt{(F_y/k_cE)}$ $0.90E\,k_c/[F_y(b/t)^2]$
Stems of tees	$0.75\sqrt{E/F_y)} < d/t < 1.03\sqrt{(E/F_y)}$ $d/t \geq 1.03\sqrt{(E/F_y)}$	$1.908 - 1.22(d/t)\sqrt{(F_y/E)}$ $0.69E/[F_y(b/t)^2]$

Note: k_c is defined in the footnote of Table 48.4, E = modulus of elasticity, F_y = specified minimum yield stress, b = width of the component element, d = depth of tee sections, t = thickness of the component element.

TABLE 48.7 Formula for Q_a

$$Q_s = \frac{\textit{effective area}}{\textit{actual area}}$$

The effective area is equal to the summation of the effective areas of the stiffened elements of the cross section. The effective area of a stiffened element is equal to the product of its thickness, t, and its effective width, b_e, given by

For flanges of square and rectangular sections of uniform thickness, when $b/t \geq 1.40\sqrt{(E/f)}$[a]:

$$b_e = 1.91t\sqrt{\frac{E}{f}}\left[1 - \frac{0.38}{(b/t)}\sqrt{\frac{E}{f}}\right] \leq b$$

For other noncircular uniformly compressed elements, when $b/t \geq 1.49\sqrt{(E/f)}$[a]:

$$b_e = 1.91t\sqrt{\frac{E}{f}}\left[1 - \frac{0.34}{(b/t)}\sqrt{\frac{E}{f}}\right] \leq b$$

For axially loaded circular sections with $0.11E/F_y < D/t < 0.45E/F_y$:

$$Q_a = \frac{0.038E}{F_y(D/t)} + \frac{2}{3}$$

Note: b = actual width of the stiffened element, t = wall thickness, E = modulus of elasticity, f = computed elastic compressive stress in the stiffened elements, D = outside diameter of circular sections.

[a] $b_e = b$ otherwise.

Built-up Compression Members

Built-up members are members made by bolting or welding together two or more standard structural shapes. For a built-up member to be fully effective (i.e., if all component structural shapes are to act as one unit, rather than as individual units), the following conditions must be satisfied:

1. Slippage of component elements near the ends of the built-up member must be prevented.
2. Adequate fasteners must be provided along the length of the member.
3. The fasteners must be able to provide sufficient gripping force on all component elements.

Condition 1 is satisfied if all component elements in contact near the ends of the built-up member are connected by a weld having a length not less than the maximum width of the member or by bolts spaced longitudinally not more than four diameters apart for a distance equal to one and a half times the maximum width of the member. Condition 2 is satisfied if continuous welds are used throughout the length of the built-up compression member. Condition 3 is satisfied if either welds or fully tightened bolts are used as the fasteners. Although condition 1 is mandatory, conditions 2 and 3 can be violated in design. If condition 2 or condition 3 is violated, the built-up member is not fully effective and slight slippage among component elements may occur. To account for the decrease in capacity due to slippage, a modified slenderness ratio is used to compute the design compressive strength when buckling of the built-up member is about an axis *coinciding* or *parallel* to at least one plane of contact for the component shapes. The modified slenderness ratio $(Kl/r)_m$ is given as follows:

If condition 2 is violated:

$$\left(\frac{KL}{r}\right)_m = \sqrt{\left(\frac{KL}{r}\right)_o^2 + \frac{0.82\,\alpha^2}{(1 + \alpha^2)}\left(\frac{a}{r_{ib}}\right)^2} \tag{48.24}$$

If condition 3 is violated:

$$\left(\frac{KL}{r}\right)_m = \sqrt{\left(\frac{KL}{r}\right)_o^2 + \left(\frac{a}{r_i}\right)^2} \tag{48.25}$$

In the above equations, $(Kl/r)_o = (Kl/r)_x$ if the buckling axis is the x axis and at least one plane of contact between component elements is parallel to that axis; $(Kl/r)_o = (Kl/r)_y$ if the buckling axis is the y axis and at least one plane of contact is parallel to that axis. a is the longitudinal spacing of the fasteners, r_i is the minimum radius of gyration of any component element of the built-up cross section, r_{ib} is the radius of gyration of an individual component relative to its centroidal axis parallel to the axis of buckling of the member, and h is the distance between centroids of component elements measured perpendicularly to the buckling axis of the built-up member.

No modification to (Kl/r) is necessary if the buckling axis is perpendicular to the planes of contact of the component shapes. Modifications to both $(Kl/r)_x$ and $(Kl/r)_y$ are required if the built-up member is so constructed that planes of contact exist in both the x and y directions of the cross section.

Once the modified slenderness ratio is computed, it is to be used in the appropriate equation to calculate F_a in allowable stress design or $\phi_c P_n$ in load and resistance factor design.

An additional requirement for the design of built-up members is that the effective slenderness ratio, Ka/r_i, of each component element, where K is the effective length factor of the component element between adjacent fasteners, does not exceed three fourths of the governing slenderness ratio of the built-up member. This provision is provided to prevent component element buckling between adjacent fasteners from occurring prior to overall buckling of the built-up member.

Example 48.2

Using LRFD, determine the size of a pair of cover plates to be bolted, using fully tightened bolts, to the flanges of a W24×229 section as shown in Fig. 48.8, so that its design strength, $\phi_c P_n$, will be increased by 20%. Also determine the spacing of the bolts along the longitudinal axis of the built-up column. The effective lengths of the section about the major $(KL)_x$ and minor $(KL)_y$ axes are both equal to 20 feet. A992 steel is to be used.

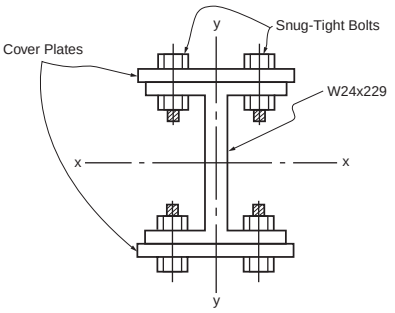

FIGURE 48.8 Design of cover plates for a compression member.

Determine design strength for the W24×229 section:
Since $(KL)_x = (KL)_y$ and $r_x > r_y$, $(KL/r)_y$ will exceed $(KL/r)_x$ and the design strength will be controlled by flexural buckling about the minor axis. Using section properties, $r_y = 3.11$ in. and $A = 67.2$ in.^{2}, obtained from the AISC-LRFD manual [AISC, 2001], the slenderness parameter λ_c about the minor axis can be calculated as follows:

$$(\lambda_c)_y = \frac{1}{\pi}\left(\frac{KL}{r}\right)_y \sqrt{\frac{F_y}{E}} = \frac{1}{3.142}\left(\frac{20\times 12}{3.11}\right)\sqrt{\frac{50}{29{,}000}} = 1.02$$

Substituting $\lambda_c = 1.02$ into Eq. (48.17), the design strength of the section is

$$\phi_c P_n = 0.85\left[67.2\left(0.658^{1.02^2}\right)50\right] = 1848 \text{ kips}$$

Determine design strength for the built-up section:
The built-up section is expected to possess a design strength that is 20% in excess of the design strength of the W24×229 section, so

$$\left(\phi_c\ P_n\right)_{r'eqd} = (1.20)(1848) = 2218 \text{ kips}$$

Determine size of the cover plates:
After cover plates are added, the resulting section is still doubly symmetric. Therefore, the overall failure mode is still flexural buckling. For flexural buckling about the minor axis (y-y), no modification to (KL/r) is required, since the buckling axis is perpendicular to the plane of contact of the component shapes, so no relative movement between the adjoining parts is expected. However, for flexural buckling about the major (x-x) axis, modification to (KL/r) is required, since the buckling axis is parallel to the plane of contact of the adjoining structural shapes and slippage between the component pieces will occur. We shall design the cover plates assuming flexural buckling about the minor axis will control and check for flexural buckling about the major axis later.

A W24×229 section has a flange width of 13.11 in.; so, as a trial, use cover plates with widths of 14 in., as shown in Fig. 48.8. Denoting t as the thickness of the plates, we have

$$\left(r_y\right)_{built\text{-}up} = \sqrt{\frac{\left(I_y\right)_{W\text{-}shape} + \left(I_y\right)_{plates}}{A_{W\text{-}shape} + A_{plates}}} = \sqrt{\frac{651 + 457.3t}{67.2 + 28t}}$$

and

$$\left(\lambda_c\right)_{y,built\text{-}up} = \frac{1}{\pi}\left(\frac{KL}{r}\right)_{y,built\text{-}up}\sqrt{\frac{F_y}{E}} = 3.17\sqrt{\frac{67.2 + 28t}{651 + 457.3t}}$$

Assuming $(\lambda)_{y,built\text{-}up}$ is less than 1.5, one can substitute the above expression for λ_c in Eq. (48.17). With $\phi_c P_n$ equals 2218, we can solve for t. The result is $t \approx 3/8$ in. Backsubstituting t = 3/8 into the above expression, we obtain $(\lambda)_{c,built\text{-}up} = 0.975$, which is indeed <1.5. So, try 14 × 3/8 in. cover plates.

Check for local buckling:
For the I section:

$$\textit{Flange:}\quad \left[\frac{b_f}{2\,t_f} = 3.8\right] < \left[0.56\sqrt{\frac{E}{F_y}} = 0.56\sqrt{\frac{29{,}000}{50}} = 13.5\right]$$

$$\textit{Web:}\quad \left[\frac{h_c}{t_w} = 22.5\right] < \left[1.49\sqrt{\frac{E}{F_y}} = 1.49\sqrt{\frac{29{,}000}{50}} = 35.9\right]$$

For the cover plates, if 3/4-in. diameter bolts are used and assuming an edge distance of 2 in., the width of the plate between fasteners will be 13.11 – 4 = 9.11 in. Therefore, we have

$$\left[\frac{b}{t} = \frac{9.11}{3/8} = 24.3\right] < \left[1.40\sqrt{\frac{E}{F_y}} = 1.40\sqrt{\frac{29{,}000}{50}} = 33.7\right]$$

Since the width–thickness ratios of all component shapes do not exceed the limiting width–thickness ratio for local buckling, local buckling is not a concern.

Check for flexural buckling about the major (x-x) axis:

Since the built-up section is doubly symmetric, the governing buckling mode will be flexural buckling regardless of the axes. Flexural buckling will occur about the major axis if the modified slenderness ratio $(KL/r)_m$ about the major axis exceeds $(KL/r)_y$. Therefore, as long as $(KL/r)_m$ is less than $(KL/r)_y$, buckling will occur about the minor axis and flexural buckling about the major axis will not control. In order to arrive at an optimal design, we shall determine the longitudinal fastener spacing, a, such that the modified slenderness ratio $(KL/r)_m$ about the major axis will be equal to $(KL/r)_y$. That is, we shall solve for a from the equation

$$\left[\left(\frac{KL}{r}\right)_m = \sqrt{\left(\frac{KL}{r}\right)_x^2 + \left(\frac{a}{r_i}\right)^2}\right] = \left[\left(\frac{KL}{r}\right)_y = 73.8\right]$$

In the above equation, $(KL/r)_x$ is the slenderness ratio about the major axis of the built-up section and r_i is the least radius of gyration of the component shapes, which in this case is the cover plate.

Substituting $(KL/r)_x = 21.7$ and $r_i = r_{cover\ plate} = \sqrt{(I/A)_{cover\ plate}} = \sqrt{[(3/8)^2/12]} = 0.108$ into the above equation, we obtain $a = 7.62$ in. Since $(KL) = 20$ ft, we shall use $a = 6$ in. for the longitudinal spacing of the fasteners.

Check for component element buckling between adjacent fasteners:

$$\left[\frac{Ka}{r_i} = \frac{1 \times 6}{0.108} = 55.6\right] \approx \left[\frac{3}{4}\left(\frac{KL}{r}\right)_y = \frac{3}{4}\left(73.8\right) = 55.4\right]$$

so the component element buckling criterion is not a concern.

Use 14 × 3/8 in. cover plates bolted to the flanges of the W24×229 section by 3/4-in.-diameter fully tightened bolts spaced 6 in. longitudinally.

Column Bracing

The design strength of a column can be increased if lateral braces are provided at intermediate points along its length in the buckled direction of the column. The AISC-LRFD specification [AISC, 1999] identifies two types of bracing systems for columns. A relative bracing system is one in which the movement of a braced point with respect to other adjacent braced points is controlled, e.g., the diagonal braces used in buildings. A nodal (or discrete) brace system is one in which the movement of a braced point with respect to some fixed point is controlled, e.g., the guy wires of guyed towers. A bracing system is effective only if the braces are designed to satisfy both stiffness and strength requirements. The following equations give the required stiffness and strength for the two bracing systems:

Required braced stiffness:

$$\beta_{cr} = \begin{cases} \dfrac{2P_u}{\phi L_{br}} & \text{for relative bracing} \\ \dfrac{8P_u}{\phi L_{br}} & \text{for nodal bracing} \end{cases} \tag{48.26}$$

where $\phi = 0.75$

P_u = the required compression strength of the column

L_{br} = the distance between braces

If L_{br} is less than L_q (the maximum unbraced length for P_u), L_{br} can be replaced by L_q in the above equations.

Required braced strength:

$$P_{br} = \begin{cases} 0.004P_u & \text{for relative bracing} \\ 0.01P_u & \text{for nodal bracing} \end{cases} \tag{48.27}$$

where P_u is defined as in Eq. (48.26).

48.5 Flexural Members

Depending on the width–thickness ratios of the component elements, steel sections used as *flexural members* are classified as compact, noncompact, and slender element sections. Compact sections are sections that can develop the cross section plastic moment (M_p) under flexure and sustain that moment through a large hinge rotation without fracture. Noncompact sections are sections that either cannot develop the cross section full plastic strength or cannot sustain a large hinge rotation at M_p, probably due to local buckling of the flanges or web. Slender elements are sections that fail by local buckling of component elements long before M_p is reached. A section is considered compact if all its component elements have width–thickness ratios less than a limiting value (denoted as λ_p in LRFD). A section is considered noncompact if one or more of its component elements have width–thickness ratios that fall in between λ_p and λ_y. A section is considered a slender element if one or more of its component elements have width–thickness ratios that exceed λ_r. Expressions for λ_p and λ_r are given in the Table 48.8.

In addition to the compactness of the steel section, another important consideration for beam design is the lateral unsupported (unbraced) length of the member. For beams bent about their strong axes, the failure modes, or limit states, vary depending on the number and spacing of lateral supports provided to brace the compression flange of the beam. The compression flange of a beam behaves somewhat like a compression member. It buckles if adequate lateral supports are not provided in a phenomenon called *lateral torsional buckling*. Lateral torsional buckling may or may not be accompanied by yielding, depending on the lateral unsupported length of the beam. Thus, lateral torsional buckling can be inelastic or elastic. If the lateral unsupported length is large, the limit state is elastic lateral torsional buckling. If the lateral unsupported length is smaller, the limit state is inelastic lateral torsional buckling. For compact section beams with adequate lateral supports, the limit state is full yielding of the cross section (i.e., plastic hinge formation). For noncompact section beams with adequate lateral supports, the limit state is flange or web local buckling. For beams bent about their weak axes, lateral torsional buckling will not occur, so the lateral unsupported length has no bearing on the design. The limit states for such beams will be formation of a plastic hinge if the section is compact and flange or web local buckling if the section is noncompact.

Beams subjected to high shear must be checked for possible web shear failure. Depending on the width–thickness ratio of the web, failure by shear yielding or web shear buckling may occur. Short, deep beams with thin webs are particularly susceptible to web shear failure. If web shear is of concern, the use of thicker webs or web reinforcements such as stiffeners is required.

Beams subjected to concentrated loads applied in the plane of the web must be checked for a variety of possible flange and web failures. Failure modes associated with concentrated loads include local flange bending (for a tensile concentrated load), local web yielding (for a compressive concentrated load), web crippling (for a compressive load), sidesway web buckling (for a compressive load), and compression buckling of the web (for a compressive load pair). If one or more of these conditions is critical, transverse stiffeners extending at least one half of the beam depth (use full depth for compressive buckling of the web) must be provided adjacent to the concentrated loads.

TABLE 48.8 λ_p and λ_r for Members under Flexural Compression

Component Element	Width–Thickness Ratio[a]	λ_p	λ_r
Flanges of I-shaped rolled beams and channels	b/t	$0.38\sqrt{(E/F_y)}$	$0.83\sqrt{(E/F_L)}$[b]
Flanges of I-shaped hybrid or welded beams	b/t	$0.38\sqrt{(E/F_{yf})}$ for nonseismic application $0.31\sqrt{(E/F_{yf})}$ for seismic application	$0.95\sqrt{[E/(F_L/k_c)]}$[c]
Flanges of square and rectangular box and hollow structural sections of uniform thickness; flange cover plates and diaphragm plates between lines of fasteners or welds	b/t	$0.939\sqrt{(E/F_y)}$ for plastic analysis	$1.40/\sqrt{(E/F_y)}$
Unsupported width of cover plates perforated with a succession of access holes	b/t	NA	$1.86\sqrt{(E/F_y)}$
Legs of single-angle struts; legs of double-angle struts with separators; unstiffened elements	b/t	NA	$0.45/\sqrt{(E/F_y)}$
Stems of tees	d/t	NA	$0.75\sqrt{(E/F_y)}$
Webs in flexural compression	h_c/t_w	$3.76\sqrt{(E/F_y)}$ for nonseismic application $3.05\sqrt{(E/F_y)}$ for seismic application	$5.70\sqrt{(E/F_y)}$[d]
Webs in combined flexural and axial compression	h_c/t_w	For $P_u/\phi_b P_y \le 0.125$: $3.76(1 - 2.75P_u/\phi_b P_y)\sqrt{(E/F_y)}$ for nonseismic application $3.05(1 - 1.54P_u/\phi_b P_y)\sqrt{(E/F_y)}$ for seismic application For $P_u/\phi_b P_y > 0.125$: $1.12(2.33 - P_u/\phi_b P_y)\sqrt{(E/F_y)} \ge 1.49\sqrt{(E/F_y)}$	$5.70(1 - 0.74P_u/\phi_b P_y)\sqrt{(E/F_y)}$
Circular hollow sections	D/t	$0.07E/F_y$	$0.31E/F_y$

Note: NA = not applicable, E = modulus of elasticity, F_y = minimum specified yield strength, F_L = smaller of $(F_{yf} - F_r)$ or F_{yw}, F_{yf} = flange yield strength, F_{yw} = web yield strength, F_r = flange compressive residual stress (10 ksi for rolled shapes, 16.5 ksi for welded shapes), k_c is as defined in the footnote of Table 48.4, $\phi_b = 0.90$, P_u = factored axial force, $P_y = A_g F_y$, D = outside diameter, t = wall thickness.

[a] See Fig. 48.5 for definitions of b, h_c, and t.

[b] For ASD, this limit is $0.56\sqrt{(E/F_y)}$.

[c] For ASD, this limit is $0.56\sqrt{E/(F_{yf}/k_c)}$, where $k_c = 4.05/(h/t)^{0.46}$ if $h/t > 70$; otherwise, $k_c = 1.0$.

[d] For ASD, this limit is $4.46\sqrt{(E/F_b)}$; F_b = allowable bending stress.

Long beams can have deflections that may be too excessive, leading to problems in serviceability. If deflection is excessive, the use of intermediate supports or beams with higher flexural rigidity is required.

The design of flexural members should satisfy, at the minimum, the following criteria: (1) flexural strength criterion, (2) shear strength criterion, (3) criteria for concentrated loads, and (4) deflection criterion. To facilitate beam design, a number of beam tables and charts are given in the AISC manuals [AISC, 1989, 2001] for both allowable stress and load and resistance factor design.

Flexural Member Design

Allowable Stress Design

Flexural Strength Criterion

The computed flexural stress, f_b, shall not exceed the allowable flexural stress, F_b, given as follows. In all equations, the minimum specified yield stress, F_y, can not exceed 65 ksi.

Compact-Section Members Bent about Their Major Axes — For $L_b \le L_c$,

$$F_b = 0.66\, F_y \tag{48.28}$$

where L_c is the smaller of $\{76b_f/\sqrt{F_y},\ 20{,}000/(d/A_f)F_y\}$ for I and channel shapes and equal to $[1950 + 1200(M_1/M_2)](b/F_y) \ge 1200(b/F_y)$ for box sections and rectangular and circular tubes in which b_f is the flange width (in.), d is the overall depth of section (ksi), A_f is the area of compression flange (in.^{2}), b is the width of cross section (in.), and M_1/M_2 is the ratio of the smaller to larger moments at the ends of the unbraced length of the beam (M_1/M_2 is positive for reverse curvature bending and negative for single curvature bending).

For the above sections to be considered as compact, in addition to having the width–thickness ratios of their component elements falling within the limiting value of λ_p, shown in Table 48.8, the flanges of the sections must be continuously connected to the webs. For box-shaped sections, the following requirements must also be satisfied: the depth-to-width ratio should not exceed 6 and the flange-to-web thickness ratio should not exceed 2.

For $L_b > L_c$, the allowable flexural stress in tension is given by

$$F_b = 0.60F_y \tag{48.29}$$

and the allowable flexural stress in compression is given by the larger value calculated from Eqs. (48.30) and (48.31). Equation (48.30) normally controls for deep, thin-flanged sections where warping restraint torsional resistance dominates, and Eq. (48.31) normally controls for shallow, thick-flanged sections where St. Venant torsional resistance dominates.

$$F_b = \begin{cases} \left[\dfrac{2}{3} - \dfrac{F_y\left(l/r_T\right)^2}{1530\times 10^3\, C_b}\right] F_y \le 0.60\, F_y, \ \text{if } \sqrt{\dfrac{102{,}000\, C_b}{F_y}} \le \dfrac{l}{r_T} < \sqrt{\dfrac{510{,}000\, C_b}{F_y}} \\ \dfrac{170{,}000\, C_b}{\left(l/r_T\right)^2} \le 0.60F_y, \ \text{if } \dfrac{l}{r_T} \ge \sqrt{\dfrac{510{,}000C_b}{F_y}} \end{cases} \tag{48.30}$$

$$F_b = \frac{12{,}000C_b}{ld/A_f} \le 0.60\, F_y \tag{48.31}$$

where l = the distance between cross sections braced against twist or lateral displacement of the compression flange (in.)

r_T = the radius of gyration of a section comprising the compression flange plus one third of the compression web area, taken about an axis in the plane of the web (in.)

A_f = the compression flange area (in.^{2})

d = the depth of cross section (in.)

$C_b = 12.5M_{max}/(2.5M_{max} + 3M_A + 4M_B + 3M_C)$

M_{max}, M_A, M_B, and M_C = the absolute values of the maximum moment, quarter-point moment, midpoint moment, and three-quarter point moment, respectively, along the unbraced length of the member.

(For simplicity in design, C_b can conservatively be taken as unity.)

It should be cautioned that Eqs. (48.30) and (48.31) are applicable only to I and channel shapes with an axis of symmetry in and loaded in the plane of the web. In addition, Eq. (48.31) is applicable only if the compression flange is solid and approximately rectangular in shape, and its area is not less than the tension flange.

Compact Section Members Bent about Their Minor Axes — Since lateral torsional buckling will not occur for bending about the minor axes, regardless of the value of L_b, the allowable flexural stress is

$$F_b = 0.75F_y \tag{48.32}$$

Noncompact Section Members Bent about Their Major Axes — For $L_b \le L_c$,

$$F_b = 0.60F_y \tag{48.33}$$

where L_c is defined as in Eq. (48.28).

For $L_b > L_c$, F_b is given in Eqs. (48.29) to (48.31).

Noncompact Section Members Bent about Their Minor Axes — Regardless of the value of L_b,

$$F_b = 0.60F_y \tag{48.34}$$

Slender Element Sections — Refer to the Section 48.10.

Shear Strength Criterion

For practically all structural shapes commonly used in constructions, the shear resistance from the flanges is small compared to the webs. As a result, the shear resistance for flexural members is normally determined on the basis of the webs only. The amount of web shear resistance is dependent on the width–thickness ratio h/t_w of the webs. If h/t_w is small, the failure mode is web yielding. If h/t_w is large, the failure mode is web buckling. To avoid web shear failure, the computed shear stress, f_v, shall not exceed the allowable shear stress, F_v, given by

$$F_v = \begin{cases} 0.40\,F_y & \text{if } \dfrac{h}{t_w} \le \dfrac{380}{\sqrt{F_y}} \\ \dfrac{C_v}{2.89}\,F_y \le 0.40\,F_y & \text{if } \dfrac{h}{t_w} > \dfrac{380}{\sqrt{F_y}} \end{cases} \tag{48.35}$$

where $C_v = 45{,}000k_v/[F_y(h/t_w)^2]$ if $C_v \le 0.8$ and $[190/(h/t_w)]\sqrt{(k_v/F_y)}$ if $C_v > 0.8$
$k_v = 4.00 + 5.34/(a/h)^2$ if $a/h \le 1.0$ and $5.34 + 4.00/(a/h)^2$ if $a/h > 1.0$
t_w = the web thickness (in.)
a = the clear distance between transverse stiffeners (in.)
h = the clear distance between flanges at the section under investigation (in.)

Criteria for Concentrated Loads

Local Flange Bending — If the concentrated force that acts on the beam flange is tensile, the beam flange may experience excessive bending, leading to failure by fracture. To preclude this type of failure, transverse stiffeners are to be provided opposite the tension flange, unless the length of the load when measured across the beam flange is less than 0.15 times the flange width, or if the flange thickness, t_f, exceeds

$$0.4\sqrt{\frac{P_{bf}}{F_y}} \tag{48.36}$$

where P_{bf} = the computed tensile force multiplied by 5/3 if the force is due to live and dead loads only or by 4/3 if the force is due to live and dead loads in conjunction with wind or earthquake loads (kips)
F_y = the specified minimum yield stress (ksi).

Local Web Yielding — To prevent local web yielding, the concentrated compressive force, R, should not exceed $0.66R_n$, where R_n is the web yielding resistance given in Eq. (48.54) or (48.55), whichever applies.

Web Crippling — To prevent web crippling, the concentrated compressive force, R, should not exceed $0.50R_n$, where R_n is the web crippling resistance given in Eq. (48.56), (48.57), or (48.58), whichever applies.

Sidesway Web Buckling — To prevent sidesway web buckling, the concentrated compressive force, R, should not exceed R_n, where R_n is the sidesway web buckling resistance given in Eq. (48.59) or (48.60), whichever applies, except the term $C_r t_w^3 t_f/h^2$ is replaced by 6,800 t_w^3/h.

Compression Buckling of the Web — When the web is subjected to a pair of concentrated forces acting on both flanges, buckling of the web may occur if the web depth clear of fillet, d_c, is greater than

$$\frac{4100\, t_w^3 \sqrt{F_y}}{P_{bf}} \tag{48.37}$$

where t_w = the web thickness
F_y = the minimum specified yield stress
P_{bf} = as defined in Eq. (48.36)

Deflection Criterion

Deflection is a serviceability consideration. Since most beams are fabricated with a camber that somewhat offsets the dead load deflection, consideration is often given to deflection due to live load only. For beams supporting plastered ceilings, the service live load deflection preferably should not exceed $L/360$, where L is the beam span. A larger deflection limit can be used if due considerations are given to ensure the proper functioning of the structure.

Example 48.3

Using ASD, determine the amount of increase in flexural capacity of a W24×55 section bent about its major axis if two 7 × 1/2 in. (178 × 13 mm) cover plates are bolted to its flanges, as shown in Fig. 48.9. The beam is laterally supported at every 5-ft (1.52-m) interval. Use A36 steel. Specify the type, diameter, and longitudinal spacing of the bolts used if the maximum shear to be resisted by the cross section is 100 kips (445 kN).

Section properties:

A W24×55 section has the following section properties: b_f = 7.005 in., t_f = 0.505 in., d = 23.57 in., t_w = 0.395 in., I_x = 1350 in.^{4}, and S_x = 114 in.^{3}

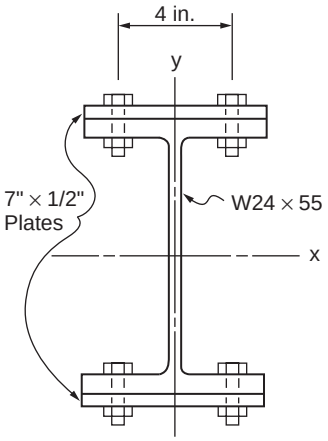

FIGURE 48.9 Beam section with cover plates.

Check compactness:
Refer to Table 48.8; assuming that the transverse distance between the two bolt lines is 4 in., we have

$$\textit{Beam flanges} \quad \left[\frac{b_f}{2\,t_f} = 6.94\right] < \left[0.38\sqrt{\frac{E}{F_y}} = 10.8\right]$$

$$\textit{Beam web} \quad \left[\frac{d}{t_w} = 59.7\right] < \left[3.76\sqrt{\frac{E}{F_y}} = 107\right]$$

$$\textit{Cover plates} \quad \left[\frac{4}{1/2} = 8\right] < \left[0.939\sqrt{\frac{E}{F_y}} = 26.7\right]$$

Therefore, the section is compact.

Determine the allowable flexural stress, F_b:
Since the section is compact and the lateral unbraced length, $L_b = 60$ in., is less than $L_c = 83.4$ in., the allowable bending stress from Eq. (48.28) is $0.66F_y = 24$ ksi.

Determine section modulus of the beam with cover plates:

$$S_{x,\,\textit{combination section}} = \frac{I_{x,\,\textit{combination section}}}{c} = \frac{1350 + 2\left[\left(\frac{1}{12}\right)(7)(1/2)^3 + (7)(1/2)(12.035)^2\right]}{\left(\frac{23.57}{2} + \frac{1}{2}\right)} = 192 \text{ in}^3$$

Determine flexural capacity of the beam with cover plates:

$$M_{x,\,\textit{combination section}} = S_{x,\,\textit{combination section}} F_b = (192)(24) = 4608 \text{ k-in}$$

Since the flexural capacity of the beam without cover plates is

$$M_x = S_x F_b = (114)(24) = 2736 \text{ k-in}$$

the increase in flexural capacity is 68.4%.

Determine diameter and longitudinal spacing of bolts:
From Chapter 46, "Mechanics of Materials," the relationship between the shear flow, q, the number of bolts per shear plane, n, the allowable bolt shear stress, F_v, the cross-sectional bolt area, A_b, and the longitudinal bolt spacing, s, at the interface of two component elements of a combination section is given by

$$\frac{n\,F_v\,A_b}{s} = q$$

Substituting $n = 2$ and $q = VQ/I = (100)[(7)(1/2)(12.035)]/2364 = 1.78$ k/in. into the above equation, we have

$$\frac{F_v\,A_b}{s} = 0.9 \text{ k/in.}$$

If 1/2-in.-diameter A325-N bolts are used, we have $A_b = \pi(1/2)^2/4 = 0.196$ in.^{2} and $F_v = 21$ ksi (from Table 48.12), from which s can be solved from the above equation to be 4.57 in. However, for ease of installation, use $s = 4.5$ in.

In calculating the section properties of the combination section, no deduction is made for the bolt holes in the beam flanges or cover plates; this is allowed provided that the following condition is satisfied

$$0.5F_u A_{fn} \geq 0.6 F_y A_{fg}$$

where F_y and F_u = the minimum specified yield strength and tensile strength, respectively
A_{fn} = the net flange area
A_{fg} = the gross flange area. For this problem,

Beam Flanges

$$\left[0.5 F_u A_{fn} = 0.5(58)(7.005 - 2 \times 1/2)(0.505) = 87.9 \text{ kips}\right]$$

$$> \left[0.6 F_y A_{fg} = 0.6(36)(7.005)(0.505) = 76.4 \text{ kips}\right]$$

Cover Plates

$$\left[0.5 F_u A_{fn} = 0.5(58)(7 - 2 - 1/2)(1/2) = 87 \text{ kips}\right]$$

$$> \left[0.6 F_y A_{fg} = 0.6(36)(7)(1/2) = 75.6 \text{ kips}\right]$$

so the use of the gross cross-sectional area to compute section properties is justified. In the event that the condition is violated, cross-sectional properties should be evaluated using an effective tension flange area A_{fe} given by

$$A_{fe} = \frac{5}{6} \frac{F_u}{F_y} A_{fn}$$

So, use 1/2-in.-diameter A325-N bolts spaced 4.5 in. apart longitudinally in two lines 4 in. apart to connect the cover plates to the beam flanges.

Load and Resistance Factor Design

Flexural Strength Criterion

Flexural members must be designed to satisfy the flexural strength criterion of

$$\phi_b M_n \geq M_u \tag{48.38}$$

where $\phi_b M_n$ is the design flexural strength and M_u is the required strength. The design flexural strength is determined as follows:

Compact Section Members Bent about Their Major Axes — For $L_b \leq L_p$ (plastic hinge formation),

$$\phi_b M_n = 0.90 M_p \tag{48.39}$$

For $L_p \leq L_b \leq L_r$ (inelastic lateral torsional buckling),

$$\phi_b M_n = 0.90 C_b \left[M_p - \left(M_p - M_r\right) \left(\frac{L_b - L_p}{L_r - L_p} \right) \right] \leq 0.90 M_p \tag{48.40}$$

For $L_b > L_r$ (elastic lateral torsional buckling),

For I-shaped members and channels:

$$\phi_b M_n = 0.90\, C_b \left[\frac{\pi}{L_b} \sqrt{EI_y GJ + \left(\frac{\pi E}{L_b} \right)^2 I_y C_w} \right] \leq 0.90\, M_p \tag{48.41}$$

For solid rectangular bars and symmetric box sections:

$$\phi_b M_n = 0.90 C_b \frac{57{,}000\sqrt{JA}}{L_b / r_y} \leq 0.90 M_p \tag{48.42}$$

The variables used in the above equations are defined as follows: L_b is the lateral unsupported length of the member and L_p and L_r are the limiting lateral unsupported lengths given in the following table:

Structural Shape	L_p	L_r
I-shaped sections and channels	$1.76 r_y/\sqrt{(E/F_{yf})}$ where r_y = radius of gyration about minor axis E = modulus of elasticity F_{yf} = flange yield strength	$[r_y X_1/F_L]\{\sqrt{[1 + \sqrt{(1 + X_2 F_L^2)}]}\}$ where r_y = radius of gyration about minor axis (in.) $X_1 = (\pi/S_x)\sqrt{(EGJA/2)}$ $X_2 = (4C_w/I_y)(S_x/GJ)^2$ F_L = smaller of $(F_{yf} - F_r)$ or F_{yw} F_{yf} = flange yield stress (ksi) F_{yw} = web yield stress (ksi) F_r = 10 ksi for rolled shapes and 16.5 ksi for welded shapes S_x = elastic section modulus about the major axis (in.^{3}) (use S_{xc}, the elastic section modulus about the major axis with respect to the compression flange if the compression flange is larger than the tension flange) I_y = moment of inertia about the minor axis (in.^{4}) J = torsional constant (in.^{4}) C_w = warping constant (in.^{6}) E = modulus of elasticity (ksi)
Solid rectangular bars and symmetric box sections	$[0.13 r_y E\sqrt{(JA)}]/M_p$ where r_y = radius of gyration about minor axis E = modulus of elasticity J = torsional constant A = cross-sectional area M_p = plastic moment capacity = $F_y Z_x$ F_y = yield stress Z_x = plastic section modulus about the major axis	$[2 r_y E\sqrt{(JA)}]/M_r$ where r_y = radius of gyration about minor axis J = torsional constant A = cross-sectional area $M_r = F_{yf} S_x$ F_y = yield stress F_{yf} = flange yield strength S_x = elastic section modulus about the major axis

Note: The L_p values given in this table are valid only if the bending coefficient C_b is equal to unity. If $C_b > 1$, the value of L_p can be increased. However, using the L_p expressions given above for $C_b > 1$ will give a conservative value for the flexural design strength.

The remaining variables in the above equations are further defined as follows:

$M_p = F_y Z_x$
$M_r = F_L S_x$ for I-shaped sections and channels and $F_{yf} S_x$ for solid rectangular bars and box sections
F_L = the smaller of $(F_{yf} - F_r)$ or F_{yw}
F_{yf} = flange yield stress (ksi)
F_{yw} = web yield stress (ksi)
F_r = 10 ksi for rolled sections and 16.5 ksi for welded sections
F_y = specified minimum yield stress
S_x = elastic section modulus about the major axis
Z_x = plastic section modulus about the major axis
I_y = moment of inertia about the minor axis
J = torsional constant
C_w = warping constant
E = modulus of elasticity
G = shear modulus
$C_b = 12.5M_{max}/(2.5\ M_{max} + 3M_A + 4M_B + 3\ M_C)$
M_{max}, M_A, M_B, and M_C = absolute values of maximum, quarter-point, midpoint, and three-quarter point moments, respectively, along the unbraced length of the member.

C_b is a factor that accounts for the effect of moment gradient on the lateral torsional buckling strength of the beam. The lateral torsional buckling strength increases for a steep moment gradient. The worst loading case as far as lateral torsional buckling is concerned is when the beam is subjected to a uniform moment resulting in single curvature bending. For this case, $C_b = 1$. Therefore, the use of $C_b = 1$ is conservative for the design of beams.

Compact Section Members Bent about Their Minor Axes — Regardless of L_b, the limit state will be plastic hinge formation:

$$\phi_b\ M_n = 0.90\ M_{py} = 0.90\ F_y\ Z_y \tag{48.43}$$

Noncompact Section Members Bent about Their Major Axes — For $L_b \le L_p'$ (flange or web local buckling),

$$\phi_b\ M_n = \phi_b\ M_{n'} = 0.90\left[M_p - \left(M_p - M_r\right)\left(\frac{\lambda - \lambda_p}{\lambda_r - \lambda_p}\right)\right] \tag{48.44}$$

where

$$L_{p'} = L_p + \left(L_r - L_p\right)\left(\frac{M_p - M_{n'}}{M_p - M_r}\right) \tag{48.45}$$

L_p, L_r, M_p, and M_r are defined as before for compact section members.

For flange local buckling, $\lambda = b_f/2t_f$ for I-shaped members and b_f/t_f for channels. λ_p and λ_r are defined in Table 48.8.

For web local buckling, $\lambda = h_c/t_w$. λ_p and λ_r are defined in Table 48.8, in which b_f is the flange width, t_f is the flange thickness, h_c is twice the distance from the neutral axis to the inside face of the compression flange less the fillet or corner radius, and t_w is the web thickness.

For $L_p' < L_b \le L_r$ (inelastic lateral torsional buckling), $\phi_b M_n$ is given by Eq. (48.40), except that the limit $0.90M_p$ is to be replaced by the limit $0.90\ M_n'$.

For $L_b > L_r$ (elastic lateral torsional buckling), $\phi_b M_n$ is the same as for compact section members, as given in Eq. (48.41) or (48.42).

Noncompact Section Members Bent about Their Minor Axes — Regardless of the value of L_b, the limit state will be either flange or web local buckling, and $\phi_b M_n$ is given by Eq. (48.42).

Slender Element Sections — Refer to Section 48.10.

Tees and Double Angles Bent about Their Major Axes — The design flexural strength for tees and double-angle beams with flange and web slenderness ratios less than the corresponding limiting slenderness ratios λ_r shown in Table 48.8 is given by

$$\phi_b M_n = 0.90\left[\frac{\pi\sqrt{EI_y GJ}}{L_b}\left(B+\sqrt{1+B^2}\right)\right] \le 0.90\left(\beta M_y\right) \tag{48.46}$$

where

$$B = \pm 2.3\left(\frac{d}{L_b}\right)\sqrt{\frac{I_y}{J}} \tag{48.47}$$

Use the plus sign for B if the entire length of the stem along the unbraced length of the member is in tension. Otherwise, use the minus sign. β equals 1.5 for stems in tension and 1.0 for stems in compression. The other variables in Eq. (48.46) are defined as before, in Eq. (48.41).

Shear Strength Criterion

For a satisfactory design, the design shear strength of the webs must exceed the factored shear acting on the cross section, i.e.,

$$\phi_v V_n \ge V_u \tag{48.48}$$

Depending on the slenderness ratios of the webs, three limit states can be identified: shear yielding, inelastic shear buckling, and elastic shear buckling. The design shear strengths that correspond to each of these limit states are given as follows:

For $h/t_w \le 2.45\sqrt{(E/F_{yw})}$ (shear yielding of web),

$$\phi_v V_n = 0.90\left[0.60 F_{yw} A_w\right] \tag{48.49}$$

For $2.45\sqrt{(E/F_{yw})} < h/t_w \le 3.07\sqrt{(E/F_{yw})}$ (inelastic shear buckling of web),

$$\phi_v V_n = 0.90\left[0.60 F_{yw} A_w \frac{2.45\sqrt{\left(E/F_{yw}\right)}}{h/t_w}\right] \tag{48.50}$$

For $3.07\sqrt{(E/F_{yw})} < h/t_w \le 260$ (elastic shear buckling of web),

$$\phi_v V_n = 0.90 A_w\left[\frac{4.52E}{\left(h/t_w\right)^2}\right] \tag{48.51}$$

The variables used in the above equations are defined as follows: h is the clear distance between flanges less the fillet or corner radius, t_w is the web thickness, F_{yw} is the yield stress of the web, $A_w = dt_w$, and d is the overall depth of the section.

Criteria for Concentrated Loads

When concentrated loads are applied normal to the flanges in planes parallel to the webs of flexural members, the flanges and webs must be checked to ensure that they have sufficient strengths ϕR_n to withstand the concentrated forces R_u, i.e.,

$$\phi R_n \geq R_u \tag{48.52}$$

The design strengths for a variety of limit states are given below.

Local Flange Bending — The design strength for local flange bending is given by

$$\phi R_n \geq 0.90\left[6.25\, t_f^2\, F_{fy}\right] \tag{48.53}$$

where t_f = the flange thickness of the loaded flange
F_{yf} = the flange yield stress

The design strength in Eq. (48.53) is applicable only if the length of load across the member flange exceeds $0.15b$, where b is the member flange width. If the length of load is less than $0.15b$, the limit state of local flange bending need not be checked. Also, Eq. (48.53) shall be reduced by a factor of half if the concentrated force is applied less than $10t_f$ from the beam end.

Local Web Yielding — The design strengths for yielding of beam web at the toe of the fillet under tensile or compressive loads acting on one or both flanges are as follows:

If the load acts at a distance from the beam end that exceeds the depth of the member,

$$\phi R_n = 1.00\left[(5k+N)F_{yw}t_w\right] \tag{48.54}$$

If the load acts at a distance from the beam end that does not exceed the depth of the member,

$$\phi R_n = 1.00\left[(2.5k+N)\, F_{yw}\, t_w\right] \tag{48.55}$$

where k = the distance from the outer face of the flange to the web toe of fillet
N = the length of bearing on the beam flange
F_{yw} = the web yield stress
t_w = the web thickness

Web Crippling — The design strengths for crippling of the beam web under compressive loads acting on one or both flanges are as follows:

If the load acts at a distance from the beam end that exceeds half the depth of the beam,

$$\phi R_n = 0.75\left\{0.80t_w^2\left[1+3\left(\frac{N}{d}\right)\left(\frac{t_w}{t_f}\right)^{1.5}\right]\sqrt{\frac{EF_{yw}t_f}{t_w}}\right\} \tag{48.56}$$

If the load acts at a distance from the beam end that does not exceed half the depth of the beam and if $N/d \leq 0.2$,

$$\phi R_n = 0.75\left\{0.40\, t_w^2\left[1+3\left(\frac{N}{d}\right)\left(\frac{t_w}{t_f}\right)^{1.5}\right]\sqrt{\frac{EF_{yw}t_f}{t_w}}\right\} \tag{48.57}$$

If the load acts at a distance from the beam end that does not exceed half the depth of the beam and if $N/d > 0.2$,

$$\phi R_n = 0.75\left\{0.40\, t_w^2 \left[1+\left(\frac{4N}{d}-0.2\right)\left(\frac{t_w}{t_f}\right)^{1.5}\right]\sqrt{\frac{EF_{yw}\, t_f}{t_w}}\right\} \tag{48.58}$$

where d is the overall depth of the section and t_f is the flange thickness. The other variables are the same as those defined in Eqs. (48.54) and (48.55).

Side Sway Web Buckling — Side sway web buckling may occur in the web of a member if a compressive concentrated load is applied to a flange not restrained against relative movement by stiffeners or lateral bracings. The side sway web buckling design strength for the member is as follows:

If the loaded flange is restrained against rotation about the longitudinal member axis and $(h/t_w)(l/b_f)$ is less than 2.3,

$$\phi R_n = 0.85\left\{\frac{C_r\, t_w^3\, t_f}{h^2}\left[1+0.4\left(\frac{h/t_w}{l/b_f}\right)^3\right]\right\} \tag{48.59}$$

If the loaded flange is not restrained against rotation about the longitudinal member axis and $(d_c/t_w)(l/b_f)$ is less than 1.7,

$$\phi R_n = 0.85\left\{\frac{C_r\, t_w^3\, t_f}{h^2}\left[0.4\left(\frac{h/t_w}{l/b_f}\right)^3\right]\right\} \tag{48.60}$$

where t_f = the flange thickness (in.)
t_w = the web thickness (in.)
h = the clear distance between flanges less the fillet or corner radius for rolled shapes (the distance between adjacent lines of fasteners or the clear distance between flanges when welds are used for built-up shapes) (in.)
b_f = the flange width (in.)
l = the largest laterally unbraced length along either flange at the point of load (in.)
C_r = 960,000 ksi if $M_u/M_y < 1$ at the point of load or 480,000 ksi if $M_u/M_y \geq 1$ at the point of load (M_y is the yield moment).

Compression Buckling of the Web — This limit state may occur in members with unstiffened webs when both flanges are subjected to compressive forces. The design strength for this limit state is

$$\phi R_n = 0.90\left[\frac{24\, t_w^3\sqrt{EF_{yw}}}{h}\right] \tag{48.61}$$

This design strength shall be reduced by a factor of half if the concentrated forces are acting at a distance less than half the beam depth from the beam end. The variables in Eq. (48.61) are the same as those defined in Eqs. (48.58) to (48.60).

Stiffeners shall be provided in pairs if any one of the above strength criteria is violated. If the local flange bending or the local web yielding criterion is violated, the stiffener pair to be provided to carry the excess R_u need not extend more than one half the web depth. The stiffeners shall be welded to the loaded flange if the applied force is tensile. They shall either bear on or be welded to the loaded flange if the applied force is compressive. If the web crippling or the compression web buckling criterion is violated, the stiffener pair to be provided shall extend the full height of the web. They shall be designed as axially loaded compression members (see Section 48.4) with an effective length factor of $K = 0.75$ and

a cross section A_g composed of the cross-sectional areas of the stiffeners, plus $25t_w^2$ for interior stiffeners and $12t_w^2$ for stiffeners at member ends.

Deflection Criterion

The deflection criterion is the same as that for ASD. Since deflection is a serviceability limit state, service (rather than factored) loads is used in deflection computations.

Continuous Beams

Continuous beams shall be designed in accordance with the criteria for flexural members given in the preceding section. However, a 10% reduction in negative moments due to gravity loads is permitted at the supports provided that:

1. The maximum positive moment between supports is increased by one tenth the average of the negative moments at the supports.
2. The section is compact.
3. The lateral unbraced length does not exceed L_c (for ASD) or L_{pd} (for LRFD),

   where L_c is as defined in Eq. (48.26) and L_{pd} is given by

$$L_{pd} = \begin{cases} \left[0.12 + 0.076\left(\dfrac{M_1}{M_2}\right)\right]\left(\dfrac{E}{F_y}\right) r_y, & \text{for I-shaped members} \\ \left[0.17 + 0.10\left(\dfrac{M_1}{M_2}\right)\right]\left(\dfrac{E}{F_y}\right) r_y \geq 0.10\left(\dfrac{E}{F_y}\right) r_y, & \text{for solid rectangular and box sections} \end{cases} \tag{48.62}$$

   in which F_y is the specified minimum yield stress of the compression flange; M_1/M_2 is the ratio of smaller to larger moments within the unbraced length, taken as positive if the moments cause reverse curvature and negative if the moments cause single curvature; and r_y is the radius of gyration about the minor axis.
4. The beam is not a hybrid member.
5. The beam is not made of high-strength steel.
6. The beam is continuous over the supports (i.e., not cantilevered).

Example 48.4

Using LRFD, select the lightest W section for the three-span continuous beam shown in Fig. 48.10a to support a uniformly distributed dead load of 1.5 k/ft (22 kN/m) and a uniformly distributed live load of 3 k/ft (44 kN/m). The beam is laterally braced at the supports A, B, C, and D. Use A36 steel.

Load combinations:

The beam is to be designed based on the worst load combination of Table 48.3. By inspection, the load combination $1.2D + 1.6L$ will control the design. Thus, the beam will be designed to support a factored uniformly distributed dead load of $1.2 \times 1.5 = 1.8$ k/ft and a factored uniformly distributed live load of $1.6 \times 3 = 4.8$ k/ft.

Placement of loads:

The uniform dead load is to be applied over the entire length of the beam, as shown in Fig. 48.10b. The uniform live load is to be applied to spans AB and CD, as shown in Fig. 48.10c, to obtain the maximum positive moment, and it is to be applied to spans AB and BC, as shown in Fig. 48.10d, to obtain the maximum negative moment.

Reduction of negative moment at supports:

Assuming the beam is compact and $L_b < L_{pd}$ (we shall check these assumptions later), a 10% reduction in support moment due to gravity load is allowed, provided that the maximum moment is increased by

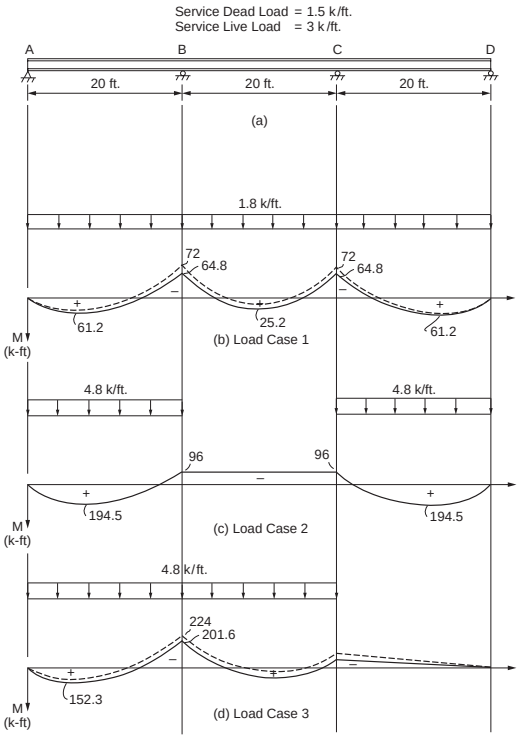

FIGURE 48.10 Design of a three-span continuous beam (1 k = 4.45 kN, 1 ft = 0.305 m).

one tenth the average of the negative support moments. This reduction is shown in the moment diagrams as solid lines in Fig. 48.10b and 48.10d. (The dotted lines in these figure parts represent the unadjusted moment diagrams.) This provision for support moment reduction takes into consideration the beneficial effect of moment redistribution in continuous beams, and it allows for the selection of a lighter section if the design is governed by negative moments. Note that no reduction in negative moments is made to the case when only spans AB and CD are loaded. This is because for this load case the negative support moments are less than the positive in-span moments.

Determination of the required flexural strength, M_u:
Combining load cases 1 and 2, the maximum positive moment is found to be 256 kip-ft. Combining load cases 1 and 3, the maximum negative moment is found to be 266 kip-ft. Thus, the design will be controlled by the negative moment and M_u = 266 kip-ft.

Beam selection:
A beam section is to be selected based on Eq. (48.38). The critical segment of the beam is span AB. For this span, the lateral unsupported length, L_b, is equal to 20 ft. For simplicity, the bending coefficient, C_b, is conservatively taken as 1. The selection of a beam section is facilitated by the use of a series of beam charts contained in the AISC-LRFD manual [AISC, 2001]. Beam charts are plots of flexural design strength $\phi_b M_n$ of beams as a function of the lateral unsupported length L_b, based on Eqs. (48.39) to (48.41). A beam is considered satisfactory for the limit state of flexure if the beam strength curve envelopes the required flexural strength for a given L_b.

For the present example, L_b = 20 ft and M_u = 266 kip-ft; the lightest section (the first solid curve that envelopes M_u = 266 kip-ft for L_b = 20 ft) obtained from the chart is a W16x67 section. Upon adding the factored dead weight of this W16x67 section to the specified loads, the required flexural strength increases from 266 to 269 kip-ft. Nevertheless, the beam strength curve still envelopes this required strength for L_b = 20 ft; therefore, the section is adequate.

Check for compactness:
For the W16×67 section,

$$\textit{Flange:} \quad \left[\frac{b_f}{2\ t_f} = 7.7\right] < \left[0.38\sqrt{\frac{E}{F_y}} = 10.8\right]$$

$$\textit{Web:} \quad \left[\frac{h_c}{t_w} = 35.9\right] < \left[3.76\sqrt{\frac{E}{F_y}} = 106.7\right]$$

Therefore, the section is compact.

Check whether $L_b < L_{pd}$:
Using Eq. (48.62), with $M_1/M_2 = 0$, $r_y = 2.46$ in., and $F_y = 36$ ksi, we have $L_{pd} = 246$ in. (or 20.5 ft). Since $L_b = 20$ ft is less than $L_{pd} = 20.5$ ft, the assumption made earlier is validated.

Check for the limit state of shear:
The selected section must satisfy the shear strength criterion of Eq. (48.48). From structural analysis, it can be shown that maximum shear occurs just to the left of support B under load case 1 (for dead load) and load case 3 (for live load). It has a magnitude of 81.8 kips. For the W16x67 section, $h/t_w = 35.9$, which is less than $2.45\sqrt{(E/F_{yw})} = 69.5$, so the design shear strength is given by Eq. (48.47). We have, for $F_{yw} = 36$ ksi and $A_w = dt_w = (16.33)(0.395)$,

$$\left[\phi_v\ V_n = 0.90\left(0.60\ F_{yw}\ A_w\right) = 125 \text{ kips}\right] > \left[V_u = 81.8 \text{ kips}\right]$$

Therefore, shear is not a concern. Normally, the limit state of shear will not control, unless for short beams subjected to heavy loads.

Check for limit state of deflection:
Deflection is a serviceability limit state. As a result, a designer should use service (not factored) loads for deflection calculations. In addition, most beams are cambered to offset deflection caused by dead loads, so only live loads are considered in deflection calculations. From structural analysis, it can be shown that maximum deflection occurs in spans AB and CD when (service) live loads are placed on those two spans. The magnitude of the deflection is 0.297 in. Assuming the maximum allowable deflection is $L/360$ where L is the span length between supports, we have an allowable deflection of $20 \times 12/360 = 0.667$ in. Since the calculated deflection is less than the allowable deflection, deflection is not a problem.

Check for the limit state of web yielding and web crippling at points of concentrated loads:
From structural analysis, it can be shown that a maximum support reaction occurs at support B when the beam is subjected to the loads shown as load case 1 (for dead load) and load case 3 (for live load). The magnitude of the reaction R_u is 157 kips. Assuming point bearing, i.e., $N = 0$, we have, for $d = 16.33$ in., $k = 1.375$ in., $t_f = 0.665$ in., and $t_w = 0.395$ in.,

$$\textit{Web Yielding:} \quad \left[\phi\ R_n = \text{Eq. } (46.54) = 97.8 \text{ kips}\right] < \left[R_u = 157 \text{ kips}\right]$$

$$\textit{Web Crippling:} \quad \left[\phi\ R_n = \text{Eq. } (46.56) = 123 \text{ kips}\right] < \left[R_u = 157 \text{ kips}\right]$$

Thus, both the web yielding and web crippling criteria are violated. As a result, we need to provide web stiffeners or a bearing plate at support B. Suppose we choose the latter, the size of the bearing plate can be determined by solving Eqs. (48.54) and (48.56) for N using $R_u = 157$ kips. The result is $N = 4.2$ and 3.3 in., respectively. So, use $N = 4.25$ in. The width of the plate, B, should conform with the flange width, b_f, of the W-section. The W16×67 section has a flange width of 10.235 in., so use $B = 10.5$ in. The thickness of the bearing plate is to be calculated from the following equation [AISC, 2001]:

$$t = \sqrt{\frac{2.22R_u\left[B - 2k/2\right]^2}{AF_y}}$$

where R_u = the factored concentrated load at the support (kips)
B = the width of the bearing plate (in.)
k = the distance from the web toe of the fillet to the outer surface of the flange (in.)
A = the area of bearing plate (in.^{2})
F_y = the yield strength of the bearing plate

Substituting R_u = 157 kips, B = 10.5 in., k = 1.375 in., A = 42 in.^{2}, and F_y = 36 ksi into the above equation, we obtain t = 1.86 in. Therefore, use a 1⅞-in. plate.

For uniformity, use the same size plate at all the supports. The bearing plates are to be welded to the supporting flange of the W section.

Use a W16×67 section. Provide bearing plates of size 1⅞ × 4 × 10½–1/2 in. at the supports.

Beam Bracing

The design strength of beams that bend about their major axes depends on their lateral unsupported length L_b. The manner a beam is braced against out-of-plane deformation affects its design. Bracing can be provided by various means, such as cross frames, cross beams, or diaphragms, or encasement of the beam flange in the floor slab [Yura, 2001]. Two types of bracing systems are identified in the AISC-LRFD specification: relative and nodal. A relative brace controls the movement of a braced point with respect to adjacent braced points along the span of the beam. A nodal (or discrete) brace controls the movement of a braced point without regard to the movement of adjacent braced points. Regardless of the type of bracing system used, braces must be designed with sufficient strength and stiffness to prevent out-of-plane movement of the beam at the braced points. Out-of-plane movement consists of lateral deformation of the beam and twisting of cross sections. Lateral stability of beams can be achieved by lateral bracing, torsional bracing, or a combination of the two. For lateral bracing, bracing shall be attached near the compression flange for members bent in single curvature (except cantilevers). For cantilevers, bracing shall be attached to the tension flange at the free end. For members bent in double curvature, bracing shall be attached to both flanges near the inflection point. For torsional bracing, bracing can be attached at any cross-sectional location.

Stiffness Requirement for Lateral Bracing

The required brace stiffness of the bracing assembly in a direction perpendicular to the longitudinal axis of the braced member, in the plane of buckling, is given by

$$\beta_{br} = \begin{cases} \dfrac{4M_u C_d}{\phi L_{br} h_o} & \text{for relative bracing} \\ \dfrac{10M_u C_d}{\phi L_{br} h_o} & \text{for nodal bracing} \end{cases} \tag{48.63}$$

where ϕ = 0.75, M_u is the required flexural strength
C_d = 1.0 for single curvature bending and 2.0 for double curvature bending near the inflection point
L_{br} = the distance between braces
h_o = the distance between flange centroids. L_{br} can be replaced by L_q (the maximum unbraced length for M_u) if $L_{br} < L_q$

Strength Requirement for Lateral Bracing

In addition to the stiffness requirement as stipulated above, braces must be designed for a required brace strength given by

$$P_{br} = \begin{cases} 0.008\dfrac{M_u C_d}{h_o} & \text{for relative bracing} \\ 0.02\dfrac{M_u C_d}{h_o} & \text{for nodal bracing} \end{cases} \tag{48.64}$$

The terms in Eq. (48.64) are defined as in Eq. (48.63).

Stiffness Requirement for Torsional Bracing

The required bracing stiffness is

$$\beta_{Tbr} = \frac{\beta_T}{\left(1 - \dfrac{\beta_T}{\beta_{\text{sec}}}\right)} \geq 0 \tag{48.65}$$

where

$$\beta_T = \begin{cases} \dfrac{2.4LM_u^2}{\phi n E I_y C_b^2} & \text{for nodal bracing} \\ \dfrac{2.4M_u^2}{\phi E I_y C_b^2} & \text{for continuous bracing} \end{cases} \tag{48.66}$$

and

$$\beta_{\text{sec}} = \begin{cases} \dfrac{3.3E}{h_o}\left(\dfrac{1.5h_o t_w^3}{12} + \dfrac{t_s b_s^3}{12}\right) & \text{for nodal bracing} \\ \dfrac{3.3Et_w^2}{12h_o} & \text{for continuous bracing} \end{cases} \tag{48.67}$$

in which $\phi = 0.75$
L = the span length
M_u = the required moment
n = the number of brace points within the span
E = the modulus of elasticity
I_y = the moment of inertia of the minor axis
C_b = the bending coefficient as defined in Section 48.5
h_o = the distance between flange centroids
t_w = the thickness of the beam web
t_s = the thickness of the web stiffener
b_s = the width of stiffener (or, for pairs of stiffeners, b_s is the total width of stiffeners)

Strength Requirement for Torsional Bracing

The connection between a torsional brace and the beam being braced must be able to withstand a moment given by

$$M_{Tbr} = \frac{0.024M_u L}{nC_b L_{br}} \tag{48.68}$$

where L_{br} is the distance between braces (if $L_{br} < L_q$; where L_q is the maximum unbraced length for M_u, use L_q). The other terms in Eq. (48.68) are defined in Eq. (48.66).

Example 48.5

Design an I-shaped cross beam 12 ft (3.7 m) in length to be used as lateral braces to brace a 30-ft (9.1-m)-long simply supported W30×90 girder at every third point. The girder was designed to carry a moment of 8000 kip-in. (904 kN-m). A992 steel is used.

Because a brace is provided at every third point, L_{br} = 10 ft = 120 in. M_u = 8000 kip-in., as stated. C_d = 1 for single curvature bending. $h_o = d - t_f = 29.53 - 0.610 = 28.92$ in. for the W30×90 section. Substituting these values into Eqs. (48.63) and (48.64) for nodal bracing, we obtain β_{br} = 30.7 kips/in. and P_{br} = 5.53 kips.

Because the cross beam will be subject to compression, its slenderness ratio, l/r, should not exceed 200. Let us try the smallest-size W section , a W4×13 section with A = 3.83 in.^{2}, r_y = 1.00 in., and $\phi_c P_n$ = 25 kips.

$$\text{Stiffness,} \quad \frac{EA}{l} = \frac{(29000)(3.83)}{12 \times 12} = 771 \text{ kips/in.} > 30.7 \text{ kips/in.}$$

$$\text{Strength,} \quad \phi_c P_n = 25 \text{ kips} > 5.53 \text{ kips}$$

$$\text{Slenderness,} \quad \frac{l}{r_y} = \frac{12 \times 12}{1.00} = 144 < 200$$

Since all criteria are satisfied, the W4×13 section is adequate.

Use W4×13 as cross beams to brace the girder.

48.6 Combined Flexure and Axial Force

When a member is subject to the combined action of bending and axial force, it must be designed to resist stresses and forces arising from both bending and axial actions. While a tensile axial force may induce a stiffening effect on the member, a compressive axial force tends to destabilize the member, and the instability effects due to member instability (P-δ effect) and frame instability (P-Δ effect) must be properly accounted for. The P-δ effect arises when the axial force acts through the lateral deflection of the member relative to its chord. The P-Δ effect arises when the axial force acts through the relative displacements of the two ends of the member. Both effects tend to increase member deflection and moment; so they must be considered in the design. A number of approaches are available in the literature to handle these so-called P-delta effects (see, for example, Galambos [1998] and Chen and Lui [1991]). The design of members subject to combined bending and axial force is facilitated by the use of interaction equations. In these equations the effects of bending and axial actions are combined in a certain manner to reflect the capacity demand on the member.

Design for Combined Flexure and Axial Force

Allowable Stress Design

The interaction equations are as follows:

If the axial force is tensile,

$$\frac{f_a}{F_t} + \frac{f_{bx}}{F_{bx}} + \frac{f_{by}}{F_{by}} \le 1.0 \tag{48.69}$$

where f_a = the computed axial tensile stress
f_{bx} and f_{by} = the computed bending tensile stresses about the major and minor axes, respectively
F_t = the allowable tensile stress (see Section 48.3)
F_{bx} and F_{by} = the allowable bending stresses about the major and minor axes, respectively (see Section 48.5).

If the axial force is compressive,

Stability requirement:

$$\frac{f_a}{F_a}+\left[\frac{C_{mx}}{(1-\dfrac{f_a}{F'_{ex}})}\right]\frac{f_{bx}}{F_{bx}}+\left[\frac{C_{my}}{(1-\dfrac{f_a}{F'_{ey}})}\right]\frac{f_{by}}{F_{by}}\le 1.0 \tag{48.70}$$

Yield requirement:

$$\frac{f_a}{0.66\,F_y}+\frac{f_{bx}}{F_{bx}}+\frac{f_{by}}{F_{by}}\le 1.0 \tag{48.71}$$

However, if the axial force is small (when $f_a/F_a \le 0.15$), the following interaction equation can be used in lieu of the above equations.

$$\frac{f_a}{F_a}+\frac{f_{bx}}{F_{bx}}+\frac{f_{by}}{F_{by}}\le 1.0 \tag{48.72}$$

The terms in the Eqs. (48.70) to (48.72) are defined as follows: f_a, f_{bx}, and f_{by} are the computed axial compressive stress, the computed bending stress about the major axis, and the computer bending stress about the minor axis, respectively. These stresses are to be computed based on a *first-order analysis*: F_y is the minimum specified yield stress; F'_{ex} and F'_{ey} are the Euler stresses about the major and minor axes ($\pi^2E/(Kl/r)_x$ and $\pi^2E/(Kl/r)_y$), respectively, divided by a factor of safety of 23/12; and C_m is a coefficient to account for the effect of moment gradient on member and frame instabilities (C_m is defined in the following section). The other terms are defined as in Eq. (48.69)

The terms in brackets in Eq. (48.70) are moment magnification factors. The computed bending stresses f_{bx} and f_{by} are magnified by these magnification factors to account for the P-delta effects in the member.

Load and Resistance Factor Design

Doubly or singly symmetric members subject to combined flexure and axial force shall be designed in accordance with the following interaction equations:

For $P_u/\phi P_n \ge 0.2$,

$$\frac{P_u}{\phi\,P_n}+\frac{8}{9}\left(\frac{M_{ux}}{\phi_b\,M_{nx}}+\frac{M_{uy}}{\phi_b\,M_{ny}}\right)\le 1.0 \tag{48.73}$$

For $P_u/\phi P_n < 0.2$,

$$\frac{P_u}{2\,\phi\,P_n}+\left(\frac{M_{ux}}{\phi_b\,M_{nx}}+\frac{M_{uy}}{\phi_b\,M_{ny}}\right)\le 1.0 \tag{48.74}$$

where, if P is tensile, P_u is the factored tensile axial force, P_n is the design tensile strength (see Section 48.3), M_u is the factored moment (preferably obtained from a second-order analysis), M_n is the design flexural

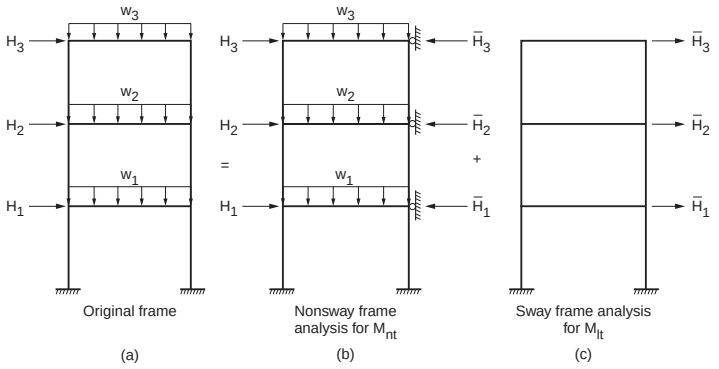

FIGURE 48.11 Calculation of M_{nt} and M_{lt}.

strength (see Section 48.5), $\phi = \phi_t$ = resistance factor for tension = 0.90, and ϕ_b = resistance factor for flexure = 0.90. If P is compressive, P_u is the factored compressive axial force, P_n is the design compressive strength (see Section 48.4), M_u is the required flexural strength (see discussion below), M_n is the design flexural strength (see Section 48.5), $\phi = \phi_c$ = resistance factor for compression = 0.85, and ϕ_b = resistance factor for flexure = 0.90.

The required flexural strength M_u shall be determined from a second-order elastic analysis. In lieu of such an analysis, the following equation may be used

$$M_u = B_1 M_{bt} + B_2 M_{lt} \tag{48.75}$$

where M_{nt} = the factored moment in a member, assuming the frame does not undergo lateral translation (see Fig. 48.11)
M_{lt} = the factored moment in a member as a result of lateral translation (see Fig. 48.11)
$B_1 = C_m/(1 - P_u/P_e) \geq 1.0$ and is the P-δ moment magnification factor
$P_e = \pi^2 EI/(KL)^2$, with $K \leq 1.0$ in the plane of bending
C_m = a coefficient to account for moment gradient (see discussion below)
$B_2 = 1/[1 - (\Sigma P_u \Delta_{oh}/\Sigma HL)]$ or $B_2 = 1/[1 - (\Sigma P_u/\Sigma P_e)]$
ΣP_u = the sum of all factored loads acting on and above the story under consideration
Δ_{oh} = the first-order interstory translation
ΣH = the sum of all lateral loads acting on and above the story under consideration
L = the story height
$P_e = \pi^2 EI/(KL)^2$

For end-restrained members that do not undergo relative joint translation and are not subject to transverse loading between their supports in the plane of bending, C_m is given by

$$C_m = 0.6 - 0.4\left(\frac{M_1}{M_2}\right)$$

where M_1/M_2 is the ratio of the smaller to larger member end moments. The ratio is positive if the member bends in reverse curvature and negative if the member bends in single curvature.

For end-restrained members that do not undergo relative joint translation and are subject to transverse loading between their supports in the plane of bending

$$C_m = 0.85$$

For unrestrained members that do not undergo relative joint translation and are subject to transverse loading between their supports in the plane of bending

$$C_m = 1.00$$

Although Eqs. (48.73) and (48.74) can be used directly for the design of *beam-columns* by using trial and error or by the use of design aids [Aminmansour, 2000], the selection of trial sections is facilitated by rewriting the interaction equations of Eqs. (48.73) and (48.74) into the so-called equivalent axial load form:

For $P_u/\phi_c P_n > 0.2$,

$$bP_u + mM_{ux} + nM_{uy} \le 1.0 \tag{48.76}$$

For $P_u/\phi_c P_n \le 0.2$,

$$b\frac{P_u}{2} + \frac{9}{8}\, mM_{ux} + \frac{9}{8}\, nM_{uy} \le 1.0 \tag{48.77}$$

where $b = 1/\phi_c P_n$
$m = 8/9\ \phi_b M_{nx}$
$n = 8/9\ \phi_b M_{ny}$

Numerical values for b, m, and n are provided in the AISC manual [AISC, 2001]. The advantage of using Eqs. (48.76) and (48.77) for preliminary design is that the terms on the left-hand side of the inequality can be regarded as an equivalent axial load, $(P_u)_{eff}$, thus allowing the designer to take advantage of the column tables provided in the manual for selecting trial sections.

48.7 Biaxial Bending

Members subjected to bending about both principal axes (e.g., purlins on an inclined roof) should be design for *biaxial bending*. Since both the moment about the major axis M_{ux} and the moment about the minor axis M_{uy} create flexural stresses over the cross section of the member, the design must take into consideration these stress combinations.

Design for Biaxial Bending

Allowable Stress Design

The following interaction equation is often used for the design of beams subject to biaxial bending:

$$f_{bx} + f_{by} \le 0.60F_y \quad \text{or} \quad \frac{M_x}{S_x} + \frac{M_y}{S_y} \le 0.60F_y \tag{48.78}$$

where M_x and M_y = the service load moments about the major and minor beam axes, respectively
S_x and S_y = the elastic section moduli about the major and minor axes, respectively
F_y = the specified minimum yield stress.

Example 48.6

Using ASD, select a W section to carry dead load moments M_x = 20 k-ft (27 kN-m) and M_y = 5 k-ft (6.8 kN-m) and live load moments M_x = 50 k-ft (68 kN-m) and M_y = 15 k-ft (20 kN-m). Use A992 steel.

Calculate service load moments:

$$M_x = M_{x,\,dead} + M_{x,\,live} = 20 + 50 = 70\,\text{k-ft}$$

$$M_y = M_{y,\,dead} + M_{y,\,live} = 5 + 15 = 20\ \text{k-ft}$$

Select section:
Substituting the above service load moments into Eq. (48.78), we have

$$\frac{70 \times 12}{S_x} + \frac{20 \times 12}{S_y} \le 0.60(50) \quad \text{or,} \quad 840 + 240\ \frac{S_x}{S_y} \le 30\ S_x$$

For W sections with a depth below 14 in. the value of S_x/S_y normally falls in the range of 3 to 8, and for W sections with a depth above 14 in. the value of S_x/S_y normally falls in the range of 5 to 12. Assuming $S_x/S_y = 10$, we have from the above equation, $S_x \ge 108$ in.^{3}. Using the Allowable Stress Design Selection Table in the AISC-ASD manual, let's try a W24×55 section ($S_x = 114$ in.^{3}, $S_y = 8.30$ in.^{3}). For the W24×55 section,

$$\left[840 + 240\frac{114}{8.30} = 4136\right] > \left[30\ S_x = 30(114) = 3420\right] \therefore \text{NG}$$

The next lightest section is W21×62 ($S_x = 127$ in.^{3}, $S_y = 13.9$ in.^{3}). For this section,

$$\left[840 + 240\ \frac{127}{13.9} = 3033\right] < \left[30\,S_x = 30(127) = 3810\right] \therefore \text{OK}$$

Therefore, use a W21×62 section.

Load and Resistance Factor Design

To avoid distress at the most severely stressed point, the following equation for the limit state of yielding must be satisfied:

$$f_{un} \le \phi_b\ F_y \tag{48.79}$$

where $f_{un} = M_{ux}/S + M_{uy}/S_y$ is the flexural stress under factored loads
S_x and S_y = the elastic section moduli about the major and minor axes, respectively
$\phi_b = 0.90$
F_y = the specified minimum yield stress

In addition, the limit state for lateral torsional buckling about the major axis should also be checked, i.e.,

$$\phi_b\ M_{nx} \ge M_{ux} \tag{48.80}$$

$\phi_b M_{nx}$ is the design flexural strength about the major axis (see Section 48.5).

To facilitate design for biaxial bending, Eq. (48.79) can be rearranged to give

$$S_x \ge \frac{M_{ux}}{\phi_b\ F_y} + \frac{M_{uy}}{\phi_b\ F_y}\left(\frac{S_x}{S_y}\right) \approx \frac{M_{ux}}{\phi_b\ F_y} + \frac{M_{uy}}{\phi_b\ F_y}\left(3.5\frac{d}{b_f}\right) \tag{48.81}$$

In the above equation, d is the overall depth and b_f is the flange width of the section. The approximation $(S_x/S_y) \approx (3.5d/b_f)$ was suggested by Gaylord et al. [1992] for doubly symmetric I-shaped sections.

48.8 Combined Bending, Torsion, and Axial Force

Members subjected to the combined effect of bending, torsion, and axial force should be designed to satisfy the following limit states:

Yielding under normal stress:

$$\phi F_y \geq f_{un} \tag{48.82}$$

where $\phi = 0.90$
F_y = the specified minimum yield stress
f_{un} = the maximum normal stress determined from an elastic analysis under factored loads

Yielding under shear stress:

$$\phi \left(0.6F_y\right) \geq f_{uv} \tag{48.83}$$

where $\phi = 0.90$
F_y = the specified minimum yield stress
f_{uv} = the maximum shear stress determined from an elastic analysis under factored loads

Buckling:

$$\phi_c F_{cr} \geq f_{un} \quad \text{or} \quad \phi_c F_{cr} \geq f_{uv}, \text{ whichever is applicable} \tag{48.84}$$

where $\phi_c F_{cr} = \phi_c P_n / A_g$, in which $\phi_c P_n$ is the design compressive strength of the member (see Section on 48.4) and A_g is the gross cross-section area
f_{un} and f_{uv} = the normal and shear stresses, respectively, as defined in Eqs. (48.82) and (48.83).

48.9 Frames

Frames are designed as a collection of structural components such as beams, beam-columns (columns), and connections. According to the restraint characteristics of the connections used in the construction, frames can be designed as type I (rigid framing), type II (simple framing), or type III (semirigid framing) in ASD or as fully restrained (rigid) and partially restrained (semirigid) in LRFD:

The design of rigid frames necessitates the use of connections capable of transmitting the full or a significant portion of the moment developed between the connecting members. The rigidity of the connections must be such that the angles between intersecting members should remain virtually unchanged under factored loads.

The design of simple frames is based on the assumption that the connections provide no moment restraint to the beam insofar as gravity loads are concerned, but these connections should have an adequate capacity to resist wind moments.

The design of semirigid frames is permitted upon evidence of the connections to deliver a predicable amount of moment restraint. Over the past two decades, a tremendous amount of work has been published in the literature on semirigid connections and frame behavior (see, for example, Chen [1987, 2000], Council on Tall Buildings and Urban Habitat [1993], Chen et al. [1996], and Faella et al. [2000]). However, because of the vast number of semirigid connections that can exhibit an appreciable difference in joint behavior, no particular approach has been recommended by any building specifications as of this writing. The design of semirigid or partially restrained frames relies on sound engineering judgment by the designer.

Semirigid and simple framings often incur inelastic deformation in the connections. The connections used in these constructions must be proportioned to possess sufficient ductility to avoid overstress of the fasteners or welds.

Regardless of the types of constructions used, due consideration must be given to account for member and frame instability (P-δ and P-Δ) effects either by the use of a second-order analysis or by other means, such as moment magnification factors or notional loads [ASCE, 1997]. The end-restrained effect on a member should also be accounted for by the use of the effective length factor K.

Frame Design

Frames can be designed as *side sway inhibited* (braced) or *side sway uninhibited* (unbraced). In side sway inhibited frames, frame *drift* is controlled by the presence of a bracing system (e.g., shear walls, diagonal, cross, or K braces, etc.). In side sway uninhibited frames, frame drift is limited by the flexural rigidity of the connected members and diaphragm action of the floors. Most side sway uninhibited frames are designed as type I or type FR frames using moment connections. Under normal circumstances, the amount of interstory drift under service loads should not exceed $h/500$ to $h/300$, where h is the story height. A higher value of interstory drift is allowed only if it does not create serviceability concerns.

Beams in side sway inhibited frames are often subject to high axial forces. As a result, they should be designed as beam-columns using beam-column interaction equations. Furthermore, vertical bracing systems should be provided for braced multistory frames to prevent vertical buckling of the frames under gravity loads.

When designing members of a frame, a designer should consider a variety of loading combinations and load patterns, and the members are designed for the most severe load cases. Preliminary sizing of members can be achieved by the use of simple behavioral models such as the simple beam model, cantilever column model, and portal and cantilever method of frame analysis (see, for example, Rossow [1996]).

Frame Bracing

The subject of frame bracing is discussed in a number of references (see, for example, SSRC [1993] and Galambos [1998]). According to the LRFD specification [AISC, 1999] the required story or panel bracing shear stiffness in side sway inhibited frames is

$$\beta_{cr} = \frac{2\sum P_u}{\phi L} \tag{48.85}$$

where $\phi = 0.75$, ΣP_u is the sum of all factored gravity load acting on and above the story or panel supported by the bracing
L = the story height or panel spacing

The required story or panel bracing force is

$$P_{br} = 0.004\sum P_u \tag{48.86}$$

48.10 Plate Girders

Plate girders are built-up beams. They are used as flexural members to carry extremely large lateral loads. A flexural member is considered as a plate girder if the width–thickness ratio of the web, h_c/t_w, exceeds $760/\sqrt{F_b}$ (F_b is the allowable flexural stress) according to ASD or λ_r (see Table 48.8) according to LRFD. Because of the large web slenderness, plate girders are often designed with transverse stiffeners to reinforce the web and to allow for postbuckling (shear) strength (i.e., *tension field action*) to develop. Table 48.9

TABLE 48.9 Web Stiffeners Requirements

Range of Web Slenderness	Stiffener Requirements
$\frac{h}{t_w} \le 260$	Plate girder can be designed without web stiffeners
$260 < \frac{h}{t_w} \le \frac{0.48E}{\sqrt{F_{yf}\left(F_{yf}+16.5\right)}}$	Plate girder must be designed with web stiffeners; the spacing of stiffeners, a, can exceed $1.5h$; the actual spacing is determined by the shear criterion
$\frac{0.48E}{\sqrt{F_{yf}\left(F_{yf}+16.5\right)}} < \frac{h}{t_w} \le 11.7\sqrt{\frac{E}{F_{yf}}}$	Plate girder must be designed with web stiffeners; the spacing of stiffeners, a, cannot exceed $1.5h$

Note: a = clear distance between stiffeners, h = clear distance between flanges when welds are used or the distance between adjacent lines of fasteners when bolts are used, t_w = web thickness, F_{yf} = compression flange yield stress (ksi).

summarizes the requirements for transverse stiffeners for plate girders based on the web slenderness ratio h/t_w. Two types of transverse stiffeners are used for plate girders: bearing stiffeners and intermediate stiffeners. Bearing stiffeners are used at unframed girder ends and at concentrated load points where the web yielding or web crippling criterion is violated. Bearing stiffeners extend the full depth of the web from the bottom of the top flange to the top of the bottom flange. Intermediate stiffeners are used when the width–thickness ratio of the web, h/t_w, exceeds 260, when the shear criterion is violated, or when tension field action is considered in the design. Intermediate stiffeners need not extend the full depth of the web, but they must be in contact with the compression flange of the girder.

Normally, the depths of plate girder sections are so large that the simple beam theory, postulating that plane sections before bending remain plane after bending, does not apply. As a result, a different set of design formulas for plate girders is required.

Plate Girder Design

Allowable Stress Design

Allowable Bending Stress

The maximum bending stress in the compression flange of the girder computed using the flexure formula shall not exceed the allowable value, F_b', given by

$$F_b' = F_b R_{PG} R_e \tag{48.87}$$

where F_b = the applicable allowable bending stress, as discussed in Section 48.5 (ksi)
R_{PG} = the plate girder stress reduction factor, $1 - 0.0005(A_w/A_f)(h/t_w - 760/\sqrt{F_b}) \le 1.0$
R_e = the hybrid girder factor, $[12 + (A_w/A_f)(3\alpha - \alpha^3)]/[12 + 2(A_w/A_f)] \le 1.0$ ($R_e = 1$ for nonhybrid girders)
A_w = the area of web
A_f = the area of compression flange
$\alpha = 0.60F_{yw}/F_b \le 1.0$
F_{yw} = the yield stress of web

Allowable Shear Stress

The allowable shear stress without tension field action is the same as that for beams given in Eq. (48.35).

The allowable shear stress with tension field action is given by

$$F_v = \frac{F_y}{2.89}\left[C_v + \frac{1 - C_v}{1.15\sqrt{1 + (a/h)^2}}\right] \le 0.40F_y \tag{48.88}$$

Note that tension field action can be considered in the design only for nonhybrid girders. If tension field action is considered, transverse stiffeners must be provided and spaced at a distance so that the computed average web shear stress, f_v, obtained by dividing the total shear by the web area, does not exceed the allowable shear stress, F_v, given by Eq. (48.88). In addition, the computed bending tensile stress in the panel where tension field action is considered can not exceed $0.60F_y$, or $(0.825 - 0.375f_v/F_v)F_y$ where f_v is the computed average web shear stress, and F_v is the allowable web shear stress given in Eq. (48.88). The shear transfer criterion given by Eq. (48.91) must also be satisfied.

Transverse Stiffeners

Transverse stiffeners must be designed to satisfy the following criteria:

Moment of inertia criterion:

With reference to an axis in the plane of the web, the moment of inertia of the stiffeners (in square inches) shall satisfy the condition

$$I_{st} \geq \left(\frac{h}{50}\right)^4 \tag{48.89}$$

where h is the clear distance between flanges (in inches).

Area criterion:

The total area of the stiffeners (in square inches) shall satisfy the condition

$$A_{st} \geq \frac{1-C_v}{2}\left[\frac{a}{h} - \frac{(a/h)^2}{\sqrt{1+(a/h)^2}}\right] YDht_w \tag{48.90}$$

where C_v = the shear buckling coefficient as defined in Eq. (48.35)
a = the stiffeners' spacing
h = the clear distance between flanges
t_w = the web thickness
Y = the ratio of web yield stress to stiffener yield stress
D = 1.0 for stiffeners furnished in pairs, 1.8 for single-angle stiffeners, and 2.4 for single-plate stiffeners.

Shear transfer criterion:

If tension field action is considered, the total shear transfer (in kips/in.) of the stiffeners shall not be less than

$$f_{vs} = h\sqrt{\left(\frac{F_{yw}}{340}\right)^3} \tag{48.91}$$

where F_{yw} = the web yield stress (ksi)
h = the clear distance between flanges (in.)

The value of f_{vs} can be reduced proportionally if the computed average web shear stress, f_v, is less than F_v given in Eq. (48.88).

Load and Resistance Factor Design

Flexural Strength Criterion

Doubly or singly symmetric single-web plate girders loaded in the plane of the web should satisfy the flexural strength criterion of Eq. (48.38). The plate girder design flexural strength is given by:

For the limit state of tension flange yielding,

$$\phi_b M_n = 0.90 \left[S_{xt} R_e F_{yt} \right] \tag{48.92}$$

For the limit state of compression flange buckling,

$$\phi_b M_n = 0.90 \left[S_{xc} R_{PG} R_e F_{cr} \right] \tag{48.93}$$

where S_{xt} = the section modulus referred to the tension flange, I_x/c_t
S_{xc} = the section modulus referred to the compression flange, I_x/c_c
I_x = the moment of inertia about the major axis
c_t = the distance from the neutral axis to the extreme fiber of the tension flange
c_c = the distance from the neutral axis to the extreme fiber of the compression flange
R_{PG} = the plate girder bending strength reduction factor, $1 - a_r[h_c/t_w - 5.70\sqrt{(E/F_{cr})}]/[1200 + 300a_r] \le 1.0$
R_e = the hybrid girder factor, $[12 + a_r(3m - m^3)]/[12 + 2a_r] \le 1.0$ ($R_e = 1$ for nonhybrid girders)
a_r = the ratio of web area to compression flange area
m = the ratio of web yield stress to flange yield stress or ratio of web yield stress to F_{cr}
F_{yt} = the tension flange yield stress; and F_{cr} is the critical compression flange stress calculated as follows:

Limit State	Range of Slenderness	F_{cr} (ksi)
Flange local buckling	$\frac{b_f}{2t_f} \le 0.38\sqrt{\frac{E}{F_{yf}}}$	F_{yf}
	$0.38\sqrt{\frac{E}{F_{yf}}} < \frac{b_f}{2t_f} \le 1.35\sqrt{\frac{E}{F_{yf}/k_c}}$	$F_{yf}\left[1 - \frac{1}{2}\left(\frac{\frac{b_f}{2t_f} - 0.38\sqrt{\frac{E}{F_{yf}}}}{1.35\sqrt{\frac{E}{F_{yf}/k_c}} - 0.38\sqrt{\frac{E}{F_{yf}}}}\right)\right] \le F_{yf}$
	$\frac{b_f}{2t_f} > 1.35\sqrt{\frac{E}{F_{yf}/k_c}}$	$\frac{26{,}200\,k_c}{\left(\frac{b_f}{2t_f}\right)^2}$
Lateral torsional buckling	$\frac{L_b}{r_t} \le 1.76\sqrt{\frac{E}{F_{yf}}}$	F_{yf}
	$1.76\sqrt{\frac{E}{F_{yf}}} < \frac{L_b}{r_T} \le 4.44\sqrt{\frac{E}{F_{yf}}}$	$C_b F_{yf}\left[1 - \frac{1}{2}\left(\frac{\frac{L_b}{r_T} - 1.76\sqrt{\frac{E}{F_{yf}}}}{4.44\sqrt{\frac{E}{F_{yf}}} - 1.76\sqrt{\frac{E}{F_{yf}}}}\right)\right] \le F_{yf}$
	$\frac{L_b}{r_T} > 4.44\sqrt{\frac{E}{F_{yf}}}$	$\frac{286{,}000\,C_b}{\left(\frac{L_b}{r_T}\right)^2}$

Note: $k_c = 4/\sqrt{(h/t_w)}$, $0.35 \le k_c \le 0.763$, b_f = compression flange width, t_f = compression flange thickness, L_b = lateral unbraced length of the girder, $r_T = \sqrt{[(t_f b_f^3/12 + h_c t_w^3/72)/(b_f t_f + h_c t_w/6)]}$, h_c = twice the distance from the neutral axis to the inside face of the compression flange less the fillet, t_w = web thickness, F_{yf} = yield stress of compression flange (ksi), C_b = bending coefficient (see Section 48.5).

F_{cr} must be calculated for both flange local buckling and lateral torsional buckling. The smaller value of F_{cr} is used in Eq. (48.93).

The plate girder bending strength reduction factor R_{PG} is a factor to account for the nonlinear flexural stress distribution along the depth of the girder. The hybrid girder factor is a reduction factor to account for the lower yield strength of the web when the nominal moment capacity is computed assuming a homogeneous section made entirely of the higher yield stress of the flange.

Shear Strength Criterion

Plate girders can be designed with or without the consideration of tension field action. If tension field action is considered, intermediate web stiffeners must be provided and spaced at a distance a such that a/h is smaller than 3 or $[260/(h/t_w)]^2$, whichever is smaller. Also, one must checked the flexure–shear interaction of Eq. (48.96), if appropriate. Consideration of tension field action is not allowed if (1) the panel is an end panel, (2) the plate girder is a hybrid girder, (3) the plate girder is a web-tapered girder, or (4) a/h exceeds 3 or $[260/(h/t_w)]^2$, whichever is smaller.

The design shear strength, $\phi_v V_n$, of a plate girder is determined as follows:

If tension field action is not considered:
$\phi_v V_n$ is the same as those for beams given in Eqs. (48.49) to (48.51).

If tension field action is considered and $h/t_w \le 1.10\sqrt{(k_v E/F_{yw})}$:

$$\phi_v V_n = 0.90\left[0.60\, A_w\, F_{yw}\right] \tag{48.94}$$

If $h/t_w > 1.10\sqrt{(k_v E/F_{yw})}$:

$$\phi_v V_n = 0.90\left[0.60\, A_w\, F_{yw}\left(C_v + \frac{1-C_v}{1.15\sqrt{1+(a/h)^2}}\right)\right] \tag{48.95}$$

where $k_v = 5 + 5/(a/h)^2$ (k_v shall be taken as 5.0 if a/h exceeds 3.0 or $[260/(h/t_w)]^2$, whichever is smaller)
$A_w = dt_w$ (where d is the section depth and t_w is the web thickness)
F_{yw} = the web yield stress
C_v = the shear coefficient, calculated as follows:

Range of h/t_w	C_v
$1.10\sqrt{\frac{k_v E}{F_{yw}}} \le \frac{h}{t_w} \le 1.37\sqrt{\frac{k_v E}{F_{yw}}}$	$\frac{1.10\sqrt{k_v E/F_{yw}}}{h/t_w}$
$\frac{h}{t_w} > 1.37\sqrt{\frac{k_v E}{F_{yw}}}$	$\frac{1.51 k_v E}{(h/t_w)^2 F_{yw}}$

Flexure–Shear Interaction

Plate girders designed for tension field action must satisfy the flexure–shear interaction criterion in regions where $0.60\phi V_n \le V_u \le \phi V_n$ and $0.75\phi M_n \le M_u \le \phi M_n$:

$$\frac{M_u}{\phi M_n} + 0.625\,\frac{V_u}{\phi V_n} \le 1.375 \tag{48.96}$$

where $\phi = 0.90$.

Bearing Stiffeners

Bearing stiffeners must be provided for a plate girder at unframed girder ends and at points of concentrated loads where the web yielding or the web crippling criterion is violated (see Section 48.5 under Criteria for Concentrated Loads). Bearing stiffeners shall be provided in pairs and extend from the upper flange to the lower flange of the girder. Denoting b_{st} as the width of one stiffener and t_{st} as its thickness, bearing stiffeners shall be portioned to satisfy the limit states as follows.

For the limit state of local buckling,

$$\frac{b_{st}}{t_{st}} \le 0.56\sqrt{\frac{E}{F_y}} \tag{48.97}$$

For the limit state of compression, the design compressive strength, $\phi_c P_n$, must exceed the required compressive force acting on the stiffeners. $\phi_c P_n$ is to be determined based on an effective length factor K of 0.75 and an effective area, A_{eff}, equal to the area of the bearing stiffeners plus a portion of the web. For end bearing, this effective area is equal to $2(b_{st}t_{st}) + 12t_w^2$, and for interior bearing, this effective area is equal to $2(b_{st}t_{st}) + 25t_w^2$, where t_w is the web thickness. The slenderness parameter, λ_c, is to be calculated using a radius of gyration $r = \sqrt{(I_{stt}/A_{eff})}$, where $I_{st} = t_{st}(2b_{st} + t_w)^3/12$.

For the limit state of bearing, the bearing strength, ϕR_n, must exceed the required compression force acting on the stiffeners. ϕR_n is given by

$$\phi R_n \ge 0.75\left[1.8F_y A_{pb}\right] \tag{48.98}$$

where F_y = the yield stress
A_{pb} = the bearing area.

Intermediate Stiffeners

Intermediate stiffeners shall be provided if (1) the shear strength capacity is calculated based on tension field action, (2) the shear criterion is violated (i.e., when the V_u exceeds $\phi_v V_n$), or (3) the web slenderness h/t_w exceeds $2.45\sqrt{(E/F_{yw})}$. Intermediate stiffeners can be provided in pairs or on one side of the web only in the form of plates or angles. They should be welded to the compression flange and the web, but they may be stopped short of the tension flange. The following requirements apply to the design of intermediate stiffeners.

Local Buckling — The width–thickness ratio of the stiffener must be proportioned so that Eq. (48.97) is satisfied to prevent failure by local buckling.

Stiffener Area — The cross-section area of the stiffener must satisfy the following criterion:

$$A_{st} \ge \frac{F_{yw}}{F_y}\left[0.15\,Dht_w\left(1-C_v\right)\frac{V_u}{\phi_v V_n} - 18\,t_w^2\right] \ge 0 \tag{48.99}$$

where F_y is the yield stress of stiffeners and D is 1.0 for stiffeners in pairs, 1.8 for single-angle stiffeners, and 2.4 for single-plate stiffeners. The other terms in Eq. (48.99) are defined as before, in Eqs. (48.94) and (48.95).

Stiffener Moment of Inertia — The moment of inertia for stiffener pairs taken about an axis in the web center or for single stiffeners taken about the face of contact with the web plate must satisfy the following criterion:

$$I_{st} \ge a\,t_w^3\left[\frac{2.5}{\left(a/h\right)^2} - 2\right] \ge 0.5\,at_w^3 \tag{48.100}$$

Stiffener Length — The length of the stiffeners, l_{st}, should fall within the range

$$h - 6\,t_w < l_{st} < h - 6\,t_w \tag{48.101}$$

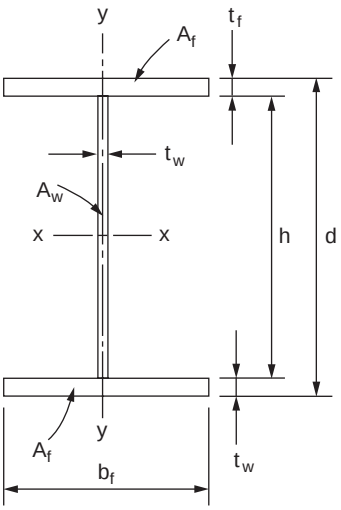
where h = the clear distance between the flanges less the widths of the flange-to-web welds
t_w = the web thickness

If intermittent welds are used to connect the stiffeners to the girder web, the clear distance between welds shall not exceed $16t_w$ or 10 in. (25.4 cm). If bolts are used, their spacing shall not exceed 12 in. (30.5 cm).

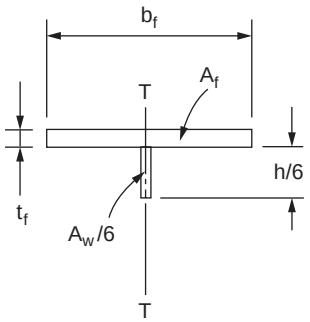
Stiffener Spacing — The spacing of the stiffeners, a, shall be determined from the shear criterion $\phi_v V_n \geq V_u$. This spacing shall not exceed the smaller of $3h$ and $[260/(h/t_w)]^2 h$.

Example 48.7

Using LRFD, design the cross section of an I-shaped plate girder, shown in Fig. 48.12a, to support a factored moment M_u of 4600 kip-ft (6240 kN-m); the dead weight of the girder is included. The girder is a 60-ft (18.3-m)-long simply supported girder. It is laterally supported at every 20-ft (6.1-m) interval. Use A36 steel.



(a) Plate Girder Nomenclature



(b) Calculation of r_T

FIGURE 48.12 Design of a plate girder cross section.

Proportion of the girder web:
Ordinarily, the overall depth-to-span ratio d/L of a building girder is in the range of 1/12 to 1/10. So, let us try $h = 70$ in.

Also, because h/t_w of a plate girder is normally in the range of $5.70\sqrt{(E/F_{yf})}$ to $11.7\sqrt{(E/F_{yf})}$, using $E =$ 29,000 ksi and $F_{yf} = 36$ ksi, let's try $t_w = 5/16$ in.

Proportion of the girder flanges:
For a preliminary design, the required area of the flange can be determined using the flange area method:

$$A_f \approx \frac{M_u}{F_y\, h} = \frac{4600 \text{ kip-ft} \times 12 \text{ in/ft}}{(36 \text{ ksi})(70 \text{ in})} = 21.7 \text{ in}^2$$

So, let $b_f = 20$ in. and $t_f = 1\frac{1}{8}$ in., giving $A_f = 22.5$ in.^{2}

Determine the design flexural strength $\phi_b M_n$ of the girder:

Calculate I_x:

$$\begin{aligned} I_x &= \sum \left[I_i + A_i\, y_i^2 \right] \\ &= \left[8932 + (21.88)(0)^2 \right] + 2\,[2.37 + (22.5)(35.56)^2] \\ &= 65840 \text{ in}^4 \end{aligned}$$

Calculate S_{xt} and S_{xc}:

$$S_{xt} = S_{xc} = \frac{I_x}{c_t} = \frac{I_x}{c_c} = \frac{65840}{35 + 1.125} = 1823 \text{ in}^3$$

Calculate r_T (refer to Fig. 48.12b):

$$r_T = \sqrt{\frac{I_T}{A_f + \frac{1}{6} A_w}} = \sqrt{\frac{(1.125)(20)^3/12 + (11.667)(5/16)^3/12}{22.5 + \frac{1}{6}(21.88)}} = 5.36 \text{ in.}$$

Calculate F_{cr}:

For flange local buckling (FLB),

$$\left[\frac{b_f}{2t_f} = \frac{20}{2(1.125)} = 8.89 \right] < \left[0.38\sqrt{\frac{E}{F_{yf}}} = 10.8 \right] \quad \text{so,} \quad F_{cr} = F_{yf} = 36 \text{ ksi}$$

For lateral torsional buckling (LTB),

$$\left[\frac{L_b}{r_T} = \frac{20 \times 12}{5.36} = 44.8 \right] < \left[1.76\sqrt{\frac{E}{F_{yf}}} = 50 \right] \quad \text{so,} \quad F_{cr} = F_{yf} = 36 \text{ ksi}$$

Calculate R_{PG}:

$$R_{PG} = 1 - \frac{a_r\left(h_c/t_w - 5.70\sqrt{(E/F_{cr})} \right)}{(1{,}200 + 300\ a_r)} = 1 - \frac{0.972\left[70/(5/16) - 5.70\sqrt{(29{,}000/36)} \right]}{\left[1200 + 300(0.972) \right]} = 0.96$$

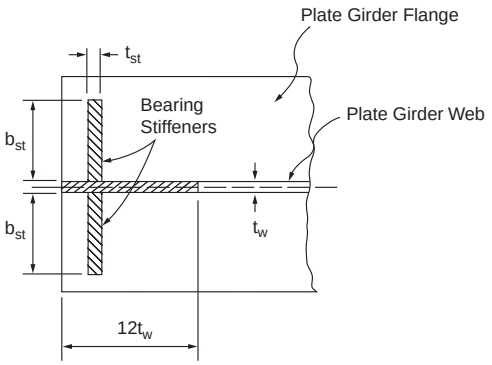


FIGURE 48.13 Design of bearing stiffeners.

Calculate $\phi_b M_n$:

$$\phi_b M_n = \text{smaller of} \begin{cases} 0.90\ S_{xt} R_e F_{yt} = (0.90)(1823)(1)(36) = 59{,}065 \text{ kip-in.} \\ 0.90\ S_x R_{PG} R_e F_{cr} = (0.90)(1823)(0.96)(1)(36) = 56{,}700 \text{ kip-in.} \end{cases}$$

$$= 56{,}700 \text{ kip-in.}$$

$$= 4725 \text{ kip-ft.}$$

Since $[\phi_b M_n = 4725$ kip-ft$] > [M_u = 4600$ kip-ft], the cross section is acceptable.

Use web plate 5/16 x 70 in. and two flange plates 1⅛ x 20 in. for the girder cross section.

Example 48.8

Design bearing stiffeners for the plate girder of the preceding example for a factored end reaction of 260 kips.

Since the girder end is unframed, bearing stiffeners are required at the supports. The size of the stiffeners must be selected to ensure that the limit states of local buckling, compression, and bearing are not violated.

Limit state of local buckling:

Refer to Fig. 48.13; try $b_{st} = 8$ in. To avoid problems with local buckling, $b_{st}/2t_{st}$ must not exceed $0.56\sqrt{(E/F_y)} = 15.8$. Therefore, try $t_{st} = 1/2$ in. So, $b_{st}/2t_{st} = 8$, which is less than 15.8.

Limit state of compression:

$$A_{eff} = 2(b_{st}t_{st}) + 12t_w^2 = 2(8)(0.5) + 12(5/16)^2 = 9.17 \text{ in.}^2$$

$$I_{st} = t_{st}(2b_{st} + t_w)^3/12 = 0.5[2(8) + 5/16]^3/12 = 181 \text{ in.}^4$$

$$r_{st} = \sqrt{(I_{st}/A_{eff})} = \sqrt{(181/9.17)} = 4.44 \text{ in.}$$

$$Kh/r_{st} = 0.75(70)/4.44 = 11.8$$

$$\lambda_c = (Kh/\pi r_{st})\sqrt{(F_y/E)} = (11.8/3.142)\sqrt{(36/29{,}000)} = 0.132$$

and from Eq. (48.17),

$$\phi_c P_n = 0.85\left(0.658^{\lambda^2}\right) F_y A_{st} = 0.85(0.658)^{0.132^2}(36)(9.17) = 279 \text{ kips}$$

Since $\phi_b P_n > 260$ kips, the design is satisfactory for compression.

Limit state of bearing:
Assuming there is a 1/4-in. weld cutout at the corners of the bearing stiffeners at the junction of the stiffeners and the girder flanges, the bearing area for the stiffener pairs is $A_{pb} = (8 - 0.25)(0.5)(2) = 7.75$ in.^{2}. Substituting this into Eq. (48.98), we have $\phi R_n = 0.75(1.8)(36)(7.75) = 377$ kips, which exceeds the factored reaction of 260 kips. So bearing is not a problem.

Use two $1/2 \times 8$ in. plates for bearing stiffeners.

48.11 Connections

Connections are structural elements used for joining different members of a framework. Connections can be classified according to:

1. the type of connecting medium used: bolted connections, welded connections, bolted–welded connections, riveted connections
2. the type of internal forces the connections are expected to transmit: shear (semirigid, simple) connections, moment (rigid) connections
3. the type of structural elements that made up the connections: single-plate-angle connections, double-web-angle connections, top- and seated-angle connections, seated beam connections, etc.
4. the type of members the connections are joining: beam-to-beam connections (beam splices), column-to-column connections (column splices), beam-to-column connections, hanger connections, etc.

To properly design a connection, a designer must have a thorough understanding of the behavior of the joint under loads. Different modes of failure can occur depending on the geometry of the connection and the relative strengths and stiffnesses of the various components of the connection. To ensure that the connection can carry the applied loads, a designer must check for all perceivable modes of failure pertinent to each component of the connection and the connection as a whole.

Bolted Connections

Bolted connections are connections whose components are fastened together primarily by bolts. The four basic types of bolts are discussed in Section 48.1 under Structural Fasteners. Depending on the direction and line of action of the loads relative to the orientation and location of the bolts, the bolts may be loaded in tension, shear, or a combination of tension and shear. For bolts subjected to shear forces, the design shear strength of the bolts also depends on whether or not the threads of the bolts are excluded from the shear planes. A letter X or N is placed at the end of the ASTM designation of the bolts to indicate whether the threads are excluded or not excluded, respectively, from the shear planes. Thus, A325-X denotes A325 bolts whose threads are excluded from the shear planes, and A490-N denotes A490 bolts whose threads are not excluded from the shear planes. Because of the reduced shear areas for bolts whose threads are not excluded from the shear planes, these bolts have lower design shear strengths than their counterparts whose threads are excluded from the shear planes.

Bolts can be used in both bearing-type connections and slip-critical connections. Bearing-type connections rely on the bearing between the bolt shanks and the connecting parts to transmit forces. Some slippage between the connected parts is expected to occur for this type of connection. Slip-critical connections rely on the frictional force that develops between the connecting parts to transmit forces. No slippage between connecting elements is expected for this type of connection. Slip-critical connections are used for structures designed for vibratory or dynamic loads, such as bridges, industrial buildings, and buildings in regions of high seismicity. Bolts used in slip-critical connections are denoted by the letter F after their ASTM designation, e.g., A325-F, A490-F.

Holes made in the connected parts for bolts may be standard size, oversize, short slotted, or long slotted. Table 48.10 gives the maximum hole dimension for ordinary construction usage.

TABLE 48.10 Nominal Hole Dimensions (in.)

Bolt Diameter, d (in.)	Hole Dimensions			
	Standard (Diameter)	Oversize (Diameter)	Short Slot (Width × Length)	Long Slot (Width × Length)
1/2	9/16	5/8	9/16 × 11/16	9/16 × 1¼
5/8	11/16	13/16	11/16 × 7/8	11/16 × 1⅜
3/4	13/16	15/16	13/16 × 1	13/16 × 1⅞
7/8	15/16	1 1/16	15/16 × 1⅛	15/16 × 2 3/16
1	1 1/16	1¼	1 1/16 × 1 5/16	1 1/16 × 2½
≥1⅛	d + 1/16	d + 5/16	(d + 1/16) × (d + 3/8)	(d + 1/16) × (2.5d)

Note: 1 in. = 25.4 mm

Standard holes can be used for both bearing-type and slip-critical connections. Oversize holes shall be used only for slip-critical connections, and hardened washers shall be installed over these holes in an outer ply. Short-slotted and long-slotted holes can be used for both bearing-type and slip-critical connections, provided that when such holes are used for bearing, the direction of slot is transverse to the direction of loading. While oversize and short-slotted holes are allowed in any or all plies of the connection, long-slotted holes are allowed only in one of the connected parts. In addition, if long-slotted holes are used in an outer ply, plate washers, or a continuous bar with standard holes having a size sufficient to cover, the slot shall be provided.

Bolts Loaded in Tension

If a tensile force is applied to the connection such that the direction of load is parallel to the longitudinal axes of the bolts, the bolts will be subjected to tension. The following conditions must be satisfied for bolts under tensile stresses.

Allowable Stress Design

For ASD the condition is

$$f_t \le F_t \tag{48.102}$$

where f_t = the computed tensile stress in the bolt
F_t = the allowable tensile stress in the bolt (see Table 48.11)

Load and Resistance Factor Design

For LRFD the condition is

$$\phi_t \, F_t \ge f_t \tag{48.103}$$

where $\phi_t = 0.75$, f_t is the tensile stress produced by factored loads (ksi)
F_t = the nominal tensile strength given in Table 48.11

Bolts Loaded in Shear

When the direction of load is perpendicular to the longitudinal axes of the bolts, the bolts will be subjected to shear. The conditions that need to be satisfied for bolts under shear stresses are as follows.

Allowable Stress Design

For bearing-type and slip-critical connections, the condition is

$$f_v \le F_v \tag{48.104}$$

where f_v = the computed shear stress in the bolt (ksi)
F_v = the allowable shear stress in the bolt (see Table 48.12)

TABLE 48.11 F_t of Bolts (ksi) (1 ksi = 6.895 MPa)

	ASD		LRFD	
Bolt Type	F_t (Static Loading)	F_t (Fatigue Loading)	F_t (Static Loading)	F_t (Fatigue Loading)
A307	20	Not allowed	45	Not allowed
A325	44	If $N \le 20{,}000$:	90	F_t is not defined, but the condition $f_t < F_{SR}$ needs to be satisfied
A490	54	F_t = same as for static loading	113	
		If $20{,}000 < N \le 500{,}000$: F_t = 40 (A325) = 49 (A490)		where f_t = tensile stress caused by service loads calculated using a net tensile area given by $A_t = \frac{\pi}{4}\left(d_b - \frac{0.9743}{n}\right)^2$
		If $N > 500{,}000$: F_t = 31 (A325) = 38 (A490)		F_{SR} is the design stress range given by $F_{SR} = \left(\frac{3.9 \times 10^8}{N}\right)^{1/3}$
		where N = number of stress range fluctuations in the design life F_u = minimum specified tensile strength (ksi)		in which d_b = nominal bolt diameter n = threads per inch N = number of stress range fluctuations in the design life

TABLE 48.12 F_v or F_n of Bolts (ksi) (1 ksi = 6.895 MPa)

Bolt Type	F_v for ASD	F_v for LRFD
A307	10.0[a] (regardless of whether or not threads are excluded from shear planes)	24.0[a] (regardless of whether or not threads are excluded from shear planes)
A325-N	21.0[a]	48.0[a]
A325-X	30.0[a]	60.0[a]
A325-F[b]	17.0 for standard size holes	17.0 for standard size holes
	15.0 for oversize and short-slotted holes	15.0 for oversize and short-slotted holes
	12.0 for long-slotted holes when direction of load is transverse to the slots	12.0 for long-slotted holes when direction of load is transverse to the slots
	10.0 for long-slotted holes when direction of load is parallel to the slots	10.0 for long-slotted holes when direction of load is parallel to the slots

A490-X	40.0[a]	75.0[a]
A490-F[b]	21.0 for standard size holes	21.0 for standard size holes
	18.0 for oversize and short-slotted holes	18.0 for oversize and short-slotted holes
	15.0 for long-slotted holes when direction of load is transverse to the slots	15.0 for long-slotted holes when direction of load is transverse to the slots
	13.0 for long-slotted holes when direction of load is parallel to the slots	13.0 for long-slotted holes when direction of load is parallel to the slots

[a] Tabulated values shall be reduced by 20% if the bolts are used to splice tension members having a fastener pattern whose length, measured parallel to the line of action of the force, exceeds 50 in. (127 cm).

[b] Tabulated values are applicable only to class A surfaces, i.e., unpainted clean mill surfaces and blast-cleaned surfaces with class A coatings (with slip coefficient = 0.33). For design strengths with other coatings, see *Load and Resistance Factor Design Specification for Structural Joints Using ASTM A325 or A490 Bolts* [RCSC, 2000].

Load and Resistance Factor Design

For bearing-type connections designed at factored loads and for slip-critical connections designed at service loads, the condition is

TABLE 48.13 Minimum Fastener Tension (kips)

Bolt Diameter (in.)	A325 Bolts	A490 Bolts
1/2	12	15
5/8	19	24
3/4	28	35
7/8	39	49
1	51	64
1⅛	56	80
1¼	71	102
1⅜	85	121
1½	103	148

$$\phi_v F_v \geq f_v \tag{48.105}$$

where ϕ_v = 0.75 for bearing-type connections design for factored loads and 1.00 for slip-critical connections designed at service loads
f_v = the shear stress produced by factored loads for bearing-type connections and by service loads for slip-critical connections (ksi)
F_v = the nominal shear strength given in Table 48.12

For slip-critical connections designed at factored loads, the condition is

$$\phi r_{str} \geq r_u \tag{48.106}$$

where ϕ = 1.0 for standard holes, 0.85 for oversize and short-slotted holes, 0.70 for long-slotted holes transverse to the direction of load, and 0.60 for long-slotted holes parallel to the direction of load
r_{str} = the design slip resistance per bolt, $1.13\mu T_b N_s$
μ = 0.33 for class A surfaces (i.e., unpainted clean mill surfaces or blast-cleaned surfaces with class A coatings), 0.50 for class B surfaces (i.e., unpainted blast-cleaned surfaces or blast-cleaned surfaces with class B coatings), and 0.35 for class C surfaces (i.e., hot-dip galvanized and roughened surfaces)
T_b = the minimum fastener tension given in Table 48.13
N_s = the number of slip planes
r_u = the required force per bolt due to factored loads

Bolts Loaded in Combined Tension and Shear

If a tensile force is applied to a connection such that its line of action is at an angle with the longitudinal axes of the bolts, the bolts will be subjected to combined tension and shear. The conditions that need to be satisfied are given below.

Allowable Stress Design

The conditions are

$$f_v \leq F_v \quad \text{and} \quad f_t \leq F_t \tag{48.107}$$

where f_v and F_v = as defined in Eq. (48.104)
f_t = the computed tensile stress in the bolt (ksi)
F_t = the allowable tensile stress given in Table 48.14

Load and Resistance Factor Design

For bearing-type connections designed at factored loads and slip-critical connections designed at service loads, the conditions are

TABLE 48.14 F_t for Bolts under Combined Tension and Shear (ksi) (1 ksi = 6.895 MPa)

Bearing-Type Connections

	ASD		LRFD	
Bolt Type	Threads Not Excluded from the Shear Plane	Threads Excluded from the Shear Plane	Threads Not Excluded from the Shear Plane	Threads Excluded from the Shear Plane
A307	$26 - 1.8f_v \le 20$		$59 - 2.5f_v \le 45$	
A325	$\sqrt{(44^2 - 4.39f_v^2)}$	$\sqrt{(44^2 - 2.15f_v^2)}$	$117 - 2.5f_v \le 90$	$117 - 2.0f_v \le 90$
A490	$\sqrt{(54^2 - 3.75f_v^2)}$	$\sqrt{(54^2 - 1.82f_v^2)}$	$147 - 2.5f_v \le 113$	$147 - 2.0f_v \le 113$

Slip-Critical Connections

For ASD:
Only $f_v \le F_v$ needs to be checked

where
f_v = computed shear stress in the bolt (ksi)
F_v = $[1 - (f_t A_b / T_b)] \times$ (values of F_v given in Table 48.12)
f_t = computed tensile stress in the bolt (ksi)
A_b = nominal cross-sectional area of bolt (in.^{2})
T_b = minimum pretension load given in Table 48.13

For LRFD:
Only $\phi_v F_v \ge f_v$ needs to be checked

where
ϕ_v = 1.0
f_v = shear stress produced by service load
F_v = $[1 - (T/0.8T_b N_b)] \times$ (values of F_v given in Table 48.12)
T = service tensile force in the bolt (kips)
T_b = minimum pretension load given in Table 48.13
N_b = number of bolts carrying the service load tension T

$$\phi_v F_v \ge f_v \quad \text{and} \quad \phi_t F_t \ge f_t \tag{48.108}$$

where ϕ_v, F_v, and f_v = as defined in Eq. (48.105),
$\phi_t = 0.75$
f_t = the tensile stress due to factored loads for bearing-type connections and to service loads for slip-critical connections (ksi)
F_t = the nominal tension stress limit for combined tension and shear given in Table 48.14

For slip-critical connections designed at factored loads, the condition is given in Eq. (48.106), except that the design slip resistance per bolt ϕr_{str} shall be multiplied by a reduction factor given by $1 - T_u/(1.13T_b N_b)$, where T_u is the factored tensile load on the connection, T_b is given in Table 48.13, and N_b is the number of bolts carrying the factored load tension T_u.

Bearing Strength at Fastener Holes

Connections designed on the basis of bearing rely on the bearing force developed between the fasteners and the holes to transmit forces and moments. The limit state for bearing must therefore be checked to ensure that bearing failure will not occur. Bearing strength is independent of the type of fastener. This is because the bearing stress is more critical on the parts being connected than on the fastener itself. The AISC specification provisions for bearing strength are based on preventing excessive hole deformation. As a result, bearing capacity is expressed as a function of the type of holes (standard, oversize, slotted), bearing area (bolt diameter times the thickness of the connected parts), bolt spacing, edge distance (L_e), strength of the connected parts (F_u), and the number of fasteners in the direction of the bearing force.

TABLE 48.15 Bearing Capacity

Conditions	ASD Allowable Bearing Stress, F_p (ksi)	LRFD Design Bearing Strength, ϕR_n (kips)
1. For standard, oversize, or short-slotted holes loaded in any direction	$L_e F_u/2d \le 1.2F_u$	$0.75[1.2L_c tF_u]$ $\le 0.75[2.4dtF_u]$[a]
2. For long-slotted holes with direction of slot perpendicular to the direction of bearing	$L_e F_u/2d \le 1.0F_u$	$0.75[1.0L_c tF_u]$ $\le 0.75[2.0dtF_u]$
3. If hole deformation at service load is not a design consideration	$L_e F_u/2d \le 1.5F_u$	$0.75[1.5L_c tF_u]$ $\le 0.75[3.0dtF_u]$

Note: L_e = distance from free edge to center of the bolt; L_c = clear distance, in the direction of force, between the edge of the hole and the edge of the adjacent hole or edge of the material; d = nominal bolt diameter; t = thickness of the connected part; F_u = specified minimum tensile strength of the connected part.

[a] This equation is also applicable to long-slotted holes when the direction of the slot is parallel to the direction of the bearing force.

Table 48.15 summarizes the expressions and conditions used in ASD and LRFD for calculating the bearing strength of both bearing-type and slip-critical connections.

Minimum Fastener Spacing

To ensure safety and efficiency and to maintain clearances between bolt nuts, as well as to provide room for wrench sockets, the fastener spacing, s, should not be less than $3d$, where d is the nominal fastener diameter.

Minimum Edge Distance

To prevent excessive deformation and shear rupture at the edge of the connected part, a minimum edge distance L_e must be provided in accordance with the values given in Table 48.16 for standard holes. For oversize and slotted holes, the values shown must be incremented by C_2, given in Table 48.17.

Maximum Fastener Spacing

A limit is placed on the maximum value for the spacing between adjacent fasteners to prevent the possibility of gaps forming or buckling from occurring in between fasteners when the load to be transmitted by the connection is compressive. The maximum fastener spacing measured in the direction of the force is given as follows.

For painted members or unpainted members not subject to corrosion, the maximum fastener spacing is the smaller of $24t$, where t is the thickness of the thinner plate and 12 in. (305 mm).

For unpainted members of weathering steel subject to atmospheric corrosion, the maximum fastener spacing is the smaller of $14t$, where t is the thickness of the thinner plate and 7 in. (178 mm).

TABLE 48.16 Minimum Edge Distance for Standard Holes (in.)

Nominal Fastener Diameter	At Sheared Edges	At Rolled Edges of Plates, Shapes, and Bars or Gas-Cut Edges
1/2	7/8	3/4
5/8	1⅛	7/8
3/4	1¼	1
7/8	1½	1⅛
1	1¾	1¼
1⅛	2	1½
1¼	2¼	1⅝
Over 1¼	1¾ × fastener diameter	1¼ × fastener diameter

Note: 1 in. = 25.4 mm

TABLE 48.17 Values of Edge Distance Increment, C_2 (in.)

Nominal Diameter of Fastener	Oversize Holes	Slotted Holes		
		Slot Transverse to Edge		Slot Parallel to Edge
		Short Slot	Long Slot[a]	
≥7/8	1/16	1/8	3*d*/4	0
1	1/8	1/8		
≥1⅛	1/8	3/16		

Note: 1 in. = 25.4 mm

[a] If the length of the slot is less than the maximum shown in Table 48.10, the value shown may be reduced by one half the difference between the maximum and the actual slot lengths.

Maximum Edge Distance

A limit is placed on the maximum value for edge distance to prevent prying action from occurring. The maximum edge distance shall not exceed the smaller of 12*t*, where *t* is the thickness of the connected part and 6 in. (15 cm).

Example 48.9

Check the adequacy of the connection shown in Fig. 48.4a. The bolts are 1-in.-diameter A325-N bolts in standard holes. The connection is a bearing-type connection.

Check bolt capacity:
All bolts are subjected to double shear. Therefore, the design shear strength of the bolts will be twice that shown in Table 48.12. Assuming each bolt carries an equal share of the factored applied load, we have from Eq. (48.105)

$$\left[\phi_v F_v = 0.75(2 \times 48) = 72 \text{ ksi}\right] > \left[f_v = \frac{208}{(6)\left(\frac{\pi\ 1^2}{4}\right)} = 44.1 \text{ ksi}\right]$$

The shear capacity of the bolt is therefore adequate.

Check bearing capacity of the connected parts:
With reference to Table 48.15, it can be seen that condition 1 applies for the present problem. Therefore, we have

$$\left[\phi R_n = 0.75(1.2L_c tF_u) = 0.75(1.2)\left(3 - 1\frac{1}{8}\right)\left(\frac{3}{8}\right)(58) = 36.7 \text{ kips}\right.$$

$$\left. < 0.75(2.4dtF_u) = 0.75(2.4)(1)\left(\frac{3}{8}\right)(58) = 39.2 \text{ kips}\right] > \left[R_u = \frac{208}{6} = 34.7 \text{ kips}\right]$$

and so bearing is not a problem. Note that bearing on the gusset plate is more critical than bearing on the webs of the channels, because the thickness of the gusset plate is less than the combined thickness of the double channels.

Check bolt spacing:
The minimum bolt spacing is $3d = 3(1) = 3$ in. The maximum bolt spacing is the smaller of $14t = 14(0.303) = 4.24$ in. or 7 in. The actual spacing is 3 in., which falls within the range of 3 to 4.24 in., so bolt spacing is adequate.

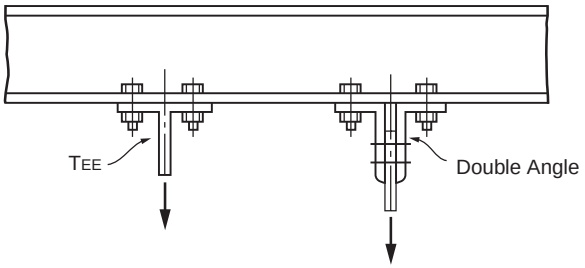

FIGURE 48.14 Hanger connections.

Check edge distance:
From Table 48.16, it can be determined that the minimum edge distance is 1.25 in. The maximum edge distance allowed is the smaller of $12t = 12(0.303) = 3.64$ in. or 6 in. The actual edge distance is 3 in., which falls within the range of 1.25 to 3.64 in., so the edge distance is adequate.

The connection is therefore adequate.

Bolted Hanger-Type Connections

A typical hanger connection is shown in Fig. 48.14. In the design of such connections, the designer must take into account the effect of *prying action*. Prying action results when flexural deformation occurs in the tee flange or angle leg of the connection (Fig. 48.15). The prying action tends to increase the tensile force, called prying force, in the bolts. To minimize the effect of prying, the fasteners should be placed as close to the tee stem or outstanding angle leg as the wrench clearance will permit (see tables on entering and tightening clearances in Volume II, Connections, of the AISC-LRFD manual [AISC, 1992]). In addition, the flange and angle thicknesses should be proportioned so that the full tensile capacities of the bolts can be developed.

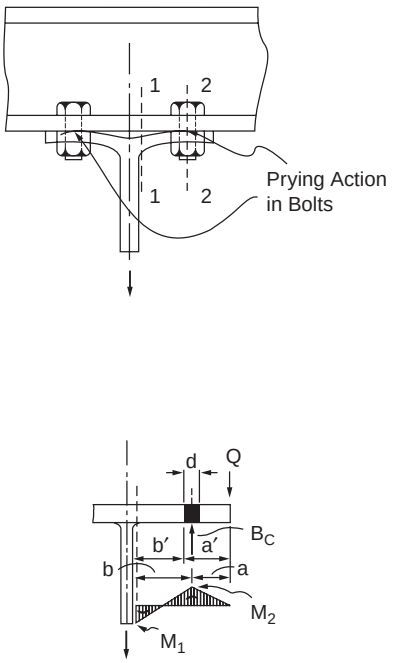

FIGURE 48.15 Prying action in hanger connections.

Two failure modes can be identified for hanger-type connections: formation of plastic hinges in the tee flange or angle leg at cross sections 1 and 2, and tensile failure of the bolts when the tensile force, including prying action B_c (=B + Q), exceeds the tensile capacity of bolt B. Since the determination of the actual prying force is rather complex, the design equation for the required thickness for the tee flange or angle leg is semiempirical in nature. It is given by the following:

If ASD is used:

$$t_{r'eqd} = \sqrt{\frac{8T\,b'}{pF_y\left(1+\delta\alpha'\right)}} \tag{48.109}$$

where T is the tensile force per bolt due to the service load, exclusive of initial tightening and prying force (kips).

The other variables are as defined in Eq. (48.110) below, except that B in the equation for α' is defined as the allowable tensile force per bolt. A design is considered satisfactory if the thickness of the tee flange or angle leg t_f exceeds $t_{req'd}$ and $B > T$.

If LRFD is used:

$$t_{r'eqd} = \sqrt{\frac{4T_u b'}{\phi_b\, pF_y\left(1+\delta\alpha'\right)}} \tag{48.110}$$

where $\phi_b = 0.90$

T_u = the factored tensile force per bolt, exclusive of initial tightening and prying force (kips)

p = the length of flange tributary to each bolt measured along the longitudinal axis of the tee or double-angle section (in.)

δ = the ratio of the net area at the bolt line to the gross area at the angle leg or stem face, $(p - d')/p$

d' = the diameter of bolt hole, bolt diameter + 1/8 in.

$$\alpha' = \frac{\left(B/T_u - 1\right)\left(a'/b'\right)}{\delta\left[1-\left(B/T_u - 1\right)\left(a'/b'\right)\right]} \le 1;$$ (if α' is less than zero, use $\alpha' = 1$)

B = the design tensile strength of one bolt, $\phi F_t A_b$ (kips) (ϕF_t is given in Table 48.11 and A_b is the nominal diameter of the bolt)

$a' = a + d/2$

$b' = b - d/2$

a = the distance from the bolt centerline to the edge of the tee flange or angle leg, but not more than $1.25b$ (in.)

b = the distance from the bolt centerline to the face of the tee stem or outstanding leg (in.).

A design is considered satisfactory if the thickness of the tee flange or angle leg t_f exceeds $t_{req'd}$ and $B > T_u$. Note that if t_f is much larger than $t_{req'd}$, the design will be too conservative. In this case, α' should be recomputed using the equation

$$\alpha' = \frac{1}{\delta}\left[\frac{4T_u b'}{\phi_b\, pt_f^2 F_y} - 1\right] \tag{48.111}$$

As before, the value of α' should be limited to the range $0 \le \alpha' \le 1$. This new value of α' is to be used in Eq. (48.110) to recalculate $t_{req'd}$.

Bolted Bracket-Type Connections

Figure 48.16 shows three commonly used bracket-type connections. The bracing connection shown in Fig. 48.16a should preferably be designed so that the line of action of the force will pass through the centroid of the bolt group. It is apparent that the bolts connecting the bracket to the column flange are subjected to combined tension and shear. As a result, the combined tensile–shear capacities of the bolts should be checked in accordance with Eq. (48.107) in ASD or Eq. (48.108) in LRFD. For simplicity, f_v and f_t are to be computed assuming that both the tensile and shear components of the force are distributed evenly to all bolts. In addition to checking for the bolt capacities, the bearing capacities of the column flange and the bracket should also be checked. If the axial component of the force is significant, the effect of prying should also be considered.

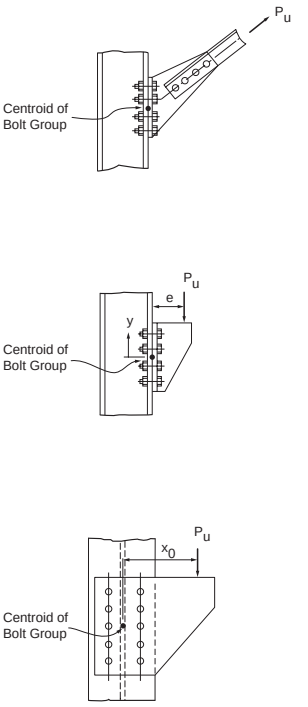

FIGURE 48.16 Bolted bracket-type connections.

In the design of the eccentrically loaded connections shown in Fig. 48.16b, it is assumed that the neutral axis of the connection lies at the center of gravity of the bolt group. As a result, the bolts above the neutral axis will be subjected to combined tension and shear, so Eq. (48.107) or (48.108) needs to be checked. The bolts below the neutral axis are subjected to shear only, so Eq. (48.104) or (48.105) applies. In calculating f_v, one can assume that all bolts in the bolt group carry an equal share of the shear force. In calculating f_t, one can assume that the tensile force varies linearly from a value of zero at the neutral axis to a maximum value at the bolt farthest away from the neutral axis. Using this assumption, f_t can be calculated from the equation Pey/I, where y is the distance from the neutral axis to the location of the bolt above the neutral axis and $I = \Sigma A_b y^2$ is the moment of inertia of the bolt areas, with A_b being the cross-sectional area of each bolt. The capacity of the connection is determined by the capacities of the bolts and the bearing capacity of the connected parts.

For the eccentrically loaded bracket connection shown in Fig. 48.16c, the bolts are subjected to shear. The shear force in each bolt can be obtained by adding vectorally the shear caused by the applied load P and the moment P_{χ_o}. The design of this type of connections is facilitated by the use of tables contained in the AISC-ASD and AISC-LRFD manuals [AISC, 1989, 2001].

In addition to checking for bolt shear capacity, one needs to check the bearing and shear rupture capacities of the bracket plate to ensure that failure will not occur in the plate.

Bolted Shear Connections

Shear connections are connections designed to resist shear force only. They are used in type 2 or type 3 construction in ASD and in type PR construction in LRFD. These connections are not expected to provide appreciable moment restraint to the connection members. Examples of these connections are shown in Fig. 48.17. The framed beam connection shown in Fig. 48.17a consists of two web angles that are often shop-bolted to the beam web and then field-bolted to the column flange. The seated beam connection shown in Fig. 48.17b consists of two flange angles often shop-bolted to the beam flange and field-bolted to the column flange. To enhance the strength and stiffness of the seated beam connection, a stiffened seated beam connection, shown in Fig.48.17c, is sometimes used to resist large shear force. Shear connections must be designed to sustain appreciable deformation, and yielding of the connections is expected. The need for ductility often limits the thickness of the angles that can be used. Most of these connections are designed with angle thicknesses not exceeding 5/8 in.

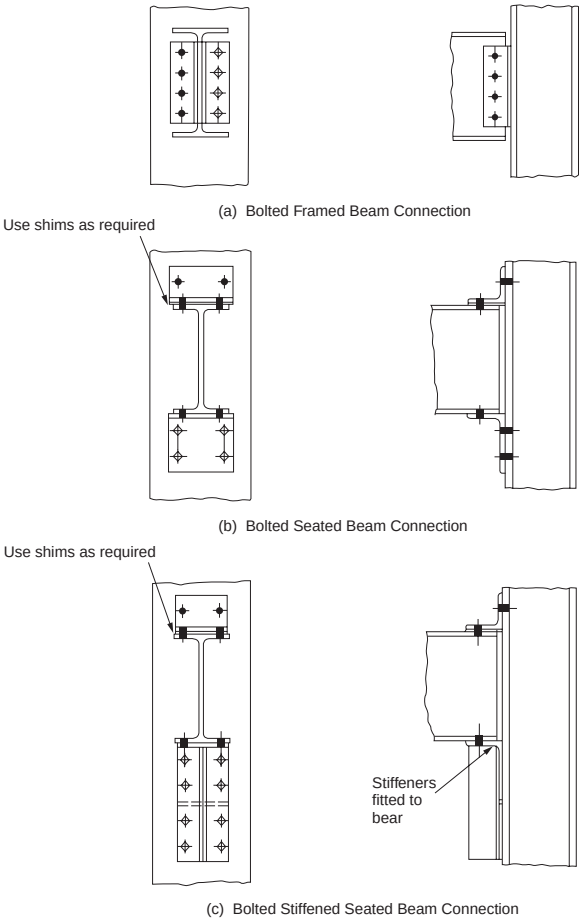

FIGURE 48.17 Bolted shear connections: (a) bolted framed beam connection, (b) bolted seated beam connection, (c) bolted stiffened seated beam connection.

The design of the connections shown in Fig. 48.17 is facilitated by the use of design tables contained in the AISC-ASD and AISC-LRFD manuals. These tables give design loads for the connections with specific dimensions based on the limit states of bolt shear, the bearing strength of the connection, the bolt bearing with different edge distances, and the block shear (for coped beams).

Bolted Moment-Resisting Connections

Moment-resisting connections are connections designed to resist both moment and shear. They are used in type 1 construction in ASD and in type FR construction in LRFD. These connections are often referred to as rigid or fully restrained connections, as they provide full continuity between the connected members and are designed to carry the full factored moments. Figure 48.18 shows some examples of moment-resisting connections. Additional examples can be found in the AISC-ASD and AISC-LRFD manuals and in Chapter 4 of the AISC manual on connections [AISC, 1992].

Design of Moment-Resisting Connections

An assumption used quite often in the design of moment connections is that the moment is carried solely by the flanges of the beam. The moment is converted to a couple F_f given by $F_f = M/(d - t_f)$ acting on the beam flanges, as shown in Fig. 48.19.

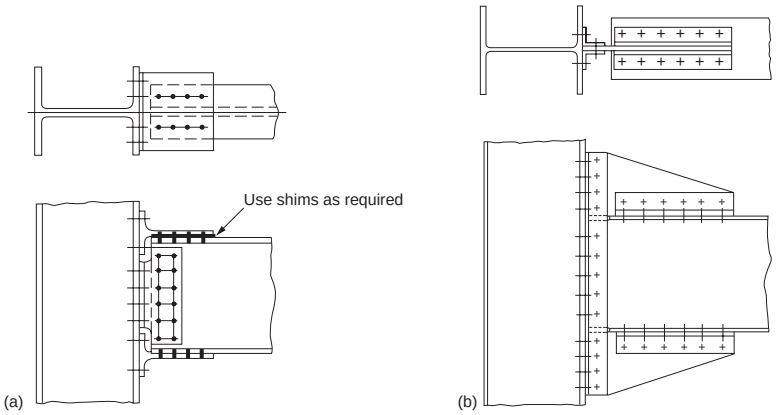

FIGURE 48.18 Bolted moment connections.

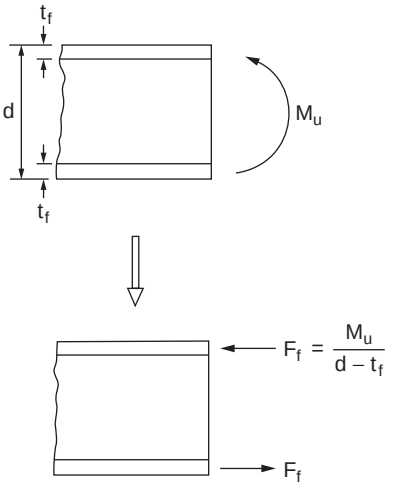

FIGURE 48.19 Flange forces in moment connections.

The design of the connection for moment is considered satisfactory if the capacities of the bolts and connecting plates or structural elements are adequate to carry the flange force F_f. Depending on the geometry of the bolted connection, this may involve checking: (1) the shear and tensile capacities of the bolts, (2) the yield and fracture strengths of the moment plate, (3) the bearing strength of the connected parts, and (4) the bolt spacing and edge distance, as discussed in the foregoing sections.

As for shear, it is common practice to assume that all the shear resistance is provided by the shear plates or angles. The design of the shear plates or angles is governed by the limit states of bolt shear, the bearing of the connected parts, and shear rupture.

If the moment to be resisted is large, the flange force may cause bending of the column flange or local yielding, crippling, or buckling of the column web. To prevent failure due to bending of the column flange or local yielding of the column web (for a tensile F_f), as well as local yielding, crippling, or buckling of the column web (for a compressive F_f), column stiffeners should be provided if any one of the conditions discussed in Section 48.5 under Criteria for Concentrated Loads is violated.

Following is a set of guidelines for the design of column web stiffeners [AISC, 1989, 2001]:

1. If local web yielding controls, the area of the stiffeners (provided in pairs) shall be determined based on any excess force beyond that which can be resisted by the web alone. The stiffeners need not extend more than one half the depth of the column web if the concentrated beam flange force F_f is applied at only one column flange.
2. If web crippling or compression buckling of the web controls, the stiffeners shall be designed as axially loaded compression members (see Section 48.4). The stiffeners shall extend the entire depth of the column web.
3. The welds that connect the stiffeners to the column shall be designed to develop the full strength of the stiffeners.

In addition, the following recommendations are given:

1. The width of the stiffener plus one half of the column web thickness should not be less than one half the width of the beam flange or the moment connection plate that applies the force.
2. The stiffener thickness should not be less than one half the thickness of the beam flange.
3. If only one flange of the column is connected by a moment connection, the length of the stiffener plate does not have to exceed one half the column depth.
4. If both flanges of the column are connected by moment connections, the stiffener plate should extend through the depth of the column web, and welds should be used to connect the stiffener plate to the column web with sufficient strength to carry the unbalanced moment on opposite sides of the column.
5. If column stiffeners are required on both the tension and compression sides of the beam, the size of the stiffeners on the tension side of the beam should be equal to that on the compression side for ease of construction.

In lieu of stiffener plates, a stronger column section should be used to preclude failure in the column flange and web.

For a more thorough discussion of bolted connections, see the book by Kulak et al. [1987]. Examples on the design of a variety of bolted connections can be found in the AISC-LRFD manual [AISC, 2001] and in the AISC manual on connections [AISC, 1992].

Welded Connections

Welded connections are connections whose components are joined together primarily by welds. The four most commonly used welding processes are discussed in Section 48.1 under Structural Fasteners. Welds can be classified according to:

- the types of welds: groove, fillet, plug, and slot
- the positions of the welds: horizontal, vertical, overhead, and flat
- the types of joints: butt, lap, corner, edge, and tee

Although fillet welds are generally weaker than groove welds, they are used more often because they allow for larger tolerances during erection than groove welds. Plug and slot welds are expensive to make and do not provide much reliability in transmitting tensile forces perpendicular to the faying surfaces. Furthermore, quality control of such welds is difficult because inspection of the welds is rather arduous. As a result, plug and slot welds are normally used just for stitching different parts of the members together.

Welding Symbols

A shorthand notation giving important information on the location, size, length, etc. for various types of welds was developed by the American Welding Society [AWS, 1987] to facilitate the detailing of welds. This system of notation is reproduced in Fig. 48.20.

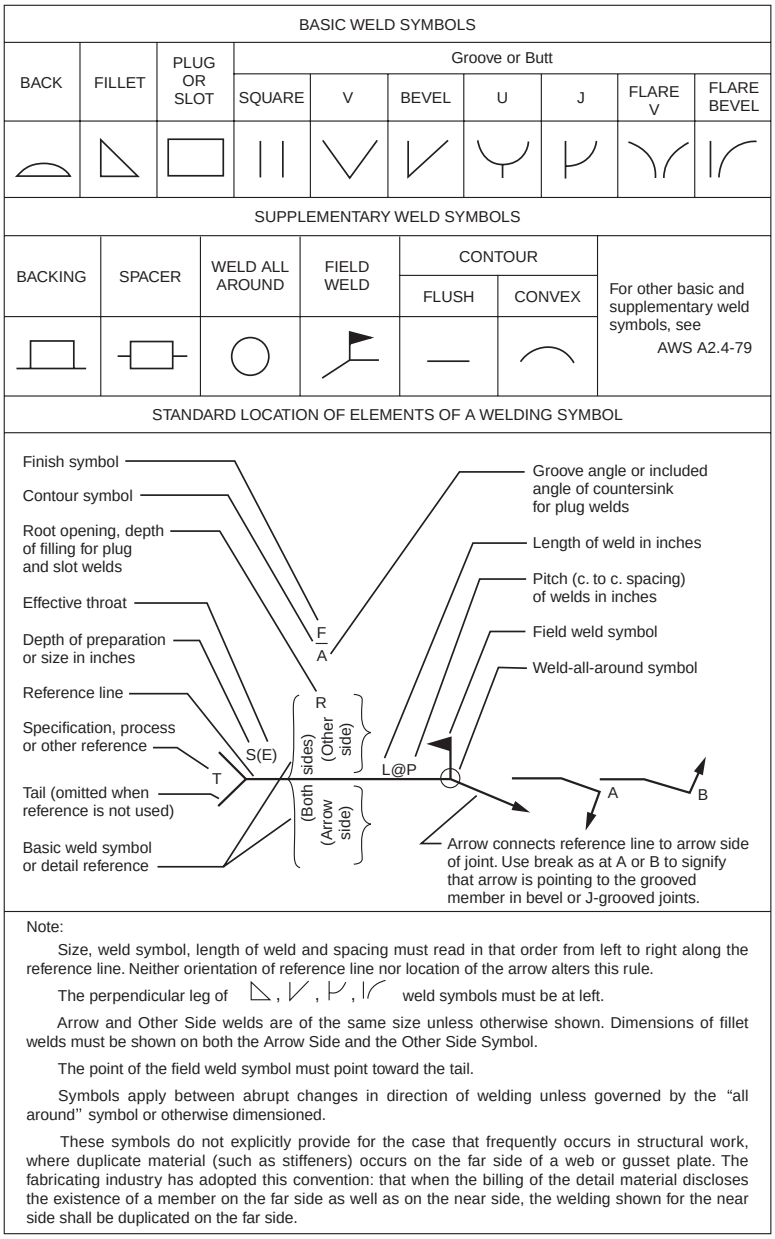

FIGURE 48.20 Basic weld symbols.

Strength of Welds

In ASD, the strength of welds is expressed in terms of allowable stress. In LRFD, the design strength of welds is taken as the smaller of the design strength of the base material ϕF_{BM} (expressed as a function of the yield stress of the material) and the design strength of the weld electrode ϕF_W (expressed as a function of the strength of the electrode F_{EXX}). These allowable stresses and design strengths are summarized in Table 48.18 [AISC, 1989, 1999]. When using ASD, the computed stress in the weld shall not exceed its allowable value. When using LRFD, the design strength of welds should exceed the required strength, obtained by dividing the load to be transmitted by the effective area of the welds.

TABLE 48.18 Strength of Welds

Types of Weld and Stress[a]	Material	ASD Allowable Stress	LRFD ϕF_{BM} or ϕF_W	Required Weld Strength Level[b,c]
		Full-Penetration Groove Weld		
Tension normal to effective area	Base	Same as base metal	$0.90F_y$	"Matching" weld must be used
Compression normal to effective area	Base	Same as base metal	$0.90F_y$	Weld metal with a strength level equal to or less than that of the "matching" weld metal must be used
Tension or compression parallel to axis of weld	Base	Same as base metal	$0.90F_y$	
Shear on effective area	Base Weld electrode	0.30 × nominal tensile strength of weld metal	$0.90[0.60F_y]$ $0.80[0.60F_{EXX}]$	
		Partial-Penetration Groove Welds		
Compression normal to effective area	Base	Same as base metal	$0.90F_y$	Weld metal with a strength level equal to or less than that of the "matching" weld metal may be used
Tension or compression parallel to axis of weld[d]				
Shear parallel to axis of weld	Base Weld electrode	0.30 × nominal tensile strength of weld metal	$0.75[0.60F_{EXX}]$	
Tension normal to effective area	Base Weld electrode	0.30 × nominal tensile strength of weld metal ≤ 0.18 × yield stress of base metal	$0.90F_y$ $0.80[0.60F_{EXX}]$	
		Fillet Welds		
Stress on effective area	Base Weld electrode	0.30 × nominal tensile strength of weld metal	$0.75[0.60F_{EXX}]$	Weld metal with a strength level equal to or less than that of "matching" weld metal may be used
Tension or compression parallel to axis of weld[d]	Base	Same as base metal	$0.90F_y$	
		Plug or Slot Welds		
Shear parallel to faying surfaces (on effective area)	Base Weld electrode	0.30 × nominal tensile strength of weld metal	$0.75[0.60F_{EXX}]$	Weld metal with a strength level equal to or less than that of "matching" weld metal may be used

[a] See below for effective area.
[b] See AWS D1.1 for "matching" weld material.
[c] Weld metal one strength level stronger than "matching" weld metal will be permitted.
[d] Fillet welds and partial-penetration groove welds joining component elements of built-up members, such as flange-to-web connections, may be designed without regard to the tensile or compressive stress in these elements parallel to the axis of the welds.

Effective Area of Welds

The effective area of groove welds is equal to the product of the width of the part joined and the effective throat thickness. The effective throat thickness of a full-penetration groove weld is taken as the thickness of the thinner part joined. The effective throat thickness of a partial-penetration groove weld is taken as

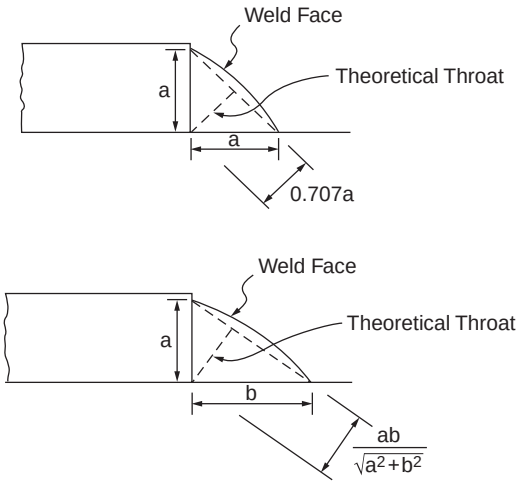

FIGURE 48.21 Effective throat of fillet welds.

the depth of the chamfer for J, U, bevel, or V (with bevel ≥60°) joints, and it is taken as the depth of the chamfer minus 1/8 in. (3 mm) for bevel or V joints if the bevel is between 45° and 60°. For flare bevel-groove welds the effective throat thickness is taken as 5*R*/16, and for flare V-groove welds the effective throat thickness is taken as *R*/2 (or 3*R*/8 for the GMAW process when $R \geq 1$ in.). *R* is the radius of the bar or bend.

The effective area of fillet welds is equal to the product of the length of the fillets, including returns, and the effective throat thickness. The effective throat thickness of a fillet weld is the shortest distance from the root of the joint to the face of the diagrammatic weld, as shown in Fig. 48.21. Thus, for an equal leg fillet weld, the effective throat is given by 0.707 times the leg dimension. For a fillet weld made by the SAW process, the effective throat thickness is taken as the leg size (for 3/8-in. or 9.5-mm and smaller fillet welds) or as the theoretical throat plus 0.11 in. or 3 mm (for fillet welds over 3/8 in. or 9.5 mm). A larger value for the effective throat thickness is permitted for welds made by the SAW process to account for the inherently superior quality of such welds.

The effective area of plug and slot welds is taken as the nominal cross-sectional area of the hole or slot in the plane of the faying surface.

Size and Length Limitations of Welds

To ensure effectiveness, certain size and length limitations are imposed for welds. For partial-penetration groove welds, minimum values for the effective throat thickness are given in Table 48.19.

TABLE 48.19 Minimum Effective Throat Thickness for Partial-Penetration Groove Welds (in.)

Thickness of the Thicker Part Joined, *t*	Minimum Effective Throat Thickness
$t \leq 1/4$	1/8
$1/4 < t \leq 1/2$	3/16
$1/2 < t \leq 3/4$	1/4
$3/4 < t \leq 1\frac{1}{2}$	5/16
$1\frac{1}{2} < t \leq 2\frac{1}{4}$	3/8
$2\frac{1}{4} < t \leq 6$	1/2
>6	5/8

Note: 1 in. = 25.4 mm

For plug welds, the hole diameter shall not be less than the thickness of the part that contains the weld plus 5/16 in. (8 mm), rounded to the next larger odd 1/16 in. (or even mm), or greater than the minimum diameter plus 1/8 in. (3 mm) or 2.25 times the thickness of the weld. The center-to-center spacing of plug welds shall not be less than four times the hole diameter. The thickness of a plug weld in material less than 5/8 in. (16 mm) thick shall be equal to the thickness of the material. In material over 5/8 in. (16 mm) thick, the thickness of the weld shall be at least one half the thickness of the material, but not less than 5/8 in. (16 mm).

For slot welds, the slot length shall not exceed ten times the thickness of the weld. The slot width shall not be less than the thickness of the part that contains the weld plus 5/16 in. (8 mm), rounded to the nearest larger odd 1/16 in. (or even mm), or larger than 2.25 times the thickness of the weld. The spacing of lines of slot welds in a direction transverse to their length shall not be less than four times the width of the slot. The center-to-center spacing of two slot welds on any line in the longitudinal direction shall not be less than two times the length of the slot. The thickness of a slot weld in material less than 5/8 in. (16 mm) thick shall be equal to the thickness of the material. In material over 5/8 in. (16 mm) thick, the thickness of the weld shall be at least one half the thickness of the material, but not less than 5/8 in. (16 mm).

For fillet welds, the minimum leg size is given in Table 48.20. The maximum leg size is equal to the thickness of the connected part along the edge of a connected part less than 1/4 in. (6 mm) thick. For thicker parts, the maximum leg size is t minus 1/16 in. (2 mm), where t is the thickness of the part. The minimum effective length of a fillet weld is four times its nominal size. If a shorter length is used, the leg size of the weld shall be taken as 1/4 in. (6 mm) its effective length for the purpose of stress computation. The effective length of end-loaded fillet welds with lengths up to 100 times the leg dimension can be set equal to the actual length. If the length exceeds 100 times the weld size, the effective length shall be taken as the actual length multiplied by a reduction factor, given by $[1.2 - 0.002(L/w)] \leq 1.0$, where L is the actual length of the end-loaded fillet weld and w is the leg size. The length of longitudinal fillet welds used alone for flat-bar tension members shall not be less than the perpendicular distance between the welds. The effective length of any segment of an intermittent fillet weld shall not be less than four times the weld size or 1½ in. (38 mm).

TABLE 48.20 Minimum Leg Size of Fillet Welds (in.)

Thickness of Thicker Part Joined, t	Minimum Leg Size
$t \leq 1/4$	1/8
$1/4 < t \leq 1/2$	3/16
$1/2 < t \leq 3/4$	1/4
$t > 3/4$	5/16

Note: 1 in. = 25.4 mm

Welded Connections for Tension Members

Figure 48.22 shows a tension angle member connected to a gusset plate by fillet welds. The applied tensile force P is assumed to act along the center of gravity of the angle. To avoid eccentricity, the lengths of the two fillet welds must be proportioned so that their resultant will act along the center of gravity of the angle. For example, if LRFD is used, the following equilibrium equations can be written:

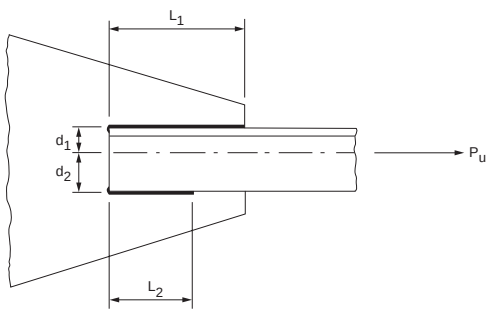

FIGURE 48.22 An eccentrically loaded welded tension connection.

Summing force along the axis of the angle:

$$\left(\phi F_M\right) t_{eff}\, L_1 + \left(\phi F_M\right) t_{eff}\, L_2 = P_u \tag{48.112}$$

Summing moment about the center of gravity of the angle:

$$\left(\phi F_M\right) t_{eff}\, L_1\, d_1 = \left(\phi F_M\right) t_{eff}\, L_2 d_2 \tag{48.113}$$

where P_u = the factored axial force
ϕF_M = the design strength of the welds as given in Table 48.18
t_{eff} = the effective throat thickness
L_1 and L_2 = the lengths of the welds
d_1 and d_2 = the transverse distances from the center of gravity of the angle to the welds.

The two equations can be used to solve for L_1 and L_2.

Welded Bracket-Type Connections

A typical welded bracket connection is shown in Fig. 48.23. Because the load is eccentric with respect to the center of gravity of the weld group, the connection is subjected to both moment and shear. The welds must be designed to resist the combined effect of direct shear for the applied load and any additional shear from the induced moment. The design of the welded bracket connection is facilitated by the use of the design tables in the AISC-ASD and AISC-LRFD manuals. In both ASD and LRFD, the load capacity for the connection is given by

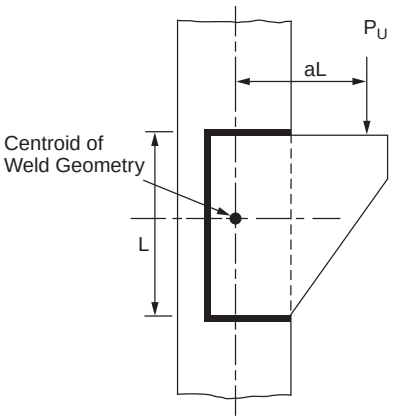

FIGURE 48.23 An eccentrically loaded welded bracket connection.

$$P = CC_1Dl \tag{48.114}$$

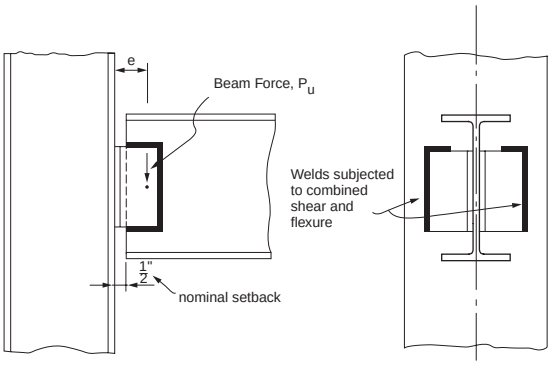
where P = the allowable load (in ASD) or factored load, P_u (in LRFD) (kips)
l = the length of the vertical weld (in.)
D = the number of sixteenths of an inch in the fillet weld size
C = the coefficient tabulated in the AISC-ASD and AISC-LRFD manuals. In the tables, values of C for a variety of weld geometries and dimensions are given
C_1 = the coefficient for electrode used (see the following table).

Electrode		E60	E70	E80	E90	E100	E110
ASD	F_v (ksi)	18	21	24	27	30	33
	C_1	0.857	1.0	1.14	1.29	1.43	1.57
LRFD	F_{EXX} (ksi)	60	70	80	90	100	110
	C_1	0.857	1.0	1.03	1.16	1.21	1.34

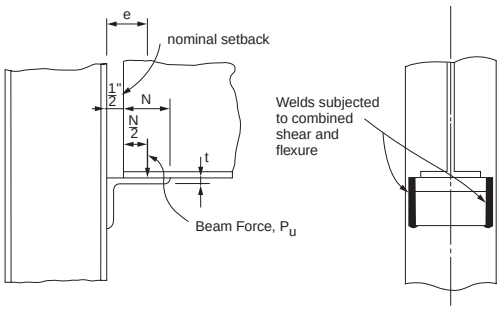
Welded Connections with Welds Subjected to Combined Shear and Flexure

Figure 48.24 shows a welded framed connection and a welded seated connection. The welds for these connections are subjected to combined shear and flexure. For the purpose of design, it is common practice to assume that the shear force per unit length, R_S, acting on the welds is a constant and is given by

$$R_S = \frac{P}{2l} \tag{48.115}$$



Welded Framed Connection



Welded Seated Connection

FIGURE 48.24 Welds subjected to combined shear and flexure.

where P = the allowable load (in ASD) or factored load, P_u (in LRFD)
l = the length of the vertical weld.

In addition to shear, the welds are subjected to flexure as a result of load eccentricity. There is no general agreement on how the flexure stress should be distributed on the welds. One approach is to assume that the stress distribution is linear, with half the weld subjected to tensile flexure stress and half subjected to compressive flexure stress. Based on this stress distribution and ignoring the returns, the flexure tension force per unit length of weld, R_F, acting at the top of the weld can be written as

$$R_F = \frac{Mc}{I} = \frac{Pe\left(l/2\right)}{2\,l^3/12} = \frac{3\,Pe}{l^2} \tag{48.116}$$

where e is the load eccentricity.

The resultant force per unit length acting on the weld, R, is then

$$R = \sqrt{R_S^2 + R_F^2} \tag{48.117}$$

For a satisfactory design, the value R/t_{eff}, where t_{eff} is the effective throat thickness of the weld, should not exceed the allowable values or design strengths given in Table 48.18.

Welded Shear Connections

Figure 48.25 shows three commonly used welded shear connections: a framed beam connection, a seated beam connection, and a stiffened seated beam connection. These connections can be designed by using

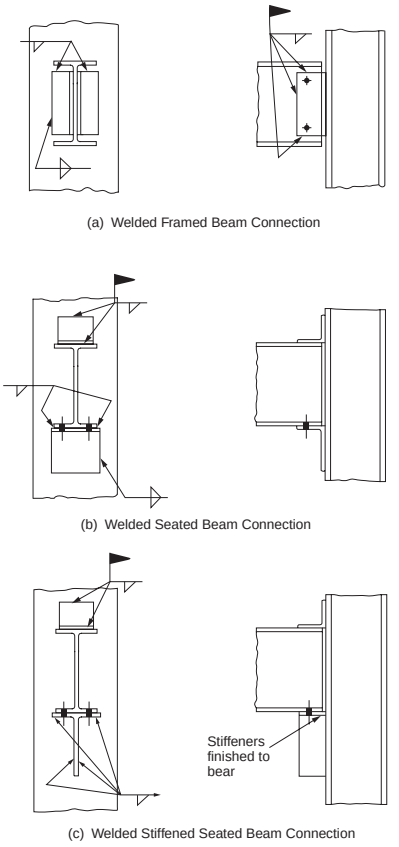


FIGURE 48.25 Welded shear connections: (a) framed beam connection, (b) seated beam connection, (c) stiffened seated beam connection.

the information presented in the earlier sections on welds subjected to eccentric shear and welds subjected to combined tension and flexure. For example, the welds that connect the angles to the beam web in the framed beam connection can be considered eccentrically loaded welds, and Eq. (48.114) can be used for their design. The welds that connect the angles to the column flange can be considered welds subjected to combined tension and flexure, and Eq. (48.117) can be used for their design. Like bolted shear connections, welded shear connections are expected to exhibit appreciable ductility, so the use of angles with thicknesses in excess of 5/8 in. should be avoided. To prevent shear rupture failure, the shear rupture strength of the critically loaded connected parts should be checked.

To facilitate the design of these connections, the AISC-ASD and AISC-LRFD manuals provide design tables by which the weld capacities and shear rupture strengths for different connection dimensions can be checked readily.

Welded Moment-Resisting Connections

Welded moment-resisting connections (Fig. 48.26), like bolted moment-resisting connections, must be designed to carry both moment and shear. To simplify the design procedure, it is customary to assume that the moment, to be represented by a couple F_f, as shown in Fig. 48.19, is to be carried by the beam flanges and that the shear is to be carried by the beam web. The connected parts (e.g., the moment plates, welds, etc.) are then designed to resist the forces F_f and shear. Depending on the geometry of the welded connection, this may include checking: (1) the yield or fracture strength of the moment plate, (2) the shear or tensile capacity of the welds, and (3) the shear rupture strength of the shear plate.

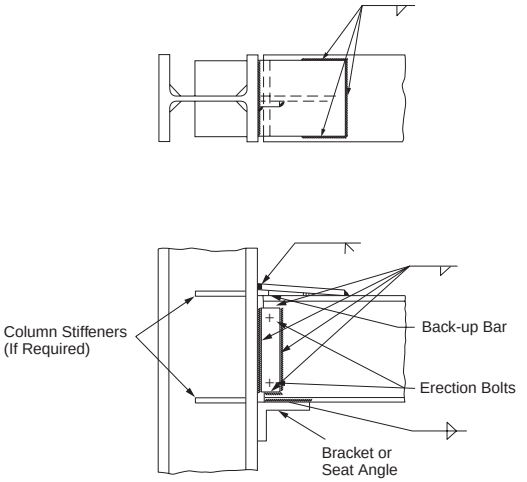

FIGURE 48.26 Welded moment connections.

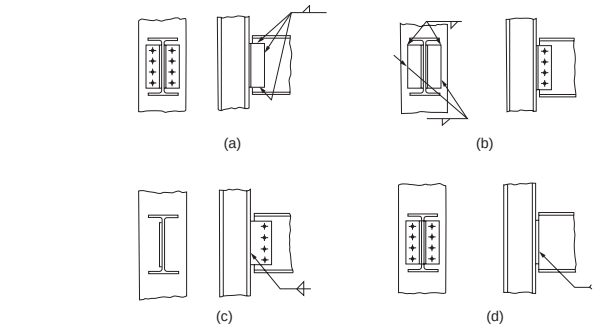
If the column to which the connection is attached is weak, the designer should consider the use of column stiffeners to prevent failure of the column flange and web due to bending, yielding, crippling, or buckling (see above, under Design of Moment-Resisting Connections).

Examples of the design of a variety of welded shear and moment-resisting connections can be found in the AISC manual on connections [AISC, 1992] and in the AISC-LRFD manual [AISC, 2001].

Shop-Welded and Field-Bolted Connections

A large percentage of connections used for construction are shop-welded and field-bolted types. These connections are usually more cost-effective than fully welded connections, and their strength and ductility characteristics often rival those of fully welded connections. Figure 48.27 shows some of these connections. The design of shop-welded and field-bolted connections is also covered in the AISC manual on connections and in the AISC-LRFD manual. In general, the following should be checked: (1) shear and



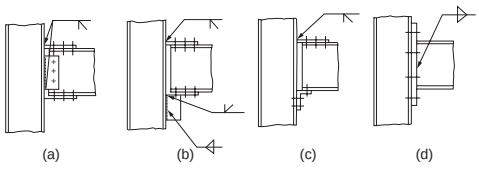


FIGURE 48.27 Shop-welded and field-bolted connections.

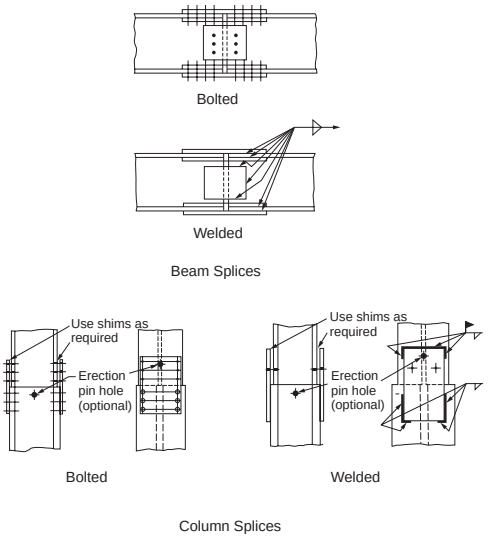

FIGURE 48.28 Bolted and welded beam and column splices.

tensile capacities of the bolts and welds, (2) bearing strength of the connected parts, (3) yield or fracture strength of the moment plate, and (4) shear rupture strength of the shear plate. Also, as for any other types of moment connections, column stiffeners shall be provided if any one of the criteria — column flange bending, local web yielding, crippling, and compression buckling of the column web — is violated.

Beam and Column Splices

Beam and column splices (Fig. 48.28) are used to connect beam or column sections of different sizes. They are also used to connect beams or columns of the same size if the design calls for an extraordinarily long span. Splices should be designed for both moment and shear, unless the designer intends to utilize the splices as internal hinges. If splices are used for internal hinges, provisions must be made to ensure that the connections possess adequate ductility to allow for large hinge rotation.

Splice plates are designed according to their intended functions. Moment splices should be designed to resist the flange force $F_f = M/(d - t_f)$ (Fig. 48.19) at the splice location. In particular, the following limit states need to be checked: yielding of the gross area of the plate, fracture of the net area of the plate (for bolted splices), bearing strengths of connected parts (for bolted splices), shear capacity of bolts (for bolted splices), and weld capacity (for welded splices). Shear splices should be designed to resist the shear forces acting at the locations of the splices. The limit states that need to be checked include the shear rupture of the splice plates, the shear capacity of bolts under an eccentric load (for bolted splices), the bearing capacity of the connected parts (for bolted splices), the shear capacity of bolts (for bolted splices), and the weld capacity under an eccentric load (for welded splices). Design examples of beam and column splices can be found in the AISC manual of connections [AISC, 1992] and in the AISC-LRFD manual [AISC, 2001].

48.12 Column Base Plates and Beam Bearing Plates (LRFD Approach)

Column Base Plates

Column base plates are steel plates placed at the bottom of columns whose function is to transmit column loads to the concrete pedestal. The design of a column base plate involves two major steps: (1) determining the size $N \times B$ of the plate, and (2) determining the thickness t_p of the plate. Generally, the size of the

plate is determined based on the limit state of bearing on concrete, and the thickness of the plate is determined based on the limit state of plastic bending of critical sections in the plate. Depending on the types of forces (axial force, bending moment, shear force) the plate will be subjected to, the design procedures differ slightly. In all cases, a layer of grout should be placed between the base plate and its support for the purpose of leveling, and anchor bolts should be provided to stabilize the column during erection or to prevent uplift for cases involving a large bending moment.

Axially Loaded Base Plates

Base plates supporting concentrically loaded columns in frames in which the column bases are assumed pinned are designed with the assumption that the column factored load P_u is distributed uniformly to the area of concrete under the base plate. The size of the base plate is determined from the limit state of bearing on concrete. The design bearing strength of concrete is given by

$$\phi_c P_p = 0.60 \left[0.85 f_c' A_1 \sqrt{\frac{A_2}{A_1}} \right] \tag{48.118}$$

where f_c' = the compressive strength of concrete
A_1 = the area of the base plate
A_2 = the area of concrete pedestal that is geometrically similar to and concentric with the loaded area, $A_1 \le A_2 \le 4A_1$

From Eq. (48.118), it can be seen that the bearing capacity increases when the concrete area is greater than the plate area. This accounts for the beneficial effect of confinement. The upper limit of the bearing strength is obtained when $A_2 = 4A_1$. Presumably, the concrete area in excess of $4A_1$ is not effective in resisting the load transferred through the base plate.

Setting the column factored load, P_u, equal to the bearing capacity of the concrete pedestal, $\phi_c P_p$, and solving for A_1 from Eq. (48.118), we have

$$A_1 = \frac{1}{A_2} \left[\frac{P_u}{0.6(0.85 f_c')} \right]^2 \tag{48.119}$$

The length, N, and width, B, of the plate should be established so that $N \times B > A_1$. For an efficient design, the length can be determined from the equation

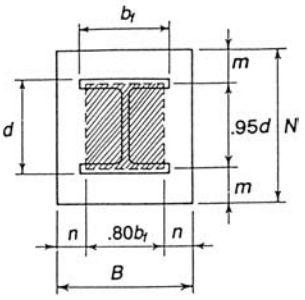
$$N \approx \sqrt{A_1} + 0.50(0.95d - 0.80b_f) \tag{48.120}$$

where $0.95d$ and $0.80b_f$ define the so-called effective load-bearing area shown crosshatched in Fig. 48.29a. Once N is obtained, B can be solved from the equation

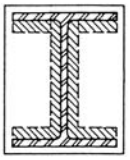
$$B = \frac{A_1}{N} \tag{48.121}$$

Both N and B should be rounded up to the nearest full inches.

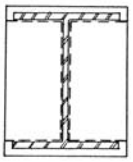
The required plate thickness, $t_{req'd}$, is to be determined from the limit state of yield line formation along the most severely stressed sections. A yield line develops when the cross section moment capacity is equal to its plastic moment capacity. Depending on the size of the column relative to the plate and the magnitude of the factored axial load, yield lines can form in various patterns on the plate. Figure 48.29 shows three models of plate failure in axially loaded plates. If the plate is large compared to the column, yield lines are assumed to form around the perimeter of the effective load-bearing area (the crosshatched area), as shown in Fig. 48.29a. If the plate is small and the column factored load is light, yield lines are



(a) Plate with Large m,n



(b) Lightly Loaded Plate with Small m, n



(c) Heavily Loaded Plate with Small m, n

FIGURE 48.29 Failure models for centrally loaded column base plates.

assumed to form around the inner perimeter of the I-shaped area, as shown in Fig. 48.29b. If the plate is small and the column factored load is heavy, yield lines are assumed to form around the inner edge of the column flanges and both sides of the column web, as shown in Fig. 48.29c. The following equation can be used to calculate the required plate thickness

$$t_{r'eqd} = l\sqrt{\frac{2\,P_u}{0.90\,F_y\,B\,N}} \tag{48.122a}$$

where l is the larger of m, n, and $\lambda n'$ given by

$$m = \frac{\left(N - 0.95\,d\right)}{2} \tag{48.122b}$$

$$n = \frac{\left(B - 0.80 b_f\right)}{2} \tag{48.122c}$$

$$n' = \frac{\sqrt{d\,b_f}}{4} \tag{48.122d}$$

and

$$\lambda = \frac{2\sqrt{X}}{1+\sqrt{1-X}} \le 1 \tag{48.122e}$$

in which

$$X = \left(\frac{4d\,b_f}{\left(d+b_f\right)^2}\right)\frac{P_u}{\phi_c\,P_p} \tag{48.122f}$$

Base Plates for Tubular and Pipe Columns

The design concept for base plates discussed above for I-shaped sections can be applied to the design of base plates for rectangular tubes and circular pipes. The critical section used to determine the plate thickness should be based on 0.95 times the outside column dimension for rectangular tubes and 0.80 times the outside dimension for circular pipes [Dewolf and Ricker, 1990].

Base Plates with Moments

For columns in frames designed to carry moments at the base, base plates must be designed to support both axial forces and bending moments. If the moment is small compared to the axial force, the base plate can be designed without consideration of the tensile force that may develop in the anchor bolts. However, if the moment is large, this effect should be considered. To quantify the relative magnitude of this moment, an eccentricity $e = M_u/P_u$ is used. The general procedures for the design of base plates for different values of e are given below [Dewolf and Ricker, 1990].

Small Eccentricity

If e is small ($e \le N/6$), the bearing stress is assumed to distribute linearly over the entire area of the base plate (Fig. 48.30). The maximum bearing stress is given by

$$f_{\max} = \frac{P_u}{B\,N} + \frac{M_u\,c}{I} \tag{48.123}$$

where $c = N/2$ and $I = BN^3/12$.

The size of the plate is to be determined by a trial-and-error process. The size of the base plate should be such that the bearing stress calculated using Eq. (48.123) does not exceed $\phi_c P_p/A_1$, i.e.,

$$0.60\left[0.85\,f_c'\sqrt{\frac{A_2}{A_1}}\right] \le 0.60\left[1.7\,f_c'\right] \tag{48.124}$$

The thickness of the plate is to be determined from

$$t_p = \sqrt{\frac{4M_{plu}}{0.90\,F_y}} \tag{48.125}$$

where M_{plu} is the moment per unit width of critical section in the plate. M_{plu} is to be determined by assuming that the portion of the plate projecting beyond the critical section acts as an inverted cantilever loaded by the bearing pressure. The moment calculated at the critical section divided by the length of the critical section (i.e., B) gives M_{plu}.

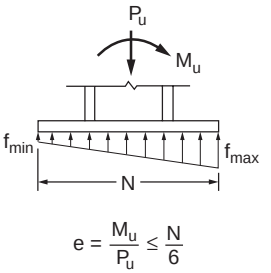


FIGURE 48.30 Eccentrically loaded column base plate (small load eccentricity).

Moderate Eccentricity

For plates subjected to moderate moments ($N/6 < e \leq N/2$), only a portion of the plate will be subjected to bearing stress (Fig. 48.31). Ignoring the tensile force in the anchor bolt in the region of the plate where no bearing occurs and denoting A as the length of the plate in bearing, the maximum bearing stress can be calculated from force equilibrium consideration as

$$f_{\max} = \frac{2P_u}{AB} \tag{48.126}$$

where $A = 3(N/2 - e)$ is determined from moment equilibrium. The plate should be proportioned such that f_{max} does not exceed the value calculated using Eq. (48.124). t_p is to be determined from Eq. (48.125).

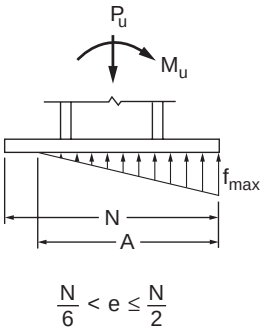

FIGURE 48.31 Eccentrically loaded column base plate (moderate load eccentricity).

Large Eccentricity

For plates subjected to large bending moments so that $e > N/2$, one needs to take into consideration the tensile force that develops in the anchor bolts (Fig. 48.32). Denoting T as the resultant force in the anchor bolts, A as the depth of the compressive stress block, and N' as the distance from the line of action of the tensile force to the extreme compression edge of the plate, force equilibrium requires that

$$T + P_u = \frac{f_{\max} AB}{2} \tag{48.127}$$

and moment equilibrium requires that

$$P_u\left(N' - \frac{N}{2}\right) + M = \frac{f_{\max} AB}{2}\left(N' - \frac{A}{3}\right) \tag{48.128}$$

The above equations can be used to solve for A and T. The size of the plate is determined using a trial-and-error process. The size should be chosen such that f_{max} does not exceed the value calculated using Eq. (48.124), A should be smaller than N', and T should not exceed the tensile capacity of the bolts.

Once the size of the plate is determined, the plate thickness t_p is calculated using Eq. (48.125). Note that there are two critical sections on the plate, one on the compression side of the plate and the other on the tension side of the plate. Two values of M_{plu} are to be calculated, and the larger value should be used to calculate t_p.

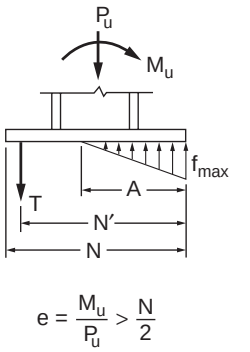

FIGURE 48.32 Eccentrically loaded column base plate (large load eccentricity).

Base Plates with Shear

Under normal circumstances, the factored column base shear is adequately resisted by the frictional force developed between the plate and its support. Additional shear capacity is also provided by the anchor bolts. For cases in which an exceptionally high shear force is expected, such as in a bracing connection, or in which uplift occurs that reduces the frictional resistance, the use of shear lugs may be necessary. Shear lugs can be designed based on the limit states of bearing on concrete and bending of the lugs. The size of the lug should be proportioned such that the bearing stress on concrete does not exceed $0.60(0.85f_c')$. The thickness of the lug can be determined from Eq. (48.125). M_{plu} is the moment per unit width at the critical section of the lug. The critical section is taken to be at the junction of the lug and the plate (Fig. 48.33).

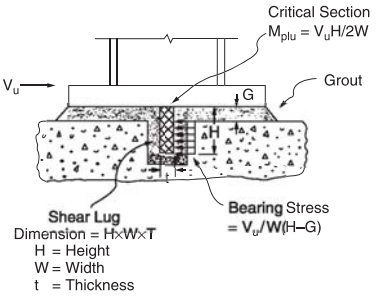

FIGURE 48.33 Column base plate subjected to shear.

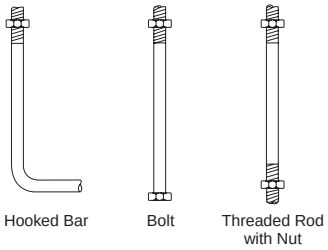

FIGURE 48.34 Base plate anchors.

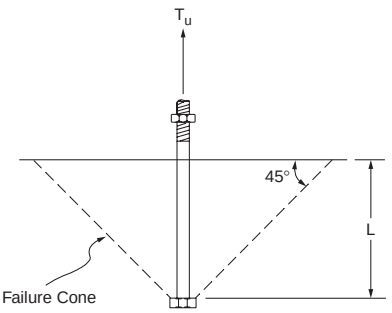

FIGURE 48.35 Cone pullout failure.

Anchor Bolts

Anchor bolts are provided to stabilize the column during erection and to prevent uplift for cases involving large moments. Anchor bolts can be cast-in-place bolts or drilled-in bolts. The latter are placed after the concrete is set and are not often used. Their design is governed by the manufacturer's specifications. Cast-in-place bolts are hooked bars, bolts, or threaded rods with nuts (Fig. 48.34) placed before the concrete is set. Anchor rods and threaded rods shall conform to one of the following ASTM specifications: A36/A36M, A193/A193M, A354, A572/A572M, A588/A588M, or F1554.

Of the three types of cast-in-place anchors shown in the figure, the hooked bars are recommended for use only in axially loaded base plates. They are not normally relied upon to carry significant tensile force. Bolts and threaded rods with nuts can be used for both axially loaded base plates or base plates with moments. Threaded rods with nuts are used when the length and size required for the specific design exceed those of standard-size bolts.

Failure of bolts or threaded rods with nuts occurs when the tensile capacities of the bolts are reached. Failure is also considered to occur when a cone of concrete is pulled out from the pedestal. This cone pullout type of failure is depicted schematically in Fig. 48.35. The failure cone is assumed to radiate out from the bolt head or nut at an angle of 45°, with tensile failure occurring along the surface of the cone

at an average stress of $4\sqrt{f_c'}$, where f_c' is the compressive strength of concrete in psi. The load that will cause this cone pullout failure is given by the product of this average stress and the projected area of the cone A_p [Marsh and Burdette, 1985]. The design of anchor bolts is thus governed by the limit states of tensile fracture of the anchors and cone pullout.

Limit State of Tensile Fracture

The area of the anchor should be such that

$$A_g \geq \frac{T_u}{\phi_t \, 0.75 \, F_u} \tag{48.129}$$

where A_g = the required gross area of the anchor
F_u = the minimum specified tensile strength
ϕ_t = 0.75 is the resistance factor for tensile fracture

Limit State of Cone Pullout

From Fig. 48.35, it is clear that the size of the cone is a function of the length of the anchor. Provided that there are sufficient edge distance and spacing between adjacent anchors, the amount of tensile force required to cause cone pullout failure increases with the embedded length of the anchor. This concept can be used to determine the required embedded length of the anchor. Assuming that the failure cone does not intersect with another failure cone or the edge of the pedestal, the required embedded length can be calculated from the equation

$$L \geq \sqrt{\frac{A_p}{\pi}} = \sqrt{\frac{\left(T_u / \phi_t \; 4 \; \sqrt{f_c'}\right)}{\pi}} \tag{48.130}$$

where A_p is the projected area of the failure cone, T_u is the required bolt force in pounds, f_c' is the compressive strength of concrete in psi, and ϕ_t is the resistance factor (assumed to be equal to 0.75). If failure cones from adjacent anchors overlap one another or intersect with the pedestal edge, the projected area A_p must be adjusted accordingly (see, for example, Marsh and Burdette [1985]).

The length calculated using the above equation should not be less than the recommended values given by Shipp and Haninger [1983]. These values are reproduced in the following table. Also shown in the table are the recommended minimum edge distances for the anchors.

Bolt Type (Material)	Minimum Embedded Length	Minimum Edge Distance
A307 (A36)	12d	5d > 4 in.
A325 (A449)	17d	7d > 4 in.

Note: d = nominal diameter of the anchor.

Beam Bearing Plates

Beam bearing plates are provided between main girders and concrete pedestals to distribute the girder reactions to the concrete supports (Fig. 48.36). Beam bearing plates may also be provided between cross beams and girders if the cross beams are designed to sit on the girders.

Beam bearing plates are designed based on the limit states of web yielding, web crippling, bearing on concrete, and plastic bending of the plate. The dimension of the plate along the beam axis, i.e., N, is determined from the web yielding or web crippling criterion (see Section 48.5 under Criteria for Concentrated Loads), whichever is more critical. The dimension B of the plate is determined from Eq. (48.121) with A_1 calculated using Eq. (48.119). P_u in Eq. (48.119) is to be replaced by R_u, the factored reaction at the girder support.

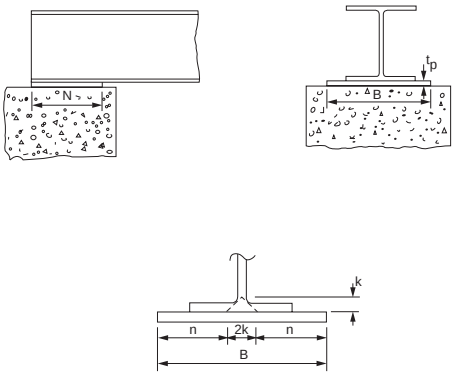

FIGURE 48.36 Beam bearing plate.

Once the size $B \times N$ is determined, the plate thickness, t_p, can be calculated using the equation

$$t_p = \sqrt{\frac{2\,R_u\,n^2}{0.90F_y\,B\,N}} \tag{48.131}$$

where R_u = the factored girder reaction
F_y = the yield stress of the plate
$n = (B - 2k)/2$, in which k is the distance from the web toe of the fillet to the outer surface of the flange

The above equation was developed based on the assumption that the critical sections for plastic bending in the plate occur at a distance k from the centerline of the web.

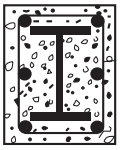
48.13 Composite Members (LRFD Approach)

Composite members are structural members made from two or more materials. The majority of composite sections used for building constructions are made from steel and concrete, although in recent years the use of fiber-reinforced polymer (FRP) has been on the rise, especially in the area of structural rehabilitation. Composite sections made from steel and concrete utilize the strength provided by steel and the rigidity provided by concrete. The combination of the two materials often results in efficient load-carrying members. Composite members may be concrete encased or concrete filled. For concrete-encased members (Fig. 48.37a), concrete is cast around steel shapes. In addition to enhancing strength and providing rigidity to the steel shapes, the concrete acts as a fireproofing material to the steel shapes. It also serves as a corrosion barrier, shielding the steel from corroding under adverse environmental conditions. For concrete-filled members (Fig. 48.37b), structural steel tubes are filled with concrete. In both concrete-encased and concrete-filled sections, the rigidity of the concrete often eliminates the problem of local buckling experienced by some slender elements of the steel sections.

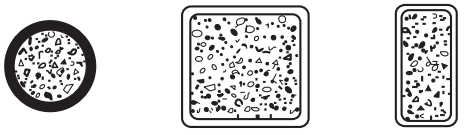
Some disadvantages associated with composite sections are that concrete creeps and shrinks. Furthermore, uncertainties with regard to the mechanical bond developed between the steel shape and the concrete often complicate the design of beam-column joints.

Composite Columns

According to the LRFD specification [AISC, 1999], a compression member is regarded as a composite column if:



(A) Concrete Encased Composite Section



(B) Concrete Filled Composite Sections

FIGURE 48.37 Composite columns.

1. the cross-sectional area of the steel section is at least 4% of the total composite area. If this condition is not satisfied, the member should be designed as a reinforced concrete column.
2. longitudinal reinforcements and lateral ties are provided for concrete-encased members. The cross-sectional area of the reinforcing bars shall be 0.007 in.^{2}/in. (180 mm^2/m) of bar spacing. To avoid spalling, lateral ties shall be placed at a spacing not greater than two thirds the least dimension of the composite cross section. For fire and corrosion resistance, a minimum clear cover of 1.5 in. (38 mm) shall be provided.
3. the compressive strength of concrete f_c' used for the composite section falls within the range of 3 ksi (21 MPa) to 8 ksi (55 MPa) for normal weight concrete and not less than 4 ksi (28 MPa) for lightweight concrete. These limits are set because they represent the range of test data available for the development of the design equations.
4. the specified minimum yield stress for the steel sections and reinforcing bars used in calculating the strength of the composite columns does not exceed 60 ksi (415 MPa). This limit is set because this stress corresponds to a strain below which the concrete remains unspalled and stable.
5. the minimum wall thickness of the steel sections for concrete-filled members is equal to $b\sqrt{(F_y/3E)}$ for rectangular sections of width b and $D\sqrt{(F_y/8E)}$ for circular sections of outside diameter D.

Design Compressive Strength

The design compressive strength, $\phi_c P_n$, shall exceed the factored compressive force, P_u. The design compressive strength for $\phi_c \le 1.5$ is given as

$$\phi_c P_n = \begin{cases} 0.85\left[\left(0.658^{\lambda_c^2}\right) A_s F_{my}\right], & \text{if } \lambda_c \le 1.5 \\ 0.85\left[\left(\dfrac{0.877}{\lambda_c^2}\right) A_s F_{my}\right], & \text{if } \lambda_c > 1.5 \end{cases} \tag{48.132}$$

where

$$\lambda_c = \frac{KL}{r_m \pi}\sqrt{\frac{F_{my}}{E_m}} \tag{48.133}$$

$$F_{my} = F_y + c_1 F_{yr}\left(\frac{A_r}{A_s}\right) + c_2 f_c'\left(\frac{A_c}{A_s}\right) \tag{48.134}$$

$$E_m = E + c_3 E_c \left(\frac{A_c}{A_s} \right) \tag{48.135}$$

r_m = the radius of gyration of steel section and shall not be less than 0.3 times the overall thickness of the composite cross section in the plane of buckling
A_c = the area of concrete
A_r = the area of longitudinal reinforcing bars
A_s = the area of the steel shape
E = the modulus of elasticity of steel
E_c = the modulus of elasticity of concrete
F_y = the specified minimum yield stress of the steel shape
F_{yr} = the specified minimum yield stress of longitudinal reinforcing bars
f_c' = the specified compressive strength of concrete
c_1, c_2, and c_3 = the coefficients given in the table below.

Type of Composite Section	c_1	c_2	c_3
Concrete-encased shapes	0.7	0.6	0.2
Concrete-filled pipes and tubings	1.0	0.85	0.4

In addition to satisfying the condition $\phi_c P_n \geq P_u$, shear connectors spaced no more than 16 in. (405 mm) apart on at least two faces of the steel section in a symmetric pattern about the axes of the steel section shall be provided for concrete-encased composite columns to transfer the interface shear force V_u' between steel and concrete. V_u' is given by

$$V_u' = \begin{cases} V_u \left(1 - \dfrac{A_s F_y}{P_n} \right) & \text{when the force is applied to the steel section} \\ V_u \left(\dfrac{A_s F_y}{P_n} \right) & \text{when the force is applied to the concrete encasement} \end{cases} \tag{48.136}$$

where V_u = the axial force in the column
A_s = the area of steel section
F_y = the yield strength of the steel section
P_n = the nominal compressive strength of the composite column without consideration of slenderness effect

If the supporting concrete area in direct bearing is larger than the loaded area, the bearing condition for concrete must also be satisfied. Denoting $\phi_c P_{nc}$ $(=\phi_c P_{n,\text{composite section}} - \phi_c P_{n,\text{steel shape alone}})$ as the portion of compressive strength resisted by the concrete and A_B as the loaded area, the condition that needs to be satisfied is

$$\phi_c P_{nc} \leq 0.65 \left[1.7 f_c' A_B \right] \tag{48.137}$$

Composite Beams

Composite beams used in construction can often be found in two forms: steel beams connected to a concrete slab by shear connectors, and concrete-encased steel beams.

Steel Beams with Shear Connectors

The design flexure strength for steel beams with shear connectors is $\phi_b M_n$. The resistance factor ϕ_b and nominal moment M_n are determined as follows:

Condition	ϕ_b	M_n
Positive moment region and $h/t_w \le 3.76\sqrt{(E/F_{yf})}$	0.85	Determined from plastic stress distribution on the composite section
Positive moment region and $h/t_w > 3.76\sqrt{(E/F_{yf})}$	0.90	Determined from elastic stress superposition considering the effects of shoring
Negative moment region	0.90	Determined for the steel section alone using equations presented in Section 49.5

Concrete-Encased Steel Beams

For steel beams fully encased in concrete, no additional anchorage for shear transfer is required if (1) at least 1½ in. (38 mm) of concrete cover is provided on top of the beam and at least 2 in. (51 mm) of cover is provided over the sides and at the bottom of the beam, and (2) spalling of concrete is prevented by adequate mesh or other reinforcing steel. The design flexural strength $\phi_b M_n$ can be computed using either an elastic or plastic analysis.

If an elastic analysis is used, ϕ_b shall be taken as 0.90. A linear strain distribution is assumed for the cross section, with zero strain at the neutral axis and maximum strains at the extreme fibers. The stresses are then computed by multiplying the strains by E (for steel) or E_c (for concrete). Maximum stress in steel shall be limited to F_y, and maximum stress in concrete shall be limited to $0.85f_c'$. Tensile strength of concrete shall be neglected. M_n is to be calculated by integrating the resulting stress block about the neutral axis.

If a plastic analysis is used, ϕ_b shall be taken as 0.90 and M_n shall be assumed to be equal to M_p, the plastic moment capacity of the steel section alone.

Composite Beam-Columns

Composite beam-columns shall be designed to satisfy the interaction of Eq. (48.73) or (48.74), whichever is applicable, with $\phi_c P_n$ calculated based on Eqs. (48.132) to (48.135), P_e calculated using $P_e = A_s F_{my}/\lambda_c^2$, and $\phi_b M_n$ calculated using the following equation [Galambos and Chapuis, 1980]:

$$\phi_b M_n = 0.90\left[Z F_y + \frac{1}{3}\left(h_2 - 2c_r\right) A_r F_{yr} + \left(\frac{h_2}{2} - \frac{A_w F_y}{1.7 f_c' h_1}\right) A_w F_y\right] \tag{48.138}$$

where Z = the plastic section modulus of the steel section
c_r = the average of the distance measured from the compression face to the longitudinal reinforcement in that face, and the distance measured from the tension face to the longitudinal reinforcement in that face
h_1 = the width of the composite section perpendicular to the plane of bending
h_2 = the width of the composite section parallel to the plane of bending
A_r = the cross-sectional area of longitudinal reinforcing bars
A_w = the web area of the encased steel shape (=0 for concrete-filled tubes)
F_y = the yield stress of the steel section
F_{yr} = the yield stress of reinforcing bars

If $0 < (P_u/\phi_c P_n) \le 0.3$, a linear interpolation of $\phi_b M_n$, calculated using the above equation and assuming that $P_u/\phi_c P_n = 0.3$, and that calculated for beams with $P_u/\phi_c P_n = 0$ (see above) should be used.

Composite Floor Slabs

Composite floor slabs (Fig. 48.38) can be designed as shored or unshored. In shored construction, temporary shores are used during construction to support the dead and accidental live loads until the concrete cures. The supporting beams are designed on the basis of their ability to develop composite action to support all factored loads after the concrete cures. In unshored construction, temporary shores

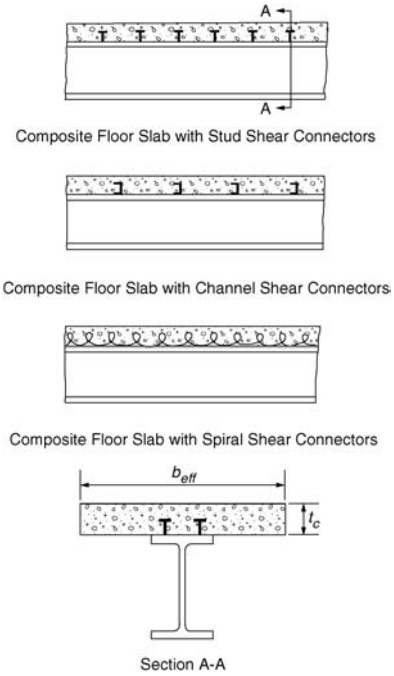


FIGURE 48.38 Composite floor slabs.

are not used. As a result, the steel beams alone must be designed to support the dead and accidental live loads before the concrete has attained 75% of its specified strength. After the concrete is cured, the composite section should have adequate strength to support all factored loads.

Composite action for the composite floor slabs shown in Fig. 48.38 is developed as a result of the presence of shear connectors. If sufficient shear connectors are provided so that the maximum flexural strength of the composite section can be developed, the section is referred to as fully composite. Otherwise, the section is referred to as partially composite. The flexural strength of a partially composite section is governed by the shear strength of the shear connectors. The horizontal shear force V_h, which should be designed for at the interface of the steel beam and the concrete slab, is given by:

In regions of positive moment:

$$V_h = \min\left(0.85 f_c' A_c, A_s F_y, \sum Q_n\right) \tag{48.139}$$

In regions of negative moment:

$$V_h = \min\left(A_r F_{yr}, \sum Q_n\right) \tag{48.140}$$

where f_c' = the compressive strength of concrete
A_c = the effective area of the concrete slab, $t_c b_{eff}$
t_c = the thickness of the concrete slab
b_{eff} = the effective width of the concrete slab = smaller of (L/4, s) for an interior beam, and smaller of (L/8 + distance from beam centerline to edge of slab, s/2 + distance from beam centerline to edge of slab) for an exterior beam
L = the beam span measured from center-to-center of the supports
s = the spacing between centerlines of adjacent beams
A_s = the cross-sectional area of the steel beam

F_y = the yield stress of the steel beam
A_r = the area of reinforcing steel within the effective area of the concrete slab
F_{yr} = the yield stress of the reinforcing steel
ΣQ_n = the sum of the nominal shear strengths of the shear connectors

The nominal shear strength of a shear connector (used without a formed steel deck) is given by:

For a stud shear connector,

$$Q_n = 0.5A_{sc}\sqrt{f'_c E_c} \le A_{sc}F_u \tag{48.141}$$

For a channel shear connector,

$$Q_n = 0.3\left(t_f + 0.5t_w\right) L_c \sqrt{f'_c E_c} \tag{48.142}$$

where A_{SC} = the cross-sectional area of the shear stud (in.^{2})
f'_c = the compressive strength of concrete (ksi)
E_c = the modulus of elasticity of concrete (ksi)
F_u = the minimum specified tensile strength of the stud shear connector (ksi)
t_f = the flange thickness of the channel shear connector (in.)
t_w = the web thickness of the channel shear connector (in.)
L_c = the length of the channel shear connector (in.)

If a formed steel deck is used, Q_n must be reduced by a reduction factor. The reduction factor depends on whether the deck ribs are perpendicular or parallel to the steel beam.

For deck ribs perpendicular to the steel beam,

$$\frac{0.85}{\sqrt{N_r}}\left(\frac{w_r}{h_r}\right)\left[\left(\frac{H_s}{h_r}\right) - 1.0\right] \le 1.0 \tag{48.143}$$

When only a single stud is present in a rib perpendicular to the steel beam, the reduction factor of Eq. (48.143) shall not exceed 0.75.

For deck ribs parallel to steel beam

$$0.6\left[\frac{w_r}{h_r}\right]\left[\left(\frac{H_s}{h_r}\right) - 1.0\right] \le 1.0 \tag{48.144}$$

The reduction factor of Eq. (48.144) is applicable only if $(w_r/h_r) < 1.5$, where N_r is the number of stud connectors in one rib at a beam intersection, not to exceed three in computations, regardless of the actual number of studs installed; w_r is the average width of the concrete rib or haunch; h_r is the nominal rib height; and H_s is the length of stud connector after welding, not to exceed the value $h_r + 3$ in. (75 mm) in computations, regardless of actual length.

For full composite action, the number of connectors required between the maximum moment point and the zero moment point of the beam is given by

$$N = \frac{V_h}{Q_n} \tag{48.145}$$

For partial composite action, the number of connectors required is governed by the condition $\phi_b M_n \ge M_u$, where $\phi_b M_n$ is governed by the shear strength of the connectors.

The placement and spacing of the shear connectors should comply with the following guidelines:

1. The shear connectors shall be uniformly spaced between the points of maximum moment and zero moment. However, the number of shear connectors placed between a concentrated load point and the nearest zero moment point must be sufficient to resist the factored moment M_u.
2. Except for connectors installed in the ribs of formed steel decks, shear connectors shall have at least 1 in. (25.4 mm) of lateral concrete cover. The slab thickness above a formed steel deck shall not be less than 2 in. (51 mm).
3. Unless located over the web, the diameter of shear studs must not exceed 2.5 times the thickness of the beam flange. For a formed steel deck, the diameter of stud shear connectors shall not exceed 3/4 in. (19 mm) and shall extend not less than 1½ in. (38 mm) above the top of the steel deck.
4. The longitudinal spacing of the studs should fall in the range of six times the stud diameter to eight times the slab thickness if a solid slab is used, or four times the stud diameter to eight times the slab thickness or 36 in. (915 mm), whichever is smaller, if a formed steel deck is used. Also, to resist uplift, the steel deck shall be anchored to all supporting members at a spacing not to exceed 18 in. (460 mm).

The design flexural strength $\phi_b M_n$ of the composite beam with shear connectors is determined as follows.

In regions of positive moments, for $h_c/t_w \leq 3.76/\sqrt{(E/F_{yf})}$, $\phi_b = 0.85$, M_n is the moment capacity determined using a plastic stress distribution assuming concrete crushes at a stress of $0.85f_c'$, and steel yields at a stress of F_y. If a portion of the concrete slab is in tension, the strength contribution of that portion of concrete is ignored. The determination of M_n using this method is very similar to the technique used for computing moment capacity of a reinforced concrete beam according to the ultimate strength method.

In regions of positive moments, for $h_c/t_w > 3.76/\sqrt{(E/F_{yf})}$, $\phi_b = 0.90$ and M_n is the moment capacity determined using the superposition of elastic stress, considering the effect of shoring. The determination of M_n using this method is quite similar to the technique used for computing the moment capacity of a reinforced concrete beam according to the working stress method.

In regions of negative moment, $\phi_b M_n$ is to be determined for the steel section alone in accordance with the requirements discussed in Section 48.5. To facilitate design, numerical values of $\phi_b M_n$ for composite beams with shear studs in solid slabs are given in tabulated form in the AISC-LRFD manual. Values of $\phi_b M_n$ for composite beams with formed steel decks are given in a publication by the Steel Deck Institute [2001].

48.14 Plastic Design

Plastic analysis and design is permitted only for steels with a yield stress not exceeding 65 ksi. The reason for this is that steels with a high yield stress lack the ductility required for inelastic deformation at hinge locations. Without adequate inelastic deformation, moment redistribution, which is an important characteristic for plastic design, cannot take place.

In plastic design, the predominant limit state is the formation of plastic hinges. Failure occurs when enough plastic hinges have formed for a collapse mechanism to develop. To ensure that plastic hinges can form and can undergo large inelastic rotation, the following conditions must be satisfied:

1. Sections must be compact, that is, the width–thickness ratios of flanges in compression and webs must not exceed λ_p in Table 48.8.
2. For columns, the slenderness parameter λ_c (see Section 48.4) shall not exceed $1.5K$, where K is the effective length factor, and P_u from gravity and horizontal loads shall not exceed $0.75A_gF_y$.
3. For beams, the lateral unbraced length L_b shall not exceed L_{pd}, where for doubly and singly symmetric I-shaped members loaded in the plane of the web,

$$L_{pd} = \frac{3600 + 2200\left(M_1/M_p\right)}{F_y} r_y \tag{48.146}$$

and for solid rectangular bars and symmetric box beams

$$L_{pd} = \frac{5000 + 3000\left(M_1/M_p\right)}{F_y}\, r_y \geq \frac{3000\, r_y}{F_y} \tag{48.147}$$

In the above equations, M_1 is the smaller end moment within the unbraced length of the beam, M_p is the plastic moment ($=Z_xF_y$) of the cross-section, r_y is the radius of gyration about the minor axis (in.), and F_y is the specified minimum yield stress (ksi).

L_{pd} is not defined for beams bent about their minor axes or for beams with circular and square cross sections, because these beams do not experience lateral torsional bucking when loaded.

Plastic Design of Columns and Beams

Provided that the above limitations are satisfied, the design of columns shall meet the condition $1.7F_aA \geq P_u$, where F_a is the allowable compressive stress given in Eq. (48.16), A is the gross cross-sectional area, and P_u is the factored axial load.

The design of beams shall satisfy the conditions $M_p \geq M_u$ and $0.55F_yt_wd \geq V_u$, where M_u and V_u are the factored moment and shear, respectively. M_p is the plastic moment capacity, F_y is the minimum specified yield stress, t_w is the beam web thickness, and d is the beam depth. For beams subjected to concentrated loads, all failure modes associated with concentrated loads (see Section 48.5 under Criteria for Concentrated Loads) should also be prevented.

Except at the location where the last hinge forms, a beam bending about its major axis must be braced to resist lateral and torsional displacements at plastic hinge locations. The distance between adjacent braced points should not exceed l_{cr}, given by

$$l_{cr} = \begin{cases} \left(\dfrac{1375}{F_y} + 25\right) r_y, & if \;\; -0.5 < \dfrac{M}{M_p} < 1.0 \\ \left(\dfrac{1375}{F_y}\right) r_y, & if \;\; -1.0 < \dfrac{M}{M_p} \leq -0.5 \end{cases} \tag{48.148}$$

where r_y = the radius of gyration about the weak axis
M = the smaller of the two end moments of the unbraced segment
M_p = the plastic moment capacity

M/M_p is taken as positive if the unbraced segment bends in reverse curvature and as negative if the unbraced segment bends in single curvature.

Plastic Design of Beam-Columns

Beam-columns designed on the basis of plastic analysis shall satisfy the following interaction equations for stability (Eq. (48.149)) and strength (Eq. (48.150)):

$$\frac{P_u}{P_{cr}} + \frac{C_m M_u}{\left(1 - \dfrac{P_u}{P_e}\right) M_m} \leq 1.0 \tag{48.149}$$

$$\frac{P_u}{P_y} + \frac{M_u}{1.18 M_p} \leq 1.0 \tag{48.150}$$

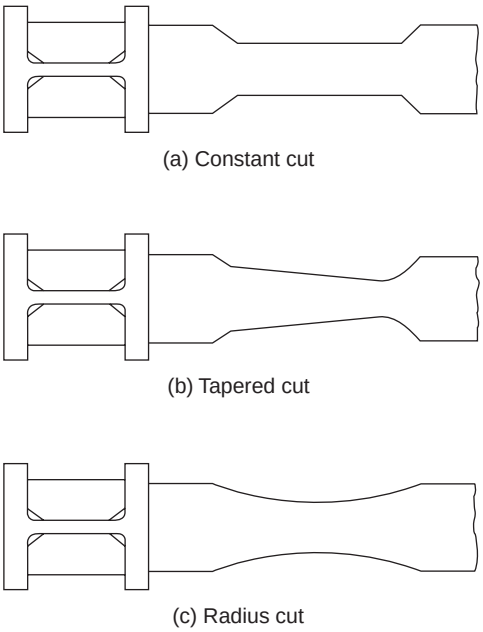

FIGURE 48.39 Reduced beam section-cut geometries.

where P_u = the factored axial load
$P_{cr} = 1.7F_aA$, F_a is defined in Eq. (48.16) (A is the cross-sectional area)
P_y = the yield load, AF_y
P_e = the Euler buckling load, $\pi^2EI/(Kl)^2$
C_m = the coefficent defined in Section 48.4
M_u = the factored moment
M_p = the plastic moment, ZF_y
M_m = the maximum moment that can be resisted by the member in the absence of an axial load, M_{px} if the member is braced in the weak direction and $\{1.07 - [(l/r_y)\sqrt{F_y}]/3160\}M_{px} \le M_{px}$ if the member is unbraced in the weak direction
l = the unbraced length of the member
r_y = the radius of gyration about the minor axis
M_{px} = the plastic moment about the major axis, Z_xF_y
F_y = the minimum specified yield stress (ksi)

Reduced Beam Section

Reduced beam section (RBS), or dogbone connection, is a type of connection in welded steel moment frames in which portions of the bottom beam flange or both top and bottom flanges are cut near the beam-to-column connection, thereby reducing the flexural strength of the beam at the RBS region and thus forcing a plastic hinge to form in a region away from the connection [Iwankiw and Carter, 1996; Engelhardt et al., 1996; Plumier, 1997]. The presence of this reduced section in the beam also tends to decrease the force demand on the beam flange welds and so mitigate the distress that may cause fracture in the connection. RBS can be bottom flange cut only or both top and bottom flange cut. Bottom-flange RBS is used if it is difficult or impossible to cut the top flange of an existing beam (e.g., if the beam is attached to a concrete floor slab). Figure 48.39 shows some typical cut geometries for RBS. The constant cut offers the advantage of ease of fabrication. The tapered cut has the advantage of matching the beam's flexural strength to the flexural demand on the beam under a gravity load. The radius cut is relatively easy to fabricate, and because

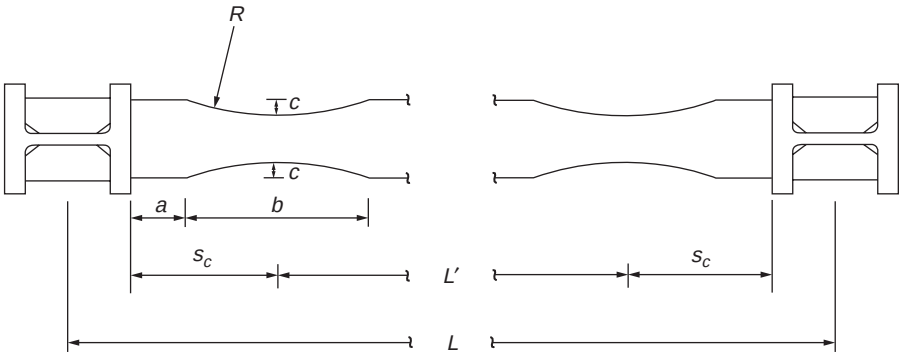

FIGURE 48.40 Key dimensions of a radius-cut reduced beam section.

the change in geometry of the cross section is rather gradual, it also has the advantage of minimizing stress concentration. Based on experimental investigations [Engelhardt et al., 1998; Moore et al., 1999], the radius-cut RBS has been shown to be a reliable connection for welded steel moment frames.

The key dimensions of a radius-cut RBS are shown in Fig. 48.40. The distance from the face of the column to the start of the cut is designated as a; the length and depth of the cut are denoted as b and c, respectively. Values of a, b, and c are given as follows [Engelhardt et al., 1998; Gross et al., 1999]:

$$a \approx (0.5 \text{ to } 0.75)b_f \tag{48.151}$$

$$b \approx (0.65 \text{ to } 0.85)d \tag{48.152}$$

$$c \approx 0.25b_f \qquad \text{for a bottom flange RBS} \tag{48.153}$$

where b_f is the beam flange width and d is the beam depth. Using geometry, the cut radius R can be calculated as

$$R = \frac{4c^2 + b^2}{8c} \tag{48.154}$$

and the distance from the face of the column to the critical plastic section s_c is given by

$$s_c = a + \frac{b}{2} \tag{48.155}$$

An optimal RBS is one in which the moment at the face of the column will be minimized. To achieve this condition, the following procedure is recommended [Gross et al., 1999]:

- Set $c = 0.25b_f$.
- Compute the RBS plastic section modulus using the equation

$$Z_{RBS} = Z_b - \frac{(ct_f)^2}{t_w} - ct_f(d - t_f) \tag{48.156}$$

- where Z_b is the plastic section modulus of the full-beam cross-section; c is the depth of cut, as shown in Fig. 48.40; and d, t_f, and t_w are the beam depth, beam flange thickness, and web thickness, respectively.

- Compute η, the ratio of the moment at the face of the column to the plastic moment of the connecting beam, from the equation

$$\eta = 1.1\left(1 + \frac{2s_c}{L'}\right)\frac{Z_{RBS}}{Z_b} + \frac{wL's_c}{2Z_bF_{yf}} \tag{48.157}$$

- where s_c is given in Eq. (48.155) and shown in Fig. 48.40, L' is the beam span between critical plastic sections (see Fig. 48.40), Z_{RBS} and Z_b are defined in Eq. (48.156), w is the magnitude of the uniformly distributed load on the beam, and F_{yf} is the beam flange yield strength.
- If $\eta < 1.05$, then the RBS dimensions are satisfactory. Otherwise, use RBS cutouts in both the top and bottom flanges, or consider using other types of moment connections [Gross et al., 1999].

Experimental studies [Uang and Fan, 1999; Yu et al., 2000; Gilton et al., 2000, Engelhardt et al., 2000] of a number of radius-cut RBS, with or without the presence of a concrete slab, have shown that the connections perform satisfactorily and exhibit sufficient ductility under cyclic loading. However, the use of RBS beams in a moment-resistant frame tends to cause an overall reduction in frame stiffness of around 4 to 7% [Grubbs, 1997]. If the increase in frame drift due to this reduction in frame stiffness is appreciable, proper allowances must be made in the analysis and design of the frame.

Defining Terms

ASD — Acronym for allowable stress design.
Beam-columns — Structural members whose primary function is to carry loads both along and transverse to their longitudinal axes.
Biaxial bending — Simultaneous bending of a member about two orthogonal axes of the cross section.
Built-up members — Structural members made of structural elements jointed together by bolts, welds, or rivets.
Composite members — Structural members made of both steel and concrete.
Compression members — Structural members whose primary function is to carry loads along their longitudinal axes.
Design strength — Resistance provided by the structural member obtained by multiplying the nominal strength of the member by a resistance factor.
Drift — Lateral deflection of a building.
Factored load — The product of the nominal load and a load factor.
Flexural members — Structural members whose primary function is to carry loads transverse to their longitudinal axes.
Limit state — A condition in which a structure or structural component becomes unsafe (strength limit state) or unfit for its intended function (serviceability limit state).
Load factor — A factor to account for the unavoidable deviations of the actual load from its nominal value and uncertainties in structural analysis in transforming the applied load into a load effect (axial force, shear, moment, etc.).
LRFD — Acronym for load and resistance factor design.
PD — Acronym for plastic design.
Plastic hinge — A yielded zone of a structural member in which the internal moment is equal to the plastic moment of the cross section.
Reduced beam section — A beam section with portions of flanges cut out to reduce the section moment capacity.
Resistance factor — A factor to account for the unavoidable deviations of the actual resistance of a member from its nominal value.
Service load — Nominal load expected to be supported by the structure or structural component under normal usage.

Shear lag — The phenomenon in which the stiffer (or more rigid) regions of a structure or structural component attract more stresses than the more flexible regions of the structure or structural component. Shear lag causes stresses to be unevenly distributed over the cross section of the structure or structural component.

Side sway inhibited frames — Frames in which lateral deflections are prevented by a system of bracing.

Side sway uninhibited frames — Frames in which lateral deflections are not prevented by a system of bracing.

Tension field action — Postbuckling shear strength developed in the web of a plate girder. Tension field action can develop only if sufficient transverse stiffeners are provided to allow the girder to carry the applied load using truss-type action after the web has buckled.

49.1 Introduction to Cold-Formed Steel Sections

Cold-formed steel products find extensive application in modern construction in both low-rise and high-rise steel buildings. Primary as well as secondary framing members in low-rise construction are fabricated using cold-formed steel sections, while in tall buildings, roof and floor decks, steel joists, wall panels, door and window frames, and sandwich panel partitions built out of cold-formed steel sections have been successfully used. In addition, these products are used in car bodies, railway coaches, storage racks, grain bins, highway products, and transmission towers. Although the uses of these products are many and varied, a multiplicity of widely different products, with a tremendous diversity of shapes, sizes, and applications, are produced in steel using the cold-forming process. This chapter is primarily concerned with the design of cold-formed steel members for use in building construction. However, the general design philosophies developed in the chapter are applicable in many cases over a wide range of other uses. More detailed information on cold-formed steel structures are available in books by Yu (1991), Rhodes (1991), and Hancock (1988).

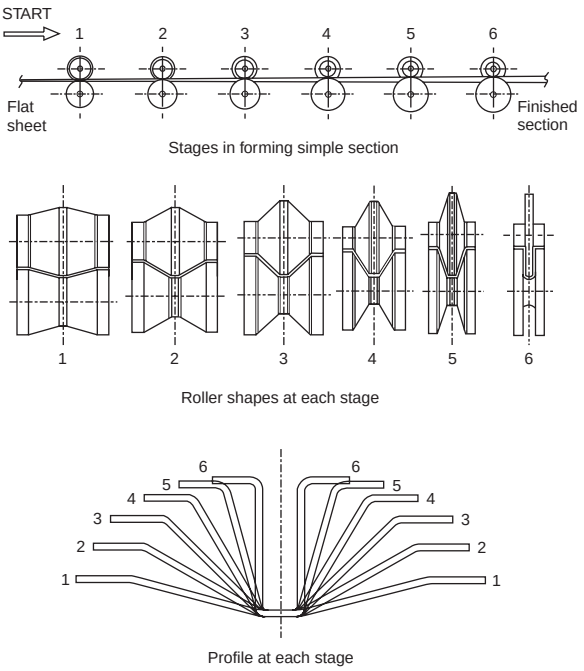

FIGURE 49.1 Stages in roll forming a simple section.

Manufacturing Methods

Cold forming is the term used to describe the manufacture of products by forming material in the cold state from a strip or sheet of uniform thickness. There is a variety of different methods of forming used for cold-formed products in general, but in the case of structural sections, the main methods used are folding, press-braking, and rolling.

Folding is the simplest process, in which specimens of short length and of simple geometry are produced from a sheet of material by folding a series of bends. This process has very limited application.

Press-braking is more widely used, and a greater variety of cross-sectional forms can be produced by this process. Here a section is formed from a length of strip by pressing the strip between shaped dies to form the profile shape. Usually each bend is formed separately. This process has limitations on the profile geometry that can be formed and, more importantly, on the lengths of sections that can be produced.

The major cold-forming process used for large-volume production is *cold rolling*. In this process strip material is formed into the desired profile shape by feeding it continuously through successive pairs of rolls. Each pair of rolls brings the form of the strip progressively closer to the final profile shape, as illustrated in Fig. 49.1. The number of pairs of rolls, or "stages," required depends on the thickness of the material and the complexity of the profile to be formed.

The cold-rolling process can be used to produce prismatic sections of virtually any profile, from a wide range of materials, with a high degree of consistency and accuracy to any desired length. Sections are rolled at speeds varying from about 10 m per min up to about 100 m per min, depending on the complexity of the profile, material being formed, equipment used, etc. Holes, notches, and cutouts can be produced in a member during the rolling process, and a pregalvanized or precoated steel strip is often used to eliminate corrosion and to produce aesthetically pleasing finished products. Typical profiles produced are shown in Fig. 49.2.

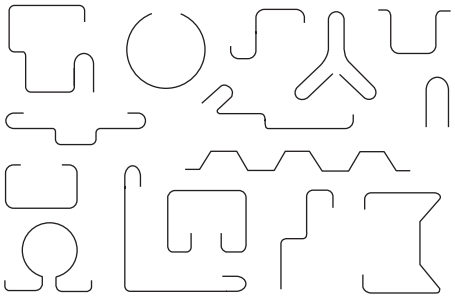

FIGURE 49.2 Typical shapes produced by roll forming.

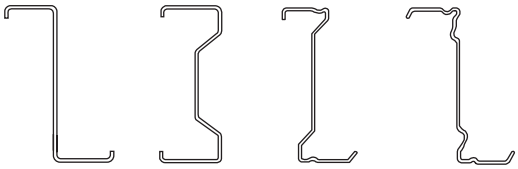

FIGURE 49.3 Types of roof purlin in common use at the present time.

Applications of Cold-Formed Steel

Trapezoidal profiles and the many variations on the trapezoidal shape are now widely used for industrial and commercial buildings, sports arenas, hotels, restaurants, and many other types of building construction. A variety of advances have been made in the field of profiled sheeting in relatively recent times. The use of fixing systems, which ensure water tightness of roofs, has been an area of development, as has the incorporation of stiffeners in the profiles. The use of foam-filled sandwich panels in which the roof or wall covering is combined with the insulation to give superior structural performance, in addition to other advantages, is an area of rapid growth. Composite steel–concrete flooring is another area in which there has been rapid growth in the last few years. Steel decks acting compositely with concrete have been used in the United Kingdom and United States for a long period.

Roof purlins, which are ideally suited for production, as cold-rolled sections account for a substantial proportion of cold-formed steel usage in buildings. Two basic shapes are used for purlins in the United Kingdom, the zeta (Z) shape (Fig. 49.3a), which was introduced from the U.S., and the sigma shape (Fig. 49.3b). Both of these shapes are very efficient in acting in conjunction with the sheeting to produce a high structural performance. Recent research and development efforts have lead to refinements in the Z-shape (Fig. 49.3c) and UltraZED-shape (Fig. 49.3d) sections. Purlin thicknesses used range from about 0.047 in. (1.2 mm) to about 0.126 in. (3.2 mm), and material of a yield strength of 50 ksi (350 N/mm^2) is becoming widely used in the production of purlins.

Storage platforms and mezzanine floor systems form another area of growing use of cold-formed steel members. In these systems the columns are often hot-rolled sections such as square hollow sections or I sections, and the beams are cold-formed sections. In lattice beam construction the boom members are generally cold-formed sections of hat or similar shape, and the lattice members may be tubular or made from round-bar or other cold-formed shapes. The concept of preengineered buildings, made largely from cold-formed steel sections in the factory and erected on site, has been a constantly recurring theme in the development of the cold-rolled sections industry, and the use of steel stud wall systems is a further step in this direction. Storage racking is another area that forms a significant outlet for cold-formed steel products. This accounts for perhaps 20% of all the constructional use of cold-formed sections and utilizes

a substantial proportion of perforated members. Storage installations range from relatively small shelving systems to extremely large and sophisticated pallet racking systems.

Advantages of Cold-Formed Steel

Cold-formed steel products have several advantages over hot-rolled steel sections. The main attractions of cold-formed steel sections are their lightness, high strength and stiffness, ease of fabrication and mass production, fast and easy erection and installation, substantial elimination of delays due to weather, more accurate detailing, nonshrinking and noncreeping at ambient temperatures, absence of formwork, protection from termites and rot, uniform quality, economy in transportation and handling, and noncombustability. The combination of these advantages can result in cost savings during construction (Yu, 1991).

Design Codes and Specifications

Since the late 1970s cold-formed steel has taken on a new importance in Europe, and there has been a period of substantial activity in research and in the development of new design codes. This began with the publication of a new Swedish design specification in 1982 (National Swedish Committee on Regulations for Steel Structures, 1982), followed by European recommendations at various stages. Insofar as the design method is concerned, some specifications use the allowable stress design approach, whereas others are based on a limit state design. The American Iron and Steel Institute (AISI) includes both allowable stress design (ASD) and load and resistance factor design (LRFD). In the United Kingdom, British Standard (BS) 5950, Part 5 (British Standards Institution, 1987), deals with the design of cold-formed steel members. This code had some amendments added in 1996. Eurocode 3: "Design of Steel Structures," Part 1.3: "General Rules, Supplementary Rules for Cold-Formed Thin Gauge Members and Sheeting," was published as a European prestandard in 1996 and is having substantial and increasing effect on cold-formed steel design throughout Europe. Both Canada (Canadian Standards Association, 1989) and Australia (Hancock, 1988) have developed their own codes, and in the United States a new version of the AISI code was published in 1996.

New design codes have also been produced in the past few years to deal with some associated topics. For example, stainless steel, dealt with by an ASCE specification in the U.S. (1990) was the subject of another new European prestandard, Eurocode 3, Part 1.4: "General Rules, Supplementary Rules for Stainless Steels," in 1996, and this was followed by new South African (1997) and Australian (2001) standards.

Range of Thicknesses

The provisions of codes apply primarily to steel sections with thickness not more than 0.33 in. (8 mm), although the use of thicker material is not precluded. Minimum thicknesses for specific applications are set by practical considerations, such as damage tolerance during handling, etc., and of course by the economics of the particular applications. With regard to the maximum thickness, 0.33 in. (8 mm) is about the limiting thickness normally rolled, although sections of up to about 0.8 in. (20 mm) can be rolled for specific applications.

Properties of Steel

The design strength of the steel used should be taken as the yield strength of the material provided that the steel has an ultimate tensile strength about 20% or more greater than the yield strength. To ensure that, if this is not the case, the design strength is reduced accordingly in some codes. In the case of steels that have no clearly defined yield strength, either the 0.2% proof stress or the stress at 0.5% total elongation in a tensile test may be taken as the design strength. The yield points of steels listed in the AISI specification range from 25 to 70 ksi (172 to 483 MPa).

The strength of members that fail by buckling is also a function of the modulus of elasticity E, the value of which is recommended as 29,500 ksi (203 kN/mm^2) by AISI in its specification for design purposes. Poisson's ratio is taken as 0.3.

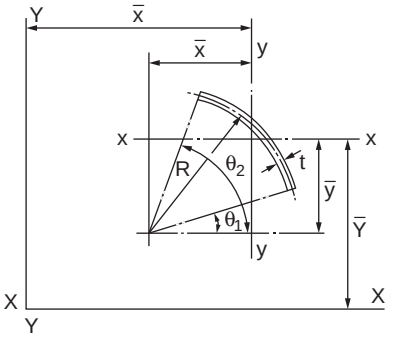

FIGURE 49.4 Geometry of a corner.

Effects of Cold Forming

Cold forming increases the yield and ultimate tensile strengths of the material being formed in the vicinity of the bend areas. Experiments suggest that the average increase in yield strength of a section is dependent on the number of bends, the area of the section, the material thickness, and the difference between the ultimate and yield strengths of the material. Significant enhancement of the yield strength due to cold forming is found only for sections composed largely of corners with small radii and having small width-to-thickness ratios. For more slender cross-sections the benefits of cold forming on enhancement of yield become substantially reduced. If a member is subjected to tension only, then it is quite permissible to use the increased yield strength for the complete cross-section. If, however, the member is subjected to compression or combinations of compression and bending, then each element should be considered separately after the initial determination of the average yield strength of a formed section. In determination of the compression yield strength of an individual element the width-to-thickness ratio of the element is important. Since there is no conclusive evidence to support the design use of enhanced yield strength in the presence of local buckling, which occurs for slender elements, enhancement of the yield strength due to cold forming should not be taken into account for slender elements subject to local buckling behavior.

Since any operation on the formed material that introduces heat, such as welding, annealing, galvanizing, etc., will affect the material properties, the use of the enhanced yield strength is prohibited if any such operation is carried out.

Calculation of Section Properties

Since many cold-formed steel sections have thin walls and small radii, the determination of section properties in many cases can be simplified by assuming that the material is concentrated at the centerline of the section and the area of elements are replaced by straight or curved "line elements." The thickness dimension t is introduced after the linear computations have been completed.

Properties of Corners

For a corner element of the geometry shown in Fig. 49.4 the properties are as follows, with the angles given in radian measure:

$$A = Rt\left(\theta_2 - \theta_1\right),\ \bar{x} = \frac{R\left(\sin\theta_2 - \sin\theta_1\right)}{\left(\theta_2 - \theta_1\right)},\ \bar{y} = \frac{R\left(\cos\theta_1 - \cos\theta_2\right)}{\left(\theta_2 - \theta_1\right)} \tag{49.1}$$

$$I_{xx} = R^3 t\left\{\frac{1}{2}\left(\theta_2 - \theta_1\right) - \frac{1}{4}\left(\sin 2\theta_2 - \sin 2\theta_1\right) - \frac{\left(\cos\theta_1 - \cos\theta_2\right)^2}{\left(\theta_2 - \theta_1\right)}\right\} \tag{49.2}$$

$$I_{yy} = R^3 t\left\{\frac{1}{2}(\theta_2 - \theta_1) + \frac{1}{4}(\sin 2\theta_2 - \sin 2\theta_1) - \frac{(\sin\theta_2 - \sin\theta_1)^2}{(\theta_2 - \theta_1)}\right\} \tag{49.3}$$

$$I_{xy} = R^3 t\left\{\frac{1}{4}(\cos 2\theta_1 - \cos 2\theta_2) - \frac{\sin(\theta_1 + \theta_2) - \frac{1}{2}(\sin 2\theta_1 + \sin 2\theta_2)}{(\theta_2 - \theta_1)}\right\} \tag{49.4}$$

In the particular case of a right angled corner with $\theta_1 = 0$ and $\theta_2 = \pi/4$ the properties may be written as follows:

$$A = \frac{\pi Rt}{2} = 1.57\ Rt,\ \bar{y} = \frac{2R}{\pi} = 0.637\ R,\ \bar{x} = \frac{2R}{\pi} = 0.637\ R \tag{49.5}$$

$$I_{xx} = I_{yy} = R^3 t\left(\frac{\pi}{4} - \frac{2}{\pi}\right) = 0.149R^3 t \tag{49.6}$$

$$I_{xy} = R^3 t\left(\frac{1}{2} - \frac{2}{\pi}\right) = -0.137R^3 t \tag{49.7}$$

Formulas for the bending properties of a number of common cross-sections, based on centerline dimensions, are given in Table 49.1.

Effects of Holes

In evaluation of the section properties of members in bending or compression, holes made specifically for fasteners such as screws, bolts, etc. may be neglected on the basis that the hole is filled with materials in any case. However, for any other openings or holes the reduction in cross-sectional area and cross-sectional properties caused by these holes or openings should be taken into account. If the section properties are to be evaluated analytically they should be calculated considering the net cross-section that has the most detrimental arrangement of holes that are not specifically for fasteners. This is not necessarily the same cross-section for bending analysis and compression analysis. This is illustrated in Fig. 49.5, where for the channel section shown the net cross-section A-A has a smaller area than cross-section B-B and is therefore critical with regard to purely compressional behavior. The second moment of area about x-x and minimum section modulus of cross-section B-B with regard to axis, however, are less than those of section A-A, and for bending strength section B-B is critical.

In the case of tension members, fasteners do not themselves effectively resist the tension loading, which is tending to open the fastener holes; holes made for fasteners must also be taken into consideration for tension loading. In determining the net area of a tension member, the cross-section that has the largest area of holes should be considered. The area that should be deducted from the gross cross-sectional area is the total cross-sectional areas of all holes in the cross section. In deducting the area of fastener holes the nominal hole diameter should be used. In the case of countersunk holes the countersunk area should also be deducted. In a tension member that has staggered holes, the weakening effects of holes that are not in the same cross-section, but close enough to interact with the holes in a given cross-section, should be taken into account. If two lines of holes are far apart, then one line of holes does not have any effect on the strength of the section at the position of the other line of holes. If the lines are close, however, then each line of holes affects the other.

49.2 Local Buckling of Plate Elements

A major advantage of cold-formed steel sections over hot-rolled sections is to be found in the relative thinness of the material from which the sections are often formed. This can lead to highly efficient and

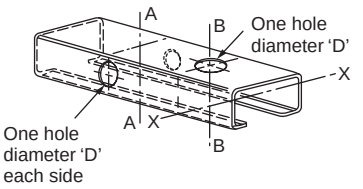

FIGURE 49.5 Channel section with holes.

weight-effective members and structures. However, the potential advantages of the thin walls can be only partially obtained, and to obtain these advantages the designer must be aware of the phenomena associated with thin-walled members and their effects on design analysis. Perhaps the most important of these phenomena is *local buckling*.

Local Buckling of Plates

When a thin plate is loaded in compression the possibility of local buckling arises. This type of buckling is so called because the length of buckles that form is similar to the dimensions of the cross-section rather than the length of the structure, as is normally the case with other types of buckling. Elastic local buckling in a member is characterized by a number of ripples, or buckles, becoming evident in the component plates, as illustrated in Fig. 49.6. This local buckling has substantial bearing on the stiffness and strength of the member, and to gain some insight into the local buckling phenomenon, we shall now examine local buckling of plate elements.

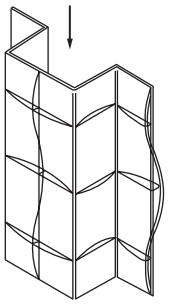

FIGURE 49.6 Local buckling in a thin-walled section.

Local Buckling Analysis

Consider the plate shown in Fig. 49.7, supported on all four edges and compressed uniformly on its longitudinal edges to produce a displacement u, as shown in the figure. Due to the loading we shall assume that out-of-plane deflections w occur as shown. We can examine the local buckling situation from a consideration of the strain energy in the plate. The strain energy due to bending U_B can be written in terms of the deflections as

$$U_B = \frac{D}{2}\iint_{\text{area}} \left\{ \left(\frac{\delta^2 w}{\delta x^2} + \frac{\delta^2 w}{\delta y^2} \right) - 2(1-\nu) \left[\frac{\delta^2 w}{\delta x^2}\frac{\delta^2 w}{\delta y^2} - \left(\frac{\delta^2 w}{\delta x \delta y} \right)^2 \right] \right\} dx\,dy \tag{49.8a}$$

The strain energy in the plate due to the membrane actions is given by

$$U_D = \frac{1}{2}\int_{\text{vol}} p_x \varepsilon_x \, d(\text{vol}) = \frac{Eta}{2}\int \left(\bar{\varepsilon} - \frac{1}{2a}\left(\frac{\partial w}{\partial x} \right)^2 \right)^2 dy \tag{49.8b}$$

where $\bar{\varepsilon}$ = the "nominal" applied strain, equal to u/a
E = the modulus of elasticity

The total strain energy stored in the plate is given by the sum of bending and membrane energies. Since the displacement of the plate ends is prescribed, the principle of minimum potential energy requires that the strain energy is a minimum. The simplest case of local buckling, very often considered in design, is that of a plate simply supported on all four edges. In this case the deflections w at buckling are given by the expression

$$w = w_c \sin\left(\frac{n\pi x}{a} \right) \sin \frac{\pi y}{b} \tag{49.9}$$

in which n indicates the number of half-sine waves into which the plate buckles in the x direction. Substituting for w in U (= U_{-D} + U_B) and performing the integrations gives the strain energy in terms

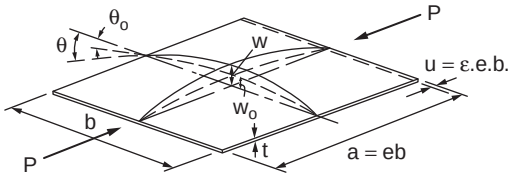

FIGURE 49.7 Uniformly compressed plates.

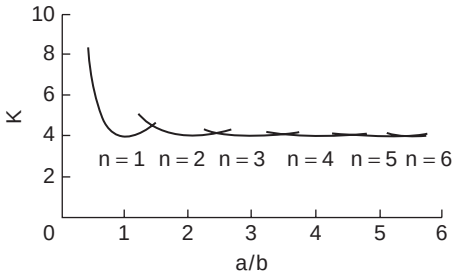

FIGURE 49.8 Variation of buckling coefficient with length for a simply supported plate.

of the deflection magnitude coefficient w_c. Using the principle of minimum potential energy it can be shown that the critical stress (p_{cr}) to cause local buckling is given as

$$p_{cr} = E\bar{\varepsilon}_{cr} = \frac{\pi^2 D}{b^2 t}\left[\frac{nb}{a} + \frac{a}{nb}\right]^2 = \frac{K\pi^2 E}{12\left(1-\nu^2\right)}\left(\frac{t}{b}\right)^2 \tag{49.10}$$

The coefficient K is called the buckling coefficient and, for the case in question, is given by

$$K = \left[\frac{nb}{a} + \frac{a}{nb}\right]^2 \tag{49.11}$$

The variation of K with the variation in the plate length-to-width ratio a/b is shown in Fig. 49.8 for various numbers of buckles n. As may be observed from this figure, the minimum value of K is 4; this occurs when the length of the plate is equal to n times the plate width. For long plates, the number of buckle half-waves that occur is approximately the same as the ratio of the plate's length to its width, and the buckling coefficient is very close to 4. For plates with different support conditions the value of the buckling coefficient becomes different from 4.

Thus the value of the stress required theoretically to produce local buckling varies inversely as the square of the plate width-to-thickness ratio. Plates with lower width-to-thickness ratios will theoretically yield before local buckling, and plates with higher width-to-thickness ratios will buckle before yielding. This statement holds true only for perfect plates. In the practical situation imperfections are always present, and the effects of local buckling are generally to be observed at stresses less than the theoretical buckling stress. Furthermore, local buckling does not necessarily signify the attainment of the full load capacity of a plate. For very thin plates, local buckling occurs at low stress levels and such plates can sustain loads greatly in excess of the buckling load. It is this capacity to carry loads beyond the local buckling load that provides the means for advantageous use of thin plates, but also requires knowledge of the adverse effects of local buckling to ensure safe design.

Postbuckling Analysis

If the plate has buckled, the magnitude of the local buckles is related to the compression magnitude. The variation of stresses with the variation in strains after buckling can be shown to be

$$p_x = E\left[\bar{\varepsilon} - \frac{4}{3}\left(\bar{\varepsilon} - \bar{\varepsilon}_{cr}\right)\sin^2\frac{\pi y}{b}\right] \tag{49.12}$$

Thus the average stress varies across the plate as indicated in Fig. 49.9. Strips of plate near the supports are relatively unaffected by local buckling and carry increased loading as further compression is applied, while strips of plate near the center shed the load and offer very little resistance to further compression. The plate may be thought of as consisting of a series of slender columns linked together, with those near

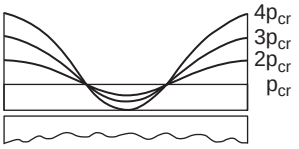

FIGURE 49.9 Variation of stress across a plate after local buckling.

the edges largely prevented from buckling and those near the center buckling relatively freely. The plate does not behave completely like a column and lose all its compression resistance after local buckling, but its resistance after buckling is confined to portions of the plate near the supported edges.

The load on the plate at any end compression is obtained by summing the stresses across the plate, i.e.,

$$p = t\int p_x\,dy = Etb\left[\bar{\varepsilon} - \frac{2}{3}\left(\bar{\varepsilon} - \bar{\varepsilon}_{cr}\right)\right] = \frac{E\,t\,b}{3}\left[\bar{\varepsilon} + 2\bar{\varepsilon}_{cr}\right] \tag{49.13}$$

The plate load grows after buckling with increasing compression, but the rate of growth is substantially reduced relative to that before buckling.

The analysis shows that after buckling the plate stiffness reduces, the edge stresses increase more quickly with the load than before buckling, and the plate center becomes inefficient at resisting the load, witnessed by the load shedding in this area. The plating could only be considered effective in resisting compression over a short width adjacent to the supports. As a rule of thumb, in ship design it was considered that a width of plate equal to 25 times the thickness could be considered to effectively resist compression adjacent to each support. Thus for a plate with supports on each edge a total width of 50t was considered to be effective in resisting compression. This was the origin of the effective width concept, now used widely in design analysis.

The Effective Width Concept

The effective width concept, as generally used in design, assumes that the portions of a plate element near the supports are fully effective in resisting load and the remainder of the element is completely ineffective. This is illustrated in Fig. 49.10, in which the varying stress distribution across an element is idealized into a constant stress acting over the two effective portions and the center part of the plate is considered completely ineffective and stress-free.

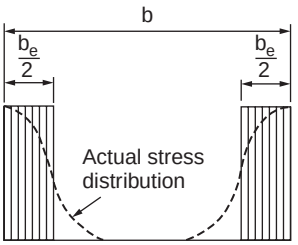

FIGURE 49.10 Effective width idealization.

In 1932 von Karman et al. produced the first theoretical explanation of the effective width concept, and in the years that followed many investigators produced further insight into this field. At the present time there is a variety of methods available for rigorous analysis of plates under many conditions of loading and support, ranging from approaches that have been set up for relatively easy use by the reader to the numerical approaches using finite elements or finite differences.

Research into cold-formed steel began largely in the U.S., and much of the original work was carried out at Cornell University, Ithaca, New York by George Winter. In dealing with local buckling, Winter (1947) produced an empirical variation of the von Karman effective width expression that, with minor modifications, has been accepted in the U.S. and in many other countries for analysis of local buckling. This expression, in the form widely used at the present time, is as follows

$$\frac{b_{eff}}{b} = \sqrt{\frac{p_{cr}}{p_{max}}}\left(1 - 0.22\sqrt{\frac{p_{cr}}{p_{max}}}\right) \tag{49.14}$$

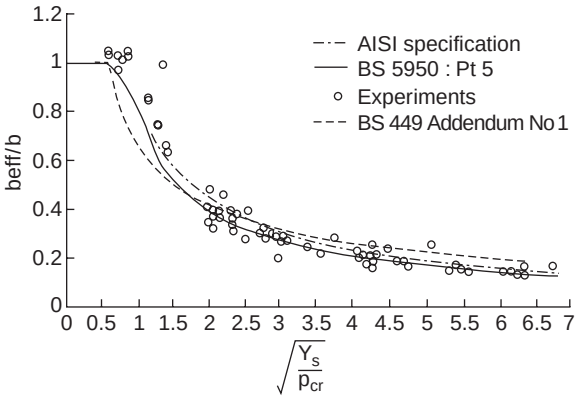

FIGURE 49.11 Effective widths from design codes and tests from various sources.

in which p_{max} = the maximum edge stress in the plate
b_{eff} = the effective width of the compression element

As per AISI recommendation, $b_{eff} = b$ for $\sqrt{\frac{p_{max}}{p_{cr}}} < 0.673$, and the b_{eff} is calculated from Eq. (49.14) for $\sqrt{\frac{p_{max}}{p_{cr}}} > 0.673$.

The basic effective width expression developed for BS 5950, Part 5 (British Standards Institution,1987), is as follows:

$$\frac{b_{eff}}{b} = \left[1+14\left(\sqrt{\frac{f_c}{p_{cr}}}-0.35\right)^4\right]^{-0.2} \tag{49.15}$$

in which f_c is the edge stress corresponding to the yield stress when failure is said to occur.

This expression is a little more cumbersome than that of Eq. (49.14), but still perfectly usable on a calculator or a small microcomputer.

Figure 49.11 shows comparison of the basic effective width expression (Eq. (49.15)) with the AISI expression (Eq. (49.14)), the CL factors of addendum 1 (British Standards Institution, 1975) to BS 449, and experiments from various sources. The experiments shown here are all on simply supported plates, and even so, a significant degree of scatter is noticeable.

Classification of Elements

In using the effective width approach to deal with elements of sections, the different types of element used in such sections need to be taken into consideration. These may be classified into four groups: stiffened elements, unstiffened elements, edge-stiffened elements, and intermediately stiffened elements. Examples of each type of element are shown in Fig. 49.12.

Stiffened elements are elements that are supported (or stiffened) by having a substantial element on both longitudinal edges. If the supporting elements are themselves stiffened, or edge stiffened, elements, then this type of element can have a width-to-thickness ratio of up to 500. For such an element the minimum K factor applied is 4.

Unstiffened elements are elements that are supported along only one longitudinal edge. In this case local buckling arises much more quickly than it does for stiffened elements, and because of this, the width-to-thickness ratio that can be covered by the code is considerably reduced. The relevant maximum width-to-thickness ratio is 60, and the minimum K factor is 0.425.

Since unstiffened elements are severely affected by local buckling, it is common practice to convert these into stiffened elements by folding the free edge of these elements to produce a lip, or a similar edge

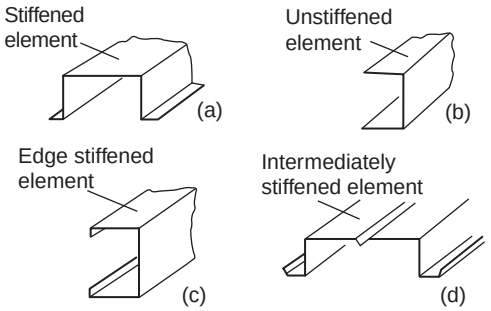

FIGURE 49.12 Types of elements found in cold-formed sections.

stiffener, to support this edge and prevent local buckling of the edge. If the edge stiffener satisfies the requirements of the code, then such an element may be treated as a stiffened element. For such an *edge-stiffened element*, however, the maximum width-to-thickness ratios are severely curtailed by the codes. In the case of an element stiffened by a simple lip, the maximum allowable width-to-thickness ratio is 60, while if any other type of edge stiffener is used, the width-to-thickness ratio can be increased to 90.

In order to improve the behavior of stiffened elements, intermediate stiffeners are often employed. This type of stiffener is usually formed during the rolling process and has the effect of transforming a slender, high b/t ratio element into two or more relatively compact subelements. This can substantially increase the effectiveness of the element. The total width of *intermediately stiffened elements* is limited to 500 times the material thickness.

Stiffened Elements

Buckling Coefficients

Stiffened elements under uniform compression are considered to be governed by effective width expression. The minimum K factor used for such elements is 4, but if higher values can be justified, then these may be used. The K factors applicable to compact elements, low b/t, can be much less than those for slender elements in the same section. In general, the elements in a section that are restrained from buckling at their natural stress induce premature buckling in the elements that restrain them, and if one element has a buckling coefficient greater than 4, others will have buckling coefficients less than 4. This mathematically correct, but rather pessimistic, view has been incorporated in some design codes, and invariably leads to lower design loads than would occur if all elements were considered simply supported.

However, it has been observed (Rhodes, 1987) that for restraining elements the effects of premature local buckling are negligible. Only when the applied loading is sufficient to attain the natural (simply supported) buckling stress of such elements do these elements suffer the effects of local buckling to any substantial degree.

Stiffened Elements under Eccentric Compression

For some stiffened elements, such as webs of beams, the loading is not pure compression, but some combination of axial loading and in-plane bending. In cases where this type of loading occurs the codes treat the situation in one of two ways, depending on the degree of bending involved. For beam webs in which the stress changes from compression to tension across the element, the effective width approach is replaced by a limiting stress approach.

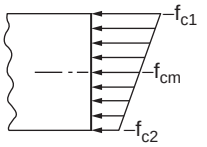

FIGURE 49.13 Element with varying stress distribution.

For cases in which an element is subjected to a combination of compression and in-plane bending in which the stress is compressive on both unloaded edges, sufficiently accurate analysis may be obtained as follows. If the stress varies from f_{c1} at one edge to f_{c2} at the other edge, as illustrated in Fig. 49.13, then the mean value of these stresses should be taken as the stress on

the element. Using this stress together with the critical stress, based on a K factor of 4, the effective width may be found as it is for uniformly compressed elements. The effective portions of the element are considered to be equally distributed adjacent to each supported edge, as for uniformly compressed elements, and the ultimate load on the element may be assumed to occur when the maximum stress reaches yield. This rather rough-and-ready method has some theoretical backing and gives reasonable and conservative results when compared with tests.

Unstiffened Elements

In open sections there are normally unstiffened elements. As these elements buckle much more quickly than stiffened elements, they constitute a rather unsatisfactory type of element with regard to load capacity, and because of this the cold-formed counterparts of common hot-rolled sections such as channels, angles, and hat sections are often lipped to increase the resistance to local buckling.

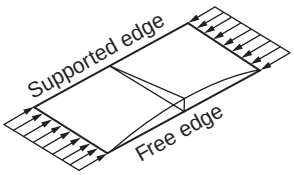

FIGURE 49.14 Unstiffened element under compression.

Unstiffened elements can also be analyzed using the approach employed earlier for stiffened elements. If we assume that the out-of-plane deflections of an unstiffened element under load, as shown in Fig. 49.14, are given by the expression

$$w = w_{max} \frac{y}{b} \sin \frac{\pi x}{a} \tag{49.16}$$

then the same type of analysis gives the following results

$$K = \left(\frac{b}{a}\right)^2 + 0.425 \tag{49.17}$$

and the relative stiffness before and after buckling is

$$\frac{E^*}{E} = \frac{4}{9} \tag{49.18}$$

The variation of K with the variation in the element length-to-width ratio is shown in Fig. 49.15. In this case the element buckles into a single half wavelength, regardless of its length, according to the analysis used. This is only true in cases where the supported edge is simply supported, such as elements of angle sections. For unstiffened elements that have some restraint on their supported edge a number of buckles are found if the element is long. However, the simply supported free condition gives a lower

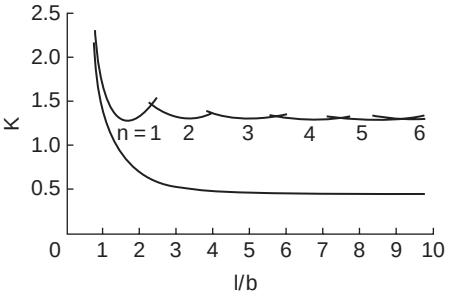

FIGURE 49.15 Variation of buckling coefficients for unstiffened elements with element length.

bound to the strength and stiffness of more restrained elements and leads to safe design. The buckling coefficients applicable to a fully fixed supported edge are also shown in Fig. 49.15 for comparison purposes.

The minimum value of K in this case is 0.425 for an element with simple support on the supported edge, based on a Poisson's ratio of 0.3. Thus the buckling load of an unstiffened element is reduced by a factor of 4/0.425, i.e., 9.4, from that of a stiffened element.

Effective Widths

Returning to our approximate analysis, if we examine the load compression behavior of a perfect plate after buckling and plot the relevant curves for stiffened and unstiffened elements, normalized with respect to the buckling point, we find that the postbuckling stiffness of the unstiffened element is greater than that of a stiffened element at a given multiple of the buckling stress. Because the effective width expressions contain the critical stress, it follows that the same expression will be rather conservative for unstiffened elements.

In the British code the effective widths so obtained are increased for unstiffened elements. The method used is to initially determine the effective width, b_{eff}, as for a stiffened element, but using the buckling coefficient applicable to the unstiffened element under examination. This is then converted to an enhanced effective width for an unstiffened element using the following equation:

$$b_{eu} = 0.89b_{eff} + 0.11b \tag{49.19}$$

Stiffeners

Edge Stiffeners

Because of the low buckling resistance of unstiffened elements and the rather unfortunate consequences that can arise, the benefits of incorporating edge stiffeners are plain to see. Adequately edge-stiffened elements can be substantially stronger than the unstiffened counterparts. In general an edge stiffener is required to eliminate, or at least minimize, any tendency for the otherwise unsupported edge of an element to displace out of plane. If a stiffener is adequate, the stiffened element will not incur deflections at the stiffened edge, and the element can be treated as a stiffened element. If, however, the stiffener does not have sufficient flexural rigidity to prevent out-of-plane deflections of the edge, the stiffener is said to be inadequate.

The precise requirements for adequacy are even now undergoing change. In various cold-formed steel design codes in the past it was accepted that for adequacy, a stiffener should prevent buckling of the element edge until the element buckled as a stiffened plate with a K factor of 4. This was shown (Desmond et al., 1981) to be an insufficient requirement, as the edge stiffener must also be able to prevent the edge of the element from buckling even after local buckling has occurred, indeed until it fails as a stiffened element if it is to do its job correctly. The requirements for adequacy in the latest AISI code and in the European recommendations have been based on this premise.

However, this is not the only difficulty in assessing stiffener adequacy. Rigorous analysis shows that the required rigidity of an edge stiffener depends not only on the geometry of the element to be stiffened, but on the geometry of the section as a whole and indeed on the geometry of the stiffener itself (Rhodes, 1983). Thus obtaining a single formula that covers all these variables with accuracy is a daunting task.

Intermediate Stiffeners

Intermediate stiffeners are becoming more widely used in cold-formed steel members. The advantages of replacing slender elements by more effective subelements of relatively compact proportions at the expense of a little extra material for the stiffener are apparent. As with edge stiffeners, the intermediate stiffeners used must have adequate rigidity to prevent deflection in the element in the region of the stiffener. Adequate and inadequate stiffeners of this type are illustrated in Fig. 49.16. The geometry of an element with a single intermediate stiffener is shown in Fig. 49.17a.

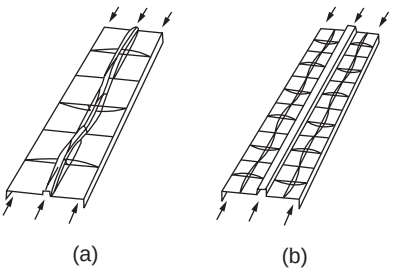

FIGURE 49.16 Intermediate stiffeners: (a) inadequate stiffeners, (b) adequate stiffeners.

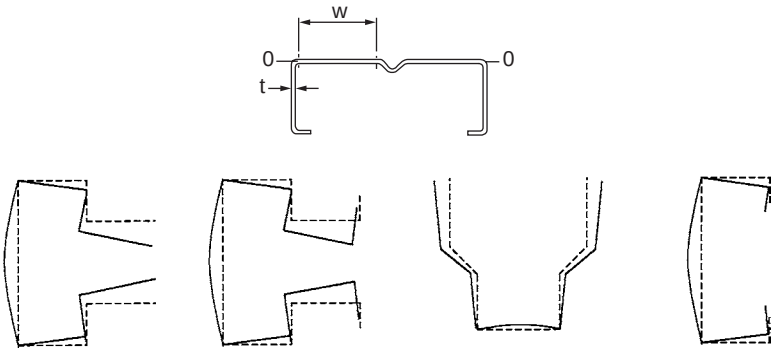

FIGURE 49.17 (a) Geometry of an element with a single intermediate stiffener. (b) Examples of distortional buckling.

If the rigidity requirement is attained by an intermediate stiffener, the effective area of the stiffened element may, under certain conditions, be evaluated from the sum of the effective areas of each individual subelement, analyzed as stiffened elements, and the stiffener area. The condition under which this is allowable is that the width-to-thickness ratios of the subelements are less than 60. Since in this case the out-of-plane deflections are eliminated near the stiffener, the hypothetical situation is that under uniform compression here, there is no shedding of load near the stiffener and this area of the element becomes fully stressed. Each subelement is therefore stressed in the same manner as a stiffened element of width w. The stiffener is also fully stressed and plays its full part in resisting the load.

Reductions in Capacity for High Width-to-Thickness Ratios

If the subelement width-to-thickness ratios are greater than 60, reductions in the subelement effective area and in the effective stiffener area must be introduced. The main reasons for this are to be found in the examination of beam behavior. Beams that have very wide, slender flanges, either in tension or compression, suffer from the tendency of these flanges more toward the neutral axis of the section under loading.

BS 5950, Part 5, takes the adverse effects into account in a rather simple way, based on the AISI specification prior to the current version. If the subelement width-to-thickness ratio, w/t, is greater than 60, the effective width of the subelement, b_{eff}, is replaced by a reduced effective width, b_{cr}, determined from the expression

$$\frac{b_{cr}}{t} = \frac{b_{eff}}{t} - 0.1\left(\frac{w}{t} - 60\right) \tag{49.20}$$

The effective stiffener area is also reduced. For w/t less than 60, the stiffener is taken as fully effective. For w/t greater than 90, the ratio of effective stiffener area, A_{eff}, to full stiffener area, A_{st}, is taken as the same as that of the ratio of the effective subelement area to the full subelement area, i.e.,

$$A_{eff} = A_{st}\frac{b_{cr}}{w} \tag{49.21}$$

For w/t values between 60 and 90 a linear interpolation formula is used to obtain the effective stiffener area. This is

$$A_{eff} = A_{st}\left(3 - 2\frac{b_{cr}}{w} + \frac{1}{30}\left(1 - \frac{b_{cr}}{w}\right)\frac{w}{t}\right) \tag{49.22}$$

This expression gives the stiffener effective area varying linearly from A_{st} at w/t = 60 to $A_{st}b_{cr}/w$ at w/t = 90.

Multiple Intermediate Stiffeners

If an element has many intermediate stiffeners that are spaced closely enough to eliminate significant local buckling, i.e., w/t is less than 30, then all stiffeners may be considered effective. However, in such a case local buckling that involves the complete element, with all stiffeners participating in the buckling, has to be guarded against. This is accomplished in a rather simple way by considering the complete element as a stiffened element without intermediate stiffeners, but having a fictitious equivalent thickness. The fictitious thickness is arranged so that the flexural rigidity of the stiffened element is the same as that of the multiply stiffened element. To accomplish this, the equivalent thickness, t_s, is taken as

$$t_s = \left(\frac{12I_s}{w_s}\right)^{1/3}$$

where I_s = the second moment of area of the full multiply stiffened element, including the intermediate stiffeners, about its own neutral axis

w_s = the complete width of the element between two webs

Distorsional Buckling

If a lip or edge stiffener, or indeed an intermediate stiffener, is not adequate, then the buckling mode that arises involves in-plane movement of the stiffener together with out-of-plane distorsion of the stiffened elements. Hancock (1988) observed that this kind of behavior was evident in some storage racking members in which the edge stiffeners were not so clearly identifiable as lips and coined the term "distorsional buckling" to cover this type of behavior. The term is now widely used to describe such behavior, and at the same time the design treatment of stiffeners has been the subject of substantial change in some recent specifications. Distortional buckling, as illustrated in Eurocode 3, Part 1.3, is shown in Fig. 49.17b for some cross-sections. In Eurocode 3, Part 1.3, distortional buckling is specified as a design consideration that must be taken into account. For edge and intermediate stiffeners recourse can be made to the relevant rules for these elements, which are extremely demanding in calculation time and which result in significant diminution of the potential capacity of a stiffened element. Indeed, in the design of Z- or C-section beams to Eurocode 3, Part 1.3, the capacity is very substantially governed by the edge stiffener.

Example 49.1

Compute the effective width of the compression (top) flange of the beam shown in Fig. 49.18; assume that the compressive stress in the flange is 25 ksi. E = 29,500 ksi and ν = 0.3.

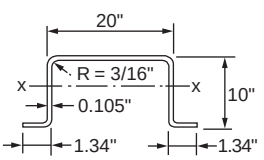

FIGURE 49.18 Example 49.1.

Solution:
The following solution is based on the AISI design code:

As the first step, compute p_{max}/p_{cr}.

$$K = 4.0$$

$$b = 20 - 2(R + t)$$

$$= 20 - 2(0.1875 + 0.105) = 19.415 \text{ in.}$$

$$\frac{b}{t} = \frac{19.415}{0.105} = 184.9$$

$$p_{cr} = \frac{4\pi^2 E}{12(1-\nu^2)} \frac{1}{(b/t)^2}$$

$$= 3.12 \text{ ksi}$$

$$p_{max} = 25 \text{ ksi}$$

$$\sqrt{\frac{p_{max}}{p_{cr}}} = 2.83 > 0.673$$

$$\therefore \quad b_{eff} = b\sqrt{\frac{p_{cr}}{p_{max}}}\left[1 - 0.22\sqrt{\frac{p_{cr}}{p_{max}}}\right]$$

$$= 6.518 \text{ in.}$$

Example 49.2

Calculate the effective width of the compression flange of the box section (Fig. 49.19) to be used as a beam bending about the x axis. Use p_{max} = 33 ksi. Assume that the beam webs are fully effective and that the bending moment is based on initiation of yielding. E = 29,500 ksi and ν = 0.3.

Solution:
The solution is in accordance with the AISI code.

Because the compression flange of the given section is a uniformly compressed stiffened element, which is supported by a web on each longitudinal edge, the effective width of the flange can be computed by using Eq. (49.14) with K = 4.0.

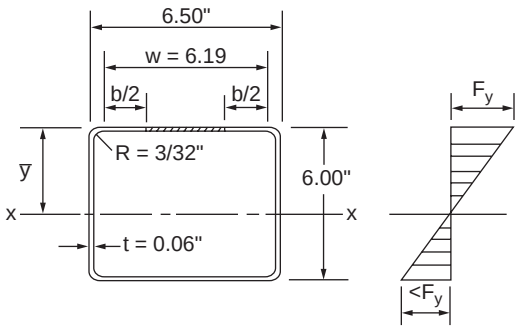

FIGURE 49.19 Example 49.2.

Given that the bending strength of the section is based on *initiation of yielding*

$$\bar{y} = \geq 3 \text{ in.}$$

$$\frac{b}{t} = \frac{6.1924}{0.06} = 103.21$$

$$p_{cr} = \frac{4\pi^2 E}{12\left(1-\nu^2\right)} \frac{1}{\left(b/t\right)^2} = 10.01 \text{ ksi}$$

$$\sqrt{\frac{p_{max}}{p_{cr}}} = \sqrt{\frac{33}{10.01}} = 1.816 > 0.673$$

$$\therefore \quad b_{eff} = b\sqrt{\frac{p_{cr}}{p_{max}}}\left[1 - 0.22\sqrt{\frac{p_{cr}}{p_{max}}}\right]$$

$$= 2.997 \text{ in.}$$

$$\approx 3 \text{ in.}$$

49.3 Members Subject to Bending

Because of the thin-walled nature of cold-formed steel sections, the effects of local buckling must, in most cases, be taken into account in determining the moment capacity and flexibility of beams. In the design of beam webs, the capacity of webs to withstand concentrated loads or support reactions must be ensured and the interaction of different effects must be taken into account. In the case of unbraced beams, the possibility of lateral torsional buckling arises, and the designer must be able to guard against this phenomenon. There are certain circumstances when the use of the simple bending theory cannot give realistic estimates of beam behavior. The most obvious of these circumstances arises in the design analysis of beams having unsymmetrical cross-sections. If such beams are not restrained continuously along their lengths, they must be analyzed taking into account the unsymmetrical nature of the behavior.

Bending of Unsymmetrical Cross Sections

Consider a thin-walled beam having a general nonsymmetrical cross-section, as shown in Fig. 49.20. If the x-x and y-y axes shown in the figure are not the principal axes of the cross-section, the application of a moment about either one of the axes will cause the beam to bend about both axes, i.e., a moment M applied about axis x-x will cause bending about both the x-x and y-y axes. There are several approaches to take account of this behavior, one of these being the use of effective moments, M_x^* and M_y^*. In this method the stresses and deflections occurring in the beam under the action of moments are dealt with as though x-x and y-y were principal axes, but with the actual moments about these axes replaced by the effective moment (Megson, 1975).

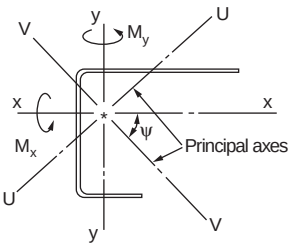

FIGURE 49.20 Beam of unsymmetrical cross-section.

Laterally Stable Beams

A laterally stable beam is a beam that has no tendency to displace in a direction perpendicular to the direction of loading. A beam may be laterally stable by virtue of its shape, or a beam may be considered

laterally stable if it is braced sufficiently to prevent potential displacements out of the plane of loading. For laterally stable beams local buckling is the major weakening effect. In the analysis of laterally stable beams according to BS 5950, Part 5, limiting web stress is used to take into account the possibility of local buckling in the webs and the effective width approach is used to take account of local buckling in the compression elements.

Limiting Web Stress

The effects of local buckling due to varying bending stresses in thin webs of beams can be quite substantial. The buckling stress in a web is generally much greater than in a compression element of the same geometry, but if the web depth-to-thickness ratio is large, local buckling of the web can still have a significant influence on the beam strength. For webs under pure bending the minimum buckling coefficient is approximately 23.9, compared with 4 for a uniformly compressed plate.

The effects of local buckling on web strength are not so easily taken into consideration, as in the case of elements under uniform compression. Effective width approaches have been investigated to take local buckling of webs into account and have been found to accomplish this task very well, but at the expense of adding further complexity to the analysis. This is mainly due to the necessity to position the effective and ineffective portions correctly. A number of design codes, including the AISI code, use the effective width approach. If a web has intermediate stiffeners, they will assist the web in resisting local buckling. There has been substantial research into this topic.

Effective Width of Compression Elements

In the case of beams the elements under compression are considered to have effective widths less than their actual widths, while all other elements are considered to have their actual dimensions. A typical effective cross section is shown in Fig. 49.21. The effective width of the compression element or elements is evaluated using effective width expression. For such elements the buckling coefficients in the case of beams are in most circumstances greater than the minimum values, since buckling of the compression elements is generally (but not always) restrained by the adjacent webs.

Moment Capacity

The moment capacity of the cross-section is determined on the basis that the maximum compressive stress on the section is p_0. This leads to two possible types of failure analysis, depending on the situation on the tension side of the cross-section, as indicated in Fig. 49.22. If the geometry of the effective cross-section is such that the compressive stress reaches p_0 before the maximum tensile stress reaches the yield

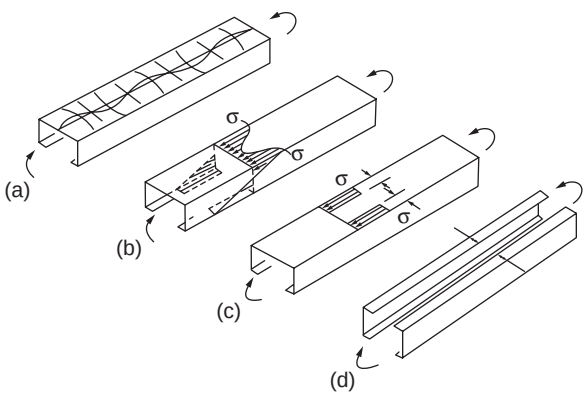

FIGURE 49.21 Effective width concept applied to laterally stable beams: (a) local buckles, (b) stress distribution, (c) idealized stress distribution on compressive element, (d) effective section.

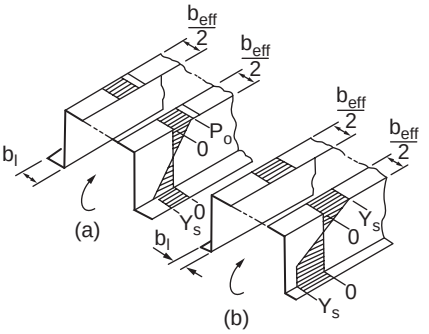

FIGURE 49.22 Failure criteria for laterally stable beams: (a) failure by compression yield — tensile stress elastic, (b) tensile stresses reach yield before failure — elastic-plastic stress distribution.

stress, as in Fig. 49.22a, then the moment capacity is evaluated using the product of compression section modulus and p_0, i.e.,

$$M_c = p_0 \times Z_c \tag{49.23}$$

where Z_c is the compression section modulus of the effective cross-section. This situation will occur in the case of members that have wide tension elements or substantially ineffective compression elements.

If, on the other hand, the tensile stresses reach yield before p_0 is attained on the compression side, as in Fig. 49.22b, the designer is allowed to take advantage of the plastic redistribution of tension stresses and thus obtain higher predictions of moment capacity than would be the case if the first yield were taken as the criterion. This necessitates an increase in the complexity of the analysis if the added capacity is to be obtained. If simplicity of analysis is more important than the requirement to obtain the most beneficial estimate of capacity, then the moment capacity can also be obtained using the product of the yield stress and tension modulus of the effective cross section. This may well, however, lead to significant underestimates of the member capacity.

Determination of Deflections

Determination of deflections is often required to satisfy deflection limitations at the working load, and in such a case the use of the fully reduced properties will often give overconservative results. This occurs because the effective section properties reduce progressively, and for thin-walled cross-sections these will be greater at the working load than at the ultimate load. In general the use of the fully reduced section properties overestimates deflections at loads below ultimate, whereas the use of the full section properties underestimates these deflections.

Plastic Bending Capacity

The potentiality of local buckling and its adverse effects is not always present for cold-formed steel sections. Since material thicknesses of up to 8 mm are covered primarily by codes and greater thicknesses are not precluded, it is possible to have very compact cross-sections, even in the case of large members, in which local buckling does not take place. In such cases the potential for fully plastic design cannot be ignored. Local buckling is the major source of impairment of the capacity of a laterally stable member to function adequately in the plastic range, and when this phenomenon is eliminated by virtue of the compactness of the cross-section, the member can behave plastically.

For compact elements the cross-section not only can withstand the fully plastic moment, but also can provide sufficient rotation capacity at the point of maximum moment to allow plastic redistribution of the moments in statically indeterminate beams. The limiting width-to-thickness ratios for compression elements of the plastic cross-section are specified in codes. Sections whose compression elements have

b/t ratios less than the limiting values may be designed using the principle of plastic analysis, providing that the following qualifying features are complied with:

1. The member is laterally stable.
2. The virgin yield strength of the material is used, and the enhanced yield due to cold-forming effects is neglected.
3. The depth-to-thickness ratio of the compression portion of the web is less than the value specified in the codes.
4. The maximum shear force is less than the value limited by the code.
5. The angle between any web and the loading plane does not exceed 20°.
6. The ratio of ultimate-to-yield strength is at least 1.08, and the total elongation at failure in a tensile test is not less than 10% over a 2-in. gauge length.

These qualifications are imposed largely on the basis of engineering judgment to avoid any possibility of underdesign through the use of plastic analysis.

Web Crushing

An important effect that must be avoided in the use of cold-formed steel beams is local crushing at support points or points of concentrated load. The thinness of the web material makes cold-formed sections susceptible to such behavior if they are supported directly on the bottom elements over a short support length. Web crushing is characterized by localized buckling in the immediate vicinity of the concentrated load or support point, as illustrated in Fig. 49.23. This type of buckling signifies the limit of the load capacity of a beam and must be avoided.

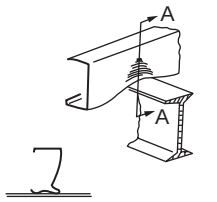

FIGURE 49.23 Web crushing at support.

In the most commonly used cold-formed beams, i.e., roof purlins, web crushing is avoided by the use of cleats that support the beam using bolts fixed through the web, thus eliminating the high compressive stresses that would be incurred if the beam was supported through its bottom flange. The use of cleats is illustrated in Fig. 49.24 and is a most effective way of overcoming the problem of web crushing.

If cleats are not to be used, then the main method of ensuring that web crushing does not occur is to make the length of support sufficiently large to avoid the possibility. The capacity of a beam web to withstand concentrated loading is dependent on the web D/t ratio, the material yield strength, the length over which the load or support takes place, the corner radius of the supported flange, the web angle, the general geometry of the cross section, and the position of the load or support point on the member.

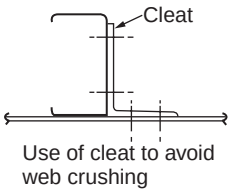

FIGURE 49.24 Use of cleat to avoid web crushing.

If concentrated loads are applied close to the ends of a member, the capacity of the web to resist these loads is less than that for loads applied far from the ends, since it is easier for the web to buckle out of plane if it has material only on one side of the support to resist buckling. In BS 5950, Part 5, the rules governing web crushing were adapted from the 1980 AISI specification, which is based largely on tests carried out at Cornell University (Winter and Pian, 1946; Zetlin, 1955), with refinements produced by further testing at the University of Missouri–Rolla (Hetrakul and Yu, 1980). A more detailed consideration of the web crushing problem and the set up of the AISI design rules is given in Yu (1991). In the recent past attempts have been made by a number of researchers, e.g., Rhodes et al. (1999) and Hoffmeyer et al. (2000), with some success, to produce design methods based to a greater extent on analysis than was the case in the past, and it is possible that the current highly empirical approach to this problem may be replaced by alternative, more analytically based methods in the future.

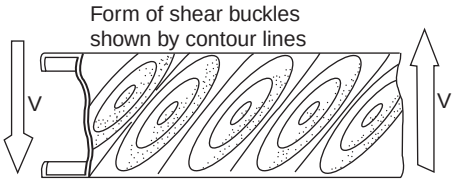

FIGURE 49.25 Shear buckling of thin web.

Shear in Webs

The primary functions of webs are to keep the flanges apart and to carry the shear loadings. It is necessary for safe design to ensure that the shear stresses in the webs do not become unacceptably large. In thin webs there are two potential sources of danger regarding the bahavior of the web in shear. The first is the possibility of shear stresses, including yield of the material, and the second is the possibility of shear buckling in the web.

Material Yielding in Shear

With regard to material yielding, the von Mises yield criterion predicts that in the case of a material under pure shear yielding will occur when the shear stress reaches 0.577 times the yield stress in simple tension. In AISI with a factor of safety equal to 1.44, shear stresses equal to 0.4 times the yield stress are allowed at the strength limit state. In the determination of the shear stress limitations with regard to yield resistance two different provisions are given, one applying to the maximum shear stress in the web and the other applying to the average shear stress in the web. The average shear stress in the web is obtained by dividing the shear force by the web area. The use of the average shear stress in design calculations is simple and expedient, but it should be borne in mind that the shear stress is not normally constant across the web, and the maximum shear stress should also be checked.

Web Buckling Due to Shear

In short, deep beams with thin webs, as illustrated in Fig. 49.25, local buckling due to shear becomes a potential problem. Under shear loading the form of the local buckles is rather different from that produced by direct stresses. The main difference lies in the fact that shear buckles are orientated at some angle to the axis of the web, as indicated in the figure. The degree of orientation depends on the relative magnitudes of the direct stresses and shear stresses in the webs, and becomes a maximum of 45° when only shear is present. This type of buckling has been investigated by many researchers (Rockey, 1967; Allen and Bulson, 1980). After buckling, the web can withstand further loading due to tensile stresses that arise to resist shear deformation. This resistance is known as *tension field action*, and for hot-rolled sections tension field action may be used in design to improve the design capacity.

In the case of cold-formed steel sections the variety of possible sections that must be covered by the design rules preclude the use of tension field action in the general case in the light of present-day knowledge, and shear buckling is taken as the limiting factor. However, in view of the underlying sources of increased safety the reductions in buckling resistance due to imperfections, etc., which are taken into account for other forms of buckling, are disregarded in the case of web buckling due to shear. In determining the shear buckling resistance, the worst case of shear on a web is considered.

Combined Effects

When different load actions take place on a member simultaneously, each action affects the general behavior, and the resistance of a member to one type of load is dependent on the magnitude of all the load actions on the member. Since in general beams are subjected to shear, bending, and support loading at the same time, the interactions of each different loading type should be checked out. Ideally in assessing

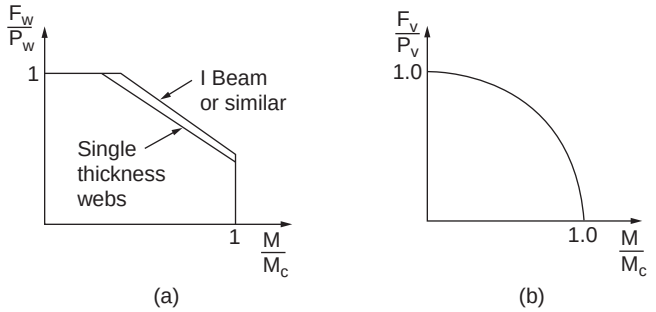

FIGURE 49.26 (a) Interaction diagram for combined web crushing and shear. (b) Interaction diagram for combined bending and shear.

the capacity of a member subject to a variety of different actions, all actions that contribute to failure should be incorporated in the assessment. This is rather difficult, however, because of the complexities of taking many actions into account at the same time, and in practice the main actions are included only in the interaction equations. Design codes give interaction equations dealing with the combinations of bending and web crushing and web crushing and shear.

Combined Bending and Web Crushing

Since the web crushing provisions were adapted from the AISI specification, the rules in BS 5950, Part 5, governing the load capacity of beams under combined bending and web crushing were naturally taken from the same source. The AISI rules were based on a series of tests carried out at the University of Missouri–Rolla (Hetrakul and Yu, 1980). Two different interaction formulas are given in BS 5950, Part 5: one for single-thickness webs and the other for I beams made from channels connected back-to-back.

For single-thickness webs the relevant interaction equation is

$$1.2\left(\frac{F_w}{P_w}\right)+\left(\frac{M}{M_c}\right)\le 1.5 \tag{49.24}$$

For I beams, or for any section where the web is provided with a high degree of rotational restraint at its junction with the flange, the relevant interaction equation is

$$1.1\left(\frac{F_w}{P_w}\right)+\left(\frac{M}{M_c}\right)=1.5 \tag{49.25}$$

In both of these equations F_w is the concentrated web load or reaction, M is the applied bending moment at the point of application of the web load, and P_w and M_c are the web crushing capacity and moment capacity, respectively, of the member. These equations are, of course, subject to the overriding conditions that P cannot be greater than P_w and M cannot be greater than M_c. The interaction diagrams are shown in Fig. 49.26a, which indicates that single-thickness webs are considered to be affected to a somewhat greater extent by the combination of effects than I-beam webs.

Combined Bending and Shear

The interaction of shear force and bending is covered in BS 5950, Part 5, by the equation

$$\left(\frac{F_v}{P_v}\right)^2+\left(\frac{M}{M_c}\right)^2\le 1 \tag{49.26}$$

where F_v and P_v are the shear force and shear capacity, respectively. This equation is illustrated in Fig. 49.26b and is the same as that used in the AISI specification. The AISI specification also has further provisions for webs fitted with transverse stiffeners at the load points.

Lateral Buckling

Lateral buckling, sometimes called lateral torsional buckling, generally occurs when a beam that is bent about its major axis develops a tendency to displace laterally, i.e., perpendicularly to the direction of loading, and twist. Many, if not most, beams used in cold-formed construction are restrained against lateral movement, in many cases continuously restrained by roof or wall cladding. In other cases restraint is afforded by other members connected to the beam in question or by bracing such as antisag bars. Such restraints reduce the potentiality of lateral buckling, but do not necessarily eliminate the problem. For example, roof purlins are generally restrained against lateral displacement by the cladding, but under wind uplift, which induces compression in the unrestrained flange, lateral buckling is still a common cause of failure. This occurs due to the flexibility of the restraining cladding and to the distortional flexibility of the purlin itself, which permits lateral movement to occur in the compression flange, even if the other flange is supported.

A further point that should be noted is that, contrary to the statement made in BS 5950, Part 5, it is not a necessary condition for lateral torsional buckling that bending take place about the major axis. In some cases beams that are bent about the minor axis may undergo this type of buckling behavior. In general, lateral torsional buckling is closely related to torsional flexural buckling in columns. Any cross-section that is susceptible to torsional flexural buckling may also have lateral buckling tendencies.

Elastic Lateral Buckling Resistance Moment

In the case of an I beam, theoretical analysis (Allen and Bulson, 1980) shows that the elastic critical moment, M_E, for a beam of length L bent in the plane of the web is given by the expression

$$M_E = \frac{\pi}{L}\left[\frac{EI_1}{\gamma}\left(GJ + EC_w\frac{\pi^2}{L^2}\right)\right]^{1/2} \tag{49.27}$$

where I_1 = the second moment of area about an axis through the web
C_w = the warping constant, G is the shear modulus
J = the torsion constant
$\gamma = 1 - I_1/I_2$, I_2 being the second moment of area about the neutral axis perpendicular to the web

Using the relationships

$$I_1 \approx \frac{B^3 t}{6} = Ar_y^2 \qquad C_w \approx I_1 \times \frac{D^2}{4}$$

where B = the flange width
D = the beam depth
A = the area of cross section
r_y = the the radius of gyration about the y axis,

$$G = \frac{E}{2(1+\nu)} = \frac{E}{2.6} \qquad J = \frac{At^2}{3}$$

This equation can then be rearranged to give

$$M_E = \frac{\pi^2 AED}{2\left(L/r_y\right)^2}\left[1 + \frac{4}{7.8\pi^2}\left(\frac{Lt}{r_y D}\right)^2\right]^{1/2} \tag{49.28}$$

The term $4/7.8p^2$ is very close to 1/20, and this forms the basis of the elastic lateral buckling resistance moment used in the AISI specification and BS 5950, Part 5, for I sections. Analysis of channels gives very similar results, and these can be dealt with using the same equation. In this equation the *effective length*, L_E, is used instead of L, and a coefficient C_b, which accounts for the variation in moment along a beam, is also incorporated.

In the case of Z-section beams, it is rather difficult to envisage such beams being used completely unrestrained against lateral movement, as the unsymmetrical behavior would make them highly flexible. The vast majority of Z sections are used as purlins, with a high degree of lateral restraint from roof cladding, and even types of cladding classified as nonrestraining offer sufficient restraint to enable these purlins to function more or less as laterally braced members if lateral buckling is not considered. In the case of Z sections that are not restrained laterally or that have very light restraint, the lateral buckling resistance is taken in the AISI specification and BS 5950, Part 5, as half of that calculated for a channel or I section. This recommendation is based on tests in the U.S. by Winter (1947).

Variation in Moment along a Beam

The coefficient C_b is used to take account of the variation in moment along a beam. Without this coefficient the buckling resistance is calculated on the basis of a uniform moment acting all along the beam, which is a most severe condition. If the moment varies along the beam, then the maximum moment to cause lateral buckling will be greater than that analyzed on the basis of the pure moment, and this is taken into account by the C_b factor.

C_b acts as a multiplying factor, and if the elastic lateral buckling moment derived for pure bending is multiplied by this factor, the resulting values of M_E become good approximations to the elastic lateral buckling moments for the case of the linearly varying bending moment along a beam. These coefficients were derived on the basis of a linearly varying bending moment distribution, but within limits they may also be used in the case of nonlinearly varying moments.

The C_b factors used in the AISI specification and BS 5950, Part 5, are, with reference to Fig. 49.27,

$$C_b = 1.75 - 1.05\beta + 0.3\beta^2 \le 2.3 \tag{49.29}$$

in which β is the ratio of the end moments.

If the maximum moment within the beam span between supports is less than the larger of the end moments, Eq. (49.29) can be used to determine C_b. If the maximum moment within the span is greater than the larger end moment, C_b must be taken as unity.

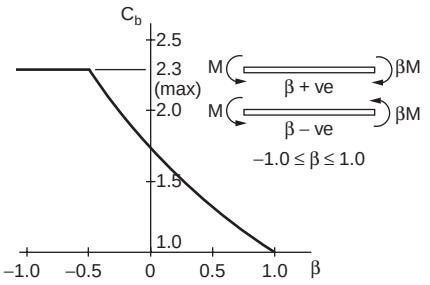

FIGURE 49.27 Variation of C_b factor with distribution of moment over the span.

Effective Lengths

The restraints afforded by the supports can have a substantial effect on the lateral buckling resistance of beams. The expressions given for M_E assume that no resistance to warping is afforded by the support. If the supports can resist torsion, however, increases in buckling resistance can be obtained. These increases in buckling resistance are derived using the well-known effective length concept, in which it is assumed that the beam has an effective length different from its actual length for the purpose of determining buckling resistance.

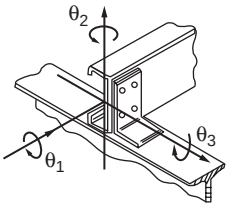

FIGURE 49.28 Support conditions with regard to effective length determination.

In estimating the effective length with regard to lateral buckling the engineer is required to exercise a degree of judgment. The effective lengths are directly affected by the degree of restraint on rotation of the beam at the supports or bracing points, and the rotations that require examination occur about three perpendicular axes, as shown in Fig. 49.28. Some assessment must be made regarding the degree of restraint afforded by the support about each axis. If it is considered that no restraint is provided against rotation about any axis, then for safe design the effective length should be taken as 1.1 times the actual span between supports or bracing members.

Destabilizing Loads

The elastic buckling resistance moment was determined initially on the basis of pure moment loading on simply supported beams. This was then modified to take account of moment variation via the C_b factors and to take account of the support restraints via the use of effective lengths. One further factor that must be taken into account concerns the position of the loading on the cross-section. If we consider the I section shown in Fig. 49.29, any twisting of the section reduces the vertical distance between the shear center and the web flange junctions. Thus during lateral buckling a load applied to the upper flange will displace further than a load applied at the shear center, while a load applied to the lower flange will displace by a lesser amount. Thus the work done by the load during buckling is greatest if applied to the upper flange and least if applied to the lower flange, and the values of the buckling stresses are dependent on this effect. For loads applied above the shear center the buckling resistance decreases, while for loads applied below the shear center the buckling resistance increases.

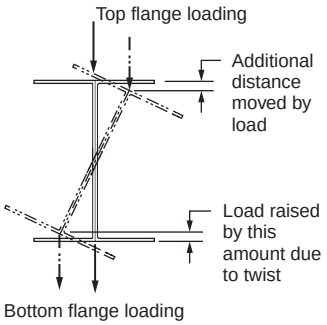

FIGURE 49.29 Stabilizing and destabilizing loads.

Example 49.3

Figure 49.30a shows a hat section that is subjected to bending about the x axis. Assuming the yield point of steel as 50 ksi, determine the allowable bending moment in accordance with AISI specifications.

Solution: Calculation of Sectional Properties

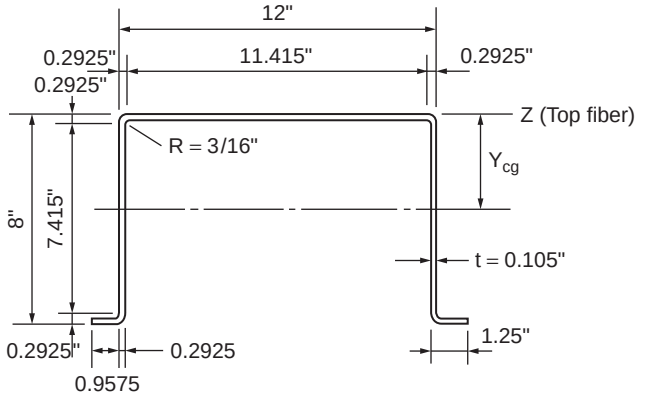
Midline dimensions shown in Fig. 49.30b are used for the calculation.

$$R' = R + t/2 = 0.240 \text{ in.}$$

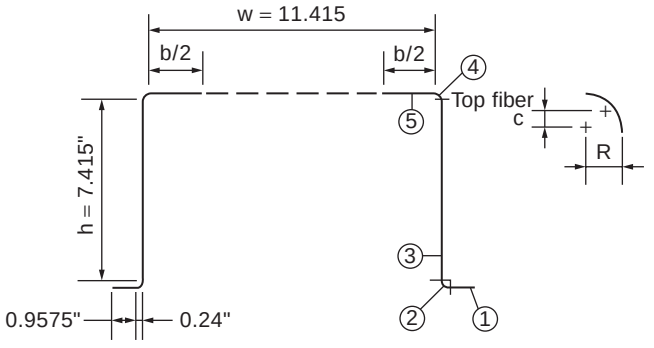
Arc length of the corner element:

$$L = 1.57R' = 0.3768 \text{ in.}$$

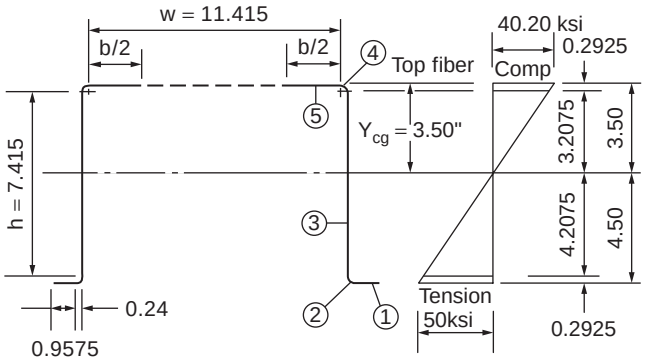
$$c = 0.637R' = 0.1529 \text{ in.}$$



(a)



(b)



(c)

FIGURE 49.30 Example 49.3.

Location of Neutral Axis — First approximation:

For the compression flange,

$$w = 12 - 2(R + t) = 11.415 \text{ in.}$$

$$\frac{w}{t} = 108.71$$

$$p_{cr} = \frac{4\pi^2 E}{12\left(1-\nu^2\right)} \frac{1}{\left(w/t\right)^2}$$

$$= \frac{4 \times \pi^2 \times 29{,}500}{12 \times \left(1-0.3^2\right)} \frac{1}{\left(108.71\right)^2} = 9.02 \text{ ksi}$$

$$p_{max} = 50 \text{ ksi}$$

$$\sqrt{\frac{p_{max}}{p_{cr}}} = \sqrt{\frac{50}{9.02}} = 2.35 > 0.673$$

$$b = w\sqrt{\frac{p_{cr}}{p_{max}}}\left[1-0.22\sqrt{\frac{p_{cr}}{p_{max}}}\right]$$

$$= 4.396 \text{ in.}$$

The neutral axis of the effective section with a reduced width of the compression flange equal to 4.396 in. can be determined as given below. The webs are assumed to be fully effective.

Element	Effective Length L (in.)	Distance from Top Fiber y (in.)	Ly (in.^{2})
1	$2 \times 0.9575 =$ 1.9150	7.9475	15.22
2	$2 \times 0.3768 =$ 0.7536	7.8604	5.92
3	$2 \times 7.4150 =$ 14.8300	4.0000	59.32
4	$2 \times 0.3768 =$ 0.7536	0.1396	0.1052
5	4.3960	0.0525	0.2310
Total	22.6482		80.7962

$$y_{cg} = \frac{\Sigma\left(Ly\right)}{\Sigma L} = \frac{80.7962}{22.6482} = 3.567 \text{ in.}$$

Because the distance y_{cg} is less than the half-depth of 4.0 in., the neutral axis is closer to the compression flange, and therefore the maximum stress occurs in the tension flange. The maximum compressive stress can be computed as follows:

$$f = 50\left(\frac{3.567}{8-3.567}\right) = 40.23 \text{ ksi}$$

Since this stress is less than the assumed value, another trial is required.

Second approximation:

Assuming that f = 40.23 ksi,

$$p_{max} = 40.23 \text{ ksi}$$

$$\sqrt{\frac{p_{max}}{p_{cr}}} = \sqrt{\frac{40.32}{9.02}} = 2.11 > 0.673$$

$$b = w\sqrt{\frac{p_{cr}}{p_{max}}}\left[1-0.22\sqrt{\frac{p_{cr}}{p_{max}}}\right] = 4.842 \text{ in.}$$

Element	Effective Length L (in.)	Distance from Top Fiber y (in.)	Ly (in.^{2})	Ly^2 (in.^{3})
1	1.9150	7.9475	15.2200	120.961
2	0.7536	7.8609	5.9200	46.537
3	14.8300	4.0000	59.3200	237.280
4	0.7536	0.1396	0.1052	0.015
5	4.8420	0.0525	0.2542	0.013
Total	23.0942		80.8194	404.806

$$y_{cg} = \frac{80.8194}{23.0942} = 3.5 \text{ in.}$$

Check the Effectiveness of the Web — Using Section B2.3 of the AISI specification, the effectiveness of the web element can be checked as follows:

From Fig. 49.30c,

$$f_1 = 50(3.2075/4.50) = 35.64 \text{ ksi}(\text{Compression})$$

$$f_2 = -50(4.2075/4.50) = -46.75(\text{tension})$$

$$= f_2/f_1 = -1.312$$

$$k = 4 + 2(1-\psi)^3 + 2(1-\psi)$$

$$= 33.341$$

$$\frac{h}{t} = \frac{7.415}{0.105} = 70.62 < 200 \text{ OK}$$

$$\lambda = \frac{1.052}{\sqrt{33.341}}(70.62)\sqrt{\frac{35.64}{29,500}}$$

$$= 0.447 < 0.673$$

$$b_e = h = 7.415 \text{ in.}$$

$$b_1 = b_e/(3-\psi) = 1.72 \text{ in.}$$

Since $\psi < -0.236$,

$$b_2 = b_e/2 = 3.7075 \text{ in.}$$

$$b_1 + b_2 = 5.4275 \text{ in.}$$

Because the computed value of $(b_1 + b_2)$ is greater than the compression portion of the web (3.2075 in.), the web element is fully effective.

Moment of Inertia and Section Modulus — The moment of inertia based on line elements is

$$2I_3' = 2\left(\frac{1}{12}\right)(7.415)^3 = 67.95$$

$$\Sigma(Ly^2) = 404.806$$

$$I_z' = 67.95 + 404.806 = 472.756 \text{ in.}^3$$

$$-(\Sigma L)(y_{cg})^2 = 23.0942(3.5)^2 = 282.9 \text{ in.}^3$$

$$I'_x = 189.85 \text{ in.}^3$$

The actual moment of inertia is

$$I_x = I'_x t = 189.85(0.105) = 19.93 \text{ in.}^4$$

The section modulus relative to the extreme tension fiber is

$$S_x = 19.93/4.50 = 4.43 \text{ in.}^3$$

Nominal and Allowable Moments — The nominal moment for section strength is

$$M_n = S_e F_y = S_x F_y = (4.43)(50) = 221.50 \text{ in-kips}$$

The allowable moment is

$$M_a = M_n/\Omega_f = 221.50/1.67 = 132.63 \text{ in-kips.}$$

49.4 Members Subject to Axial Load

Axial loading is a very common and very important type of loading, and the requirements to deal with this type of loading in cold-formed steel members vary according to the type of loading, tension or compression, and geometry and use of the member. Due to the thinness of the walls in cold-formed steel sections and the variety of different cross-sectional shapes that can be produced, types of behavior not commonly found in traditional hot-rolled members can occur, and these must be recognized and taken into account in design. Codes provide design methods to deal with the various phenomena associated with thin-walled sections in a fairly simple manner.

Short Struts

Local buckling must be taken into consideration in the analysis of members in compression. We have seen in previous chapters how individual elements are dealt with in this regard. In the case of complete sections subjected to compression we must take into account the possibility of local buckling in all elements of a cross section. To do so we consider initially a short length of member that is acted upon by compressive loads, as shown in Fig. 49.31.

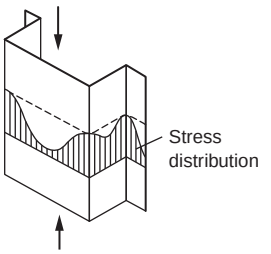


FIGURE 49.31 Short length of compressed member.

Due to the compressive loads, each element of the cross-section can suffer local buckling. We therefore consider each flat element in turn, find the effective width — and hence effective area — of the element, and sum these, together with the areas of the corners, to obtain the total effective area, A_{eff}. The ratio of the effective cross-sectional area to the full cross-sectional area, A, is denoted as Q, i.e.,

$$Q = \frac{A_{eff}}{A} \tag{49.30}$$

The factor Q was adopted partly because it described more realistically the actual situation in a cross-section, e.g., effective and ineffective portions.

The load capacity of a short strut under uniform compression is given by the product of the effective area (A_{eff}) and the yield stress (Y_s), i.e.,

$$P_{cs} = QAY_s \tag{49.31}$$

Flexural Buckling

Euler Buckling

We have seen how short uniformly compressed members behave and how the effects of local buckling must be taken into account in design analysis. For long members under compression, different modes of failure arise, due to overall buckling. We shall first consider buckling due to flexure, or Euler buckling. Euler buckling occurs when a long, slender member, i.e., a column, is compressed. The elastic buckling load, or Euler load, for such a column under pinned-end conditions is well known as

$$P_E = \frac{\pi^2 EI}{\ell^2} \tag{49.32}$$

where I = the relevant second moment of area
E = the elasticity modulus
ℓ = the column length

By writing $I = Ar^2$, where r is the radius of gyration of the cross section corresponding to I, Eq. (49.32) can be put in terms of the critical, or Euler buckling, stress, p_E, as follows:

$$p_E = \frac{\pi^2 E}{\left(\ell/r\right)^2} \tag{49.33}$$

As the length of the column increases, the critical stress to cause Euler buckling decreases, so that for a very long column Euler buckling occurs at extremely low stress levels. In the case of local buckling we have seen that the local buckling stress is relatively unaffected by length. Thus for long columns the effects of local buckling do not arise, and in determining the Euler load for such a column we do not need to take local buckling into account.

Effective Lengths

If the ends of a column are not pinned, but subject to some other degree of fixity, Eqs. (49.32) and (49.33) do not apply directly, but must be modified to take the actual end conditions into account. In design, this is often accomplished using the effective length concept, in which the actual column length L is replaced by an effective length L_E in the equations. The effective length of a column is normally taken as the distance between the points of contraflexure in a buckled column. Values for the effective length as a proportion of the actual length between supports are given in the AISI specification and BS 5950, Part 5, for a number of conditions of column support.

The ratio of effective length to the relevant radius of gyration of a column is termed the *slenderness ratio*. Maximum permitted values of the slenderness ratios of columns are given in codes for different types of members. For members that normally act in tension, but may be subject to load reversal due to the action of wind, high slenderness ratios are permitted. For members subjected to loads other than wind loads, the maximum slenderness ratio is given as 180 in BS 5950, and AISI stipulates a maximum value of 200.

In the design analysis of columns the complete range of slenderness ratios must be catered to. We have seen that for short columns local buckling is important and Euler buckling is of little consequence, while for long columns Euler buckling assumes the highest significance and local buckling has little effect. For

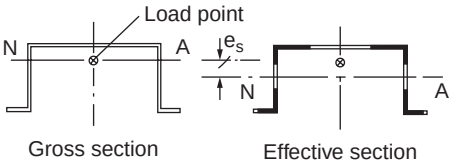

FIGURE 49.32 Neutral axis shift for locally buckled cross-section.

short members that are fully effective failure occurs when the load reaches the squash load, i.e., $Y_s \times A$. If local buckling is present, this load is modified, due to the local buckling effects, to $Y_s \times A_{eff}$, or QY_sA. If the slenderness ratio is greater than a fixed value, Euler buckling occurs and the failure load reduces with an increase in the slenderness ratio.

Real columns are, of course, not perfect, and column imperfections cause some bending to occur even in very short members, thus hastening yield in these members and causing failure at loads less than the Euler load. It is imperative that the effects of imperfections are accounted for in the design analysis.

Effects of Neutral Axis Shift

If we examine the gross cross section and the effective cross section together, as illustrated in Fig. 49.32, we can see that the effects of local buckling have been not only to alter its effective area, but also to change the geometry, since some elements have become more ineffective than others. Because of this the neutral axis of the effective cross-section moves from its original position as local buckling progresses. If the loading is applied at the centroid of the full cross section, it becomes eccentric to the centroid of the effective cross-section, thus inducing bending in the member.

It is therefore evident that any section that is not doubly symmetric and that is subject to loads inducing local buckling effects is likely to incur bending in addition to axial load if the loading is applied through its centroid. The degree of bending incurred depends on the distance that the effective neutral axis is displaced from its initial position, and this in turn depends on the degree of local buckling undergone by the member. Since this bending has the effect of reducing the column load capacity, and since the magnitude of the neutral axis shift increases with load, it should make for conservative estimates of load capacity if the neutral axis shift is determined on the basis of the short strut load, P_{cs}.

If the neutral axis of the effective section is displaced by an amount e_s from that of the gross cross section, the moment produced by a load applied through the original neutral axis is the product of load P and displacement e_s. To take the combination of axial load and moment into account a simple linear interaction formula is used:

$$\frac{M}{M_c} + \frac{P}{P_c} = 1 \tag{49.34}$$

where M_c is the moment capacity in the absence of axial load, determined as illustrated in the previous chapter, and P_c is the failure load of the column under uniform compression. At the ultimate load of the member, P, the moment acting is $P \times e_s$. Eq. (49.34) becomes

$$\frac{P'_c e_s}{M_c} + \frac{P'_c}{P_c} = 1 \tag{49.35}$$

The full effects of neutral axis shift will not be incurred in practice for columns that are not, in fact, pinned end. If the effective length of a column is less than the full length between supports, any accurate assessment of the effects of neutral axis shift is complex, and there is as yet no satisfactory solution to this question. Experimental results suggest that for completely fixed ends the effects of neutral axis shift may be completely neglected in assessing the column capacity.

Torsional Flexural Buckling

Theoretical Basis

Apart from local buckling, perhaps the major difference in behavior between hot-rolled steel and cold-formed steel structural members is to be found in the relative susceptibility of the latter to *torsional flexural buckling*. Designers in hot-rolled steel do not come across this phenomenon to a great extent, partly because hot-rolled steel sections are generally thicker and more compact than cold-formed steel sections, but more generally because of the greater variety of sectional shapes that are designed in cold-formed steel. When dealing with members that are of arbitrary cross-section, a more general theoretical approach must be adopted than that used in the earlier sections of this chapter.

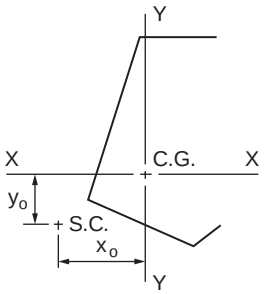

FIGURE 49.33 Generally unsymmetrical cross-section.

Consider a member having a generally unsymmetrical cross section, as depicted in Fig. 49.33. If this member is loaded in compression, it is not possible to determine by inspection the direction in which the cross-section will move during buckling. For such a cross section, on the basis of classical theory, which is detailed in Murray (1984) and Allen and Bulson (1980), the deflections of the member will have components in the x and y directions and twisting will also occur about the shear center, or center of twist. Indeed, if precise analysis of the situation were to be carried out, it would be found that distortion, or change in shape of the cross-section, is also a distinct possibility in thin-walled sections, but this complicates the analysis considerably.

The application of classical theory to deal with cold-formed steel sections has been researched extensively at Cornell University in the U.S. (Chajes and Winter, 1965; Peköz and Celebi, 1969), and Yu (1991) gives a thorough summary of the design approach based on this work. If we consider that the section of Fig. 49.33 is loaded through its centroid, and axes x-x and y-y are the principal axes, then the buckling load, which in the general case is due to a combination of biaxial flexure and twisting, and thus denoted P_{TF}, may be obtained from the following equation:

$$\frac{I_C}{A}\left(P_{TF}-P_{EY}\right)\left(P_{TF}-P_{EX}\right)\left(P_{TF}-P_T\right)-P_{TF}^2\left\{y_o^2\left(P_{TF}-P_{EX}\right)+x_o^2\left(P_{TF}-P_{EY}\right)\right\}=0 \qquad (49.36)$$

In this equation I_c is the polar second moment of area with respect to the shear center of the section; P_{EX} and P_{EY} are the critical loads for buckling about the x and y axes, respectively; and P_T is the torsional buckling load. The dimensions x_o and y_o are the distances between the centroid of the section and its shear center measured in the x and y directions, respectively. The smallest root of the equation gives the value of P_{TF} of interest, and this is always less than or equal to the smallest value of the individual critical loads.

If the member has simple support conditions, as normally defined, at its ends, then P_{EX} and P_{EY} are simply the Euler loads for buckling about the x-x and y-y axes, respectively. The torsional buckling load, P_T, however, is not fully described by the commonly accepted simple support conditions; closer examination of the support conditions must be carried out to define this load.

P_T is defined by the following equation:

$$P_T=\frac{1}{r_o^2}\left(GJ+k\pi^2E\frac{C_w}{L_E^2}\right) \qquad (49.37)$$

where G = the shear modulus for the material
J = the torsion constant for the section

C_w = the *warping constant* for the section
r_o = the polar radius of gyration about the shear center, given by

$$r_o = \left(r_x^2 + r_y^2 + x_o^2 + y_o^2\right)^{1/2} \tag{49.38}$$

where r_x and r_y are radii of gyration corresponding to the x and y axes, respectively.

The constant k is dependent on the degree of warping restraint afforded by the end connections of the column. If warping is completely unrestrained, then k = 1. There is, as can be seen, an analogy with the Euler load for flexural buckling, in which a fully fixed column has a buckling load four times as great as the corresponding simply supported column.

Warping Restraint

We can see that a column that is nominally simply supported, or simply supported with regard to flexural buckling, may exhibit a wide range of variation in buckling load under the more general torsional flexural buckling situation. If the walls of such a column are very thin, then for column lengths of commercial applicability the torsion constant, J, which is equal to $Sbt^3/3$, can become very small in comparison with C_w/L_E^2, and the degree of warping restraint becomes very important.

The degree of warping restraint by different types of end connections is not easy to quantify, as it depends on a wide range of factors. However, warping of the ends is often prevented by the end plates, and the effects of torsional flexural buckling are often minimized. This assumption of full warping restraint is therefore optimistic for the general case.

In the AISI specification, and in the various design codes based on the AISI specification, the opposite view is taken. Here it is assumed that for safe design no account should be taken of the effects of connections on warping restraint, and so torsional flexural buckling is based on k = 1. This gives much lower design loads for many cases and results in torsional flexural buckling being the governing design criterion for a much wider range of section shapes than is the case. Eurocode 3, Part 1.3, considers a column to have an effective length with regard to torsional flexural buckling, and this effective length may be different from that for flexural buckling and depends on the degree of torsion and warping restraint at the column ends. This code gives some indicative drawings of the connections for which restraint may be considered sufficient to take the restraints applied into account in estimating the effective length.

Members under Combined Bending and Compression

Under practical conditions structural members are very often subjected to combinations of bending and axial loading. The interaction of the different effects must be taken into account when this occurs. When the axial loading is compressive there are possibilities that the different types of buckling that can occur for both beams and columns may interact with each other, and this must be guarded against. Even in the case of members subjected to combinations of bending and tension there are possibilities that buckling of some form may occur, and this must be taken into consideration. In this section, however, we shall consider combinations of compressive forces and bending.

Under hypothetical simplified conditions in which buckling effects are absent and a member behaves perfectly elastically until failure occurs when the maximum stress reaches yield, the effects of each different type of loading that acts on a member can simply be added together to produce an equation governing the capacity under simultaneous applications of moment, M, and axial load, P:

$$\frac{P}{P_s} + \frac{M}{M_y} = 1 \tag{49.39}$$

where P_s = the load capacity in the absence of moments
M_y = the moment capacity in the absence of axial loads

If buckling possibilities are negligible and if the material has any postyield capacity, this type of equation tends to give conservative results of the load-carrying capacity of the member under combined loadings. If, on the other hand, there is any tendency for the member to undergo buckling, then this type of equation can underestimate the degree of interaction and give nonconservative estimates of carrying capacity.

The AISI recommends that the axial force and bending moments satisfy the following interaction equations:

$$\frac{P}{P_a}+\frac{C_{mx}M_x}{M_{ax}\alpha_x}+\frac{C_{my}M_y}{M_{ay}\alpha_y}\le 1.0 \tag{49.40}$$

$$\frac{P}{P_{a0}}+\frac{M_x}{M_{ax}}+\frac{M_y}{M_{ay}}\le 1.0 \tag{49.41}$$

When $P/P_a \le 0.15$, the following formula may be used in lieu of the above two formulas:

$$\frac{P}{P_a}+\frac{M_x}{M_{ax}}+\frac{M_y}{M_{ay}}\le 1.0 \tag{49.42}$$

where P = the applied axial load

M_x and M_y = the applied moments with respect to the centroidal axes of the effective section determined for the axial load alone

P_a = the allowable axial load determined in accordance with Section C4

P_{a0} = the allowable axial load determined in accordance with Section C4, with $F_n = F_y$

M_{ax} and M_{ay} = the allowable moments about the centroidal axes determined in accordance with Section C3

C_{mx} and C_{my} = the coefficients, whose values shall be taken from the AISI specifications

$1/a_x$ and $1/a_y$ = the magnification factors, $1/[1 - (O_cP/P_{cr})]$, in which O_c is the factor of safety used in determining P_a and

$$P_{cr} = \frac{\pi^2 E I_b}{(K_b L_b)^2} \quad 46$$

For the above equation, I_b is the moment of inertia of the full, unreduced cross-section about the axis of bending; L_b is the actual unbraced length in the plane of bending; and K_b is the effective length factor in the plane of bending.

BS 5950 considers two different possibilities that should be examined in dealing with the interaction of axial compression and bending:

1. The capacity of the member may be exceeded locally at discrete points at which the maximum loadings occur.
2. The overall capacity of the member to resist buckling due to the action of the combined loadings may be exceeded.

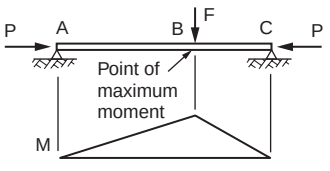

FIGURE 49.34 Moment variation along a member with axial and transverse loading.

The first possibility is likely to occur in members subjected largely to bending with some additional axial loading. At points of maximum moment, as indicated in Fig. 49.34, the effects of the axial loading on the ultimate condition must be considered. This situation can be adequately covered by a linear interaction equation, and in BS 5950, Part 5, the following expression is used to check

the local capacity of a member subjected to axial load F_c and bending moments M_x and M_y about the x and y axes, respectively:

$$\frac{F_c}{P_{cs}} + \frac{M_x}{M_{cx}} + \frac{M_y}{M_{cy}} \le 1 \tag{49.43}$$

where P_{cs} is the axial load capacity in the absence of moments and M_{cx} and M_{cy} are the moment capacities if the member is subjected only to bending about the relevant axis in the absence of all other load actions.

This equation should be satisfied at discrete points on the member where the local load or moment magnitudes are at their peak. It is worthy of mention here that this equation takes account of local buckling effects, since the calculated load and moment capacities are determined on the basis of the methods already described in this book.

The second possibility that must be considered is that the overall buckling capacity of the member may be attained by a combination of loads. The types of buckling, in addition to local buckling, that are possible are flexural buckling or torsional flexural buckling of members loaded largely in compression and lateral torsional buckling of members loaded largely in bending. A suitable overall buckling capacity check should consider all of these possibilities. BS 5950, Part 5, prescribes two interaction equations to deal with the overall buckling capacity check; the particular equation to be used in any given situation is dependent upon whether or not lateral torsional buckling is a possibility. Eurocode 3, Part 1.3, uses a single interaction equation for combined bending and compression (although a modified equation must also be satisfied for members susceptible to lateral torsional buckling), and this equation is substantially different from those of the AISI code or the U.K. code. Comparisons of all three codes with experimental results have not been conclusive to date and suggest that despite the differences in setup the various methods are reasonably accurate and safe.

Members under Combined Bending and Tension

In the case of members subjected to combinations of bending and tension there is not, in general, any need for an overall buckling capacity check, as the application of tensile loads has no tendency to increase the possibility of overall buckling. There are, of course, possibilities that the effects of local buckling may be present in the member, since not all elements of a cross-section will be in tension under the combination of loads.

In BS 5950, Part 5, an interaction equation of the same form as Eq. (49.39) is used to check the local capacity at discrete points on a member. The relevant equation is

$$\frac{F_t}{P_t} + \frac{M_x}{M_{cx}} + \frac{M_y}{M_{cy}} \le 1 \tag{49.44}$$

with

$$\frac{M_x}{M_{cx}} \le 1 \qquad \frac{M_y}{M_{cy}} \le 1$$

In this equation F_t and P_t are the applied tensile load and the tensile capacity of the member, respectively; M_{cx} and M_{cy} are the moment capacities computed in the absence of any other loading. Since M_{cx}, for example, is evaluated on the basis of an effective cross-section, local buckling is automatically taken into account in the interaction equation.

Example 49.4

Compute the allowable axial load for the square tubular column shown in Fig. 49.35. Assume that the yield point of steel is 40 ksi and $K_xL_x = K_yL_y = 10$ ft.

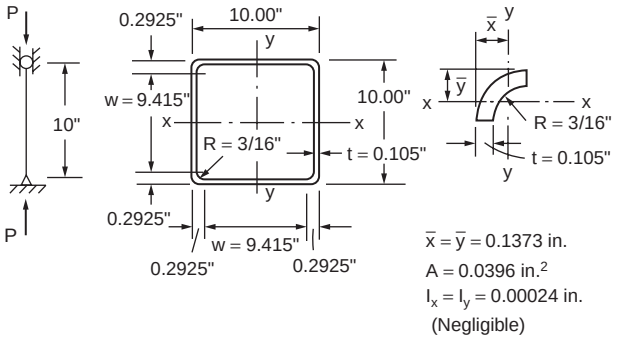

FIGURE 49.35 Example 49.4.

Solution:

The solution given below is based on the AISI code.

Since the square tube is a doubly symmetric closed section, it will not be subject to torsional flexural buckling.

Sectional Properties of Full Section

$$b = 10.00 - 2(R + t) = 10.00 - 2(0.1875 + 0.105) = 9.415 \text{ in.}$$

$$A = 4(9.415 \times 0.105 + 0.0396) = 4.113 \text{ in.}^2$$

$$I_x = I_y = 2(0.105)\left[\frac{1}{12}(9.415)^3 + 9.415\left(5 - \frac{0.105}{2}\right)^2\right] + 4(0.0396)(5.0 - 0.1373)^2$$

$$= 66.75 \text{ in.}^4$$

$$r_x = r_y = \sqrt{\frac{I_x}{A}} = \sqrt{\frac{66.75}{4.113}} = 4.029 \text{ in.}$$

Nominal Buckling Stress, F_n — The elastic flexural buckling stress, F_e, is computed as follows:

$$\frac{KL}{r} = \frac{10 \times 12}{4.029} = 29.78 < 200 \qquad \text{O.K.}$$

$$F_e = \frac{\pi^2 E}{(KL/r)^2} = \frac{\pi^2 (29{,}500)}{(29.78)^2} = 328.3 \text{ ksi}$$

Since $F_e > F_y/2 = 20$ ksi,

$$F_n = F_y\left(1 - F_y/4F_e\right)$$

$$= 40\left[1 - 40/(4 \times 328.3)\right]$$

$$= 38.78 \text{ ksi}$$

Effective Area, A_{eff} — Because the given square tube is composed of four stiffened elements, the effective width of stiffened elements subjected to uniform compression can be computed by using k = 4.0:

$$b/t = 9.415/0.105 = 89.67$$

$$p_{cr} = \frac{4\pi^2 E}{12\left(1-\nu^2\right)}\frac{1}{\left(b/t\right)^2} = 13.26 \text{ ksi}$$

$$\sqrt{\frac{f_{max}}{p_{cr}}} = \sqrt{\frac{40}{13.26}} = 1.737$$

Since $\sqrt{\frac{f_{max}}{p_{cr}}} > 0.63755$,

$$b_{eff} = b\sqrt{\frac{p_{cr}}{f_{max}}}\left[1-0.22\sqrt{\frac{p_{cr}}{f_{max}}}\right]$$

$$= 4.73 \text{ in.}$$

The effective area is $(4.73 \times 0.105 + 0.0396) = 2.145$ in.^{2}

Nominal and Allowable Loads:

$$P_n = A_e F_n = \left(2.145\right)\left(38.78\right) = 83.18 \text{ kips}$$

$$P_a = P_n/\Omega_c = 83.18/1.92 = 43.32 \text{ kips}$$

The use of $\Omega_c = 1.92$ is because the section is not fully effective.

49.5 Connections for Cold-Formed Steelwork

All of the connection methods applicable to hot-rolled sections, such as bolting and welding, are also applicable to cold-formed steel sections at the thicker end of the range. In the case of thinner cold-formed steel sections an extremely wide assortment of proprietary fasteners and fastening techniques exists. This wide range raises problems in setting realistic and reliable approaches to defining connection strength, and evaluation of the connection properties on the basis of testing is generally undertaken.

Types of Fastener

Davies (Rhodes, 1991) listed fasteners in three main groupings, as shown in Table 49.2

The selection of the most suitable type of fastener for a given application is governed by several factors, notably:

1. load-bearing requirements viz. strength, stiffness, and deformation capacity
2. economic requirements viz. number of fasteners required, cost of labor and materials, skill required in fabrication, design life, maintenance, and ability to be dismantled

TABLE 49.2 Typical Applications of Different Types of Fastener

Thin to Thin	Thin to Thick or Thin to Hot Rolled	Thick to Thick or Thick to Hot Rolled
Self-drilling self-tapping screws	Self-drilling self-tapping screws	Bolts
Blind rivets	Fired pins	Arc welds
Single-flare V welds	Bolts	
Spot welds	Arc puddle welds	
Lock seaming		

TABLE 49.3 Permissible Bearing Stress in Bolted Connections

Code	Bearing Stress	Basis
Addendum 1 (April 1975) to BS 449	$1.4U_s$	Permissible stress
BS 5950, Part 1 (hot-rolled)	$0.64(U_s + Y_s)$	Limit state
BS 5950, Part 5 (cold formed)[a]		Limit state
(a) $t \leq 1$ mm	$2.1Y_s$	
(b) 1 mm $\leq t \leq$ 3 mm	$(1.65 + 0.45t)Y_s$	
(c) 3 mm $\leq t \leq$ 8 mm	$3.0Y_s$	
AISI specification (August 1986)		
(a) with washers		
(b) without washers		Permissible stress
European recommendations		
(a) $t \leq 1$ mm	$1.35U_s$ to $1.50U_s$	
(b) 3 mm $\leq t \leq$ 6mm	$1.00U_s$ to $1.35U_s$	
Eurocode 3, Part 1.3	$2.1Y_s$	Limit state
	$4.3Y_s$	
	$2.5\ U_s$	Limit state

Note: Y_s = yield stress of fastened sheet, U_s = ultimate stress of fastened sheet.

[a] Values in BS 5950, Part 5, are reduced by 25% unless two washers are used.

3. durability viz. resistance to aggressive environments
4. watertightness
5. appearance

Although structural engineers tend to be primarily concerned with the most economical way of meeting the load-bearing requirements, in many applications other factors may be equally important.

Bolts

The use of bolts to connect cold-formed steel components follows a practice similar to that of hot-rolled construction; however, because of the thinness of the material and the relatively small size of the components, the main design considerations tend to be end distance and bearing. With regard to bearing it is worth noting that hot-rolled steel design codes tend to have significantly different design treatments of this than cold-formed steel codes. This may be partially due to the different behavior of thin material, but is mainly due to the adoption of different philosophies by the writers of cold-formed steel and hot-rolled steel codes. In British codes in particular, the cold-formed steel rules are based on strength design, while the hot-rolled steel rules are based on limiting slip. Table 49.3, from Davies (Rhodes, 1991), shows the comparison between permissible bearing stresses in bolted connections according to various codes.

Self-Tapping Screws

Self-tapping screws fall into two distinct types, depending on whether or not they require a predrilled hole. Conventional self-tapping screws require a predrilled hole and fall into a number of subgroups, depending on the type of thread, head, and washer. Self-drilling self-tapping screws drill their own hole and form their own thread in a single operation. There are two basic types, depending on the thickness of the base material. Both of these screws are usually combined with washers that serve to increase the load-bearing capacity or sealing ability.

Blind Rivets

Blind rivets are normally used for fastening two thin sheets of material together when access is available from one side only. These are installed in a single operation, for example, by pulling a mandrel that forms a head on the blind side of the rivet and expands the rivet shank. Fastening is completed when the mandrel either pulls through or breaks off. This type of fastener generally requires strength considerably in excess of the sheet material to minimize possibilities of brittle failure.

Fired Pins

These pins, as the name suggests, are fired through thin material into thicker base material to form a connection. Two different methods of firing the pins are commonly used: powder actuation and pneumatic actuation. In the former the pins are fired from a tool that contains an explosive cartridge, and in the latter compressed air is used as the firing agent. Fired pins generally provide a very tight grip and a very good sealing capability.

Spot Welds

Electrical resistance spot welds are a widely used method of connecting thin sheets. In the United Kingdom these are governed by BS 1140, General Requirements for Spot Welding of Light Assemblies in Mild Steel, and recommendations regarding weld sizes and capacities are provided in BS 5950, Part 5, and the AISI specification. Further information on loads in resistance spot welds has been given by Baehre and Berggren (1973).

Arc Welds

Conventional fillet and butt welds are applicable to cold-formed steel sections if the material is relatively thick, and in such cases design considerations are the same as those for hot-rolled sections. In the case of thinner material a wide range of special weld types are used in, but not outside of, the U.S. . Guidance on making these special welds has been given by Blodgett (1978). Expressions for the evaluation of the ultimate loads for various types of these connections are available from a large testing and analysis program carried out by Peköz and McGuire (1979).

Clinch Joints and Rosette Joints

A relatively new method of connecting components together is *mechanical clinching*. This technique was originally developed for use in the automobile industry, but in recent years has found a number of applications in cold-formed steel construction and has been the subject of substantial research (e.g., Davies et al., 1996). In making clinched joints, hydraulic tools are used as a punch-and-die set that shears and deforms the material to be connected to produce a connection in which material from one sheet bears on material from another, and the connection is dependent only on the parent material.

Another type of connection that is uniquely suited to light-gauge material and requires no additional fixings is the Rosette joint. In this joint holes are punched into the two adjoining strips of material at the connection point, with one of the sheets having a reduced diameter to form a collar. In the joining process the collar is snapped into the hole in the adjoining strip, and the Rosette tool penetrates the hole and collar, expands, and is pulled back to crimp the collar to the opposite side of the hole, thus producing a secure connection. Details of Rosette joints may be found, for example, in Makelainen et al. (1999).

Assemblies of Fasteners

The available information on the the behavior of assemblies of fasteners in light-gauge steelwork suggests that the performance of such assemblies is not in any way inferior to that of similar connection assemblies in hot-rolled members. Connections in cold-formed members, however, do tend to be more flexible and ductile than in hot-rolled members, and herein lies a bonus that is well appreciated in some areas of cold-formed steel usage. The ductility afforded by such connections can provide the "plastic plateau" behavior that often occurs in hot-rolled sections, thus allowing redistribution of moments in the postyield range. A prime example of this in the United Kingdom is the wide use of "sleeves" in purlin design. These sleeves are used to connect purlins in a semirigid fashion, which produces a moment distribution close to the ideal at the point of failure.

49.6 Sheeting and Decking

There has been in the recent past a substantial increase in the usage of profiled sheeting and decking, and this has been accompanied by a corresponding development of the design principles applicable to

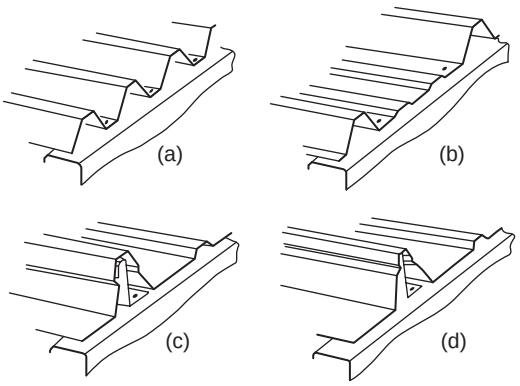

FIGURE 49.36 Typical roof sheeting profiles.

this type of construction. Although only a few years ago 3-in. corrugated profiles or simple trapezoidal profiles were the norm, today there is a multiplicity of different shapes available. Profiles can be obtained in a wide variety of colors, surface coatings, etc., with a life to first maintenance of up to 25 years. There have been a large number of developments of structural improvements, involving the use of thinner material, of increased yield strength in highly stiffened profiles. It is most probable, however, that in this area improvements in aesthetics, utility, and durability outweigh the structural improvements.

Profiles for Roof Sheeting

Cold roof construction is the term applied to construction in which profiled steel sheeting is used as the outer waterproof skin of a roof, with insulation placed inside this skin. It is important that the skin should provide the optimum resistance to moisture penetration, and the side laps should occur near the crests of the corrugations. With modern fasteners, e.g., self-drilling self-tapping screws with neoprene washers, it is quite permissible to fix the sheeting to the roof purlins through the troughs. These fasteners satisfactorily prevent moisture penetration, while providing various structural benefits in the fixity provided to the purlins over through-crest fixings.

Modern profiles can be grouped into four main types, as illustrated in Fig. 49.36. For the trapezoidal profile shown in Fig. 49.36a, it is found that to obtain the most economic use of material for a given span and loading, using standard analysis procedures, the thickness of material and web slope angle that result are impractical, the thickness usually being very small and the web slope very shallow. Fairly wide variations in the trapezoidal geometry result in relatively small variations in the economy, and the design of this type of sheeting is generally governed by practical considerations. In the profile of Fig. 49.36b, again a fairly widely used shape of profile, the trapezoidal shape is altered to incorporate intermediate stiffeners in the lower flanges. In order to reduce or eliminate the requirement to penetrate the skin with fasteners, concealed fixed or standing seam sheeting has been developed over a number of years (Fig. 49.36c and d). The fixing in these systems is generally by means of clips that connect mechanically to the sheeting and by screws to the purlin, with the mechanical connections to the sheeting often incorporated in the standing seam, eliminating penetration of the sheeting. In this type of system the purlin–sheeting connections are less useful in providing stability to the purlin than the more direct screw fixings, and may necessitate close consideration of purlin design in such circumstances.

Profiles for Roof Decking

Profiled steel decking, supporting a built-up finish, including insulation and waterproofing, is often termed *warm roof construction*. In this type of construction there is a tendency toward longer spans, more complex profiles, and the use of higher strength steels. A typical profile resulting from these tendencies is shown in Fig. 49.37. The profile depth is of the order of 4 in., and the material yield strength is of the

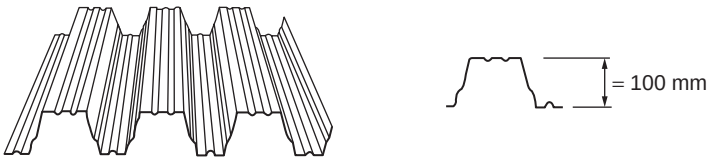

FIGURE 49.37 Typical long-span decking profiles.

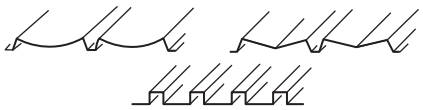

FIGURE 49.38 Typical wall cladding profiles.

order of 50 ksi. These profiles are suitable for spans up to 30 ft and can thus eliminate the need for purlins. In general, stiffeners are rolled into both the flanges and the webs, as flanges and webs are slender and require stiffeners for efficiency.

There are nowadays a large number of different design specifications dealing with roof decking. In Europe calculation procedures for complex shapes, as shown in Fig. 49.37, have been developed in Sweden for incorporation into the Swedish code of practice (Höglund, 1980), and these procedures form the basis of the European recommendations (ECCS, 1983), as well as the national standards of some European countries, for example, DIN 18807 (1987). These procedures have been verified by a very substantial number of tests (Baehre and Fick, 1982).

Wall Coverings

Wall cladding carries significant wind loading and must satisfy structural considerations. However, the aesthetic considerations here are so strong, since the appearance of a building is very substantially dependent on the sheeting, that aesthetics are often the primary consideration. Typical wall cladding profiles are shown in Fig. 49.38. By virtue of the variety of profiles available, the wide range of coatings and colors, and the possibility of orienting the cladding in any desired direction, there is substantial scope for imagination and artistry in the use of modern wall coverings in building design.

Composite Panels

Composite panels, having outer faces of thin steel (or other material such as aluminum) and an internal core of foamed plastic (such as polyurethane or expanded polystyrene), are now widely used in construction (Fig. 49.39). The design criteria for composite panels are complex and are not discussed here.

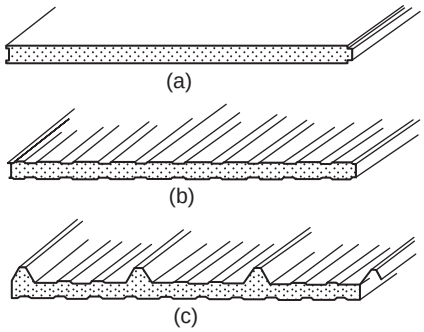

FIGURE 49.39 Typical sandwich panels: (a) panel with flat faces, (b) panel with profiled faces, (c) panel with profiled face.

However, this type of construction must be mentioned because of its current growth and future potentialities. Foam-filled composite construction utilizes the favorable attributes of skin and core materials in combination. The core connects the metal skins, while ensuring that they are kept a distance apart to provide flexural capacity for the panel, and also provides a degree of resistance to local buckling of the skins. The skins protect the core from accidental damage and from the elements. Foam-filled panels combine a high load-carrying capacity with low weight, attractive appearance, and other made-to-order attributes, such as an extremely high thermal insulation capacity, to provide very good solutions to a variety of construction problems.

49.7 Storage Racking

The term *storage racking* covers an extremely wide range of products that have as their purpose the storage of material in a secure and easily accessible manner. Storage racking systems range from small shelving systems to extremely large rack-clad buildings. The components used in storage racking are largely of cold-formed steel, and the storage racking industry is one of the major users of cold-formed steel.

The forerunners of the modern storage structures were slotted-angle products first introduced in the 1930s. These consisted of cold-formed angle sections with perforations to provide a means whereby the designer could utilize the simplicity and flexibility of connections thus permitted to produce storage systems in a variety of shapes and configurations. By this means simple shelving could be provided for warehouses of any size. From these beginnings natural evolution lead to the present-day situation. It was found that for many systems bolted connections could be beneficially replaced by clips or other proprietory connections, and a wide variety of alternative connection methods were developed for different systems. Although perforated angles had much in their favor for some purposes, particularly for smaller storage systems, the requirements for bracing in these torsionally weak members meant that for many purposes other shapes of cross-sections were superior. Nowadays slotted angles are still widely used for shelving systems, but in larger storage racking systems other perforated members, generally monosymmetric, are used as columns, while normally unperforated members are used as beams.

Components

Beams

In pallet racking the most common types of beams used are boxed beams, made from two interlocking lipped channels (Fig. 49.40a), and open-section beams (Fig. 49.40b), which may be stepped to receive the edge of a shelf (Fig. 49.40c). The boxed beam is generally more structurally efficient than the open beam, but for lighter loads the economical aspects can favor the open section. Over the normal range of spans used in storage racking the limiting factor for the beams used is most often the bending capacity. The most common configuration of beam loading is that shown in Fig. 49.41 with two pallets in place.

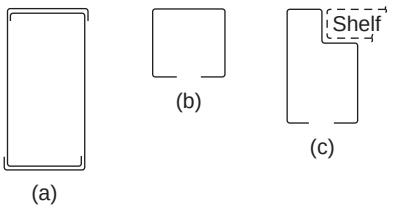

FIGURE 49.40 Typical beam profiles: (a) box, (b), open, (c) stepped open.

Uprights

Figure 49.42 shows typical perforated upright profiles used in storage racking at the present time. These are, in the main, developments from the simple lipped channel section. The developments generally involve the addition of more bends, which can be used to assist the attachment of bracing members, as well as to enhance the structural capacity of the uprights. The bracing members, often of channel section,

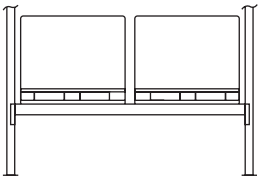

FIGURE 49.41 Two-pallet beam loading.

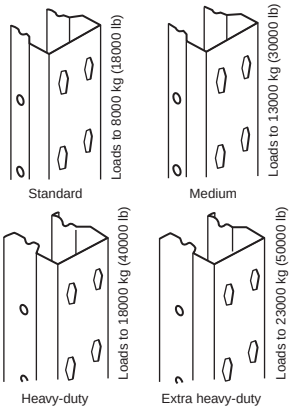

FIGURE 49.42 Typical upright profiles.

connect through the rear circular holes of the section, while the beams are connected, via beam end connectors, through the perforations on the front face. The loads carried by the uprights are spread into the floor through base plates. These are normally thin plates, of about 3 mm thick, which are bolted to the upright and to the floor.

Beam End Connectors

The beams used in storage racking are generally connected to the uprights via beam end connectors. These are generally made from hot-rolled material and are welded to the ends of the beam to provide a means of connecting the beam to the upright at any of a large number of positions through the perforations in the uprights. The connectors have hooks that fit through the upright perforations to provide a semirigid connection between the beam and upright. In evaluation of the behavior of beams and uprights the connection behavior is very important. The moment rotation behavior of beam end connectors is normally obtained on the basis of testing, and the strength and stiffness values so obtained are used in design analysis of the structure.

Design Codes of Practice

In Europe storage racking systems are generally considered to lie outside the scope of the normal codes of practice for structural design. This is largely because of the presence of perforations in uprights and other components. In the United Kingdom the Storage Equipment Manufacturers Association (SEMA) devised and published its own code of practice (SEMA, 1980). In Europe the Federation Europeene de la Manutention (FEM) has in recent years prepared a new code of practice (FEM, 1986) that is at completion stage and will have currency throughout Europe, eventually superseding the SEMA code in the United Kingdom and similar codes in other countries. This code is written in limit state to be compatible with Eurocode 3.

Defining Terms

Beam — A straight or curved structural member, primarily supporting loads applied at right angles to the longitudinal axis.

Beam-column — A beam that also functions to transmit compressive axial force.

Bifurcation — A term relating to the load-deflection behavior of a perfectly straight and perfectly centered compression element at critical load.

Blind rivet — Mechanical fastener capable of joining workpieces together where access to the assembly is limited to one side only.

Buckle — To kink, wrinkle, bulge, or otherwise lose original shape as a result of elastic or inelastic strain.

Buckling load — The load at which a compressed element, member, or frame collapses in service or buckles in a loading test.

Cladding — Profiled sheet for walls.

Cold-formed steel structural members — Shapes that are manufactured by press-braking blanks sheared from sheets, cut length of coils or plates, or by roll forming cold- or hot-rolled coils or sheets.

Composite slab — Floor in which the structural bearing capacity is formed by the cooperation of concrete and floor decking (as reinforcement).

Critical load — The load at which bifurcation occurs, as determined by a theoretical stability analysis.

Effective length — The equivalent or effective length that, in the buckling formula for a hinged-end column, results in the same elastic critical load as that for the framed member or other compression element under consideration at its theoretical critical load.

Effective width — Reduced width of a compression element in a flexure or compression members computed to account for local buckling when the flat width-to-thickness ratio exceeds a certain limit.

Flat width — Width of the straight portion of the element, excluding the bent portion of the section.

Flat width-to-thickness ratio — Ratio of the flat width of an element to its thickness.

Flexural buckling — Buckling of a column due to flexure.

Initial imperfection — Deviation from perfect geometry, for example, initial crookedness of a member or initial out-of-flatness of a plate.

Limit state — Condition beyond which a structure would cease to be fit for its intended use.

Local buckling — Buckling of the walls of elements of a section characterized by a formation of waves or ripples along the member. It modifies the capacity of cross-sections.

Multiple stiffened element — An element stiffened between webs, or between a web and a stiffened edge, by means of intermediate stiffeners parallel to the direction of stress.

Residual stress — The stresses that exist in an unloaded member after it has been formed into a finished product.

Safety factor — A ratio of the stress (or strength) at incipient failure to the computed stress (or strength) at design load.

Self-drilling screw — Screw that drills its own hole and forms its mating thread in one operation.

Self-tapping screw — Screw that taps a counterthread in a prepared hole.

Sheeting — Profiled sheet for floors, roofs, or walls.

Stiffened or partially stiffened element — A flat compression element in which both edges parallel to the direction of stress are stiffened either by a web, flange, stiffening lip, or intermediate stiffener.

Tension field action — Postbuckling behavior of a plate girder panel under shear force, during which diagonal compressive stresses cause the web to form diagonal waves.

Thickness — Thickness of base steel in cold-formed sections.

Torsional buckling — Buckling of a column by twisting.

Torsional flexural buckling — A mode of buckling in which compression members can bend and twist simultaneously. This type of buckling mode is critical, in particular when the shear center of the section does not coincide with the centroid.

Unstiffened element — A flat compression element that is stiffened at one of the two edges parallel to the direction of stress.

Web crippling — Failure mode of the web of a beam caused by the combination of a bending moment and a concentrated load.

Yield point — The maximum stress recorded in a tensile or compressive test of steel specimen prior to entering the plastic range.

Yield strength — In a tension or compression test, the stress at which there is a specified amount of measured deviation from an extension of the initial linear stress–strain plot.

Further Information

The *Guide to Stability Design Criteria for Metal Structures*, by Theodore V. Galambos, is the most comprehensive treatment of stability design of metal structures. It covers a wide range of topics, including the postbuckling strength of unstiffened and stiffened plates, plate girders, and thin-walled metal girders.

Cold-Formed Steel in Tall Buildings, edited by W.W. Yu et al., deals with the state-of-the-art design guide devoted to the most efficient and economical use of cold-formed steel in high-rise buildings.

Background to Buckling, by H.G. Allen and P.S. Bulson, provides a coherent account of the buckling problem, including an analytical treatment for studying the stability of plates and shells. Provides a valuable aid to forging the vital links between research, analysis, and design.

Plated Structures: Stability and Strength, by R. Narayanan, deals with various aspects related to stability problems of plated structures.

The Stressed Skin Design of Steel Buildings, by E.R. Bryan, and *Manual of Stressed Skin Diaphragm Design*, by E.R. Bryan and J.M. Davies, provide design methods and recommendations for roof decking and wall cladding profiles.

The Proceedings of the International Conference on Cold-Formed Steel Structures, edited by W.W. Yu et al. and available in a number of volumes, extensively covers all aspects of cold-formed steel structures.

At this point in the history of development of reinforced and prestressed concrete it is necessary to reexamine the fundamental approaches to design of these composite materials. Structural engineering is a worldwide industry. Designers from one nation or a continent are faced with designing a project in

another nation or continent. The decades of efforts dedicated to harmonizing concrete design approaches worldwide have resulted in some successes but in large part have led to further differences and numerous different design procedures. It is this abundance of different design approaches, techniques, and code regulations that justifies and calls for the need for a unification of design approaches throughout the entire range of structural concrete, from plain to fully prestressed [Breen, 1991].

The effort must begin at all levels: university courses, textbooks, handbooks, and standards of practice. Students and practitioners must be encouraged to think of a single continuum of structural concrete. Based on this premise, this chapter on concrete design is organized to promote such unification. In addition, effort will be directed at dispelling the present unjustified preoccupation with complex analysis procedures and often highly empirical and incomplete sectional mechanics approaches that tend to both distract the designers from fundamental behavior and impart a false sense of accuracy to beginning designers. Instead, designers will be directed to give careful consideration to overall structure behavior, remarking the adequate flow of forces throughout the entire structure.

50.1 Properties of Concrete and Reinforcing Steel

The designer needs to be knowledgeable about the properties of concrete, reinforcing steel, and prestressing steel. This part of the chapter summarizes the material properties of particular importance to the designer.

Properties of Concrete

Workability is the ease with which the ingredients can be mixed and the resulting mix handled, transported, and placed with little loss in homogeneity. Unfortunately, workability cannot be measured directly. Engineers therefore try to measure the consistency of the concrete by performing a slump test.

The slump test is useful in detecting variations in the uniformity of a mix. In the slump test, a mold shaped as the frustum of a cone, 12 in. (305 mm) high with an 8 in. (203 mm) diameter base and 4 in. (102 mm) diameter top, is filled with concrete (ASTM Specification C143). Immediately after filling, the mold is removed and the change in height of the specimen is measured. The change in height of the specimen is taken as the slump when the test is done according to the ASTM Specification.

A well-proportioned workable mix settles slowly, retaining its original shape. A poor mix crumbles, segregates, and falls apart. The slump may be increased by adding water, increasing the percentage of fines (cement or aggregate), entraining air, or by using an admixture that reduces water requirements; however, these changes may adversely affect other properties of the concrete. In general, the slump specified should yield the desired consistency with the least amount of water and cement.

Concrete should withstand the weathering, chemical action, and wear to which it will be subjected in service over a period of years; thus, durability is an important property of concrete. Concrete resistance to freezing and thawing damage can be improved by increasing the watertightness, entraining 2 to 6% air, using an air-entraining agent, or applying a protective coating to the surface. Chemical agents damage or disintegrate concrete; therefore, concrete should be protected with a resistant coating. Resistance to wear can be obtained by use of a high-strength, dense concrete made with hard aggregates.

Excess water leaves voids and cavities after evaporation, and water can penetrate or pass through the concrete if the voids are interconnected. Watertightness can be improved by entraining air or reducing water in the mix, or it can be prolonged through curing.

Volume change of concrete should be considered, since expansion of the concrete may cause buckling and drying shrinkage may cause cracking. Expansion due to alkali-aggregate reaction can be avoided by using nonreactive aggregates. If reactive aggregates must be used, expansion may be reduced by adding pozzolanic material (e.g., fly ash) to the mix. Expansion caused by heat of hydration of the cement can be reduced by keeping cement content as low as possible; using Type IV cement; and chilling the aggregates, water, and concrete in the forms. Expansion from temperature increases can be reduced by

using coarse aggregate with a lower coefficient of thermal expansion. Drying shrinkage can be reduced by using less water in the mix, using less cement, or allowing adequate moist curing. The addition of pozzolans, unless allowing a reduction in water, will increase drying shrinkage. Whether volume change causes damage usually depends on the restraint present; consideration should be given to eliminating restraints or resisting the stresses they may cause [MacGregor, 1992].

Strength of concrete is usually considered its most important property. The compressive strength at 28 days is often used as a measure of strength because the strength of concrete usually increases with time. The compressive strength of concrete is determined by testing specimens in the form of standard cylinders as specified in ASTM Specification C192 for research testing or C31 for field testing. The test procedure is given in ASTM C39. If drilled cores are used, ASTM C42 should be followed.

The suitability of a mix is often desired before the results of the 28-day test are available. A formula proposed by W. A. Slater estimates the 28-day compressive strength of concrete from its 7-day strength:

$$S_{28} = S_7 + 30\sqrt{S_7} \tag{50.1}$$

where S_{28} = 28-day compressive strength, psi, and
S_7 = 7-day compressive strength, psi.

Strength can be increased by decreasing water-cement ratio, using higher strength aggregate, using a pozzolan such as fly ash, grading the aggregates to produce a smaller percentage of voids in the concrete, moist curing the concrete after it has set, and vibrating the concrete in the forms. The short-time strength can be increased by using Type III portland cement, accelerating admixtures, and by increasing the curing temperature.

The stress-strain curve for concrete is a curved line. Maximum stress is reached at a strain of 0.002 in./in., after which the curve descends.

The modulus of elasticity, E_c, as given in ACI 318-89 (Revised 92), *Building Code Requirements for Reinforced Concrete* [ACI Committee 318, 1992], is:

$$E_c = w_c^{1.5} 33\sqrt{f_c'} \quad \text{lb/ft}^3 \text{ and psi} \tag{50.2a}$$

$$E_c = w_c^{1.5} 0.043\sqrt{f_c'} \quad \text{kg/m}^3 \text{ and MPa} \tag{50.2b}$$

where w_c = unit weight of concrete, and
f_c' = compressive strength at 28 days.

Tensile strength of concrete is much lower than the compressive strength — about $7\sqrt{f_c'}$ for the higher-strength concretes and $10\sqrt{f_c'}$ for the lower-strength concretes.

Creep is the increase in strain with time under a constant load. Creep increases with increasing water-cement ratio and decreases with an increase in relative humidity. Creep is accounted for in design by using a reduced modulus of elasticity of the concrete.

Lightweight Concrete

Structural lightweight concrete is usually made from aggregates conforming to ASTM C330 that are usually produced in a kiln, such as expanded clays and shales. Structural lightweight concrete has a density between 90 and 120 lb/ft^3 (1440–1920 kg/m^3).

Production of lightweight concrete is more difficult than normal-weight concrete because the aggregates vary in absorption of water, specific gravity, moisture content, and amount of grading of undersize. Slump and unit weight tests should be performed often to ensure uniformity of the mix. During placing and finishing of the concrete, the aggregates may float to the surface. Workability can be improved by increasing the percentage of fines or by using an air-entraining admixture to incorporate 4 to 6% air.

Dry aggregate should not be put into the mix, because it will continue to absorb moisture and cause the concrete to harden before placement is completed. Continuous water curing is important with lightweight concrete.

No-fines concrete is obtained by using pea gravel as the coarse aggregate and 20 to 30% entrained air instead of sand. It is used for low dead weight and insulation when strength is not important. This concrete weighs from 105 to 118 lb/ft^3 (1680–1890 kg/m^3) and has a compressive strength from 200 to 1000 psi (1–7 MPa).

A porous concrete made by gap grading or single-size aggregate grading is used for low conductivity or where drainage is needed.

Lightweight concrete can also be made with gas-forming or foaming agents which are used as admixtures. Foam concretes range in weight from 20 to 110 lb/ft^3 (320–1760 kg/m^3). The modulus of elasticity of lightweight concrete can be computed using the same formula as normal concrete. The shrinkage of lightweight concrete is similar to or slightly greater than for normal concrete.

Heavyweight Concrete

Heavyweight concretes are used primarily for shielding purposes against gamma and x-radiation in nuclear reactors and other structures. Barite, limonite and magnetite, steel punchings, and steel shot are typically used as aggregates. Heavyweight concretes weigh from 200 to 350 lb/ft^3 (3200 to 5600 kg/m^3) with strengths from 3200 to 6000 psi (22–41 MPa). Gradings and mix proportions are similar to those for normal weight concrete. Heavyweight concretes usually do not have good resistance to weathering or abrasion.

High-Strength Concrete

Concretes with strengths in excess of 6000 psi (41 MPa) are referred to as high-strength concretes. Strengths up to 18,000 psi (124 MPa) have been used in buildings.

Admixtures such as superplasticizers, silica fume, and supplementary cementing materials such as fly improve the dispersion of cement in the mix and produce workable concretes with lower water-cement ratios, lower void ratios, and higher strength. Coarse aggregates should be strong, fine-grained gravel with rough surfaces.

For concrete strengths in excess of 6000 psi (41 MPa), the modulus of elasticity should be taken as

$$E_c = 40{,}000\sqrt{f_c'} + 1.0 \times 10^6 \tag{50.3}$$

where f_c' = compressive strength at 28 days, psi [ACI Committee 36]. The shrinkage of high-strength concrete is about the same as that for normal concrete.

Reinforcing Steel

Concrete can be reinforced with welded wire fabric, deformed reinforcing bars, and prestressing tendons.

Welded wire fabric is used in thin slabs, thin shells, and other locations where space does not allow the placement of deformed bars. Welded wire fabric consists of cold drawn wire in orthogonal patterns — square or rectangular and resistance-welded at all intersections. The wires may be smooth (ASTM A185 and A82) or deformed ASTM A497 and A496). The wire is specified by the symbol W for smooth wires or D for deformed wires followed by a number representing the cross-sectional area in hundredths of a square inch. On design drawings it is indicated by the symbol WWF followed by spacings of the wires in the two 90° directions. Properties for welded wire fabric are given in Table 50.1.

The deformations on a deformed reinforcing bar inhibit longitudinal movement of the bar relative to the concrete around it. Table 50.2 gives dimensions and weights of these bars. Reinforcing bar steel can

TABLE 50.1 Wire and Welded Wire Fabric Steels

AST Description	Wire Size Designation	Minimum Yield Stress,[a] f_y ksi	Minimum Yield Stress,[a] f_y MPa	Minimum Tensile Strength ksi	Minimum Tensile Strength MPa
A82-79 (cold-drawn wire) (properties apply when material is to be used for fabric)	W1.2 and larger[b]	65	450	75	520
	Smaller than W1.2	56	385	70	480
A185-79 (welded wire fabric)	Same as A82; this is A82 material fabricated into sheet (so-called "mesh") by the process of electric welding.				
A496-78 (deformed steel wire) (properties apply when material is to be used for fabric)	D1–D131[c]	70	480	80	550
A497-79	Same as A82 or A496; this specification applies for fabric made from A496, or from a combination of A496 and A82 wires.				

[a] The term "yield stress" refers to either *yield point,* the well-defined deviation from perfect elasticity, or *yield strength,* the value obtained by a specified offset strain for material having no well-defined yield point.
[b] The W number represents the nominal cross-sectional area in square inches multiplied by 100, for smooth wires.
[c] The D number represents the nominal cross-sectional area in square inches multiplied by 100, for deformed wires.

18	2.257	57.3	4.00	25.81	13.60	20.24

be made of billet steel of grades 40 and 60 having minimum specific yield stresses of 40,000 and 60,000 psi, respectively (276 and 414 MPa) (ASTM A615) or low-alloy steel of grade 60, which is intended for applications where welding and/or bending is important (ASTM A706). Presently, grade 60 billet is the most predominately used for construction.

Prestressing tendons are commonly in the form of individual wires or groups of wires. Wires of different strengths and properties are available with the most prevalent being the 7-wire low-relaxation strand conforming to ASTM A416. ASTM A416 also covers a stress-relieved strand, which is seldom used in construction nowadays. Properties of standard prestressing strands are given in Table 50.3. Prestressing tendons could also be bars; however, this is not very common. Prestressing bars meeting ASTM A722 have been used in connections between members.

The modulus of elasticity for non-prestressed steel is 29,000,000 psi (200,000 MPa). For prestressing steel, it is lower and also variable, so it should be obtained from the manufacturer. For 7-wire strands conforming to ASTM A416, the modulus of elasticity is usually taken as 27,000,000 psi (186,000 MPa).

TABLE 50.3 Standard Prestressing Strands, Wires, and Bars

Tendon Type	Grade f_{pu} ksi	Nominal Dimension Diameter in.	Area in.^{2}	Weight plf

50.2 Proportioning and Mixing Concrete

Proportioning Concrete Mix

A concrete mix is specified by the weight of water, sand, coarse aggregate, and admixture to be used per 94-pound bag of cement. The type of cement (Table 50.4), modulus of the aggregates, and maximum size of the aggregates (Table 50.5) should also be given. A mix can be specified by the weight ratio of cement to sand to coarse aggregate with the minimum amount of cement per cubic yard of concrete.

In proportioning a concrete mix, it is advisable to make and test trial batches because of the many variables involved. Several trial batches should be made with a constant water-cement ratio but varying

TABLE 50.4 Types of Portland Cement*

Type	Usage
I	Ordinary construction where special properties are not required
II	Ordinary construction when moderate sulfate resistance or moderate heat of hydration is desired
III	When high early strength is desired
IV	When low heat of hydration is desired
V	When high sulfate resistance is desired

*According to ASTM C150.

TABLE 50.5 Recommended Maximum Sizes of Aggregate*

Minimum Dimension of Section, in.	Maximum Size, in., of Aggregate for Reinforced-Concrete Beams, Columns, Walls	Heavily Reinforced Slabs	Lightly Reinforced or Unreinforced Slabs

	C	5.4	205	215	380

**Concrete Manual,* U.S. Bureau of Reclamation.

ratios of aggregates to obtain the desired workability with the least cement. To obtain results similar to those in the field, the trial batches should be mixed by machine.

When time or other conditions do not allow proportioning by the trial batch method, Table 50.6 may be used. Start with mix B corresponding to the appropriate maximum size of aggregate. Add just enough water for the desired workability. If the mix is undersanded, change to mix A; if oversanded, change to mix C. Weights are given for dry sand. For damp sand, increase the weight of sand 10 lb, and for very wet sand, 20 lb per bag of cement.

Admixtures

Admixtures may be used to modify the properties of concrete. Some types of admixtures are set accelerators, water reducers, air-entraining agents, and waterproofers. Admixtures are generally helpful in improving quality of the concrete. However, if admixtures are not properly used, they could have undesirable effects; it is therefore necessary to know the advantages and limitations of the proposed admixture. The ASTM Specifications cover many of the admixtures.

Set accelerators are used (1) when it takes too long for concrete to set naturally, such as in cold weather, or (2) to accelerate the rate of strength development. Calcium chloride is widely used as a set accelerator. If not used in the right quantities, it could have harmful effects on the concrete and reinforcement.

Water reducers lubricate the mix and permit easier placement of the concrete. Since the workability of a mix can be improved by a chemical agent, less water is needed. With less water but the same cement content, the strength is increased. Since less water is needed, the cement content could also be decreased, which results in less shrinkage of the hardened concrete. Some water reducers also slow down the concrete set, which is useful in hot weather and in integrating consecutive pours of the concrete.

Air-entraining agents are probably the most widely used type of admixture. Minute bubbles of air are entrained in the concrete, which increases the resistance of the concrete to freeze-thaw cycles and the use of ice-removal salts.

Waterproofing chemicals are often applied as surface treatments, but they can be added to the concrete mix. If applied properly and uniformly, they can prevent water from penetrating the concrete surface. Epoxies can also be used for waterproofing. They are more durable than silicone coatings, but they may

be more costly. Epoxies can also be used for protection of wearing surfaces, patching cavities and cracks, and glue for connecting pieces of hardened concrete.

Mixing

Materials used in making concrete are stored in batch plants that have weighing and control equipment and bins for storing the cement and aggregates. Proportions are controlled by automatic or manually operated scales. The water is measured out either from measuring tanks or by using water meters.

Machine mixing is used whenever possible to achieve uniform consistency. The revolving drum-type mixer and the countercurrent mixer, which has mixing blades rotating in the opposite direction of the drum, are commonly used.

Mixing time, which is measured from the time all ingredients are in the drum, "should be at least 1.5 minutes for a 1-yd^3 mixer, plus 0.5 min for each cubic yard of capacity over 1 yd^3" [ACI 304-73, 1973]. It also is recommended to set a maximum on mixing time since overmixing may remove entrained air and increase fines, thus requiring more water for workability; three times the minimum mixing time can be used as a guide.

Ready-mixed concrete is made in plants and delivered to job sites in mixers mounted on trucks. The concrete can be mixed en route or upon arrival at the site. Concrete can be kept plastic and workable for as long as 1.5 hours by slow revolving of the mixer. Mixing time can be better controlled if water is added and mixing started upon arrival at the job site, where the operation can be inspected.

50.3 Flexural Design of Beams and One-Way Slabs

Reinforced Concrete Strength Beams

The basic assumptions made in flexural design are:

1. Sections perpendicular to the axis of bending that are plane before bending remain plane after bending.
2. A perfect bond exists between the reinforcement and the concrete such that the strain in the reinforcement is equal to the strain in the concrete at the same level.
3. The strains in both the concrete and the reinforcement are assumed to be directly proportional to the distance from the neutral axis (ACI 10.2.2) [ACI Committee 318, 1992].
4. Concrete is assumed to fail when the compressive strain reaches 0.003 (ACI 10.2.3).
5. The tensile strength of concrete is neglected (ACI 10.2.5).
6. The stresses in the concrete and reinforcement can be computed from the strains using stress-strain curves for concrete and steel, respectively.
7. The compressive stress-strain relationship for concrete may be assumed to be rectangular, trapezoidal, parabolic, or any other shape that results in prediction of strength in substantial agreement with the results of comprehensive tests (ACI 10.2.6). ACI 10.2.7 outlines the use of a rectangular compressive stress distribution which is known as the Whitney rectangular stress block. For other stress distributions *see Reinforced Concrete Mechanics and Design* by James G. MacGregor [1992].

Analysis of Rectangular Beams with Tension Reinforcement Only

Equations for M_n and ϕM_n: Tension Steel Yielding.

Consider the beam shown in Fig. 50.1. The compressive force, C, in the concrete is

$$C = \left(0.85 f_c'\right) ba \tag{50.3}$$

The tension force, T, in the steel is

$$T = A_s f_y \tag{50.4}$$

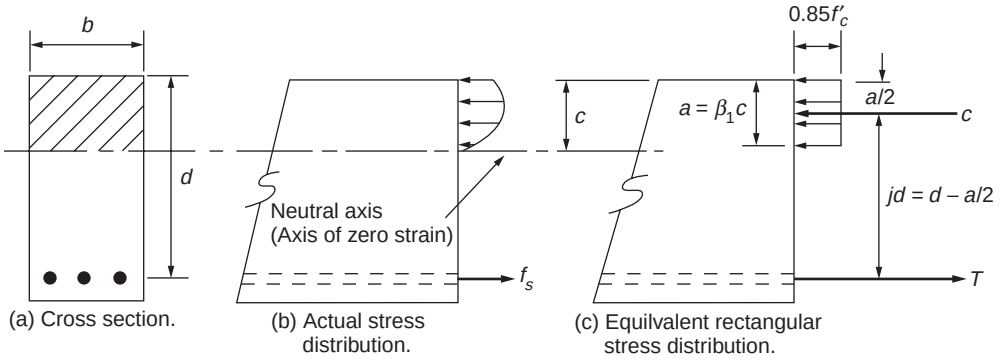

FIGURE 50.1 Stresses and forces in a rectangular beam. (*Source:* MacGregor, 1992.)

For equilibrium, $C = T$, so the depth of the equivalent rectangular stress block, a, is

$$a = \frac{A_s f_y}{0.85 f'_c b} \tag{50.5}$$

Noting that the internal forces C and T form an equivalent force-couple system, the internal moment is

$$M_n = T\left(d - a/2\right) \tag{50.6}$$

or

$$M_n = C\left(d - a/2\right)$$

ϕM_n is then

$$\phi M_n = \phi T\left(d - a/2\right) \tag{50.7}$$

or

$$\phi M_n = \phi C\left(d - a/2\right)$$

where $\phi = 0.90$.

Equation for M_n and ϕM_n: Tension Steel Elastic.
The internal forces and equilibrium are given by:

$$C = T$$
$$0.85 f'_c ba = A_s f_s \tag{50.8}$$
$$0.85 f'_c ba = \rho bd E_s \varepsilon_s$$

From strain compatibility (see Fig. 50.1),

$$\varepsilon_s = \varepsilon_{cu}\left(\frac{d - c}{c}\right) \tag{50.9}$$

Substituting ε_s into the equilibrium equation, noting that $a = \beta_1 c$, and simplifying gives

$$\left(\frac{0.85f_c'}{\rho E_s \varepsilon_{cu}}\right)a^2 + (d)a - \beta_1 d^2 = 0 \tag{50.10}$$

which can be solved for a. Equations (50.6) and (50.7) can then be used to obtain M_n and ϕM_n.

Reinforcement Ratios.

The reinforcement ratio, ρ, is used to represent the relative amount of tension reinforcement in a beam and is given by

$$\rho = \frac{A_s}{bd} \tag{50.11}$$

At the balanced strain condition the maximum strain, ε_{cu}, at the extreme concrete compression fiber reaches 0.003 just as the tension steel reaches the strain $\varepsilon_y = f_y/E_s$. The reinforcement ratio in the balanced strain condition, ρ_b, can be obtained by applying equilibrium and compatibility conditions. From the linear strain condition, Fig. 50.1,

$$\frac{c_b}{d} = \frac{\varepsilon_{cu}}{\varepsilon_{cu} + \varepsilon_y} = \frac{0.003}{0.003 + \dfrac{f_y}{29{,}000{,}000}} = \frac{87{,}000}{87{,}000 + f_y} \tag{50.12}$$

The compressive and tensile forces are:

$$\begin{aligned} C_b &= 0.85f_c'b\beta_1 c_b \\ T_b &= f_y A_{sb} = \rho_b bd f_y \end{aligned} \tag{50.13}$$

Equating C_b to T_b and solving for ρ_b gives

$$\rho_b = \frac{0.85f_c'\beta_1}{f_y}\left(\frac{c_b}{d}\right) \tag{50.14}$$

which on substitution of Eq. (50.12) gives

$$\rho_b = \frac{0.85f_c'\beta_1}{f_y}\left(\frac{87{,}000}{87{,}000 + f_y}\right) \tag{50.15}$$

ACI 10.3.3 limits the amount of reinforcement in order to prevent nonductile behavior:

$$\max \rho = 0.75\rho_b \tag{50.16}$$

ACI 10.5 requires a minimum amount of flexural reinforcement:

$$\rho_{\min} = \frac{200}{f_y} \tag{50.17}$$

Analysis of Beams with Tension and Compression Reinforcement

For the analysis of doubly reinforced beams, the cross section will be divided into two beams. Beam 1 consists of the compression reinforcement at the top and sufficient steel at the bottom so that $T_1 = C_s$; beam 2 consists of the concrete web and the remaining tensile reinforcement, as shown in Fig. 50.2.

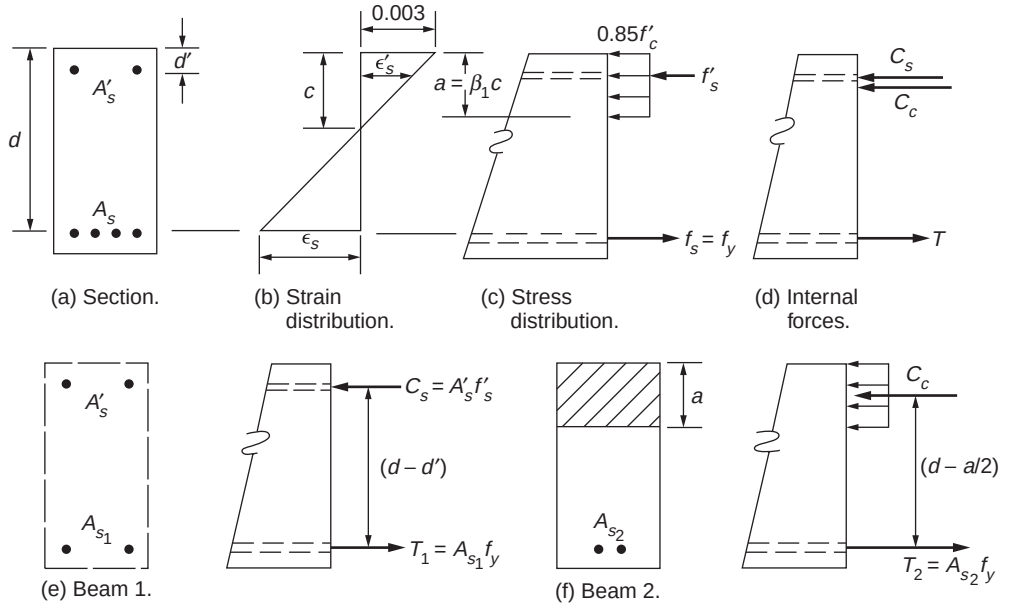

FIGURE 50.2 Strains, stresses, and forces in beam with compression reinforcement. (*Source:* MacGregor, 1992.)

Equation for M_n: Compression Steel Yields.

The area of tension steel in beam 1 is obtained by setting $T_1 = C_s$, which gives $A_{s1} = A'_s$. The nominal moment capacity of beam 1 is then

$$M_{n1} = A'_s f_y (d - d') \tag{50.18}$$

Beam 2 consists of the concrete and the remaining steel, $A_{s2} = A_s - A_{s1} = A_s - A'_s$. The compression force in the concrete is

$$C = 0.85 f'_c ba \tag{50.19}$$

and the tension force in the steel for beam 2 is

$$T = (A_s - A'_s) f_y \tag{50.20}$$

The depth of the compression stress block is then

$$a = \frac{(A_s - A'_s) f_y}{0.85 f'_c b} \tag{50.21}$$

Therefore, the nominal moment capacity for beam 2 is

$$M_{n2} = (A_s - A'_s) f_y (d - a/2) \tag{50.22}$$

The total amount capacity for a doubly reinforced beam with compression steel yielding is the summation of the moment capacity for beam 1 and beam 2; therefore,

$$M_n - A'_s f_y (d - d') + (A_s - A'_s) f_y (d - a/2) \tag{50.23}$$

Equation for M_n: Compression Steel Does Not Yield.
Assuming that the tension steel yields, the internal forces in the beam are

$$\begin{aligned} T &= A_s f_y \\ C_c &= 0.85 f_c' ba \\ C_s &= A_s' \left(E_s \varepsilon_s' \right) \end{aligned} \tag{50.24}$$

where

$$\varepsilon_s' = \left(1 - \frac{\beta_1 d'}{a} \right) (0.003) \tag{50.25}$$

From equilibrium, $C_s + C_c = T$ or

$$0.85 f_c' ba + A_s' E_s \left(1 - \frac{\beta_1 d'}{a} \right) (0.003) = A_s f_y \tag{50.26}$$

This can be rewritten in quadratic form as

$$\left(0.85 f_c' b \right) a^2 + \left(0.003 A_s' E_s - A_s f_y \right) a - \left(0.003 A_s' E_s \beta_1 d' \right) = 0 \tag{50.27}$$

where a can be calculated by means of the quadratic equation. Therefore, the nominal moment capacity in a doubly reinforced concrete beam where the compression steel does not yield is

$$M_n = C_c \left(d - \frac{a}{2} \right) + C_s \left(d - d' \right) \tag{50.28}$$

Reinforcement Ratios.
The reinforcement ratio at the balanced strain condition can be obtained in a similar manner as that for beams with tension steel only. For compression steel yielding, the balanced ratio is

$$\left(\rho - \rho' \right)_b = \frac{0.85 f_c' \beta_1}{f_y} \left(\frac{87{,}000}{87{,}000 + f_y} \right) \tag{50.29}$$

For compression steel not yielding, the balanced ratio is

$$\left(\rho - \frac{\rho' f_s'}{f_y} \right)_b = \frac{0.85 f_c' \beta_1}{f_y} \left(\frac{87{,}000}{87{,}000 + f_y} \right) \tag{50.30}$$

The maximum and minimum reinforcement ratios as given in ACI 10.3.3 and 10.5 are

$$\begin{aligned} \rho_{\max} &= 0.75 \rho_b \\ \rho_{\min} &= \frac{200}{f_y} \end{aligned} \tag{50.31}$$

Prestressed Concrete Strength Design

Elastic Flexural Analysis

In developing elastic equations for prestress, the effects of prestress force, dead load moment, and live load moment are calculated separately, and then the separate stresses are superimposed, giving

$$f = -\frac{F}{A} \pm \frac{Fey}{I} \pm \frac{My}{I} \tag{50.32}$$

where (–) indicates compression and (+) indicates tension. It is necessary to check that the stresses in the extreme fibers remain within the ACI-specified limits under any combination of loadings that may occur. The stress limits for the concrete and prestressing tendons are specified in ACI 18.4 and 18.5 [ACI Committee 318, 1992].

ACI 18.2.6 states that the loss of area due to open ducts shall be considered when computing section properties. It is noted in the commentary that section properties may be based on total area if the effect of the open duct area is considered negligible. In pretensioned members and in post-tensioned members after grouting, section properties can be based on gross sections, net sections, or effective sections using the transformed areas of bonded tendons and nonprestressed reinforcement.

Flexural Strength

The strength of a prestressed beam can be calculated using the methods developed for ordinary reinforced concrete beams, with modifications to account for the differing nature of the stress-strain relationship of prestressing steel compared with ordinary reinforcing steel.

A prestressed beam will fail when the steel reaches a stress f_{ps}, generally less than the tensile strength f_{pu}. For rectangular cross-sections the nominal flexural strength is

$$M_n = A_{ps} f_{ps} d - \frac{a}{2} \tag{50.33}$$

where

$$a = \frac{A_{ps} f_{ps}}{0.85 f_c' b} \tag{50.34}$$

The steel stress f_{ps} can b found based on strain compatibility or by using approximate equations such as those given in ACI 18.72. The equations in ACI are applicable only if the effective prestress in the steel, f_{se}, which equals P_e/A_{ps}, is not less than 0.5 f_{pu}. The ACI equations are as follows.

(a) For members with bonded tendons:

$$f_{ps} = f_{pu}\left(1 - \frac{\gamma_p}{\beta_1}\left[\rho \frac{f_{pu}}{f_c'} + \frac{d}{d_p}(\omega - \omega')\right]\right) \tag{50.35}$$

If any compression reinforcement is taken into account when calculating f_{ps} with Eq. (50.35), the following applies:

$$\left[\rho_p \frac{f_{pu}}{f_c'} + \frac{d}{d_p}(\omega - \omega')\right] \geq 0.17 \tag{50.36}$$

and

$$d' \le 0.15 d_p$$

(b) For members with unbonded tendons and with a span-to-depth ratio of 35 or less:

$$f_{ps} = f_{se} + 10{,}000 + \frac{f'_c}{100\rho_p} \le \left\{ \begin{matrix} f_{py} \\ f_{se} + 60{,}000 \end{matrix} \right\} \tag{50.37}$$

(c) For members with unbonded tendons and with a span-to-depth ratio greater than 35:

$$f_{ps} = f_{se} + 10{,}000 + \frac{f'_c}{300\rho_p} \le \left\{ \begin{matrix} f_{py} \\ f_{se} + 30{,}000 \end{matrix} \right\} \tag{50.38}$$

The flexural strength is then calculated from Eq. (50.33). The design strength is equal to ϕM_n, where $\phi = 0.90$ for flexure.

Reinforcement Ratios

ACI requires that the total amount of prestressed and nonprestressed reinforcement be adequate to develop a factored load at least 1.2 times the cracking load calculated on the basis of a modulus of rupture of 7.5 $\sqrt{f'_c}$.

To control cracking in members with unbonded tendons, some bonded reinforcement should be uniformly distributed over the tension zone near the extreme tension fiber. ACI specifies the minimum amount of bonded reinforcement as

$$A_s = 0.004A \tag{50.39}$$

where A is the area of the cross section between the flexural tension face and the center of gravity of the gross cross section. ACI 19.9.4 gives the minimum length of the bonded reinforcement.

To ensure adequate ductility, ACI 18.8.1 provides the following requirement:

$$\left\{ \begin{matrix} \omega_p \\ \omega_p + \left(\dfrac{d}{d_p}\right)(\omega - \omega') \\ \omega_{pw} + \left(\dfrac{d}{d_p}\right)(\omega_w - \omega'_w) \end{matrix} \right\} \le 0.36\beta_1 \tag{50.40}$$

ACI allows each of the terms on the left side to be set equal to 0.85 a/d_p in order to simplify the equation.

When a reinforcement ratio greater than $0.36\beta_1$ is used, ACI 18.8.2 states that the design moment strength shall not be greater than the moment strength based on the compression portion of the moment couple.

50.4 Columns under Bending and Axial Load

Short Columns under Minimum Eccentricity

When a symmetrical column is subjected to a concentric axial load, P, longitudinal strains develop uniformly across the section. Because the steel and concrete are bonded together, the strains in the

concrete and steel are equal. For any given strain it is possible to compute the stresses in the concrete and steel using the stress-strain curve for the two materials. The forces in the concrete and steel are equal to the stresses multiplied by the corresponding areas. The total load on the column is the sum of the forces in the concrete and steel:

$$P_o = 0.85 f_c' \left(A_g - A_{st} \right) + f_y A_{st} \tag{50.41}$$

To account for the effect of incidental moments, ACI 10.3.5 specifies that the maximum design axial load on a column be, for spiral columns,

$$\phi P_{n(\max)} = 0.85\phi \left[.85 f_c' \left(A_g - A_{st} \right) + f_y A_{st} \right] \tag{50.42}$$

and for tied columns,

$$\phi P_{n(\max)} = 0.80\phi \left[.85 f_c' \left(A_g - A_{st} \right) + f_y A_{st} \right] \tag{50.43}$$

For high values of axial load, ϕ values of 0.7 and 0.75 are specified for tied and spiral columns, respectively (ACI 9.3.2.2b) [ACI Committee 318, 1992].

Short columns are sufficiently stocky such that slenderness effects can be ignored.

Short Columns under Axial and Bending

Almost all compression members in concrete structures are subjected to moments in addition to axial loads. Although it is possible to derive equations to evaluate the strength of columns subjected to combined bending and axial loads, the equations are tedious to use. For this reason, interaction diagrams for columns are generally computed by assuming a series of strain distributions, each corresponding to a particular point on the interaction diagram, and computing the corresponding values of P and M. Once enough such points have been computed, the results are summarized in an interaction diagram. For examples on determining the interaction diagram, see *Reinforced Concrete Mechanics and Design* by James G. MacGregor [1992] or *Reinforced Concrete Design* by Chu-Kia Wang and Charles G. Salmon [1985].

Figure 50.3 illustrates a series of strain distributions and the resulting points on the interaction diagram. Point A represents pure axial compression. Point B corresponds to crushing at one face and zero tension at the other. If the tensile strength of concrete is ignored, this represents the onset of cracking on the bottom face of the section. All points lower than this in the interaction diagram represent cases in which the section is partially cracked. Point C, the farthest right point, corresponds to the balanced strain condition and represents the change from compression failures for higher loads and tension failures for lower loads. Point D represents a strain distribution where the reinforcement has been strained to several times the yield strain before the concrete reaches it crushing strain.

The horizontal axis of the interaction diagram corresponds to pure bending where $\phi = 0.9$. A transition is required from $\phi = 0.7$ or 0.75 for high axial loads to $\phi = 0.9$ for pure bending. The change in ϕ begins at a capacity ϕP_a, which equals the smaller of the balanced load, ϕP_b, or $0.1 f_c' Ag$. Generally, ϕP_b exceeds $0.1 f_c' Ag$ except for a few nonrectangular columns.

ACI Publications SP-17A(85), *A Design Handbook for Columns,* contains nondimensional interaction diagrams as well as other design aids for column [ACI Committee 340, 1990].

Slenderness Effects

ACI 10.11 describes an approximate slenderness-effect design procedure based on the moment magnifier concept. The moments are computed by ordinary frame analysis and multiplied by a moment magnifier that is a function of the factored axial load and the critical buckling load of the column. The following gives a summary of the moment magnifier design procedure for slender columns in frames.

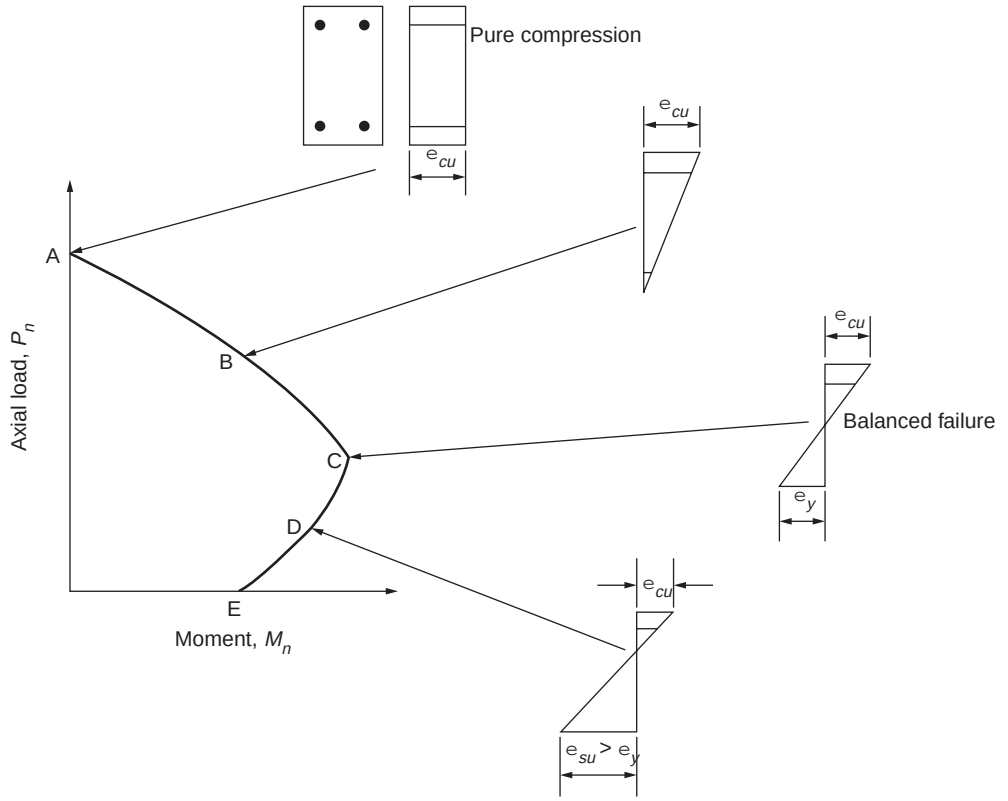

FIGURE 50.3 Strain distributions corresponding to points on interaction diagram.

1. *Length of column.* The unsupported length, l_u, is defined in ACI 10.11.1 as the clear distance between floor slabs, beams, or other members capable of giving lateral support to the column.
2. *Effective length.* The effective length factors, k, used in calculating δ_b shall be between 0.5 and 1.0 (ACI 10.11.2.1). The effective length factors used to compute δ_s shall be greater than 1 (ACI 10.11.2.2). The effective length factors can be estimated using ACI Fig. R10.11.2 or using ACI Equations (A)–(E) given in ACI R10.11.2. These two procedures require that the ratio, ψ, of the columns and beams be known:

$$\psi = \frac{\sum\left(E_c I_c / l_c\right)}{\sum\left(E_b I_b / l_b\right)} \tag{50.44}$$

   In computing ψ it is acceptable to take the EI of the column as the uncracked gross $E_c I_g$ of the columns and the EI of the beam as $0.5\, E_c I_g$.
3. *Definition of braced and unbraced frames.* The ACI Commentary suggests that a frame is braced if either of the following are satisfied:
   (a) If the stability index, Q, for a story is less than 0.04, where

$$Q = \frac{\sum P_u \Delta_u}{H_u h_s} \le 0.04 \tag{50.45}$$

   (b) If the sum of the lateral stiffness of the bracing elements in a story exceeds six times the lateral stiffness of all of the columns in the story.

4. *Radius of gyration.* For a rectangular cross section r equals 0.3 h, and for a circular cross section r equals 0.25 h. For other sections, r equals $\sqrt{I/A}$.
5. *Considerations of slenderness effects.* ACI 10.11.4.1 allows slenderness effects to be neglected for columns in braced frames when

$$\frac{kl_u}{r} < 34 - 12\frac{M_{1b}}{M_{2b}} \tag{50.46}$$

ACI 10.11.4.2 allows slenderness effects to be neglected for columns in unbraced frames when

$$\frac{kl_u}{r} < 22 \tag{50.47}$$

If kl_u/r exceeds 100, ACI 10.11.4.3 states that design shall be based on second-order analysis.
6. *Minimum moments.* For columns in a braced frame, M_{2b} shall be not less than the value given in ACI 10.11.5.4. In an unbraced frame ACI 10.11.5.5 applies for M_{2s}.
7. *Moment magnifier equation.* ACI 10.11.5.1 states that columns shall be designed for the factored axial load, P_u, and a magnified factored moment, M_c, defined by

$$M_c = \delta_b M_{2b} + \delta_s M_{2s} \tag{50.48}$$

where M_{2b} is the larger factored end moment acting on the column due to loads causing no appreciable sidesway (lateral deflections less than $l/1500$) and M_{2s} is the larger factored end moment due to loads that result in an appreciable sidesway. The moments are computed from a conventional first-order elastic frame analysis. For the above equation, the following apply:

$$\delta_b = \frac{C_m}{1 - P_u/\phi P_c} \geq 1.0$$
$$\delta_s = \frac{1}{1 - \sum P_u/\phi \sum P_c} \geq 1.0 \tag{50.49}$$

For members braced against sidesway, ACI 10.11.5.1 gives $\delta_s = 1.0$.

$$C_m j = 0.6 + 0.4\frac{M_{1b}}{M_{2b}} \geq 0.4 \tag{50.50}$$

The ratio M_{1b}/M_{2b} is taken as positive if the member is bent in single curvature and negative if the member is bent in double curvature. Equation (50.50) applies only to columns in braced frames. In all other cases, ACI 10.11.5.3 states that $C_m = 1.0$.

$$P_c = \frac{\pi^2 EI}{\left(kl_u\right)^2} \tag{50.51}$$

where

$$EI = \frac{E_c I_g/5 + E_s I_{se}}{1 + \beta_d} \tag{50.52}$$

or, approximately

$$EI = \frac{E_c I_g/2.5}{1 + \beta_d} \tag{50.53}$$

When computing δ_b,

$$\beta_d = \frac{\text{Axial load due to factored dead load}}{\text{Total factored axial load}} \tag{50.54}$$

when computing δ_s,

$$\beta_d = \frac{\text{Factored sustained lateral shear in the story}}{\text{Total factored lateral shear in the story}} \tag{50.55}$$

If δ_b or δ_s is found to be negative, the column should be enlarged. If either δ_b or δ_s exceeds 2.0, consideration should be given to enlarging the column.

Columns under Axial Load and Biaxial Bending

The nominal ultimate strength of a section under biaxial bending and compression is a function of three variables, P_n, M_{nx}, and M_{ny}, which may also be expressed as P_n acting at eccentricities $e_y = M_{nx}/P_n$ and $e_x = M_{ny}/P_n$ with respect to the x and y axes. Three types of failure surfaces can be defined. In the first type, S_1, the three orthogonal axes are defined by P_n, e_x, and e_y; in the second type, S_2, the variables defining the axes are $1/P_n$, e_x, and e_y; and in the third type, S_3, the axes are P_n, M_{nx}, and M_{ny}. In the presentation that follows, the Bresler reciprocal load method makes use of the reciprocal failure surface S_2, and the Bresler load contour method and the PCA load contour method both use the failure surface S_3.

Bresler Reciprocal Load Method

Using a failure surface of type S_2, Bresler proposed the following equation as a means of approximating a point of the failure surface corresponding to prespecified eccentricities e_x and e_y:

$$\frac{1}{P_{ni}} = \frac{1}{P_{nx}} + \frac{1}{P_{ny}} - \frac{1}{P_0} \tag{50.56}$$

where P_{ni} = nominal axial load strength at given eccentricity along both axes
P_{nx} = nominal axial load strength at given eccentricity along x axis
P_{ny} = nominal axial load strength at given eccentricity along y axis
P_0 = nominal axial load strength for pure compression (zero eccentricity)

Test results indicate that Eq. (50.46) may be inappropriate when small values of axial load are involved, such as when P_n/P_0 is in the range of 0.06 or less. For such cases the member should be designed for flexure only.

Bresler Load Contour Method

The failure surface S_3 can be thought of as a family of curves (load contours) each corresponding to a constant value of P_n. The general nondimensional equation for the load contour at constant P_n may be expressed in the following form:

$$\left(\frac{M_{nx}}{M_{ox}}\right)^{\alpha_1} + \left(\frac{M_{ny}}{M_{oy}}\right)^{\alpha_2} = 1.0 \tag{50.57}$$

where $M_{nx} = P_n e_y$; $M_{ny} = P_n e_x$
$M_{ox} = M_{nx}$ capacity at axial load P_n when M_{ny} (or e_x) is zero
$M_{oy} = M_{ny}$ capacity at axial load P_n when M_{nx} (or e_y) is zero

The exponents α_1 and α_2 depend on the column dimensions, amount and arrangement of the reinforcement, and material strengths. Bresler suggests taking $\alpha_1 = \alpha_2 = \alpha$. Calculated values of α vary from 1.15 to 1.55. For practical purposes, α can be taken as 1.5 for rectangular sections and between 1.5 and 2.0 for square sections.

PCA (Parme–Gowens) Load Contour Method

This method has been developed as an extension of the Bresler load contour method in which the Bresler interaction equation (50.57) is taken as the basic strength criterion. In this approach, a point on the load contour is defined in such a way that the biaxial moment strengths M_{nx} and M_{ny} are in the same ratio as the uniaxial moment strengths M_{ox} and M_{oy},

$$\frac{M_{ny}}{M_{nx}} = \frac{M_{oy}}{M_{ox}} = \beta \tag{50.58}$$

The actual value of β depends on the ratio of P_n to P_0 as well as the material and cross-sectional properties, with the usual range of values between 0.55 and 0.70. Charts for determining β can be found in ACI Publication SP-17A(85), *A Design Handbook for Columns* [ACI Committee 340, 1990].

Substituting Eq. (50.48) into Eq. (50.57),

$$\begin{aligned} \left(\frac{\beta M_{ox}}{M_{ox}}\right)^{\alpha} + \left(\frac{\beta M_{oy}}{M_{oy}}\right)^{\alpha} &= 1 \\ 2\beta^{\alpha} &= 1 \\ \beta^{\alpha} &= 1/2 \\ \alpha &= \frac{\log 0.5}{\log \beta} \end{aligned} \tag{50.59}$$

thus,

$$\left(\frac{M_{nx}}{M_{ox}}\right)^{\log 0.5/\log \beta} + \left(\frac{M_{ny}}{M_{oy}}\right)^{\log 0.5/\log \beta} = 1 \tag{50.60}$$

For more information on columns subjected to biaxial bending, see *Reinforced Concrete Design* by Chu-Kia Wang and Charles G. Salmon [1985].

50.5 Shear and Torsion

Reinforced Concrete Beams and One-Way Slabs Strength Design

The cracks that form in a reinforced concrete beam can be due to flexure or a combination of flexure and shear. Flexural cracks start at the bottom of the beam, where the flexural stresses are the largest. Inclined cracks, also called *shear cracks* or *diagonal tension cracks,* are due to a combination of flexure and shear. Inclined cracks must exist before a shear failure can occur.

Inclined cracks form in two different ways. In thin-walled I-beams in which the shear stresses in the web are high while the flexural stresses are low, a web-shear crack occurs. The inclined cracking shear can be calculated as the shear necessary to cause a principal tensile stress equal to the tensile strength of the concrete at the centroid of the beam.

In most reinforced concrete beams, however, flexural cracks occur first and extend vertically in the beam. These alter the state of stress in the beam and cause a stress concentration near the tip of the crack. In time, the flexural cracks extend to become flexure-shear cracks. Empirical equations have been developed to calculate the flexure-shear cracking load, since this cracking cannot be predicted by calculating the principal stresses.

In the ACI Code, the basic design equation for the shear capacity of concrete beams is as follows:

$$V_u \le \phi V_n \tag{50.61}$$

where V_u = the shear force due to the factored loads
ϕ = the strength reduction factor equal to 0.85 for shear
V_n = the nominal shear resistance, which is given by

$$V_n = V_c + V_s \tag{50.62}$$

where V_c = the shear carried by the concrete
V_s = the shear carried by the shear reinforcement

The torsional capacity of a beam as given in ACI 11.6.5 is as follows:

$$T_u \le \phi T_n \tag{50.63}$$

where T_u = the torsional moment due to factored loads
ϕ = the strength reduction factor equal to 0.85 for torsion
T_n = the nominal torsional moment strength given by

$$T_n = T_c + T_c \tag{50.64}$$

where T_c = the torsional moment strength provided by the concrete
T_s = the torsional moment strength provided by the torsion reinforcement

Design of Beams and One-Way Slabs Without Shear Reinforcement: for Shear

The critical section for shear in reinforced concrete beams is taken at a distance d from the face of the support. Sections located at a distance less than d from the support are designed for the shear computed at d.

Shear Strength Provided by Concrete.

Beams without web reinforcement will fail when inclined cracking occurs or shortly afterwards. For this reason the shear capacity is taken equal to the inclined cracking shear. ACI gives the following equations for calculating the shear strength provided by the concrete for beams without web reinforcement subject to shear and flexure:

$$V_c = 2\sqrt{f_c'}\, b_w d \tag{50.65}$$

or, with a more detailed equation:

$$V_c = \left(1.9\sqrt{f_c'} + 2500\rho_w \frac{V_u d}{M_u}\right) b_w d \le 3.5\sqrt{f_c'}\, b_w d \tag{50.66}$$

The quantity $V_u d/M_u$ is not to be taken greater than 1.0 in computing V_c where M_u is the factored moment occurring simultaneously with V_u at the section considered.

Combined Shear, Moment, and Axial Load.
For members that are also subject to axial compression, ACI modifies Eq. (50.65) as follows (ACI 11.3.1.2):

$$V_c = 2\left(1+\frac{N_u}{2000A_k}\right)\sqrt{f_c'}\,b_w d \tag{50.67}$$

where N_u is positive in compression. ACI 11.3.2.2 contains a more detailed calculation for the shear strength of members subject to axial compression.

For members subject to axial tension, ACI 11.3.1.3 states that shear reinforcement shall be designed to carry total shear. As an alternative, ACI 11.3.2.3 gives the following for the shear strength of member subject to axial tension:

$$V_c = 2\left(1+\frac{N_u}{500Ag}\right)\sqrt{f_c'}\,b_w d \tag{50.68}$$

where N_u is negative in tension. In Eq. (50.67) and (50.68) the terms $\sqrt{f_c'}\ N_u/A_g$, 2000, and 500 all have units of psi.

Combined Shear, Moment, and Torsion.
For members subject to torsion, ACI 11.3.1.4 gives the equation for the shear strength of the concrete as the following:

$$V_c = \frac{2\sqrt{f_c'}\,b_w d}{\sqrt{1+\left(2.5C_t T_u/V_u\right)^2}} \tag{50.69}$$

where

$$T_u \geq \phi\left(0.5\sqrt{f_c'}\sum x^2 y\right)$$

Design of Beams and One-Way Slabs Without Shear Reinforcements: for Torsion.

ACI 11.6.1 requires that torsional moments be considered in design if

$$T_u \geq \phi\left(0.5\sqrt{f_c'}\sum x^2 y\right) \tag{50.70}$$

Otherwise, torsion effects may be neglected.

The critical section for torsion is taken at a distance d from the face of support, and sections located at a distance less than d are designed for the torsion at d. If a concentrated torque occurs within this distance, the critical section is taken at the face of the support.

Torsional Strength Provided by Concrete.
Torsion seldom occurs by itself; bending moments and shearing forces are typically present also. In an uncracked member, shear forces as well as torques produce shear stresses. Flexural shear forces and torques interact in a way that reduces the strength of the member compared with what it would be if shear or torsion were acting alone. The interaction between shear and torsion is taken into account by the use of a circular interaction equation. For more information, refer to *Reinforced Concrete Mechanics and Design* by James G. MacGregor [1992].

The torsional moment strength provided by the concrete is given in ACI 11.6.6.1 as

$$T_c = \frac{0.8\sqrt{f_c'}\,x^2 y}{\sqrt{1+\left(0.4V_u/C_t T_u\right)^2}} \tag{50.71}$$

Combined Torsion and Axial Load.

For members subject to significant axial tension, ACI 11.6.6.2 states that the torsion reinforcement must be designed to carry the total torsional moment, or as an alternative modify T_c as follows:

$$T_c = \frac{0.8\sqrt{f_c'}\,x^2 y}{\sqrt{1+\left(0.4V_u/C_t T_u\right)^2}}\left(1+\frac{N_u}{500A_g}\right) \tag{50.72}$$

where N_u is negative for tension.

Design of Beams and One-Way Slabs without Shear Reinforcement

Minimum Reinforcement.

ACI 11.5.5.1 requires a minimum amount of web reinforcement to be provided for shear and torsion if the factored shear force V_u exceeds one half the shear strength provided by the concrete ($V_u \geq 0.5\phi V_c$) except in the following:

(a) Slabs and footings
(b) Concrete joist construction
(c) Beams with total depth not greater than 10 inches, 2½ times the thickness of the flange, or ½ the width of the web, whichever is greatest

The minimum area of shear reinforcement shall be at least

$$A_{v(\min)} = \frac{50b_w s}{f_y} \quad \text{for} \quad T_u < \phi\left(0.5\sqrt{f_c'}\sum x^2 y\right) \tag{50.73}$$

When torsion is to be considered in design, the sum of the closed stirrups for shear and torsion must satisfy the following:

$$A_v + 2A_t \geq \frac{50b_w s}{f_y} \tag{50.74}$$

where A_v = the area of two legs of a closed stirrup
A_t = the area of only one leg of a closed stirrup

Design of Stirrup Reinforcement for Shear and Torsion

Shear Reinforcement.

Shear reinforcement is to be provided when $V_u \geq \phi V_c$, such that

$$V_s \geq \frac{V_u}{\phi} - V_c \tag{50.75}$$

The design yield strength of the shear reinforcement is not to exceed 60,000 psi.

When the shear reinforcement is perpendicular to the axis of the member, the shear resisted by the stirrups is

$$V_s = \frac{A_v f_y d}{s} \tag{50.76}$$

If the shear reinforcement is inclined at an angle α, the shear resisted by the stirrups is

$$V_s = \frac{A_v f_y\left(\sin\alpha + \cos\alpha\right)d}{s} \tag{50.77}$$

The maximum shear strength of the shear reinforcement is not to exceed $8\sqrt{f_c'}\,b_w d$ as stated in ACI 11.5.6.8.

Spacing Limitations for Shear Reinforcement.
ACI 11.5.4.1 sets the maximum spacing of vertical stirrups as the smaller of $d/2$ or 24 inches. The maximum spacing of inclined stirrups is such that a 45° line extending from midheight of the member to the tension reinforcement will intercept at least stirrup.

If V_s exceeds $4\sqrt{f_c'}b_w d$, the maximum allowable spacings are reduced to one half of those just described.

Torsion Reinforcement.
Torsion reinforcement is to be provided when $T_u \geq \phi T_c$, such that

$$T_s \geq \frac{T_u}{\phi} - T_c \tag{50.78}$$

The design yield strength of the torsional reinforcement is not to exceed 60,000 psi.

The torsional moment strength of the reinforcement is computed by

$$T_s = \frac{A_t \alpha_t x_1 y_1 f_y}{s} \tag{50.79}$$

where

$$\alpha_t = \left[0.66 + 0.33\left(y_t / x_t\right)\right] \geq 1.50 \tag{50.80}$$

where A_t is the area of one leg of a closed stirrup resisting torsion within a distance s. The torsional moment strength is not to exceed 4 T_c as given in ACI 11.6.9.4.

Longitudinal reinforcement is to be provided to resist axial tension that develops as a result of the torsional moment (ACI 11.6.9.3). The required area of longitudinal bars distributed around the perimeter of the closed stirrups that are provided as torsion reinforcement is to be

$$A_l \geq 2A_t \frac{\left(x_1 + y_1\right)}{s}$$

$$A_l \geq \left[\frac{400xs}{f_y}\left(\frac{T_u}{T_u + \dfrac{V_u}{3C_t}}\right) = 2A_t\right]\left(\frac{x_1 + y_1}{s}\right) \tag{50.81}$$

Spacing Limitations for Torsion Reinforcement.
ACI 11.6.8.1 gives the maximum spacing of closed stirrups as the smaller of $(x_1 + y_1)/4$ or 12 inches.

The longitudinal bars are to be spaced around the circumference of the closed stirrups at not more than 12 inches apart. At least one longitudinal bar is to be placed in each corner of the closed stirrups (ACI 11.6.8.2).

Design of Deep Beams

ACI 11.8 covers the shear design of deep beams. This section applies to members with $l_n/d < 5$ that are loaded on one face and supported on the opposite face so that compression struts can develop between the loads and the supports. For more information on deep beams, see *Reinforced Concrete Mechanics and Design,* 2nd ed. by James G. MacGregor [1992].

The basic design equation for simple spans deep beams is

$$V_u \leq \phi\left(V_c + V_s\right) \tag{50.82}$$

where V_c = the shear carried by the concrete
V_s = the shear carried by the vertical and horizontal web reinforcement

The shear strength of deep beams shall not be taken greater than

$$V_n = 8\sqrt{f_c'}\,b_w d \quad \text{for} \quad l_n/d \le 2$$
$$V_n = \frac{2}{3}\left(10 + \frac{l_n}{d}\right)\sqrt{f_c'}\,b_w d \quad \text{for} \quad 2 \le l_n/d \le 5 \tag{50.83}$$

Design for shear is done at a critical section located at 0.15 l_n from the face of support in uniformly loaded beams, and at the middle of the shear span for beams with concentrated loads. For both cases, the critical section shall not be farther than d from the face of the support. The shear reinforcement required at this critical section is to be used throughout the span.

The shear carried by the concrete is given by

$$V_c = 2\sqrt{f_c'}\,b_w d \tag{50.84}$$

or, with a more detailed calculation,

$$V_c = \left(3.5 - 2.5\frac{M_u}{V_u d}\right)\left(1.9\sqrt{f_c'} + 2500\rho_w \frac{V_u d}{M_u}\right)b_w d \le 6\sqrt{f_c'}\,b_w d \tag{50.85}$$

where

$$\left(3.5 - 2.5\frac{M_u}{V_u d}\right) \le 2.5 \tag{50.86}$$

In Eqs. (50.85) and (50.86) M_u and V_u are the factored moment and shear at the critical section.

Shear reinforcement is to be provided when $V_u \ge \phi V_c$ such that

$$V_s = \frac{V_u}{\phi} - V_c \tag{50.87}$$

where

$$V_s = \left[\frac{A_v}{s}\left(\frac{1 + l_n/d}{12}\right) + \frac{A_{vh}}{s_2}\left(\frac{11 - l_n/d}{12}\right)\right]f_y d \tag{50.88}$$

where A_v and s = the area and spacing of the vertical shear reinforcement and A_{vh} and s_2 refer to the horizontal shear reinforcement.

ACI 11.8.9 and 11.8.10 require minimum reinforcement in both the vertical and horizontal sections as follows:

$$A_v \ge 0.0015 b_w s \tag{50.89}$$

$$s \le \left\{\begin{matrix} d/5 \\ 18 \text{ in.} \end{matrix}\right\} \tag{50.90}$$

$$A_{vh} \ge 0.0025 b_w s_2 \tag{50.91}$$

$$s_2 \le \left\{\begin{matrix} d/3 \\ 18 \text{ in.} \end{matrix}\right\} \tag{50.92}$$

Prestressed Concrete Beams and One-Way Slabs Strength Design

At loads near failure, a prestressed beam is usually heavily cracked and behaves similarly to an ordinary reinforced concrete beam. Many of the equations developed previously for design of web reinforcement for nonprestressed beams can also be applied to prestressed beams.

Shear design is based on the same basic equation as before,

$$V_u \le \phi\left(V_c + V_s\right)$$

where $\phi = 0.85$.

The critical section for shear is taken at a distance $h/2$ from the face of the support. Sections located at a distance less than $h/2$ are designed for the shear computed at $h/2$.

Shear Strength Provided by the Concrete

The shear force resisted by the concrete after cracking has occurred is taken as equal to the shear that caused the first diagonal crack. Two types of diagonal cracks have been observed in tests of prestressed concrete.

1. Flexure-shear cracks, occurring at nominal shear V_{ci}, start as nearly vertical flexural cracks at the tension face of the beam, then spread diagonally upward toward the compression face.
2. Web shear cracks, occurring at nominal shear V_{cw}, start in the web due to high diagonal tension, then spread diagonally both upward and downward.

The shear strength provided by the concrete for members with effective prestress force not less than 40% of the tensile strength of the flexural reinforcement is

$$V_c = \left(0.6\sqrt{f_c'} + 700\frac{V_u d}{M_u}\right) b_w d \le 2\sqrt{f_c'}\, b_w d \tag{50.93}$$

V_c may also be computed as the lesser of V_{ci} and V_{cw}, where

$$V_{ci} = 0.6\sqrt{f_c'}\, b_w d + V_d + \frac{V_i M_{cr}}{M_{\max}} \ge 1.7\sqrt{f_c'}\, b_w d \tag{50.94}$$

$$M_{cr} = \left(\frac{I}{y_t}\right)\left(6\sqrt{f_c'} + f_{pc} - f_d\right) \tag{50.95}$$

$$V_{cw} = \left(3.5\sqrt{f_c'} + 0.3 f_{pc}\right) b_w d + V_p \tag{50.96}$$

In Eqs. (50.94) and (50.96) d is the distance from the extreme compression fiber to the centroid of the prestressing steel or $0.8h$, whichever is greater.

Shear Strength Provided by the Shear Reinforcement

Shear reinforcement for prestressed concrete is designed in a similar manner as for reinforced concrete, with the following modifications for minimum amount and spacing.

Minimum Reinforcement.

The minimum area of shear reinforcement shall be at least

$$A_{v(\min)} = \frac{50 b_w s}{f_y} \quad \text{for} \quad T_u < \phi\left(0.5\sqrt{f_c'}\sum x^2 y\right) \tag{50.97}$$

or

$$A_{v(\min)} = \frac{A_{ps} f_{pu} s}{80 f_y d}\sqrt{\frac{d}{b_w}} \tag{50.98}$$

Spacing Limitations for Shear Reinforcement.
ACI 11.5.4.1 sets the maximum spacing of vertical stirrups as the smaller of (3/4)h or 24 in. The maximum spacing of inclined stirrups is such that a 45° line extending from midheight of the member to the tension reinforcement will intercept at least one stirrup.

If V_s exceeds $4\sqrt{f_c'}b_w d$, the maximum allowable spacings are reduced to one-half of those just described.

50.6 Development of Reinforcement

The development length, l_d, is the shortest length of bar in which the bar stress can increase from zero to the yield strength, f_y. If the distance from a point where the bar stress equals f_y to the end of the bar is less than the development length, the bar will pull out of the concrete. Development lengths are different for tension and compression.

Development of Bars in Tension

ACI Fig. R12.2 gives a flow chart for determining development length. The steps are outlined below.

The basic tension development lengths have been found to be (ACI 12.2.2). For no. 11 and smaller bars and deformed wire:

$$l_{db} = \frac{0.04 A_b f_y}{\sqrt{f_c'}} \tag{50.99}$$

For no. 14 bars:

$$l_{db} = \frac{0.085 f_y}{\sqrt{f_c'}} \tag{50.100}$$

For no. 18 bars:

$$I_{db} = \frac{0.125 f_y}{\sqrt{f_c'}} \tag{50.101}$$

where $\sqrt{f_c'}$ is not to be taken greater than 100 psi.

The development length, l_d, is computed as the product of the basic development length and modification factors given in ACI 12.2.3, 12.2.4, and 12.2.5. The development length obtained from ACI 12.2.2 and 12.2.3.1 through 12.2.3.5 shall not be less than

$$\frac{0.03 d_b f_y}{\sqrt{f_c'}} \tag{50.102}$$

as given in ACI 12.2.3.6.

The length computed from ACI 12.2.2 and 12.2.3 is then multiplied by factors given in ACI 12.2.4 and 12.2.5. The factors given in ACI 12.2.3.1 through 12.2.3.3 and 12.2.4 are required, but the factors in ACI 12.2.3.4, 12.2.3.5, and 12.2.5 are optional.

The development length is not to be less than 12 inches (ACI 12.2.1).

Development of Bars in Compression

The basic compression development length is (ACI 12.3.2)

$$l_{db} = \frac{0.02 d_b f_y}{\sqrt{f_c'}} \geq 0.003 d_b f_y \tag{50.103}$$

The development length, l_d, is found as the product of the basic development length and applicable modification factors given in ACI 12.3.3.

The development length is not to be less than 8 inches (ACI 12.3.1).

Development of Hooks in Tension

The basic development length for a hooked bar with f_y = 60,000 psi as (ACI 12.5.2)

$$l_{db} = \frac{1200 d_b}{\sqrt{f'_c}} \tag{50.104}$$

The development length, l_{dh}, is found as the product of the basic development length and applicable modification factors given in ACI 12.5.3.

The development length of the hook is not to be less than 8 bar diameters or 6 inches (ACI 12.5.1).

Hooks are not to be used to develop bars in compression.

Splices, Bundled Bars, and Web Reinforcement

Splices

Tension Lap Splices.

ACI 12.15 distinguishes between two types of tension lap splices depending on the amount of reinforcement provided and the fraction of the bars spliced in a given length — see ACI Table R12.15.2. The splice lengths for each splice class are as follows:

Class A splice : $1.0 l_d$
Class B splice : $1.3 l_d$

where l_d is the tensile development length as computed in ACI 12.2 without the modification factor for excess reinforcement given in ACI 12.2.5. The minimum splice length is 12 inches.

Lap splices are not to be used for bars larger than no. 11 except at footing to column joints and for compression lap splices of no. 14 and no. 18 bars with smaller bars (ACI 12.14.2.1). The center-to-center distance between two bars in a lap splice cannot be greater than one-fifth the required lap splice length with a maximum of 6 inches (ACI 12.14.2.3). ACI 21.3.2.3 requires that tension lap splices of flexural reinforcement in beams resisting seismic loads be enclosed by hoops or spirals.

Compression Lap Splices.

The splice length for a compression lap splice is given in ACI 12.16.1 as

$$l_s = 0.0005 f_y d_b \quad \text{for} \quad f_y \le 60{,}000 \text{ psi} \tag{50.105}$$

$$l_s = \left(0.0009 f_y - 24\right) d_b \quad \text{for} \quad f_y > 60{,}000 \text{ psi} \tag{50.106}$$

but not less than 12 inches. For f'_c less than 3000 psi, the lap length must be increased by one-third.

When different size bars are lap spliced in compression, the splice length is to be the larger of:

1. Compression splice length of the smaller bar, or
2. Compression development length of larger bar.

Compression lap splices are allowed for no. 14 and no. 18 bars to no. 11 or smaller bars (ACI 12.16.2).

End-Bearing Splices.

End-bearing splices are allowed for compression only where the compressive stress is transmitted by bearing of square cut ends held in concentric contact by a suitable device. According to ACI 12.16.4.2

bar ends must terminate in flat surfaces within 1½° of right angles to the axis of the bars and be fitted within 3° of full bearing after assembly. End-bearing splices are only allowed in members containing closed ties, closed stirrups, or spirals.

Welded Splices or Mechanical Connections.
Bars stressed in tension or compression may be spliced by welding or by various mechanical connections. ACI 12.14.3, 12.15.3, 12.15.4, and 12.16.3 govern the use of such splices. For further information see *Reinforced Concrete Design,* by Chu-Kia Wang and Charles G. Salmon [1985].

Bundled Bars

The requirements of ACI 12.4.1. specify that the development length for bundled bars be based on that for the individual bar in the bundle, increased by 20% for a three-bar bundle and 33% for a four-bar bundle. ACI 12.4.2 states that "a unit of bundled bars shall be treated as a single bar of a diameter derived from the equivalent total area" when determining the appropriate modification factors in ACI 12.2.3 and 12.2.4.3.

Web Reinforcement

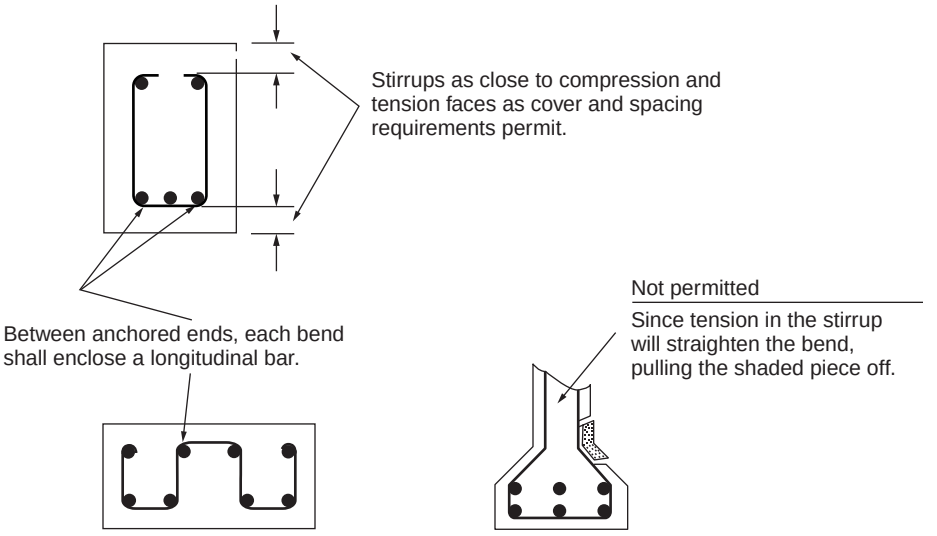
ACI 12.13.1 requires that the web reinforcement be as close to the compression and tension faces as cover and bar-spacing reinforcements permit. The ACI Code requirements for stirrup anchorage are illustrated in Fig. 50.4.

(a) ACI 12.13.3. requires that each bend away from the ends of a stirrup enclose a longitudinal bar, as seen in Fig. 50.a(4).
(b) For no. 5 or D31 wire stirrups and smaller with any yield strength and for no. 6, 7, and 8 bars with a yield strength of 40,000 psi or less, ACI 12.13.2.1 allows the use of a standard hook around longitudinal reinforcement, as shown in Fig. 50.4(b).
(c) For no. 6, 7, and 8 stirrups with f_y greater than 40,000 psi, ACI 12.13.2.2 requires a standard hook around a longitudinal bar plus an embedment between midheight of the member and the outside end of the hook of at least $0.01 d_b f_y / \sqrt{f'_c}$.
(d) Requirements for welded wire fabric forming U stirrups are given in ACI 12.13.2.3.
(e) Pairs of U stirrups that form a closed unit shall have a lap length of $1.3 l_d$ as shown in Fig. 50.4(c). This type of stirrup has proven unsuitable in seismic areas.
(f) Requirements for longitudinal bars bent to act as shear reinforcement are given in ACI 12.13.4.

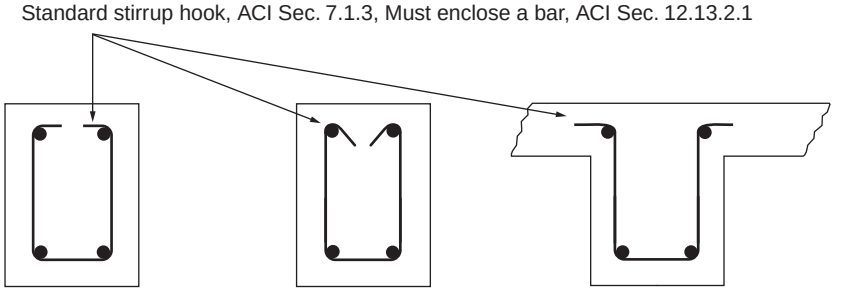
50.7 Two-Way Systems

Definition

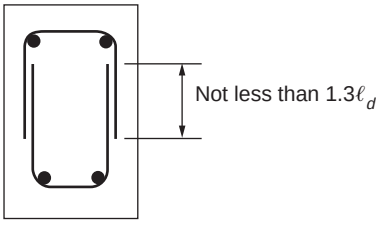
When the ratio of the longer to the shorter spans of a floor panel drops below 2, the contribution of the longer span in carrying the floor load becomes substantial. Since the floor transmits loads in two directions, it is defined as a *two-way system,* and flexural reinforcement is designed for both directions. Two-way systems include *flat plates, flat slabs, two-way slabs,* and *waffle slabs* (see Fig. 50.5). The choice between these different types of two-way systems is largely a matter of the architectural layout, magnitude of the design loads, and span lengths. A flat plate is simply a slab of uniform thickness supported directly on columns, generally suitable for relatively light loads. For larger loads and spans, a flat slab becomes more suitable with the column capitals and drop panels providing higher shear and flexural strength. A slab supported on beams on all sides of each floor panel is generally referred to as a two-way slab. A waffle slab is equivalent to a two-way joist system or may be visualized as a solid slab with recesses in order to decrease the weight of the slab.



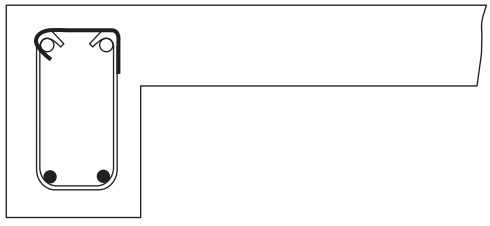
(a) General requirements.



(b) Stirrup anchorage requirements for No. 5 and smaller bars as per ACI Secs. 7.1.3 and 12.13.2.1.



(c) Stirrup anchorage as per ACI Sec. 12.13.5.



(d) Two piece closed stirrup —Beams with torsion of compression reinforcement. ACI Secs. 7.11 and 11.6.7.3.

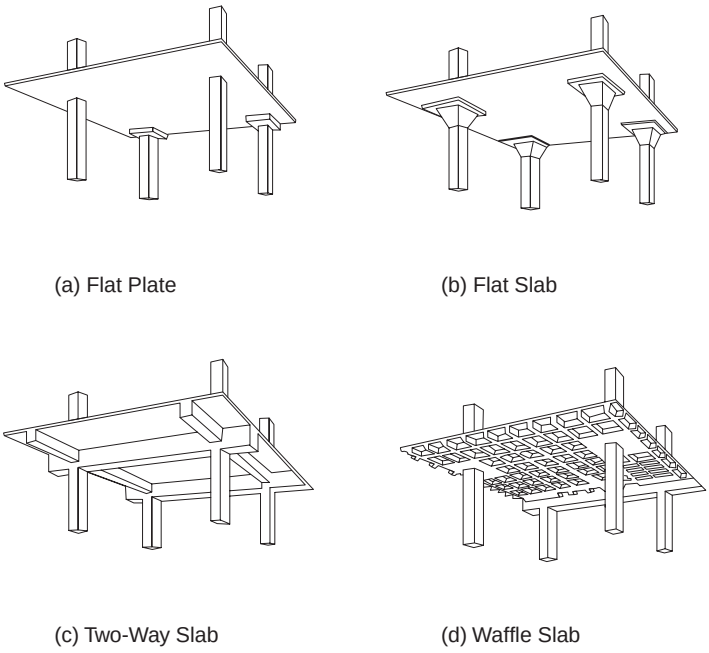

FIGURE 50.5 Two-way systems.

Design Procedures

The ACI Code [ACI Committee 318, 1992] states that a two-way slab system "may be designed by any procedure satisfying conditions of equilibrium and geometric compatibility if shown that the design strength at every section is at least equal to the required strength.… and that all serviceability conditions, including specified limits on deflections, are met" (p. 204). There are a number of possible approaches to the analysis and design of two-way systems based on elastic theory, limit analysis, finite element analysis, or combination of elastic theory and limit analysis. The designer is permitted by the ACI Code to adopt any of these approaches provided that all safety and serviceability criteria are satisfied. In general, only for cases of a complex two-way system or unusual loading would a finite element analysis be chosen as the design approach. Otherwise, more practical design approaches are preferred. The ACI Code details two procedures — the *direct design method* and the *equivalent frame method* — for the design of floor systems with or without beams. These procedures were derived from analytical studies based on elastic theory in conjunction with aspects of limit analysis and results of experimental tests. The primary difference between the direct design method and equivalent frame method is in the way moments are computed for two-way systems.

The *yield-line theory* is a limit analysis method devised for slab design. Compared to elastic theory, the yield-line theory gives a more realistic representation of the behavior of slabs at the ultimate limit state, and its application is particularly advantageous for irregular column spacing. While the yield-line method is an upper-bound limit design procedure, *strip method* is considered to give a lower-bound design solution. The strip method offers a wide latitude of design choices and it is easy to use; these are often cited as the appealing features of the method.

Some of the earlier design methods based on moment coefficients from elastic analysis are still favored by many designers. These methods are easy to apply and give valuable insight into slab behavior; their use is especially justified for many irregular slab cases where the preconditions of the direct design method are not met or when column interaction is not significant. Table 50.7 lists the moment coefficients taken from method 2 of the 1963 ACI Code. As in the 1989 code, two-way slabs are divided into column strips and middle strips as indicated by Fig. 50.6, where l_1 and l_2 are the center-to-center span lengths of the

TABLE 50.7 Elastic Moment Coefficients for Two-Way Slabs

Moments	Short Span, Span Ratio, Short/Long 1.0	0.9	0.8	0.7	0.6	0.5 and less	Long Span, All Span Ratios

TABLE 50.8 Minimum Thickness of Two-Way Slabs without Beams

Yield Stress f_y, psi[1]	Exterior Panels: Without Edge Beams	Exterior Panels: With Edge Beams[2]	Interior Panels
Without Drop Panels			
40,000	$l_n/33$	$l_n/36$	$l_n/36$
60,000	$l_n/30$	$l_n/33$	$l_n/33$
With Drop Panels			
40,000	$l_n/36$	$l_n/40$	$l_n/40$
60,000	$l_n/33$	$l_n/36$	$l_n/36$

[1] For values of reinforcement yield stress between 40,000 and 60,000 psi minimum thickness shall be obtained by linear interpolation.

[2] Slabs with beams between columns along exterior edges. The value of α for the edge beam shall not be less than 0.8.

Source: ACI Committee 318, 1992.

floor panel. A column strip is a design strip with a width on each side of a column centerline equal to $0.25l_2$ or $0.25l_1$, whichever is less. A middle strip is a design strip bounded by two column strips. Taking the moment coefficients from Table 50.7, bending moments per unit width M for the middle strips are computed from the formula

$$M = (\text{Coef.})wl_s^2$$

Where w is the total uniform load per unit area and l_s is the shorter span length of l_1 and l_2. The average moments per unit width in the column strip is taken as two-thirds of the corresponding moments in the middle strip.

Minimum Slab Thickness and Reinforcement

ACI Code Section 9.5.3 contains requirements to determine minimum slab thickness of a two-way system for deflection control. For slabs without beams, the thickness limits are summarized by Table 50.8, but thickness must not be less than 5 in. for slabs without drop panels or 4 in. for slabs with drop panels. In Table 50.8 l_n is the length of clear span in the long direction and α is the ratio of flexural stiffness of beam section to flexural stiffness of a width of slab bounded laterally by centerline of adjacent panel on each side of beam.

For slabs with beams, it is necessary to compute the minimum thickness h from

$$h = \frac{l_n\left(0.8 + \dfrac{f_y}{200{,}000}\right)}{36 + 5\beta\left(\alpha_m - 0.12\left(1 + \dfrac{1}{\beta}\right)\right)} \tag{50.108}$$

but not less than

$$h = \frac{l_n\left(0.8 + \dfrac{f_y}{200{,}000}\right)}{36 + 9\beta} \tag{50.109}$$

and need not be more than

$$h = \frac{l_n\left(0.8 + \dfrac{f_y}{200{,}000}\right)}{36} \tag{50.110}$$

where β is the ratio of clear spans in long-to-short direction and α_m is the average value of α for all beams on edges of a panel. In no case should the slab thickness be less than 5 in. for $\alpha_m < 2.0$ or less than 3½ in. for $\alpha_m \geq 2.0$.

Minimum reinforcement in two-way slabs is governed by shrinkage and temperature controls to minimize cracking. The minimum reinforcement area stipulated by the ACI Code shall not be less than 0.0018 times the gross concrete area when grade 60 steel is used (0.0020 when grade 40 or grade 50 is used). The spacing of reinforcement in two-way slabs shall exceed neither two times the slab thickness nor 18 in.

Direct Design Method

The direct design method consists of a set of rules for the design of two-way slabs with or without beams. Since the method was developed assuming designs and construction, its application is restricted by the code to two-way systems with a minimum of three continuous spans, successive span lengths that do not differ by more than one-third, columns with offset not more than 10% of the span, and all loads are due to gravity only and uniformly distributed with live load not exceeding three times dead load. The direct design method involves three fundamental steps: (1) determine the total factored static moment; (2) distribute the static moment to negative and positive sections; and (3) distribute moments to column and middle strips and to beams, if any. The total factored static moment M_o for a span bounded laterally by the centerlines of adjacent panels (see Fig. 50.6) is given by

$$M_o = \frac{w_u l_2 l_n^2}{8} \tag{50.111}$$

In an interior span, $0.6M_o$ is assigned to each negative section and $0.35M_o$ is assigned to the positive section. In an end span, M_o is distributed according to Table 50.9. If the ratio of dead load to live load is less than 2, the effect of pattern loading is accounted for by increasing the positive moment following provisions in ACI Section 13.6.10. Negative and positive moments are then proportioned to the column strip following the percentages in Table 50.10, where β_t is the ratio of the torsional stiffness of edge beam section to flexural stiffness of a width of slab equal to span length of beam. The remaining moment not resisted by the column strip is proportionately assigned to the corresponding half middle strip. If beams are present, they are proportioned to resist 80% of column strip moments. When $(\alpha l_2/l_1)$ is less than 1.0, the proportion of column strip moments resisted by beams is obtained by linear interpolation between 85% and zero. The shear in beams is determined from loads acting on tributary areas projected from the panel corners at 45 degrees.

TABLE 50.9 Direct Design Method — Distribution of Moment in End Span

	(1)	(2)	(3)	(4)	(5)
			Slab without Beams between Interior Supports		
	Exterior Edge Unrestrained	Slab with Beams between All Supports	Without Edge Beam	With Edge Beam	Exterior Edge Fully Restrained

Equivalent Frame Method

For two-way systems not meeting the geometric or loading preconditions of the direct design method, design moments may be computed by the equivalent frame method. This is a more general method and involves the representation of the three-dimensional slab system by dividing it into a series of two-dimensional "equivalent" frames (Fig. 50.6). The complete analysis of a two-way system consists of analyzing the series of equivalent interior and exterior frames that span longitudinally and transversely through the system. Each equivalent frame, which is centered on a column line and bounded by the center lines of the adjacent panels, comprises a horizontal slab-beam strip and equivalent columns extending above and below the slab beam (Fig. 50.7). This structure is analyzed as a fame for loads acting in the plane of the frame, and the moments obtained at critical sections across the slab-beam strip are distributed to the column strip, middle strip, and beam in the same manner as the direct design method (see Table 50.10). In its original development, the equivalent frame method assumed that analysis would be done by moment distribution. Presently, frame analysis is more easily accomplished in design practice with computers using general purpose programs based on the direct stiffness method. Consequently, the equivalent frame method is now often used as a method for modeling a two-way system for computer analysis.

For the different types of two-way systems, the moment of inertias for modeling the slab-beam element of the equivalent frame are indicated in Fig. 50.8. Moments of inertia of slab beams are based on the gross area of concrete; the variation in moment of inertia along the axis is taken into account, which in practice would mean that a node would be located on the computer model where a change of moment of inertia occurs. To account for the increased stiffness between the center of the column and the face of column, beam, or capital, the moment of inertia is divided by the quantity $(1 - c_2/l_2)^2$, where c_2 and l_2 are measured transverse to the direction of the span. For column modeling, the moment of inertia at any cross section outside of joints or column capitals may be based on the gross area of concrete, and the moment of inertia from the top to bottom of the slab-beam joint is assumed infinite.

Torsion members (Fig. 50.7) are elements in the equivalent frame that provide moment transfer between the horizontal slab beam and vertical columns. The cross section of torsional members are assumed to consist of the portion of slab and beam having a width according to the conditions depicted in Fig. 50.9. The stiffness K_t of the torsional member is calculated by the following expression:

$$K_t = \sum \frac{9E_{cs}C}{l_2\left(1 - \frac{c_2}{l_2}\right)^3} \tag{50.112}$$

where E_{cs} is the modulus of elasticity of the slab concrete and the torsional constant C may be evaluated by dividing the cross section into separate rectangular parts and carrying out the following summation:

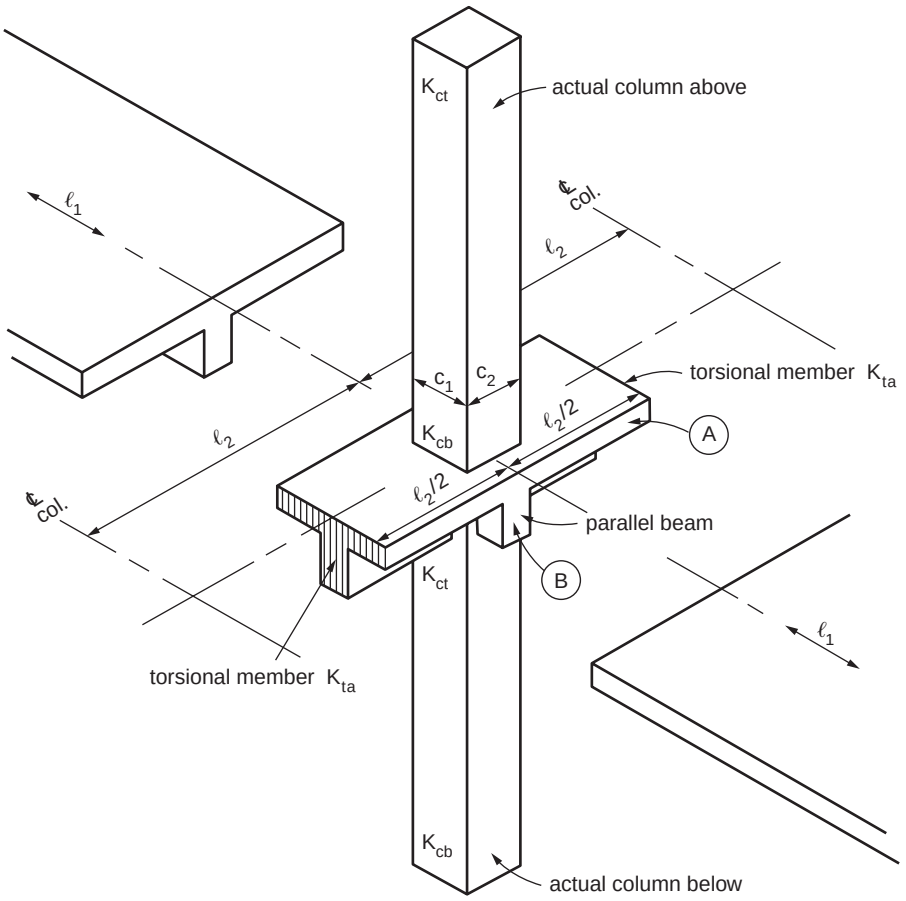

FIGURE 50.7 Equivalent column (columns plus torsional members).

$$C = \sum \left(1 - 0.63\frac{x}{y}\right)\frac{x^3 y}{3} \tag{50.113}$$

where x and y are the shorter and longer dimension, respectively, of each rectangular part. Where beams frame into columns in the direction of the span, the increased torsional stiffness K_{ta} is obtained by multiplying the value K_t obtained from Eq. (50.112) by the ratio of (a) moment inertia of slab with such beam, to (b) moment of inertia of slab without such beam. Various ways have been suggested for incorporating torsional members into a computer model of an equivalent fame. The model implied by the ACI Code is one that has the slab beam connected to the torsional members, which are projected out of the plane of the columns. Others have suggested that the torsional members be replaced by rotational springs at column ends or, alternatively, at the slab-beam ends. Or, instead of rotational springs, columns may be modeled with an equivalent value of the moment of inertia modified by the equivalent column stiffness K_{ec} given in the commentary of the code. Using Fig. 50.7, K_{ec} is computed as

$$K_{ec} = \frac{K_{ct} + K_{cb}}{1 + \dfrac{K_{ct} + K_{cb}}{K_{ta} + K_{ta}}} \tag{50.114}$$

where K_{ct} and K_{cb} are the top and bottom flexural stiffnesses of the column.

Detailing

The ACI Code specifies that reinforcement in two-way slabs without beams have minimum extensions as prescribed in Fig. 50.10. Where adjacent spans are unequal, extensions of negative moment reinforcement

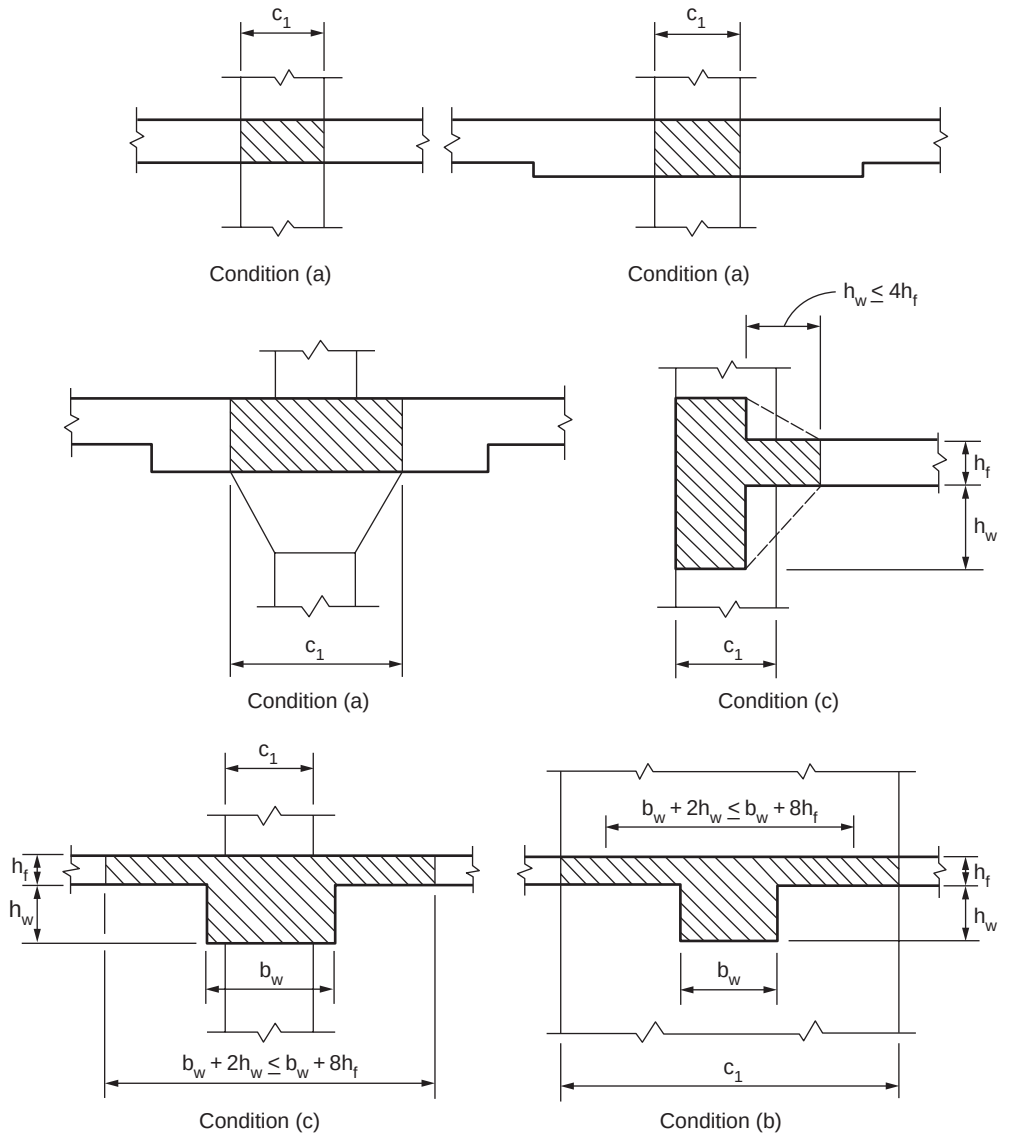

FIGURE 50.9 Torsional members. (*Source:* ACI Committee 318, 1992.)

shall be based on the longer span. Bent bars may be used only when the depth-span ratio permits use of bends 45 degrees or less. And at least two of the column strip bottom bars in each direction shall be continuous or spliced at the support with Class A splices or anchored within support. These bars must pass through the column and be placed within the column core. The purpose of this "integrity steel" is to give the slab some residual capacity following a single punching shear failure.

The ACI Code requires drop panels to extend in each direction from centerline of support a distance not less than one-sixth the span length, and the drop panel must project below the slab at least one-quarter of the slab thickness. The effective support area of a column capital is defined by the intersection of the bottom surface of the slab with the largest right circular cone whose surfaces are located within the column and capital and are oriented no greater than 45 degrees to the axis of the column.

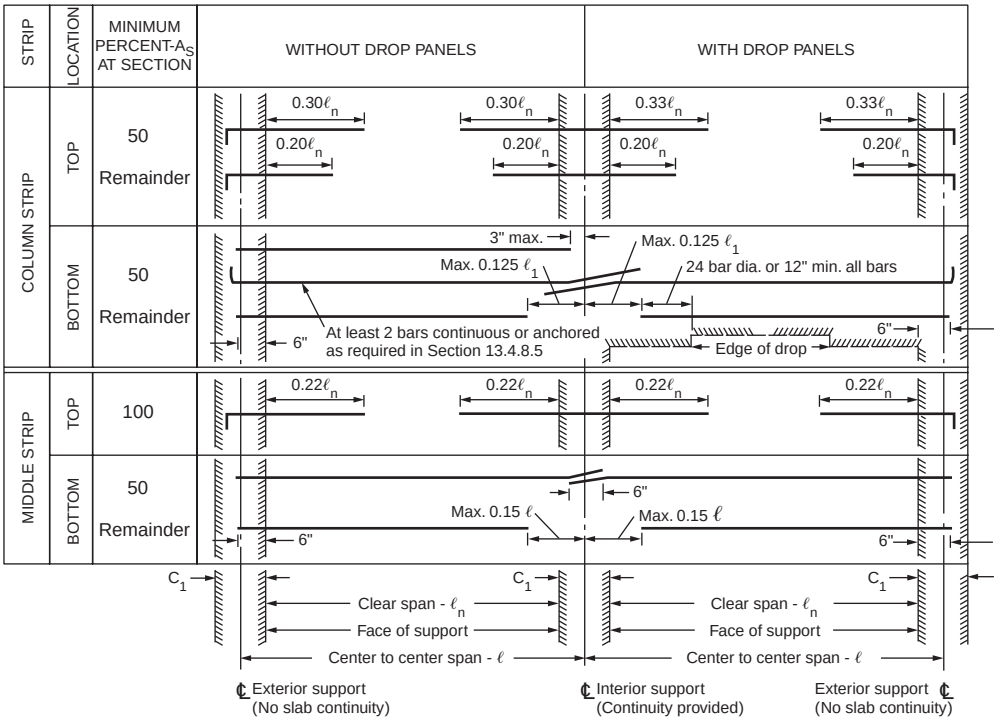

FIGURE 50.10 Minimum extensions for reinforcement in two-way slabs without beams. (*Source:* ACI Committee 318, 1992.)

50.8 Frames

A structural frame is a three-dimensional structural system consisting of straight members that are built monolithically and have rigid joints. The frame may be one bay long and one story high — such as portal frames and gable frames — or it may consist of multiple bays and stories. All members of the frame are considered continuous in the three directions, and the columns participate with the beams in resisting external loads.

Consideration of the behavior of reinforced concrete frames at and near the ultimate load is necessary to determine the possible distributions of bending moment, shear force, and axial force that could be used in design. It is possible to use a distribution of moments and forces different from that given by linear elastic structural analysis if the critical sections have sufficient ductility to allow redistribution of actions to occur as the ultimate load is approached. Also, in countries that experience earthquakes, a further important design is the ductility of the structure when subjected to seismic-type loading, since present seismic design philosophy relies on energy dissipation by inelastic deformations in the event of major earthquakes.

Analysis of Frames

A number of methods have been developed over the years for the analysis of continuous beams and frames. The so-called classical methods — such as application of the theorem of three moments, the method of least work, and the general method of consistent deformation — have proved useful mainly in the analysis of continuous beams having few spans or of very simple frames. For the more complicated cases usually met in practice, such methods prove to be exceedingly tedious, and alternative approaches are preferred. For many years the closely related methods of slope deflection and moment distribution provided the basic analytical tools for the analysis of indeterminate concrete beams and frames. In offices

with access to high-speed digital computers, these have been supplanted largely by matrix methods of analysis. Where computer facilities are not available, moment distribution is still the most common method. Approximate methods of analysis, based either on an assumed shape of the deformed structure or on moment coefficients, provide a means for rapid estimation of internal forces and moments. Such estimates are useful in preliminary design and in checking more exact solutions, and in structures of minor importance may serve as the basis for final design.

Slope Deflection

The method of slope deflection entails writing two equations for each member of a continuous frame, one at each end, expressing the end moment as the sum of four contributions: (1) the restraining moment associated with an assumed fixed-end condition for the loaded span, (2) the moment associated with rotation of the tangent to the elastic curves at the near end of the member, (3) the moment associated with rotation of the tangent at the far end of the member, and (4) the moment associated with translation of one end of the member with respect to the other. These equations are related through application of requirements of equilibrium and compatibility at the joints. A set of simultaneous, linear algebraic equations results for the entire structure, in which the structural displacements are unknowns. Solution for these displacements permits the calculation of all internal forces and moments.

This method is well suited to solving continuous beams, provided there are not very many spans. Its usefulness is extended through modifications that take advantage of symmetry and antisymmetry, and of hinge-end support conditions where they exist. However, for multistory and multibay frames in which there are a large number of members and joints, and which will, in general, involve translation as well as rotation of these joints, the effort required to solve the correspondingly large number of simultaneous equations is prohibitive. Other methods of analysis are more attractive.

Moment Distribution

The method of moment distribution was developed to solve problems in frame analysis that involve many unknown joint displacements. This method can be regarded as an iterative solution of the slope-deflection equations. Starting with fixed-end moments for each member, these are modified in a series of cycles, each converging on the precise final result, to account for rotation and translation of the joints. The resulting series can be terminated whenever one reaches the degree of accuracy required. After obtaining member-end moments, all member stress resultants can be obtained by use of the laws of statics.

Matrix Analysis

Use of matrix theory makes it possible to reduce the detailed numerical operations required in the analysis of an indeterminate structure to systematic processes of matrix manipulation, which can be performed automatically and rapidly by computer. Such methods permit the rapid solution of problems involving large numbers of unknowns. As a consequence, less reliance is placed on special techniques limited to certain types of problems; powerful methods of general applicability have emerged, such as the matrix displacement method. Account can be taken of such factors as rotational restraint provided by members perpendicular to the plane of a frame. A large number of alternative loadings may be considered. Provided that computer facilities are available, highly precise analyses are possible at lower cost than for approximate analyses previously employed.

Approximate Analysis

In spite of the development of refined methods for the analysis of beams and frames, increasing attention is being paid to various approximate methods of analysis. There are several reasons for this. Prior to performing a complete analysis of an indeterminate structure, it is necessary to estimate the proportions of its members in order to know their relative stiffness upon which the analysis depends. These dimensions can be obtained using approximate analysis. Also, even with the availability of computers, most engineers find it desirable to make a rough check of results — using approximate means — to detect gross errors. Further, for structures of minor importance, it is often satisfactory to design on the basis of results obtained by rough calculation.

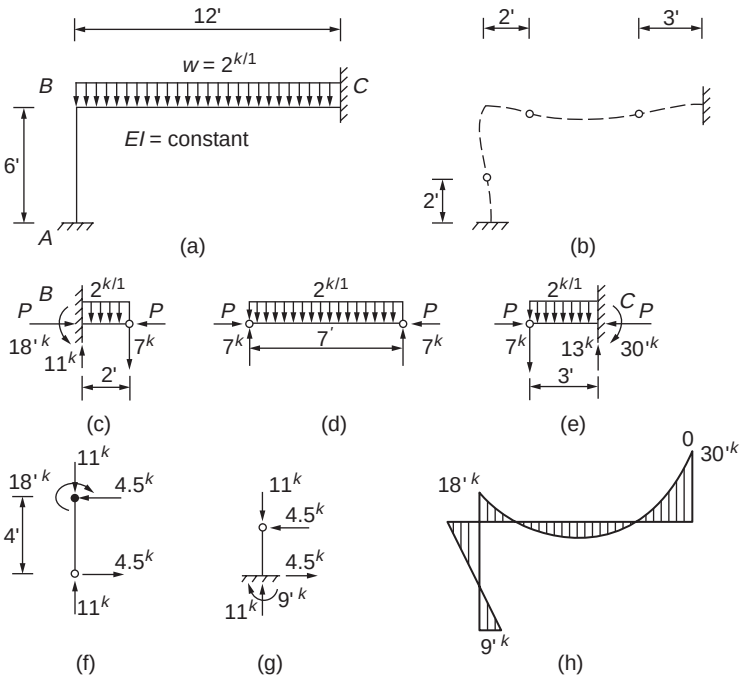

FIGURE 50.11 Approximate analysis of rigid frame. (*Source:* Nilson and Winter, 1992.)

Provided that points of infection (locations in members at which the bending moment is zero and there is a reversal of curvature of the elastic curve) can be located accurately, the stress resultants for a frame structure can usually be found on the basis of static equilibrium alone. Each portion of the structure must be in equilibrium under the application of its external loads and the internal stress resultants. The use of approximate analysis in determining stress resultants in frames is illustrated using a simple rigid frame in Fig. 50.11.

ACI Moment Coefficients

The ACI Code [ACI Committee 318, 1992] includes moment and shear coefficients that can be used for the analysis of buildings of usual types of construction, span, and story heights. They are given in ACI Code Sec. 8.3.3. The ACI coefficients were derived with due consideration of several factors: a maximum allowable ratio of live to dead load (3:1); a maximum allowable span difference (the larger of two adjacent spans not exceed the shorter by more than 20%); the fact that reinforced concrete beams are never simply supported but either rest on supports of considerable width, such as walls, or are built monolithically like columns; and other factors. Since all these influences are considered, the ACI coefficients are necessarily quite conservative, so that actual moments in any particular design are likely to be considerably smaller than indicated. Consequently, in many reinforced concrete structures, significant economy can be effected by making a more precise analysis.

Limit Analysis

Limit analysis in reinforced concrete refers to the redistribution of moments that occurs throughout a structure as the steel reinforcement at a critical section reaches its yield strength. Under working loads, the distribution of moments in a statically indeterminate structure is based on elastic theory and the whole structure remains in the elastic range. In limit design, where factored loads are used, the distribution of moments at failure when a mechanism is reached is different from that distribution based on

elastic theory. The ultimate strength of the structure can be increased as more sections reach their ultimate capacity. Although the yield of the reinforcement introduces large deflections, which should be avoided under service, a statically indeterminate structure does not collapse when the reinforcement of the first section yields. Furthermore, a large reserve of strength is present between the initial yielding and the collapse of the structure.

In steel design the term *plastic design* is used to indicate the change in the distribution of moments in the structure as the steel fibers, at a critical section, are stressed to their yield strength. Limit analysis of reinforced concrete developed as a result of earlier research on steel structures. Several studies had been performed on the principles of limit design and the rotation capacity of reinforced concrete plastic hinges.

Full utilization of the plastic capacity of reinforced concrete beams and frames requires an extensive analysis of all possible mechanisms and an investigation of rotation requirements and capacities at all proposed hinge locations. The increase of design time may not be justified by the limited gains obtained. On the other hand, a restricted amount of redistribution of elastic moments can safely be made without complete analysis and may be sufficient to obtain most of the advantages of limit analysis.

A limited amount of redistribution is permitted under the ACI Code, depending upon a rough measure of available ductility, without explicit calculation of rotation requirements and capacities. The ratio ρ/ρ_b — or in the case of doubly reinforced members, $(\rho - \rho')/\rho_b$ — is used as an indicator of rotation capacity, where ρ_b is the balanced steel ratio. For singly reinforced members with $\rho = \rho_b$, experiments indicate almost no rotation capacity, since the concrete strain is nearly equal to ε_{cu} when steel yielding is initiated. Similarly, in a doubly reinforced member, when $\rho - \rho' = \rho_b$, very little rotation will occur after yielding before the concrete crushes. However, when ρ or $\rho - \rho'$ is low, extensive rotation is usually possible. Accordingly, ACI Code Sec. 8.3 provides as follows:

> Except where approximate values for moments are used, it is permitted to increase or decrease negative moments calculated by elastic theory at supports of continuous flexural members for any assumed loading arrangement by not more than $20[1 - (\rho - \rho')/\rho_b]$ percent. The modified negative moments shall be used for calculating moments at sections within the spans. Redistribution of negative moments shall be made only when the section at which moment is reduced is so designed that ρ or $\rho - \rho'$ is not greater than $0.5\rho_b$ [1992].

Design for Seismic Loading

The ACI Code contains provisions that are currently considered to be the minimum requirements for producing a monolithic concrete structure with adequate proportions and details to enable the structure to sustain a series of oscillations into the inelastic range of response without critical decay in strength. The provisions are intended to apply to reinforced concrete structures located in a seismic zone where major damage to construction has a high possibility of occurrence, and are designed with a substantial reduction in total lateral seismic forces due to the use of lateral load-resisting systems consisting of ductile moment-resisting frames. The provisions for frames are divided into sections on flexural members, columns, and joints of frames. Some of the important points stated are summarized below.

Flexural Members

Members having a factored axial force not exceeding $A_g f_c'/10$, where A_g is gross section of area (in.^{2}), are regarded as flexural members. An upper limit is placed on the flexural steel ratio ρ. The maximum value of ρ should not exceed 0.025. Provision is also made to ensure that a minimum quantity of top and bottom reinforcement is always present. Both the top and the bottom steel are to have a steel ratio of at least $200/f_y$, with the steel yield strength f_y in psi throughout the length of the member. Recommendations are also made to ensure that sufficient steel is present to allow for unforeseen shifts in the points of contraflexure. At column connections, the positive moment capacity should be at least 50% of the negative moment capacity, and the reinforcement should be terminated in the far face of the column using a hook plus any additional extension necessary for anchorage.

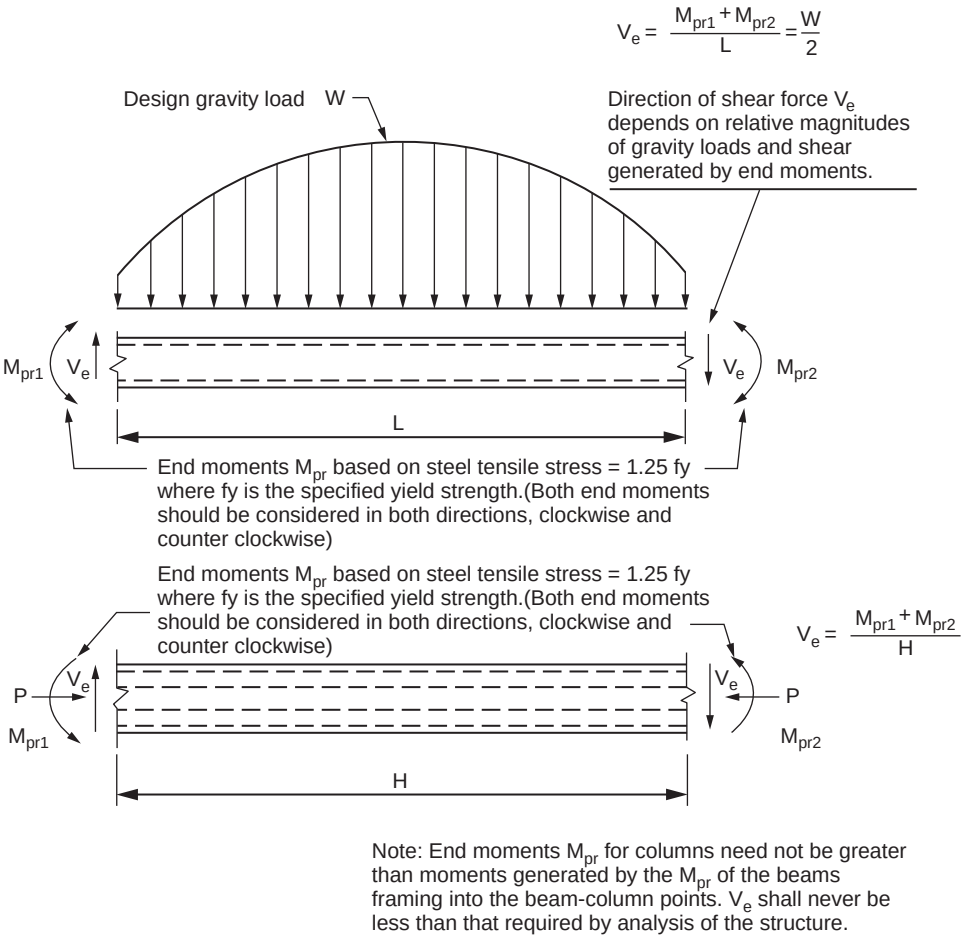

FIGURE 50.12 Design shears for girders and columns. (*Source:* ACI 318, 1992.)

The design shear force V_e should be determined from consideration of the static forces on the portion of the member between faces of the joints. It should be assumed that moments of opposite sign corresponding to probable strength M_{pr} act at the joint faces and that the member is loaded with the factored tributary gravity load along its span. Figure 50.12 illustrates the calculation. Minimum web reinforcement is provided throughout the length of the member, and spacing should not exceed $d/4$ in plastic hinge zones and $d/2$ elsewhere, where d is effective depth of member. The stirrups should be closed around bars required to act as compression reinforcement and in plastic hinge regions, and the spacing should not exceed specified values.

Columns

Members having a factored axial force exceeding $A_g f'_c/10$ are regarded as columns of frames serving to resist earthquake forces. These members should satisfy the conditions that the shortest cross-sectional dimension — measured on a straight line passing through the geometric centroid — should not be less than 12 in. and that the ratio of the shortest cross-sectional dimension to the perpendicular dimension should not be less than 0.4. The flexural strengths of the columns should satisfy

$$\sum M_e \geq (6/5) \sum M_g \tag{50.115}$$

where $\sum M_e$ is sum of moments, at the center of the joint, corresponding to the design flexural strength of the columns framing into that joint and where $\sum M_g$ is sum of moments, at the center of the joint, corresponding to the design flexural strengths of the girders framing into that joint. Flexural strengths should be summed such that the column moments oppose the beam moments. Eq. (50.115) should be satisfied for beam moments acting in both directions in the vertical plane of the frame considered. The requirement is intended to ensure that plastic hinges form in the girders rather than the columns.

The longitudinal reinforcement ratio is limited to the range of 0.01 to 0.06. The lower bound to the reinforcement ratio refers to the traditional concern for the effects of time-dependent deformations of the concrete and the desire to have a sizable difference between the cracking and yielding moments. The upper bound reflects concern for steel congestion, load transfer from floor elements to column in low-rise construction, and the development of large shear stresses. Lap splices are permitted only within the center half of the member length and should be proportioned as tension splices. Welded splices and mechanical connections are allowed for splicing the reinforcement at any section, provided not more than alternate longitudinal bars are spliced at a section and the distance between splices is 24 in. or more along the longitudinal axis of the reinforcement.

If Eq. (50.115) is not satisfied at a joint, columns supporting reactions from that joint should be provided with transverse reinforcement over their full height to confine the concrete and provide lateral support to the reinforcement. Where a spiral is used, the ratio of volume of spiral reinforcement to the core volume confined by the spiral reinforcement, ρ_s, should be at least that given by

$$\rho_s = 0.45 \frac{f_c'}{f_y}\left(\frac{A_g}{A_c} - 1\right) \tag{50.116}$$

but not less than $0.12\, f_c'/f_{yh}$, where A_c is the area of core of spirally reinforced compression member measured to outside diameter of spiral in in.^{2} and f_{yh} is the specified yield strength of transverse reinforcement in psi. When rectangular reinforcement hoop is used, the total cross-sectional area of rectangular hoop reinforcement should not be less than that given by

$$A_{sh} = 0.3\left(sh_c f_c'/f_{yh}\right)\left[\left(A_g/A_{ch}\right) - 1\right] \tag{50.117}$$

$$A_{sh} = 0.09\, sh_c f_c'/f_{yh} \tag{50.118}$$

where s is the spacing of transverse reinforcement measured along the longitudinal axis of column, h_c is the cross-sectional dimension of column core measured center-to-center of confining reinforcement, and A_{sh} is the total cross-sectional area of transverse reinforcement (including crossties) within spacing s and perpendicular to dimension h_c. Supplementary crossties, if used, should be of the same diameter as the hoop bar and should engage the hoop with a hook. Special transverse confining steel is required for the full height of columns that support discontinuous shear walls.

The design shear force V_c should be determined from consideration of the maximum forces that can be generated at the faces of the joints at each end of the column. These joint forces should be determined using the maximum probable moment strength M_{pr} of the column associated with the range of factored axial loads on the column. The column shears need not exceed those determined from joint strengths based on the probable moment strength M_{pr}, of the transverse members framing into the joint. In no case should V_e be less than the factored shear determined by analysis of the structure (Fig. 50.12).

Joints of Frames

Development of inelastic rotations at the faces of reinforced concrete frames is associated with strains in the flexural reinforcement well in excess of the yield strain. Consequently, joint shear force generated by the flexural reinforcement is calculated for a stress of $1.25 f_y$ in the reinforcement.

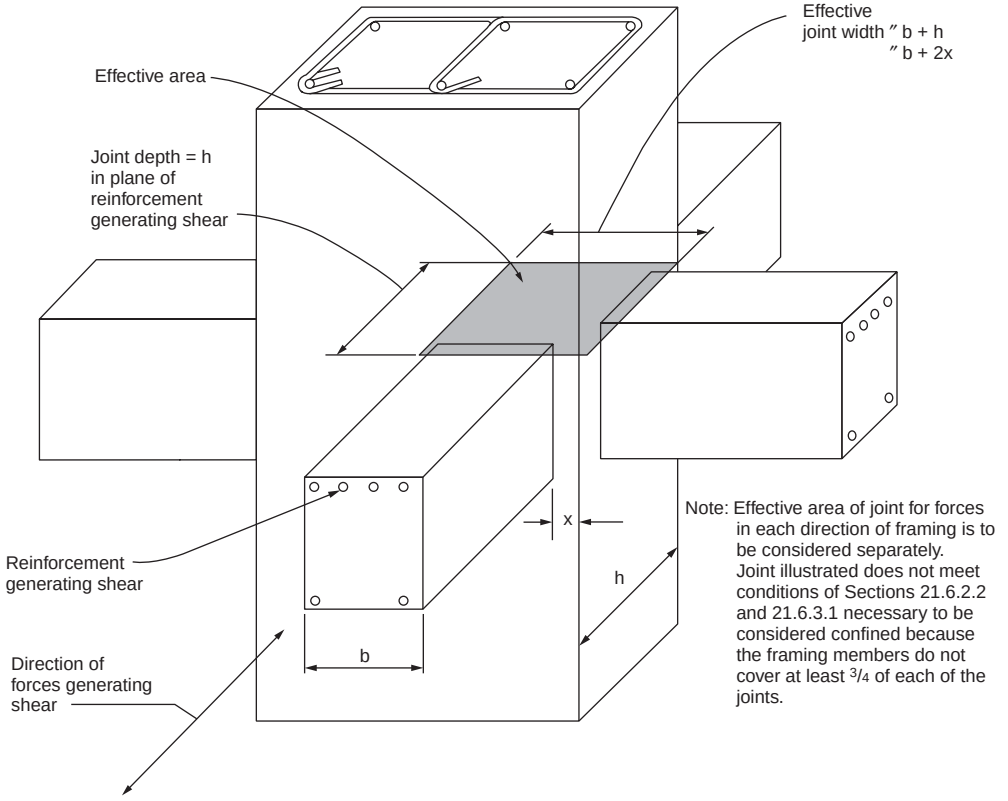

FIGURE 50.13 Effective area of joint. (*Source:* ACI Committee 318, 1992.)

Within the depth of the shallowed framing member, transverse reinforcement equal to at least one-half the amount required for the column reinforcement should be provided where members frame into all four sides of the joint and where each member width is at least three-fourths the column width. Transverse reinforcement as required for the column reinforcement should be provided through the joint to provide confinement for longitudinal beam reinforcement outside the column core if such confinement is not provided by a beam framing into the joint.

The nominal shear strength of the joint should not be taken greater than the forces specified below for normal weight aggregate concrete:

20 $\sqrt{f_c'}A_j$ for joints confined on all four faces

15 $\sqrt{f_c'}A_j$ for joints confined on three faces or on two opposite faces

12 $\sqrt{f_c'}A_j$ for others

where A_j is the effective cross-sectional area within a joint in a plane parallel to plane of reinforcement generating shear in the joint (see Fig. 50.13). A member that frames into a face is considered to provide confinement to the joint if at least three-quarters of the face of the joint is covered by the framing member. A joint is considered to be confined if such confining members frame into all faces of the joint. For lightweight-aggregate concrete, the nominal shear strength of the joint should not exceed three-quarters of the limits given above.

Details of minimum development length for deformed bars with standard hooks embedded in normal and lightweight concrete and for straight bars are contained in ACI Code Sec. 21.6.4.

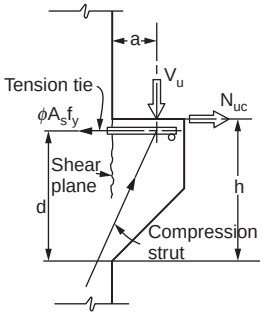

FIGURE 50.14 Structural action of a corbel. (*Source:* ACI Committee 318, 1992.)

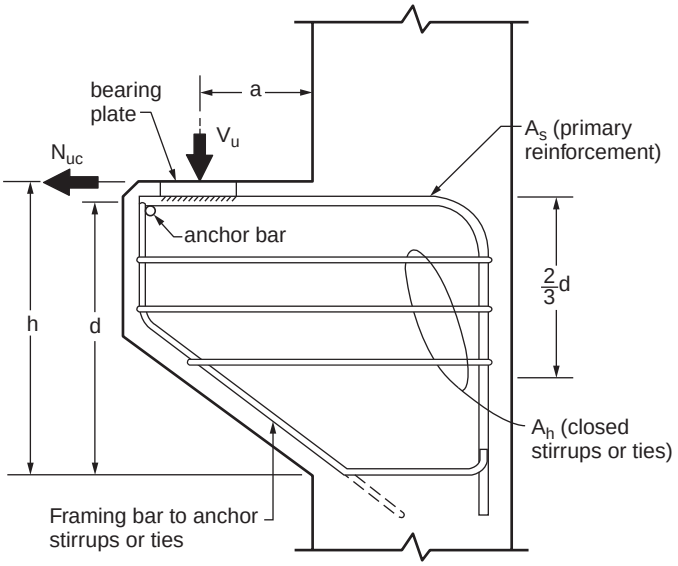

FIGURE 50.15 Notation used. (*Source:* ACI Committee 318, 1992.)

50.9 Brackets and Corbels

Brackets and corbels are cantilevers having shear span to depth ratio, a/d, not greater than unity. The shear span a is the distance from the point of load to the face of support, and the distance d shall be measured at face of support (see Fig. 50.14).

The corbel shown in Fig. 50.14 may fail by shearing along the interface between the column and the corbel, by yielding of the tension tie, by crushing or splitting of the compression strut, or by localized bearing or shearing failure under the loading plate.

The depth of a bracket or corbel at its outer edge should be less than one-half of the required depth d at the support. Reinforcement should consist of main tension bars with area A_s and shear reinforcement with area A_h (see Fig. 50.15 for notation). The area of primary tension reinforcement A_s should be made equal to the greater of $(A_f + A_n)$ or $(2A_{vf}/3 + A_n)$, where A_f is the flexural reinforcement required to resist moment $[V_u a + N_{uc}(h - d)]$, A_n is the reinforcement required to resist tensile force N_{uc}, and A_{vf} is the shear-friction reinforcement required to resist shear V_u:

$$A_f = \frac{M_u}{\phi f_y j d} = \frac{V_u a + N_{uc}(h-d)}{\phi f_y j d} \tag{50.119}$$

$$A_n = \frac{N_{uc}}{\phi f_y} \tag{50.120}$$

$$A_{vf} = \frac{V_u}{\phi f_y \mu} \tag{50.121}$$

In the above equations, f_y is the reinforcement yield strength; ϕ is 0.9 for Eq. (50.119) and 0.85 for Eqs. (50.120) and (50.121). In Eq. (50.119), the lever arm jd can be approximated for all practical purposes in most cases as $0.85d$. Tensile force N_{uc} in Eq. (50.120) should not be taken less than $0.2V_u$ unless special provisions are made to avoid tensile forces. Tensile force N_{uc} should be regarded as a live load even when tension results from creep, shrinkage, or temperature change. In Eq. (50.121), $V_i/\phi (= V_n)$ should not be taken greater than $0.2f'_c b_w d$ nor $800 b_w d$ in pounds in normal-weight concrete. For "all-lightweight" or "sand-lightweight" concrete, shear strength V_n should not be taken greater than $(0.2 - 0.07a/d)f'_c b_w d$ nor $(800 - 280a/d)b_w d$ in pounds. The coefficient of friction μ in Eq. (50.121) should be 1.4λ for concrete placed monolithically, 1.0λ for concrete placed against hardened concrete with surface intentionally roughened, 0.6λ for concrete placed against hardened concrete not intentionally roughened, and 0.7λ for concrete anchored to as-rolled structural steel by headed studs or by reinforcing bars, where λ is 1.0 for normal weight concrete, 0.85 for "sand-lightweight" concrete, and 0.75 for "all-lightweight" concrete. Linear interpolation of λ is permitted when partial sand replacement is used.

The total area of closed stirrups or ties A_h parallel to A_s should not be less than $0.5(A_s - A_n)$ and should be uniformly distributed within two-thirds of the depth of the bracket adjacent to A_s.

At front face of bracket or corbel, primary tension thermal A_s should be anchored in one of the following ways: (a) by a structural weld to a transverse bar of at least equal size; weld to be designed to develop specified yield strength f_y of A_s bars; (b) by bending primary tension bars A_s back to form a horizontal loop, or (c) by some other means of positive anchorage. Also, to ensure development of the yield strength of the reinforcement A_s near the load, bearing area of load on bracket or corbel should not project beyond straight portion of primary tension bars A_s, nor project beyond interior face of transverse anchor bar (if one is provided). When corbels are designed to resist horizontal forces, the bearing plate should be welded to the tension reinforcement A_s.

50.10 Footings

Footings are structural members used to support columns and walls and to transmit and distribute their loads to the soil in such a way that (a) the load bearing capacity of the soil is not exceeded, (b) excessive settlement, differential settlement, and rotations are prevented, and (c) adequate safety against overturning or sliding is maintained. When a column load is transmitted to the soil by the footing, the soil becomes compressed. The amount of settlement depends on many factors, such as the type of soil, the load intensity, the depth below ground level, and the type of footing. If different footings of the same structure have different settlements, new stresses develop in the structure. Excessive differential settlement may lead to the damage of nonstructural members in the buildings, even failure of the affected parts.

Vertical loads are usually applied at the centroid of the footing. If the resultant of the applied loads does not coincide with the centroid of the bearing area, a bending moment develops. In this case, the pressure on one side of the footing will be greater than the pressure on the other side causing higher settlement on one side and a possible rotation of the footing.

If the bearing soil capacity is different under different footings — for example, if the footings of a building are partly on soil and partly on rock — a differential settlement will occur. It is customary in such cases to provide a joint between the two parts to separate them, allowing for independent settlement.

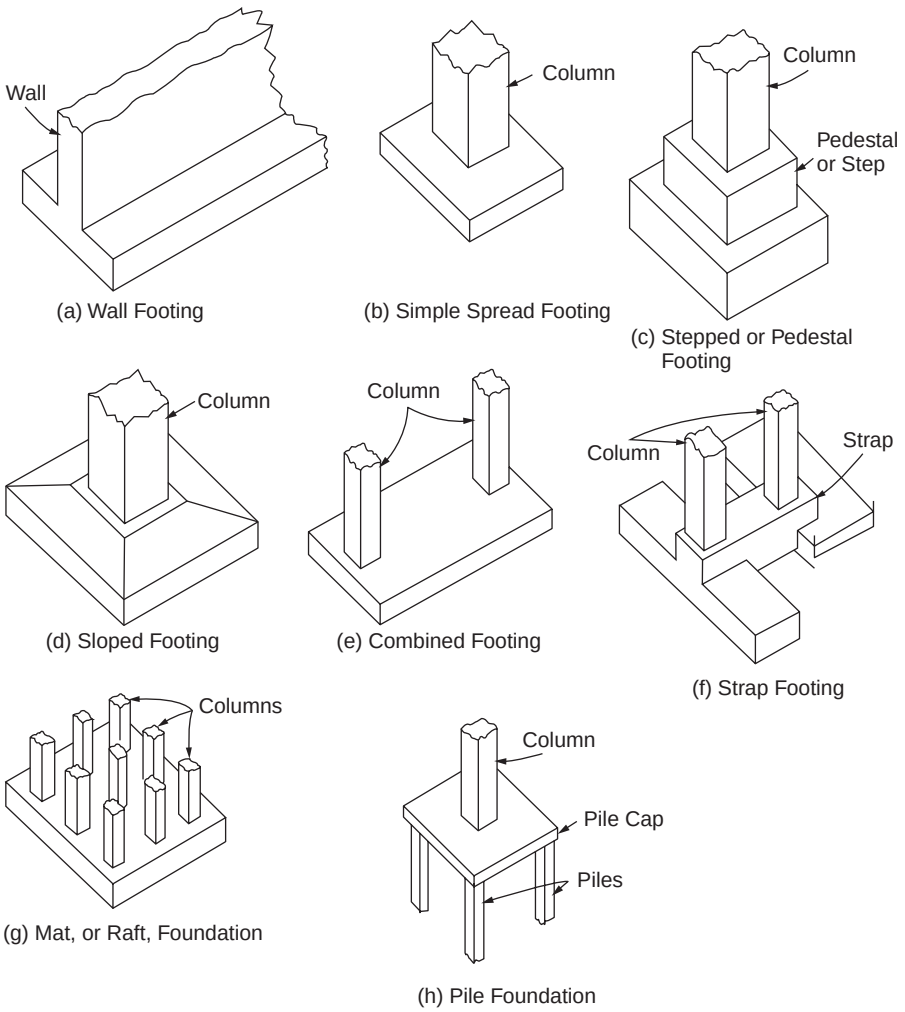

FIGURE 50.16 Common types of footings for walls and columns. (*Source:* ACI Committee 340, 1990.)

Types of Footings

Different types of footings may be used to support building columns or walls. The most commonly used ones are illustrated in Fig. 50.16(a–g). A simple file footing is shown in Fig. 50.16(h).

For walls, a spread footing is a slab wider than the wall and extending the length of the wall [Fig. 50.16(a)]. Square or rectangular slabs are used under single columns [Fig. 50.16(b–d)]. When two columns are so close that their footings would merge or nearly touch, a combined footing [Fig. 50.16(e)] extending under the two should be constructed. When a column footing cannot project in one direction, perhaps because of the proximity of a property line, the footing may be helped out by an adjacent footing with more space; either a combined footing or a strap (cantilever) footing [Fig. 50.169f)] may be used under the two.

For structures with heavy loads relative to soil capacity, a mat or raft foundation [Fig. 50.16(g)] may prove economical. A simple form is a thick, two-way-reinforced-concrete slab extending under the entire structure. In effect, it enables the structure to float on the soil, and because of its rigidity it permits negligible differential settlement. Even greater rigidity can be obtained by building the raft foundation as an inverted beam-and-girder floor, with the girders supporting the columns. Sometimes, also, inverted flat slabs are used as mat foundations.

Design Considerations

Footings must be designed to carry the column loads and transmit them to the soil safely while satisfying code limitations. The design procedure must take the following strength requirements into consideration:

- The area of the footing based on the allowable bearing soil capacity
- Two-way shear or punching shear
- One-way shear
- Bending moment and steel reinforcement required
- Dowel requirements
- Development length of bars
- Differential settlement

These strength requirements will be explained in the following sections.

Size of Footings

The required area of concentrically loaded footings is determined from

$$A_{req} = \frac{D+L}{q_a} \tag{50.122}$$

where q_a is allowable bearing pressure and D and L are, respectively, unfactored dead and live loads. Allowable bearing pressures are established from principles of soil mechanics on the basis of load tests and other experimental determinations. Allowable bearing pressures q_a under service loads are usually based on a safety factor of 2.5 and 3.0 against exceeding the ultimate bearing capacity of the particular soil and to keep settlements within tolerable limits. The required area of footings under the effects of wind W or earthquake E is determined from the following:

$$A_{req} = \frac{D+L+W}{1.33q_a} \quad \text{or} \quad \frac{D+L+E}{1.33q_a} \tag{50.123}$$

It should be noted that footing sizes are determined for unfactored service loads and soil pressures, in contrast to the strength design of reinforced concrete members, which utilizes factored loads and factored nominal strengths.

A footing is eccentrically loaded if the supported column is not concentric with the footing area or if the column transmits — at its juncture with the footing — not only a vertical load but also a bending moment. In either case, the load effects at the footing base can be represented by the vertical load P and a bending moment M. The resulting bearing pressures are again assumed to be linearly distributed. As long as the resulting eccentricity $e = M/P$ does not exceed the kern distance k of the footing area, the usual flexure formula

$$q_{\max,\min} = \frac{P}{A} + \frac{Mc}{I} \tag{50.124}$$

permits the determination of the bearing pressures at the two extreme edges, as shown in Fig. 50.17(a). The footing area is found by trial and error from the condition $q_{\max} \le q_a$. If the eccentricity falls outside the kern, Eq. (50.124) gives a negative value for q along one edge of the footing. Because no tension can be transmitted at the contact area between soil and footing, Eq. (50.124) is no longer valid and bearing pressures are distributed as in Fig. 50.17(b).

Once the required footing area has been determined, the footing must then be designed to develop the necessary strength to resist all moments, shears, and other internal actions caused by the applied loads. For this purpose, the load factors of the ACI Code apply to footings as to all other structural components.

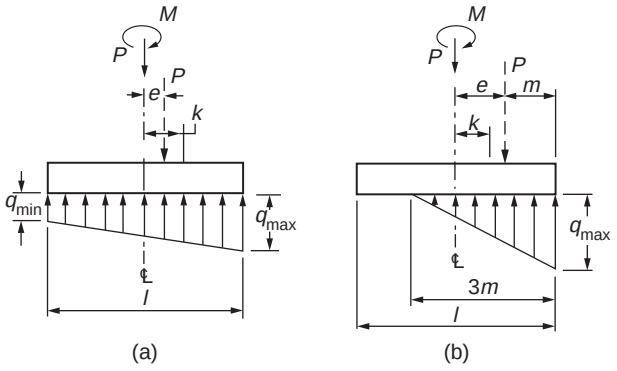

FIGURE 50.17 Assumed bearing pressures under eccentric footings. (*Source:* Wang and Salmon, 1985.)

Depth of footing above bottom reinforcement should not be less than 6 in. for footings on soil, nor less that 12 in. from footings on piles.

Two-Way Shear (Punching Shear)

ACI Code Sec. 11.12.2 allows a shear strength V_c of footings without shear reinforcement for two-way shear action as follows:

$$V_c = \left(2 + \frac{4}{\beta_c}\right)\sqrt{f_c'}\, b_o d \le 4\sqrt{f_c'}\, b_o d \tag{50.125}$$

where β_c is the ratio of long side to short side of rectangular area, b_o is the perimeter of the critical section taken at $d/2$ from the loaded area (column section), and d is the effective depth of footing. This shear is a measure of the diagonal tension caused by the effect of the column load on the footing. Inclined cracks may occur in the footing at a distance $d/2$ from the face of the column on all sides. The footing will fail as the column tries to punch out part of the footing, as shown in Fig. 50.18.

One-Way Shear

For footings with bending action in one direction, the critical section is located at a distance d from the face of the column. The diagonal tension at section m-m in Fig. 50.19 can be checked as is done in beams. The allowable shear in this case is equal to

$$\phi V_c = 2\phi\sqrt{f_c'}\, bd \tag{50.126}$$

where b is the width of section m-m. The ultimate shearing force at section m-m can be calculated as follows:

$$V_u = q_u b\left(\frac{L}{2} - \frac{c}{2} - d\right) \tag{50.127}$$

where b is the side of footing parallel to section m-m.

Flexural Reinforcement and Footing Reinforcement

The theoretical sections for moment occur at face of the column (section n-n, Fig. 50.20). The bending moment in each direction of the footing must be checked and the appropriate reinforcement must be provided. In square footings the bending moments in both directions are equal. To determine the reinforcement required, the depth of the footing in each direction may be used. As the bars in one

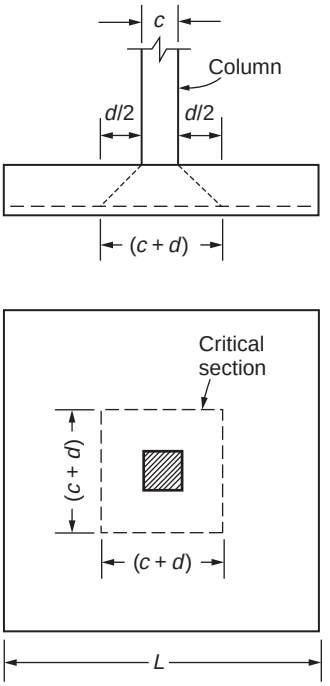

FIGURE 50.18 Punching shear (two-way). (*Source:* MacGregor, 1992.)

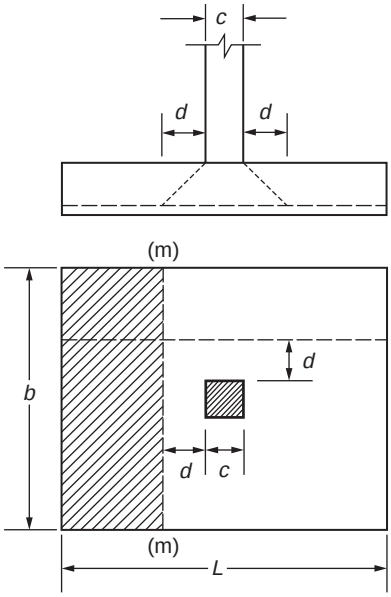

FIGURE 50.19 One-way shear. (*Source:* MacGregor, 1992.)

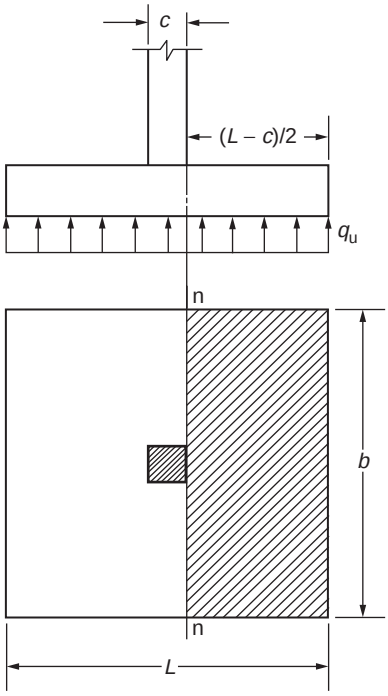

FIGURE 50.20 Critical section of bending moment. (*Source:* MacGregor, 1992.)

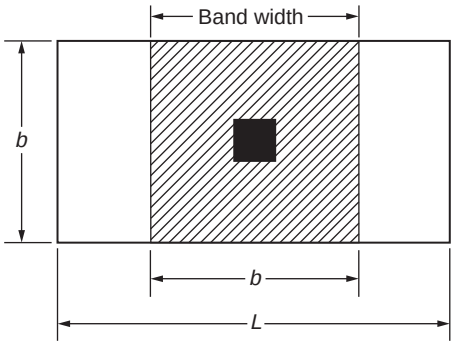

FIGURE 50.21 Band width for reinforcement distribution. (*Source:* MacGregor, 1992.)

direction rest on top of the bars in the other direction, the effective depth d varies with the diameter of the bars used. The value of d_{min} may be adopted.

The depth of footing is often controlled by the shear, which requires a depth greater than that required by the bending moment. The steel reinforcement in each direction can be calculated in the case of flexural members as follows:

$$A_s = \frac{M_u}{\phi f_y (d - a/2)} \tag{50.128}$$

The minimum steel percentage requirement in flexural members is equal to $200/f_y$. However, ACI Code Sec. 10.5.3 indicates that for structural slabs of uniform thickness, the minimum area and maximum spacing of steel in the direction of bending should be as required for shrinkage and temperature reinforcement. This last minimum steel reinforcement is very small and a higher minimum reinforcement ratio is recommended, but not greater than $200/f_y$.

The reinforcement in one-way footings and two-way footings must be distributed across the entire width of the footing. In the case of two-way rectangular footings, ACI Code Sec. 15.4.4 specifies that in the long direction the total reinforcement must be placed uniformly within a band width equal to the length of the short side of the footing according to

$$\frac{\text{Reinforcement band width}}{\text{Total reinforcement in short direction}} = \frac{2}{\beta + 1} \tag{50.129}$$

where β is the ratio of the long side to the short side of the footing. The band width must be centered on the centerline of the column (Fig. 50.21). The remaining reinforcement in the short direction must be uniformly distributed outside the band width. This remaining reinforcement percentage should not be less than required for shrinkage and temperature.

When structural steel columns or masonry walls are used, the critical sections for moments in footings are taken at halfway between the middle and the edge of masonry walls, and halfway between the face of the column and the edge of the steel base place (ACI Code Sec. 15.4.2).

Bending Capacity of Column at Base

The loads from the column act on the footing at the base of the column, on an area equal to the area of the column cross section. Compressive forces are transferred to the footing directly by bearing on the concrete. Tensile forces must be resisted by reinforcement, neglecting any contribution by concrete.

Forces acting on the concrete at the base of the column must not exceed the bearing strength of concrete as specified by the ACI Code Sec. 10.15:

$$N = \phi (0.85 f_c' A_1) \tag{50.130}$$

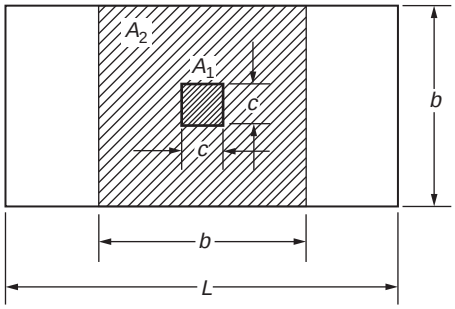

FIGURE 50.22 Bearing areas on footings. $A_1 = c^2$, $A_2 = b^2$. (*Source:* MacGregor, 1992.)

where ϕ is 0.7 and A_1 is the bearing area of the column. The value of the bearing strength given in Eq. (50.130) may be multiplied by a factor $\sqrt{A_2/A_1} \leq 2.0$ for bearing on footings when the supporting surface is wider on all sides other than the loaded area. Here A_2 is the area of the part of the supporting footing that is geometrically similar to and concentric with the loaded area (Fig. 50.22). Since $A_2 > A_1$, the factor $\sqrt{A_2/A_1}$ is greater than unity, indicating that the allowable bearing strength is increased because of the lateral support from the footing area surrounding the column base. If the calculated bearing force is greater than N or the modified one with $r\sqrt{A_2/A_1}$, reinforcement must be provided to transfer the excess force. This is achieved by providing dowels or extending the column bars into the footing. If the calculated bearing force is less than either N or the modified one with $r\sqrt{A_2/A_1}$, then minimum reinforcement must be provided. ACI Code Sec. 15.8.2 indicates that the minimum area of the dowel reinforcement is at least $0.005A_g$ but not less than 4 bars, where A_g is the gross area of the column section of the supported member. The minimum reinforcement requirements apply to the case in which the calculated bearing forces are greater than N or the modified one with $r\sqrt{A_2/A_1}$.

Dowel on Footings

It was explained earlier that dowels are required in any case, even if the bearing strength is adequate. The ACI Code specifies a minimum steel ratio $\rho = 0.005$ of the column section as compared to $\rho = 0.01$ as minimum reinforcement for the column itself. The minimum number of dowel bars needed is four; these may be placed at the four corners of the column. The dowel bars are usually extended into the footing, bent at their ends, and tied to the main footing reinforcement.

ACI Code Sec. 15.8.2 indicates that #14 and #18 longitudinal bars, in compression only, may be lap-spliced with dowels. Dowels should not be larger than #11 bar and should extend (1) into supported member a distance not less than the development length of #14 or 18″ bars or the splice length of the dowels — whichever is greater, and (2) into the footing a distance not less than the development length of the dowels.

Development Length of the Reinforcing Bars

The critical sections for checking the development length of the reinforcing bars are the same as those for bending moments. Calculated tension or compression in reinforcement at each section should be developed on each side of that section by embedment length, hook (tension only) or mechanical device, or a combination thereof. The development length for a compression bar is

$$l_d = 0.02 f_y d_b \sqrt{f'_c} \tag{50.131}$$

but not less than $0.0003 f_y d_b \geq 8$ in. For other values, refer to ACI Code, Chapter 12. Dowels bars must also be checked for proper development length.

Differential Settlement

Footings usually support the following loads:

- Dead loads from the substructure and superstructure
- Live loads resulting from materials or occupancy
- Weight of materials used in backfilling
- Wind loads

Each footing in a building is designed to support the maximum load that may occur on any column due to the critical combination of loadings, using the allowable soil pressure.

The dead load, and maybe a small portion of the live load, may act continuously on the structure. The rest of the live load may occur at intervals and on some parts of the structure only, causing different loadings on columns. Consequently, the pressure on the soil under different loadings will vary according to the loads on the different columns, and differential settlement will occur under the various footings of one structure. Since partial settlement is inevitable, the problem is defined by the amount of differential settlement that the structure can tolerate. The amount of differential settlement depends on the variation in the compressibility of the soils, the thickness of the compressible material below foundation level, and the stiffness of the combined footing and superstructure. Excessive differential settlement results in cracking of concrete and damage to claddings, partitions, ceilings, and finishes.

For practical purposes it can be assumed that the soil pressure under the effect of sustained loadings is the same for all footings, thus causing equal settlements. The sustained load (or the usual load) can be assumed equal to the dead load plus a percentage of the live load, which occurs very frequently on the structure. Footings then are proportioned for these sustained loads to produce the same soil pressure under all footings. In no case is the allowable soil bearing capacity to be exceeded under the dead load plus the maximum live load for each footing.

Wall Footings

The spread footing under a wall [Fig. 50.16(a)] distributes the wall load horizontally to preclude excessive settlement. The wall should be so located on the footings as to produce uniform bearing pressure on the soil (Fig. 50.23), ignoring the variation due to bending of the footing. The pressure is determined by dividing the load per foot by the footing width.

The footing acts as a cantilever on opposite sides of the wall under downward wall loads and upward soil pressure. For footings supporting concrete walls, the critical section for bending moment is at the face of the wall; for footings under masonry walls, halfway between the middle and edge of the wall.

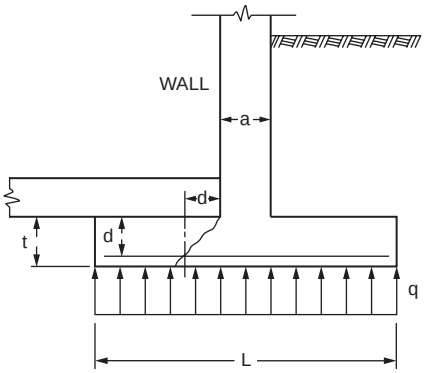

FIGURE 50.23 Reinforced-concrete wall footing. (*Source:* Wang and Salmon, 1985.)

Hence, for a one-foot-long strip of symmetrical concrete-wall footing, symmetrically loaded, the maximum moment, ft-lb, is

$$M_u = \frac{1}{8} q_u (L - a)^2 \tag{50.132}$$

where q_u = the uniform pressure on soil (lb/ft^2)
L = the width of footing (ft)
a = wall thickness (ft)

For determining shear stresses, the vertical shear force is computed on the section located at a distance d from the face of the wall. Thus,

$$V_u = q_u \left(\frac{L - a}{2} - L \right) \tag{50.133}$$

The calculation of development length is based on the section of maximum moment.

Single-Column Spread Footings

The spread footing under a column [Fig. 50.16(b–d)] distributes the column load horizontally to prevent excessive total and differential settlement. The column should be located on the footing so as to produce uniform bearing pressure on the soil, ignoring the variation due to bending of the footing. The pressure equals the load divided by the footing area.

In plan, single-column footings are usually square. Rectangular footings are used if space restrictions dictate this choice or if the supported columns are of strongly elongated rectangular cross section. In the simplest form, they consist of a single slab [Fig. 50.16(b)]. Another type is that of Fig. 50.16(c), where a pedestal or cap is interposed between the column and the footing slab; the pedestal provides for a more favorable transfer of load and in many cases is required in order to provide the necessary development length for dowels. This form is also known as a *stepped footing*. All parts of a stepped footing must be poured in a single pour in order to provide monolithic action. Sometimes sloped footings like those in Fig. 50.16(d) are used. They require less concrete than stepped footings, but the additional labor necessary to produce the sloping surfaces (formwork, etc.) usually makes stepped footings more economical. In general, single-slab footings [Fig. 16(b)] are most economical for thicknesses up to 3 ft.

The required bearing area is obtained by dividing the total load, including the weight of the footing, by the selected bearing pressure. Weights of footings, at this stage, must be estimated and usually amount to 4 to 8% of the column load, the former value applying to the stronger types of soils.

Once the required footing area has been established, the thickness h of the footing must be determined. In single footings the effective depth d is mostly governed by shear. Two different types of shear strength are distinguished in single footings: two-way (or punching) shear and one-way (or beam) shear. Based on the Eqs. (50.125) and (50.126) for punching and one-way shear strength, the required effective depth of footing d is calculated.

Single-column footings represent, as it were, cantilevers projecting out from the column in both directions and loaded upward by the soil pressure. Corresponding tension stresses are caused in both these directions at the bottom surface. Such footings are therefore reinforced by two-layers of steel, perpendicular to each other and parallel to the edge. The steel reinforcement in each direction can be calculated using Eq. (50.128). The critical sections for development length of footing bars are the same as those for bending. Development length may also have to be checked at all vertical planes in which changes of section or of reinforcement occur, as at the edges of pedestals or where part of the reinforcement may be terminated.

When a column rests on a footing or pedestal, it transfers its load to only a part of the total area of the supporting member. The adjacent footing concrete provides lateral support to the directly loaded

part of the concrete. This causes triaxial compression stresses that increase the strength of the concrete, which is loaded directly under the column. The design bearing strength of concrete must not exceed the one given in Eq. (50.130) for forces acting on the concrete at the base of column and the modified one with $r\sqrt{A_2/A_1}$ for supporting area wider than the loaded area. If the calculated bearing force is greater than the design bearing strength, reinforcement must be provided to transfer the excess force. This is done either by extending the column bars into the footing or by providing dowels, which are embedded in the footing and project above it.

Combined Footings

Spread footings that support more than one column or wall are known as *combined footings*. They can be divided into two categories: those that support two columns, and those that support more than two (generally large numbers of) columns.

In buildings where the allowable soil pressure is large enough for single footings to be adequate for most columns, two-column footings are seen to become necessary in two situations: (1) if columns are so close to the property line that single-column footings cannot be made without projecting beyond that line, and (2) if some adjacent columns are so close to each other that their footings would merge.

When the bearing capacity of the subsoil is low so that large bearing areas become necessary, individual footings are replaced by continuous strip footings, which support more than two columns and usually all columns in a row. Mostly, such strips are arranged in both directions, in which case a grid foundation is obtained, as shown in Fig. 50.24. Such a grid foundation can be done by single footings because the individual strips of the grid foundation represent continuous beams whose moments are much smaller than the cantilever moments in large single footings that project far out from the column in all four directions.

For still lower bearing capacities, the strips are made to merge, resulting in a mat foundation, as shown in Fig. 50.25. That is, the foundation consists of a solid reinforced concrete slab under the entire building. In structural action such a mat is very similar to a flat slab or a flat plate, upside down — that is, loaded upward by the bearing pressure and downward by the concentrated column reactions. The mat foundation evidently develops the maximum available bearing area under the building. If the soil's capacity is so low that even this large bearing area is insufficient, some form of deep foundation, such as piles or caissons, must be used.

Grid and mat foundations may be designed with the column pedestals — as shown in Figs. 50.24 and 50.25 — or without them, depending on whether or not they are necessary for shear strength and the development length of dowels. Apart from developing large bearing areas, another advantage of grid and mat foundations is that their continuity and rigidity help in reducing differential settlements of individual columns relative to each other, which may otherwise be caused by local variations in the quality of subsoil,

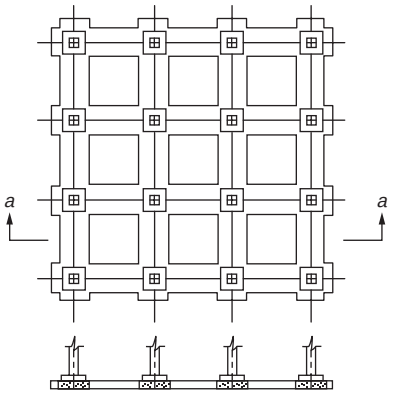

FIGURE 50.24 Grid foundation. (*Source:* Wang and Salmon, 1985).

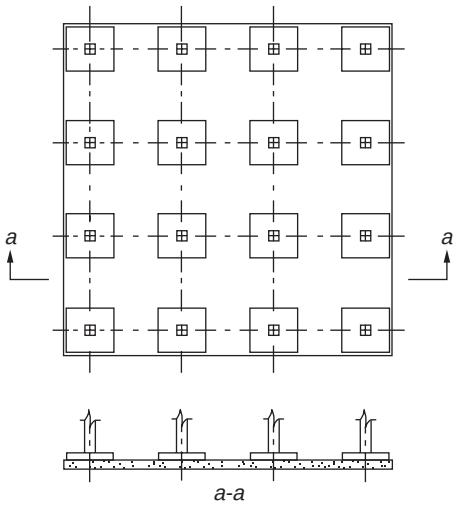

FIGURE 50.25 Mat foundation. (*Source:* Wang and Salmon, 1985.)

or other causes. For this purpose, continuous spread foundations are frequently used in situations where the superstructure or the type of occupancy provides unusual sensitivity to differential settlement.

Two-Column Footings

The ACI Code does not provide a detailed approach for the design of combined footings. The design, in general, is based on an empirical approach. It is desirable to design combined footings so that the centroid of the footing area coincides with the resultant of the two column loads. This produces uniform bearing pressure over the entire area and forestalls a tendency for the footings to tilt. In plan, such footings are rectangular, trapezoidal, or T shaped, the details of the shape being arranged to produce coincidence of centroid and resultant. The simple relationships of Fig. 50.26 facilitate the determination of the shapes of the bearing area [Fintel, 1985]. In general, the distances m and n are given, the former being the distance from the center of the exterior column to the property line and the latter the distance from that column to the resultant of both column loads.

Another expedient, which is used if a single footing cannot be centered under an exterior column, is to place the exterior column footing eccentricity and to connect it with the nearest interior column by a beam or strap. This strap, being counterweighted by the interior column load, resists the tilting tendency of the eccentric exterior footings and equalizes the pressure under it. Such foundations are known as *strap, cantilever,* or *connected footings.*

The strap may be designed as a rectangular beam spacing between the columns. The loads on it include its own weight (when it does not rest on the soil) and the upward pressure from the footings. Width of the strap usually is selected arbitrarily as equal to that of the largest column plus 4 to 8 inches so that column forms can be supported on top of the strap. Depth is determined by the maximum bending moment. The main reinforcing in the strap is placed near the top. Some of the steel can be cut off where not needed. For diagonal tension, stirrups normally will be needed near the columns (Fig. 50.27). In addition, longitudinal placement steel is set near the bottom of the strap, plus reinforcement to guard against settlement stresses.

The footing under the exterior column may be designed as a wall footing. The portions on opposite sides of the strap act as cantilevers under the constant upward pressure of the soil. The interior footing should be designed as a single-column footing. The critical section for punching shear, however, differs from that for a conventional footing. This shear should be computed on a section at a distance $d/2$ from the sides and extending around the column at a distance $d/2$ from its faces, where d is the effective depth of the footing.

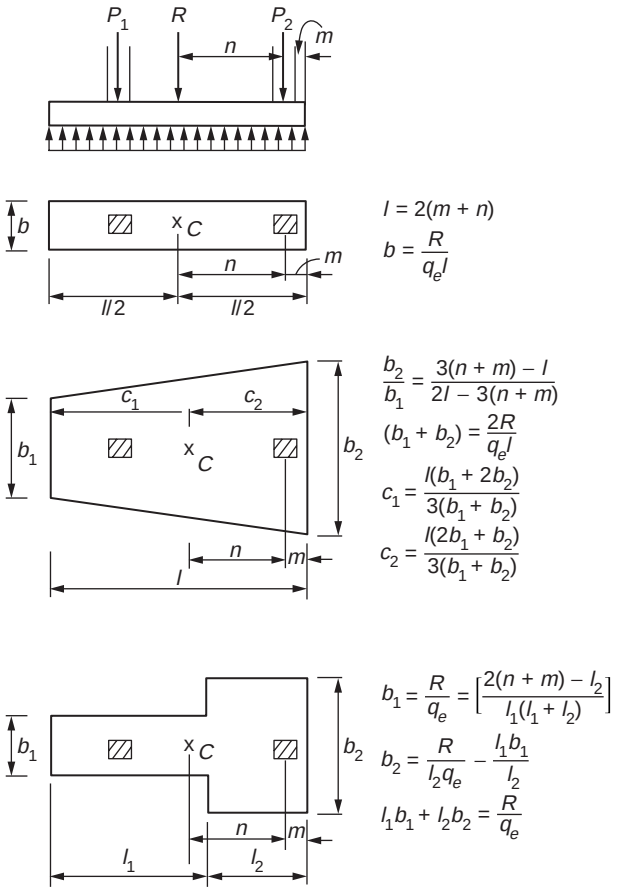

FIGURE 50.26 Two-column footings. (*Source:* Fintel, 1985.)

Strip, Grid, and Mat Foundations

In the case of heavily loaded columns, particularly if they are to be supported on relatively weak or uneven soils, continuous foundations may be necessary. They may consist of a continuous strip footing supporting all columns in a given row, or more often, of two sets of such strip footings intersecting at right angles so that they form one continuous grid foundation (Fig. 50.24). For even larger loads or weaker soils the strips are made to merge, resulting in a mat foundation (Fig. 50.25).

For the design of such continuous foundations it is essential that reasonably realistic assumptions be made regarding the distribution of bearing pressures, which act as upward loads on the foundation. For compressible soils it can be assumed in first approximation that the deformation or settlement of the soil at a given location and the bearing pressure at that location are proportional to each other. If columns are spaced at moderate distances and if the strip, grid, or mat foundation is very rigid, the settlements in all portions of the foundation will be substantially the same. This means that the bearing pressure, also known as *subgrade reaction,* will be the same provided that the centroid of the foundation coincides with the resultant of the loads. If they do not coincide, then for such rigid foundations the subgrade reaction can be assumed as linear and determine from statics in the same manner as discussed for single footings. In this case, all loads — the downward column loads as well as the upward-bearing pressures — are known. Hence, moments and shear forces in the foundation can be found by statics alone. Once these are determined, the design of strip and grid foundations is similar to that of inverted continuous beams, and design of mat foundations is similar to that of inverted flat slabs or plates.

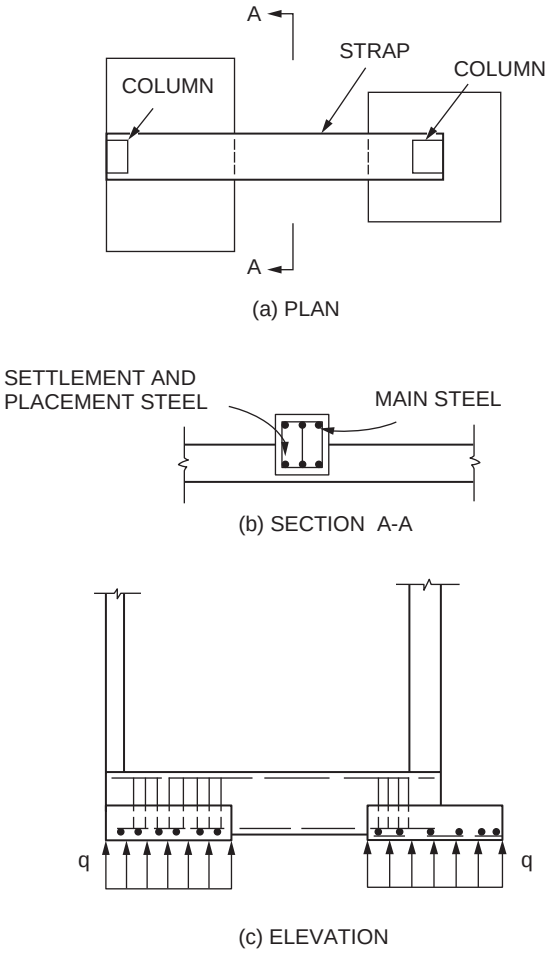

FIGURE 50.27 Strap (cantilever) footing. (*Source:* Fintel, 1985.)

On the other hand, if the foundation is relatively flexible and the column spacing large, settlements will no longer be uniform or linear. For one thing, the more heavily loaded columns will cause larger settlements, and thereby larger subgrade reactions, than the lighter ones. Also, since the continuous strip or slab midway between columns will deflect upward relative to the nearby columns soil settlement — and thereby the subgrade reaction — will be smaller midway between columns rather than directly at the columns. This is shown schematically in Fig. 50.28. In this case the subgrade reaction can no longer be assumed as uniform. A reasonably accurate but fairly complex analysis can then be made using the theory of beams on elastic foundations.

A simplified approach has been developed that covers the most frequent situations of strip and grid foundations [ACI Committee 436, 1966]. The method first defines the conditions under which a foundation can be regarded as rigid so that uniform or overall linear distribution of subgrade reactions can be assumed. This is the case when the average of two adjacent span lengths in a continuous strip does not exceed $1.75/\lambda$, provided also that the adjacent span and column loads do not differ by more than 20% of the larger value. Here,

$$\lambda = 4\sqrt{\frac{k_s b}{3E_c I}} \tag{50.134}$$

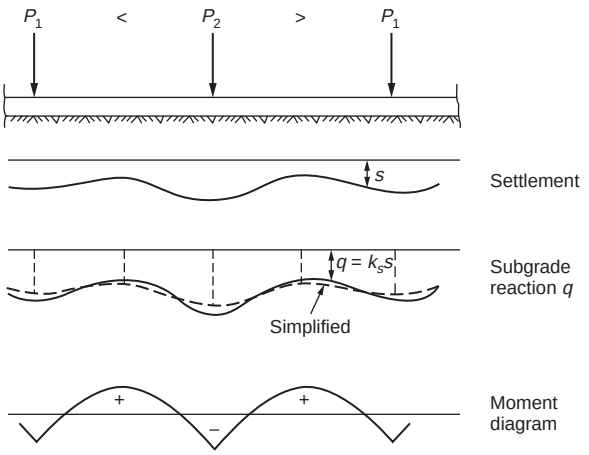

FIGURE 50.28 Strip footing. (*Source:* Fintel, 1985.)

where $k_s = S\,k_s'$

k_s' = coefficient of subgrade reaction as defined in soils mechanics, basically force per unit area required to produce unit settlement, kips/ft^3

b = width of footing, ft

E_c = modulus of elasticity of concrete, kips/ft^2

I = moment of inertia of footing, ft^4

S = shape factor, being $[(b + 1)/2b]^2$ for granular soils and $(n + 0.5)/1.5n$ for cohesive soils, where n is the ratio of longer to shorter side of strip

If the average of two adjacent spans exceeds $1.75/\lambda$, the foundation is regarded as flexible. Provided that adjacent spans and column loads differ by no more than 20%, the complex curvilinear distribution of subgrade reaction can be replaced by a set of equivalent trapezoidal reactions, which are also shown in Fig. 50.28. The report of ACI Committee 436 contains fairly simple equations for determining the intensities of the equivalent pressures under the columns and at the middle of the spans and also gives equations for the positive and negative moments caused by these equivalent subgrade reactions. With this information, the design of continuous strip and grid footings proceeds similarly to that of footings under two columns.

Mat foundations likewise require different approaches, depending on whether they can be classified as rigid or flexible. As in strip footings, if the column spacing is less than $1/\lambda$, the structure may be regarded as rigid, the soil pressure can be assumed as uniformly or linearly distributed, and the design is based on statics. On the other hand, when the foundation is considered flexible as defined above, and if the variation of adjacent column loads and spans is not greater than 20%, the same simplified procedure as for strip and grid foundations can be applied to mat foundations. The mat is divided into two sets of mutually perpendicular strip footings of width equal to the distance between midspans, and the distribution of bearing pressures and bending moments is carried out for each strip. Once moments are determined, the mat is in essence treated the same as a flat slab or plate, with the reinforcement allocated between column and middle strips as in these slab structures.

This approach is feasible only when columns are located in a regular rectangular grid pattern. When a mat that can be regarded as rigid supports columns at random locations, the subgrade reactions can still be taken as uniform or as linearly distributed and the mat analyzed by statics. If it is a flexible mat that supports such randomly located columns, the design is based on the theory of plates on elastic foundation.

Footings on Piles

If the bearing capacity of the upper soil layers is insufficient for a spread foundation, but firmer strata are available at greater depth, piles are used to transfer the loads to these deeper strata. Piles are generally arranged in groups or clusters, one under each column. The group is capped by a spread footing or cap that distributes the column load to all piles in the group. Reactions on caps act as concentrated loads at the individual piles, rather than as distributed pressures. If the total of all pile reactions in a cluster is divided by area of the footing to obtain an equivalent uniform pressure, it is found that this equivalent pressure is considerably higher in pile caps than for spread footings. Thus, it is in any event advisable to provide ample rigidity — that is, depth for pile caps — in order to spread the load evenly to all piles.

As in single-column spread footings, the effective portion of allowable bearing capacities of piles, R_a, available to resist the unfactored column loads is the allowable pile reaction less the weight of footing, backfill, and surcharge per pile. That is,

$$R_e = R_a - W_f \tag{50.135}$$

where W_f is the total weight of footing, fill, and surcharge divided by the number of piles.

Once the available or effective pile reaction R_e is determined, the number of piles in a concentrically loaded cluster is the integer next larger than

$$n = \frac{D+L}{R_e} \tag{50.136}$$

The effects of wind and earthquake moments at the foot of the columns generally produce an eccentrically loaded pile cluster in which different piles carry different loads. The number and location of piles in such a cluster is determined by successive approximation from the condition that the load on the most heavily loaded pile should not exceed the allowable pile reaction R_a. Assuming a linear distribution of pile loads due to bending, the maximum pile reaction is

$$R_{\max} = \frac{P}{n} + \frac{M}{I_{pg}/C} \tag{50.137}$$

where P = the maximum load (including weight of cap, backfill, etc.)
M = the moment to be resisted by the pile group, both referred to the bottom of the cap
I_{pg} = the moment of inertia of the entire pile group about the centroidal axis about which bending occurs
c = the distance from that axis to the extreme pile

Piles are generally arranged in tight patterns, which minimizes the cost of the caps, but they cannot be placed closer than conditions of deriving and of undisturbed carrying capacity will permit. AASHTO requires that piles be spaced at least 2 ft 6 in. center to center and that the distance from the side of a pile to the nearest edge of the footing be 9 in. or more.

The design of footings on piles is similar to that of single-column spread footings. One approach is to design the cap for the pile reactions calculated for the factored column loads. For a concentrically loaded cluster this would give $R_u = (1.4D + 1.7L)/n$. However, since the number of piles was taken as the next larger integer according to Eq. (50.137), determining R_u in this manner can lead to a design where the strength of the cap is less than the capacity of the pile group. It is therefore recommended that the pile reaction for strength design be taken as

$$R_u = R_e \times \text{Average load factor} \tag{50.138}$$

where the average load factor is $(1.4D + 1.7L)/(D + L)$. In this manner the cap is designed to be capable of developing the full allowable capacity of the pile group.

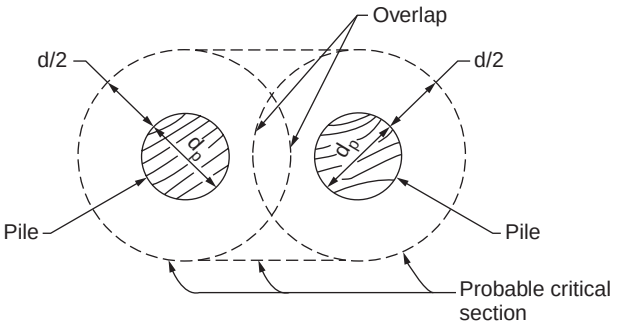

FIGURE 50.29 Modified critical section for shear with overlapping critical perimeters.

As in single-column spread footings, the depth of the pile cap is usually governed by shear. In this regard both punching and one-way shear need to be considered. The critical sections are the same as explained earlier under "Two-Way Shear (Punching Shear)" and "One-Way Shear." The difference is that shears on caps are caused by concentrated pile reactions rather than by distributed bearing pressures. This poses the question of how to calculate shear if the critical section intersects the circumference of one or more piles. For this case the ACI Code accounts for the fact that pile reaction is not really a point load, but is distributed over the pile-bearing area. Correspondingly, for piles with diameters d_p, it stipulates as follows:

> Computation of shear on any section through a footing on piles shall be in accordance with the following:
>
> (a) The entire reaction from any pile whose center is located $d_p/2$ or more outside this section shall be considered as producing shear on that section.
>
> (b) The reaction from any pile whose center is located $d_p/2$ or more inside the section shall be considered as producing no shear on that section.
>
> (c) For intermediate portions of the pile center, the portion of the pile reaction to be considered as producing shear on the section shall be based on straight-line interpolation between the full value at $d_p/2$ outside the section and zero at $d_p/2$ inside the section [1992].

In addition to checking punching and one-way shear, punching shear must be investigated for the individual pile. Particularly in caps on a small number of heavily loaded piles, it is this possibility of a pile punching upward through the cap which may govern the required depth. The critical perimeter for this action, again, is located at a distance $d/2$ outside the upper edge of the pile. However, for relatively deep caps and closely spaced piles, critical perimeters around adjacent piles may overlap. In this case, fracture, if any, would undoubtedly occur along an outward-slanting surface around both adjacent piles. For such situations the critical perimeter is so located that its length is a minimum, as shown for two adjacent piles in Fig. 50.29.

50.11 Walls

Panel, Curtain, and Bearing Walls

As a general rule, the exterior walls of a reinforced concrete building are supported at each floor by the skeleton framework, their only function being to enclose the building. Such walls are called *panel walls.* They may be made of concrete (often precast), cinder concrete block, brick, tile blocks, or insulated metal panels. The thickness of each of these types of panel walls will vary according to the material, type of construction, climatological conditions, and the building requirements governing the particular locality in which the construction takes place. The pressure of the wind is usually the only load that is considered in determining the structural thickness of a wall panel, although in some cases exterior walls are used as diaphragms to transmit forces caused by horizontal loads down to the building foundations.

Curtain walls are similar to panel walls except that they are not supported at each story by the frame of the building; rather, they are self supporting. However, they are often anchored to the building frame at each floor to provide lateral support.

A bearing wall may be defined as one that carries any vertical load in addition to its own weight. Such walls may be constructed of stone masonry, brick, concrete block, or reinforced concrete. Occasional projections or pilasters add to the strength of the wall and are often used at points of load concentration. Bearing walls may be of either single or double thickness, the advantage of the latter type being that the air space between the walls renders the interior of the building less liable to temperature variation and makes the wall itself more nearly moistureproof. On account of the greater gross thickness of the double wall, such construction reduces the available floor space.

According to ACI Code Sec. 14.5.2 the load capacity of a wall is given by

$$\phi P_{nw} = 0.55\phi f'_c A_g \left[1 - \left(\frac{kl_c}{32h}\right)^2\right] \tag{50.139}$$

where ϕP_{nw} = design axial load strength
A_g = gross area of section, in.^{2}
l_c = vertical distance between supports, in.
h = thickness of wall, in.
ϕ = 0.7

and where the effective length factor k is taken as 0.8 for walls restrained against rotation at top or bottom or both, 1.0 for walls unrestrained against rotation at both ends, and 2.0 for walls not braced against lateral translation.

In the case of concentrated loads, the length of the wall to be considered as effective for each should not exceed the center-to-center distance between loads; nor should it exceed the width of the bearing plus 4 times the wall thickness. Reinforced concrete bearing walls should have a thickness of at least 1/25 times the unsupported height or width, whichever is shorter. Reinforced concrete bearing walls of buildings should be not less than 4 in. thick.

Minimum ratio of horizontal reinforcement area to gross concrete area should be 0.0020 for deformed bars not larger than #5 — with specified yield strength not less than 60,000 psi or 0.0025 for other deformed bars — or 0.0025 for welded wire fabric not larger than W31 or D31. Minimum ratio of vertical thermal area to gross concrete area should be 0.0012 for deformed bars not larger than #5 — with specified yield strength not less than 60,000 psi or 0.0015 for other deformed bars — or 0.0012 for welded wire fabric not larger than W31 or D31. In addition to the minimum reinforcement requirement, not less than two #5 bars shall be provided around all window and door openings. Such bars shall be extended to develop the bar beyond the corners of the openings but not less than 24 in.

Walls more than 10 in. thick should have reinforcement for each direction placed in two layers parallel with faces of wall. Vertical and horizontal reinforcement should not be spaced further apart than three times the wall thickness, or 18 in. Vertical reinforcement need not be enclosed by lateral ties if vertical reinforcement area is not greater than 0.01 times gross concrete area, or where vertical reinforcement is not required as compression reinforcement.

Quantity of reinforcement and limits of thickness mentioned above are waived where structural analysis shows adequate strength and stability. Walls should be anchored to intersecting elements such as floors, roofs, or to columns, pilasters, buttresses, and intersecting walls, or footings.

Basement Walls

In determining the thickness of basement walls, the lateral pressure of the earth, if any, must be considered in addition to other structural features. If it is part of a bearing wall, the lower portion may be designed either as a slab supported by the basement and floors or as a retaining wall, depending upon the type of

construction. If columns and wall beams are available for support, each basement wall panel of reinforced concrete may be designed to resist the earth pressure as a simple slab reinforced in either one or two directions. A minimum thickness of 7.5 in. is specified for reinforced concrete basement walls. In wet ground a minimum thickness of 12 in. should be used. In any case, the thickness cannot be less than that of the wall above.

Care should be taken to brace a basement wall thoroughly from the inside (1) if the earth is backfilled before the wall has obtained sufficient strength to resist the lateral pressure without such assistance, or (2) if it is placed before the first-floor slab is in position.

Partition Walls

Interior walls used for the purpose of subdividing the floor area may be made of cinder block, brick, precast concrete, metal lath and plaster, clay tile, or metal. The type of wall selected will depend upon the fire resistance required; flexibility of rearrangement; ease with which electrical conduits, plumbing, etc., can be accommodated; and architectural requirements.

Shear Walls

Horizontal forces acting on buildings — for example, those due to wind of seismic action — can be resisted by a variety of means. Rigid-frame resistance of the structure, augmented by the contribution of ordinary masonry walls and partitions, can provide for wind loads in many cases. However, when heavy horizontal loading is likely — such as would result from an earthquake — reinforced concrete shear walls are used. These may be added solely to resist horizontal forces; alternatively, concrete walls enclosing stairways or elevator shafts may also serve as shear walls.

Figure 50.30 shows a building with wind or seismic forces represented by arrows acting on the edge of each floor or roof. The horizontal surfaces act as deep beams to transmit loads to vertical resisting elements A and B. These shear walls, in turn, act as cantilever beams fixed at their base to carry loads down to the foundation. They are subjected to (1) a variable shear, which reaches maximum at the base, (2) a bending moment, which tends to cause vertical tension near the loaded edge and compression at the far edge, and (3) a vertical compression due to ordinary gravity loading from the structure. For the building shown, additional shear walls C and D are provided to resist loads acting in the log direction of the structure.

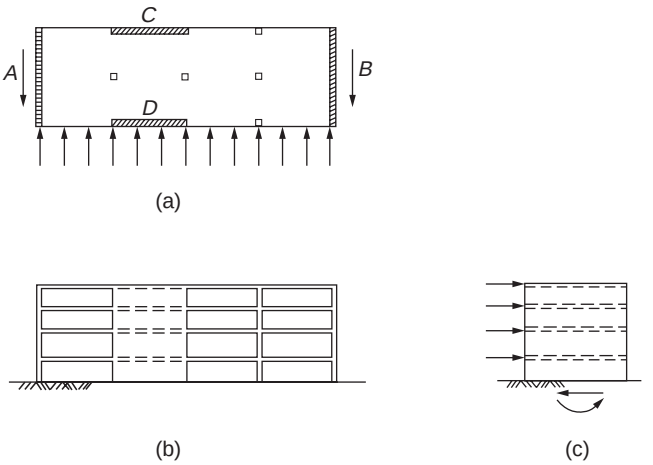

FIGURE 50.30 Building with shear walls subject to horizontal loads: (a) typical floor; (b) front elevation; (c) end elevation.

The design basis for shear walls, according to the ACI Code, is of the same general form as that used for ordinary beams:

$$V_u \le \phi V_n \tag{50.140}$$

$$V_n = V_c + V_s \tag{50.141}$$

Shear strength V_n at any horizontal section for shear in plane of wall should not be taken greater than $10\sqrt{f_c'}h_d$. In this and all other equations pertaining to the design of shear walls, the distance of d may be taken equal to $0.8l_w$. A larger value of d, equal to the distance from the extreme compression face to the center of force of all reinforcement in tension, may be used when determined by a strain compatibility analysis.

The value of V_c, the nominal shear strength provided by the concrete, may be based on the usual equations for beams, according to ACI Code. For walls subjected to vertical compression,

$$V_c = 2\sqrt{f_c'}hd \tag{50.142}$$

and for walls subjected to vertical tension N_u,

$$V_c = 2\left(1 + \frac{N_u}{500A_g}\right)\sqrt{f_c'}hd \tag{50.143}$$

where N_u is the factored axial load in pounds, taken negative for tension, and A_g is the gross area of horizontal concrete section in square inches. Alternatively, the value of V_c may be based on a more detailed calculation, as the lesser of

$$V_c = 3.3\sqrt{f_c'}hd + \frac{N_u d}{4l_w} \tag{50.144}$$

or

$$V_c = \left[0.6\sqrt{f_c'} + \frac{l_w\left(1.25\sqrt{f_c'} + 0.2N_u/l_w h\right)}{M_u/V_u - l_w/2}\right]hd \tag{50.145}$$

Eq. (50.144) corresponds to the occurrence of a principal tensile stress of approximately $4\sqrt{f_c'}$ at the centroid of the shear-wall cross section. Eq. (50.145) corresponds approximately to the occurrence of a flexural tensile stress of $6\sqrt{f_c'}$ at a section $l_w/2$ above the section being investigated. Thus the two equations predict, respectively, web-shear cracking and flexure-shear cracking. When the quantity $M_u/V_u - l_w/2$ is negative, Eq. (50.145) is inapplicable. According to the ACI Code, horizontal sections located closer to the wall base than a distance $l_w/2$ or $h_w/2$, whichever less, may be designed for the same V_c as that computed at a distance $l_w/2$ or $h_w/2$.

When the factored shear force V_u does not exceed $\phi V_c/2$, a wall may be reinforced according to the minimum requirements given in Sec. 12.1. When V_u exceeds $\phi V_c/2$, reinforcement for shear is to be provided according to the following requirements.

The nominal shear strength V_s provided by the horizontal wall steel is determined on the same basis as for ordinary beams:

$$V_s = \frac{A_v f_y d}{s_2} \tag{50.146}$$

where A_v = the area of horizontal shear reinforcement within vertical distance s_2 (in.^{2})
s_2 = the vertical distance between horizontal reinforcement, (in.)
f_y = the yield strength of reinforcement, psi

Substituting Eq. (50.146) into Eq. (50.141), then combining with Eq. (50.140), one obtains the equation for the required area of horizontal shear reinforcement within a distance s_2:

$$A_v = \frac{(V_u - \phi V_c)s_2}{\phi f_y d} \tag{50.147}$$

The minimum permitted ratio of horizontal shear steel to gross concrete area of vertical section, ρ_n, is 0.0025 and the maximum spacing s_2 is not to exceed $l_w/5$, $3h$, or 18 in.

Test results indicate that for low shear walls, vertical distributed reinforcement is needed as well as horizontal reinforcement. Code provisions require vertical steel of area A_h within a spacing s_1, such that the ratio of vertical steel to gross concrete area of horizontal section will not be less than

$$\rho_n = 0.0025 + 0.5\left(2.5 - \frac{h_w}{l_w}\right)(\rho_h - 0.0025) \tag{50.148}$$

nor less than 0.0025. However, the vertical steel ratio need not be greater than the required horizontal steel ratio. The spacing of the vertical bars is not to exceed $l_w/3$, $3h$, or 18 in.

Walls may be subjected to flexural tension due to overturning moment, even when the vertical compression from gravity loads is superimposed. In many but not all cases, vertical steel is provided, concentrated near the wall edges, as in Fig. 50.31. The required steel area can be found by the usual methods for beams.

The ACI Code contains requirements for the dimensions and details of structural walls serving as part of the earthquake-force resisting systems. The reinforcement ratio, ρ_v (= A_{sv}/A_{cv}; where A_{cv} is the net area of concrete section bounded by web thickness and length of section in the direction of shear force considered, and A_{sv} is the projection on A_{cv} of area of distributed shear reinforcement crossing the plane of A_{cv}), for structural walls should not be less than 0.0025 along the longitudinal and transverse axes. Reinforcement provided for shear strength should be continuous and should be distributed across the shear plane. If the design shear force does not exceed $A_{cv}\sqrt{f'_c}$, the shear reinforcement may conform to the reinforcement ratio given in Sec. 12.1. At least two curtains of reinforcement should be used in a wall if the in-plane factored shear force assigned to the wall exceeds $2A_{cv}\sqrt{f'_c}$. All continuous reinforcement in structural walls should be anchored or spliced in accordance with the provisions for reinforcement in tension for seismic design.

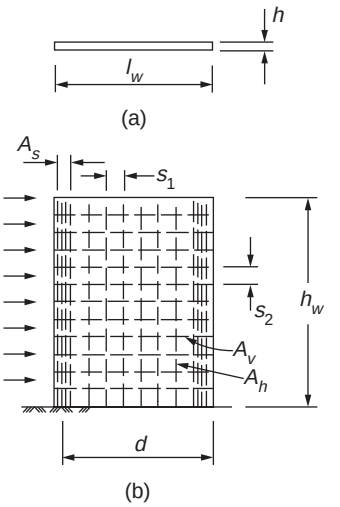

FIGURE 50.31 Geometry and reinforcement of typical shear wall; (a) cross section; (b) elevation.

Proportioning and details of structural walls that resist shear forces caused by earthquake motion is contained in the ACI Code Sec. 21.7.3.

51.1 Introduction

History

Composite construction as we know it today was first used in both a building and a bridge in the U.S. over a century ago. The first forms of composite structures incorporated the use of steel and concrete for flexural members, and the issue of longitudinal slip between these elements was soon identified [1].

Composite steel–concrete beams are the earliest form of the composite construction method. In the U.S. a patent by an American engineer was developed for the shear connectors at the top flange of a universal steel section to prevent longitudinal slip. This was the beginning of the development of fully composite systems in steel and concrete.

Concrete-encased steel sections were initially developed in order to overcome the problem of fire resistance and to ensure that the stability of the steel section was maintained throughout loading. The steel section and concrete act compositely to resist axial force and bending moments.

Composite tubular columns were developed because they provided permanent and integral formwork for a compression member and were instrumental in reducing construction times and consequently costs. They reduce the requirement of lateral reinforcement and costly tying, as well as providing easier connection to steel universal beams of a steel-framed structure.

Composite slabs have been introduced recently to consider the increase in strength that can be achieved if the profiled steel sheeting is taken into account in strength calculations. Composite slabs provide permanent and integral reinforcement, which eliminates the need for placing and stripping of plywood and timber formwork.

More recently, composite slab and beam systems have been developed for reinforced concrete framed construction; this provides advantages similar to those attributed to composite slabs for reinforced concrete slab and beam systems. These advantages include reduced construction time due to elimination of formwork, and elimination of excessive amounts of reinforcing steel. This subsequently reduces the span-to-depth ratios of typical beams and also reduces labor costs.

In this chapter, a thorough review is given of research into composite construction, including beams, columns, and profiled composite slabs. Furthermore, design methods are herein summarized for various pertinent failure modes.

Applications

Composite construction has been mainly applied to bridges and multistory buildings, with the more traditional forms of composite beams and composite columns. This section will look at the various applications of composite construction to both bridges and buildings.

Bridges

Composite construction with bridges allows the designer to take full advantage of the steel section in tension by shifting the compression force into the concrete slab in sagging bending. This is made possible through the transfer of longitudinal shear force through traditional headed-stud shear connectors. Headed-stud shear connectors not only provide the transfer of shear force, but also help to assist lateral stability of the section. The top flange of the steel section is essentially fully laterally restrained by the presence of shear connectors at very close spacing, as illustrated in Fig. 51.1.

Buildings

In steel-framed buildings throughout the world, composite floors are essentially the status quo in order to achieve an economic structure. This is for quite a few reasons. First, composite slabs allow reduced construction time by eliminating the need for propping and falsework in the slab-pouring phase. Furthermore, composite beams are economical, as they reduce the structural depth of the floor and thereby increase the available floors in a given building.

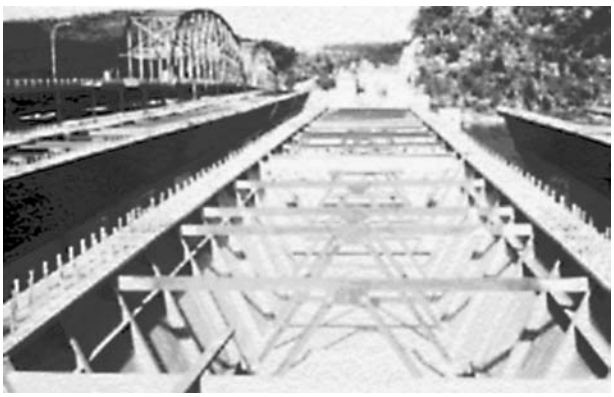

FIGURE 51.1 Composite box girders, Hawkesbury River Bridge, Australia.

FIGURE 51.2 Composite steel–concrete floors, Grosvenor Place, Sydney.

FIGURE 51.3 Composite steel–concrete beams and slabs, car park, Australia.

Other Structures

In addition to bridges and buildings, composite slab and beam systems have seen considerable application in car park structures. Steel and steel–concrete composite construction provide a lighter structure with reduced foundation loads, as shown in Fig. 51.3.

Case Studies

Grosvenor Place, Sydney

Grosvenor Place is considered to be one of the more prestigious office buildings in Sydney, which integrates modern technology within the building fabric to allow office inhabitants great flexibility in the manner in which it is occupied. The structural system of the building consists of an elliptical core with radial steel beams, which span to a perimeter steel frame. These composite beams span up to 15 m and are designed to be composite for strength and serviceability. Furthermore, the beams also take account of semirigidity by a specially designed connection to the elliptical core.

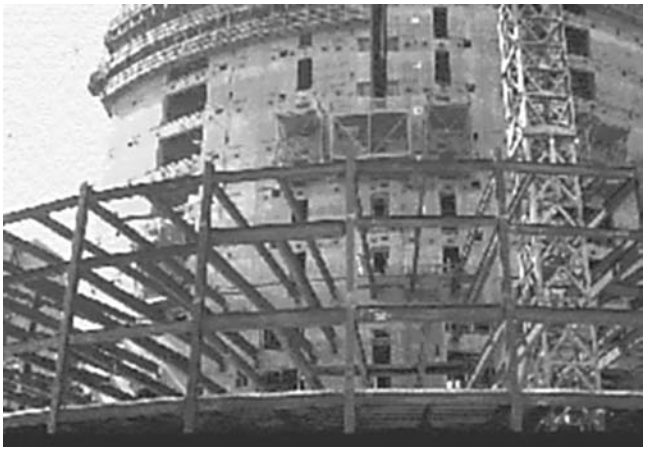

FIGURE 51.4 Grosvenor Place, Sydney.

The slabs are designed as one-way slabs, which consist of profiled steel sheeting spanning compositely between steel beams. The steel perimeter columns were designed as steel columns, although they are encased in concrete for fire resistance purposes, and are not designed compositely. The building is shown during construction in Fig. 51.4.

Forrest Place, Perth

Forrest Place is a multistory steel building that was designed with a rectangular concrete core to resist lateral loads and is combined with a perimeter steel frame, which consists of concrete-filled steel box columns. The beams were designed as steel–concrete composite beams, and the slabs are composite, utilizing permanent metal deck formwork. Elements of the building during construction are shown in Fig. 51.5.

FIGURE 51.5 Composite construction, Forrest Plaza, Perth.

Republic Plaza, Singapore

Republic Plaza is one of the tallest buildings in Singapore and thus required an efficient structural system for both gravity and lateral loading. The building consists of an internal reinforced concrete shear core, and beams span to an external perimeter frame, which is actually coupled to the core for the purposes of lateral load resistance. The perimeter frame consists of concrete-filled steel tubes that are designed compositely, as illustrated in Fig. 51.6.

One Raffles Link, Singapore

This is an eight-story building with wide-span column-free space specially tailored for banking and financial sector clients. The composite floor slab is supported by prefabricated cellform beams, which act as main girders, and standard sections as secondary floor beams. The 18-m span girders comprise 1300-mm-deep cellform sections with regularly spaced 900-mm-diameter circular web openings, spaced at 1350-mm centers. The beams are fabricated from 914-deep, 305-wide standard I sections, cut and welded to achieve the desired depth. The cellform beam, as shown in Fig. 51.7, was preferred because it is lightweight and permits the passing of all building services through the beam web. It therefore dispenses with the usual requirement of providing a dedicated services zone beneath the beams. The service cores of the building have been utilized for resisting lateral loads. This design approach allowed the entire structural steel frame to be designed and detailed as pin connected.

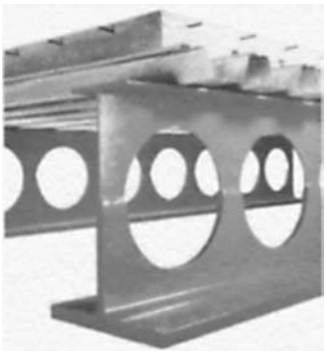

FIGURE 51.7 (a) One Raffles Link, Singapore. (b) Cellform beam.

51.2 Composite Construction Systems for Buildings

Composite Floor Systems

Composite floor systems typically involve structural steel beams, joists, girders, or trusses made composite via shear connectors, with a concrete floor slab to form an effective T-beam flexural member resisting primarily gravity loads [2]. The versatility of the system results from the inherent strength of the concrete floor component in compression and the tensile strength of the steel member. The main advantages of combining the use of steel and concrete materials for building construction are:

- Steel and concrete may be arranged to produce an ideal combination of strength, with concrete efficient in compression and steel in tension.
- Composite systems are lighter in weight (about 20 to 40% lighter than concrete construction). Because of their light weight, site erection and installation are easier, and thus labor costs can be minimized. Foundation costs can also be reduced.

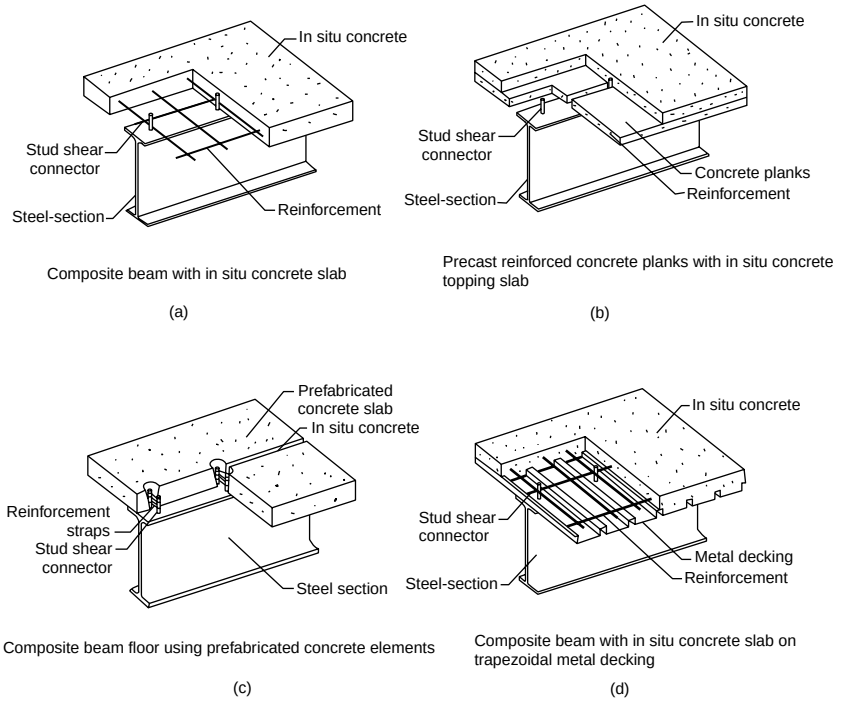

FIGURE 51.8 Composite beams.

- The construction time is reduced, since casting of additional floors may proceed without having to wait for the previously cast floors to gain strength. The steel decking system provides positive moment reinforcement for the composite floor, requires only small amounts of reinforcement to control cracking, and provides fire resistance.
- The construction of composite floors does not require highly skilled labor. The steel decking acts as permanent formwork. Composite beams and slabs can accommodate raceways for electrification, communication, and air distribution systems. The slab serves as a ceiling surface to provide easy attachment of a suspended ceiling.
- The composite slab, when fixed in place, can act as an effective in-plane diaphragm, which may provide effective lateral bracing to beams.
- Concrete provides corrosion and thermal protection to steel at elevated temperatures. Composite slabs of a 2-h fire rating can be easily achieved for most building requirements.

The floor slab may be constructed by the following methods:

- a flat-soffit reinforced concrete slab (Fig. 51.8(a))
- precast concrete planks with cast *in situ* concrete topping (Fig. 51.8(b))
- precast concrete slab with *in situ* grouting at the joints (Fig, 51.8(c))
- a metal steel deck with concrete, either composite or noncomposite (Fig. 51.8(d))

The composite action of the metal deck results from side embossments incorporated into the steel sheet profile. The composite floor system produces a rigid horizontal diaphragm, providing stability to the overall building system, while distributing wind and seismic shears to the lateral load-resisting systems.

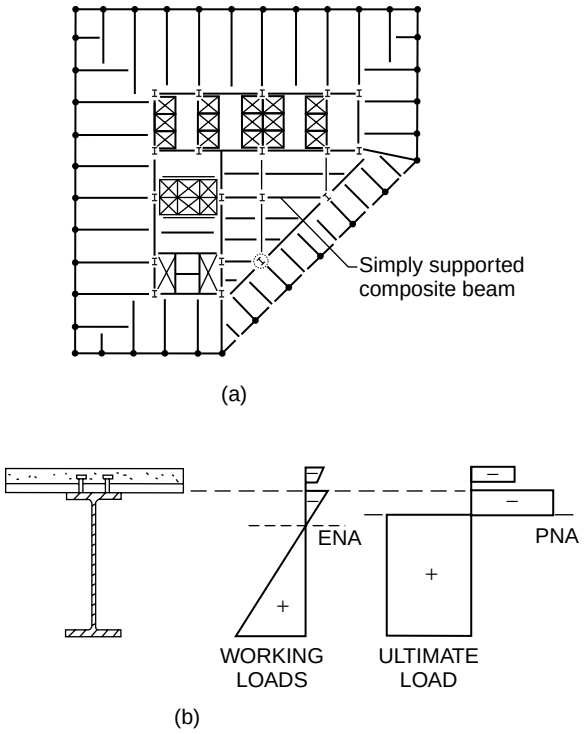

FIGURE 51.9 (a) Composite floor plan. (b) Stress distribution in a composite cross section.

Composite Beams and Girders

Steel and concrete composite beams may be formed by shear connectors connecting the concrete floor to the top flange of the steel member. Concrete encasement will provide fire resistance to the steel member. Alternatively, direct sprayed-on cementitious and board-type fireproofing materials may be used economically to replace the concrete insulation on the steel members. The most common arrangement found in composite floor systems is a rolled or built-up steel beam connected to a formed steel deck and concrete slab (Fig. 51.8(d)). The metal deck typically spans unsupported between steel members, while also providing a working platform for concreting work.

Figure 51.9(a) shows a typical building floor plan using composite steel beams. The stress distribution at working loads in a composite section is shown schematically in Fig. 51.9(b). The neutral axis is normally located very near to the top flange of the steel section. Therefore, the top flange is lightly stressed. From a construction point of view, a relatively wide and thick top flange must be provided for proper installation of shear studs and metal decking. However, the increased fabrication costs must be evaluated, which tend to offset the savings from material efficiency.

A number of composite girder forms allow passage of mechanical ducts and related services through the depth of the girder (Fig. 51.10). Successful composite beam design requires the consideration of various serviceability issues, such as long-term (creep) deflections and floor vibrations. Of particular concern is the occupant-induced floor vibrations. The relatively high flexural stiffness of most composite floor framing systems results in relatively low vibration amplitudes, and therefore is effective in reducing perceptibility. Studies have shown that short- to medium-span (6- to 12-m) composite floor beams perform quite well and have rarely been found to transmit annoying vibrations to the occupants. Particular care is required for long-span beams of more than 12 m.

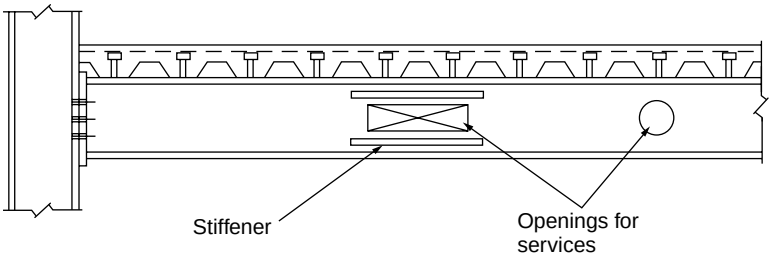

FIGURE 51.10 Web opening with horizontal reinforcement.

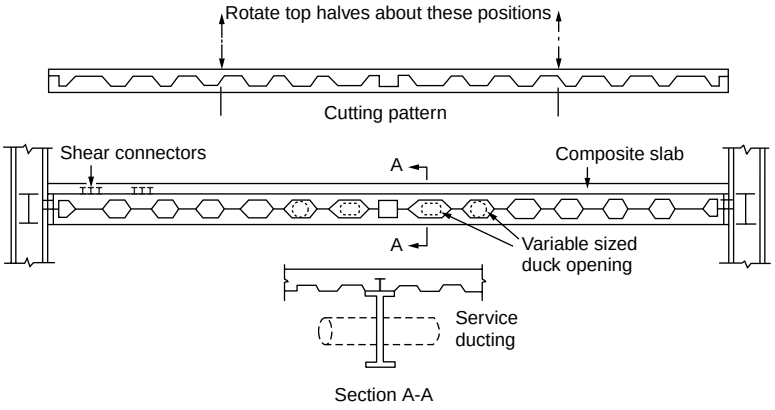

FIGURE 51.11 Composite castellated beams.

Long-Span Flooring Systems

Long spans impose a burden on the beam design in terms of a larger required flexural stiffness for serviceability design. Besides satisfying serviceability and ultimate strength limit states, the proposed system must also accommodate the incorporation of mechanical services within normal floor zones. Several practical options for long-span construction are available, and they are discussed in the following subsections.

Beams with Web Openings

Standard castellated beams can be fabricated from hot-rolled beams by cutting along a zigzag line through the web. The top and bottom half-beams are then displaced to form castellations (Fig. 51.11). Castellated composite beams can be used effectively for lightly serviced buildings. Although composite action does not increase the strength significantly, it increases the stiffness, and hence reduces deflection and the problem associated with vibration. Castellated beams have limited shear capacity and are best used as long-span secondary beams where loads are low or where concentrated loads can be avoided. Their use may be limited due to the increased fabrication cost and the fact that the standard castellated openings are not big enough to accommodate the large mechanical ductwork common in modern high-rise buildings.

Horizontal stiffeners may be required to strengthen the web opening, and they are welded above and below the opening. The height of the opening should not be more than 70% of the beam depth, and the length should not be more than twice the beam depth. The best location for the opening is in the low shear zone of the beams. This is because the webs do not contribute much to the moment resistance of the beam.

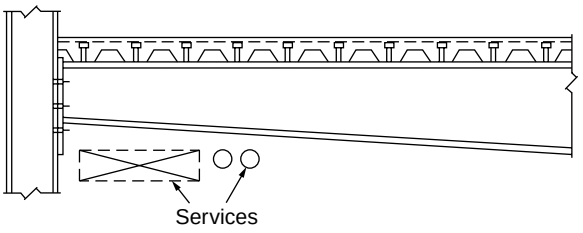

FIGURE 51.12 Tapered composite beam.

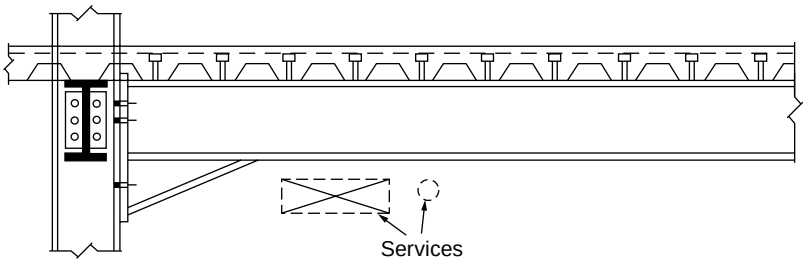

FIGURE 51.13 Haunched composite beam.

Fabricated Tapered Beams

The economic advantage of fabricated beams is that they can be designed to provide the required moment and shear resistance along the beam span in accordance with the loading pattern along the beam. Several forms of tapered beams are possible. A simply supported beam design with a maximum bending moment at the midspan would require that they all effectively taper to a minimum at both ends (Fig. 51.12), whereas a rigidly connected beam would have a minimum depth toward the midspan. To make the best use of this system, services should be placed toward the smaller depth of the beam cross sections. The spaces created by the tapered web can be used for running services of modest size (Fig. 51.12).

A hybrid girder can be formed with the top flange made of lower strength steel than the steel grade used for the bottom flange. The web plate can be welded to the flanges by double-sided fillet welds. Web stiffeners may be required at the change of section when the taper slope exceeds approximately 6°. Stiffeners are also required to enhance the shear resistance of the web, especially when the web slenderness ratio is too high. Tapered beams are found to be economical for spans up to 20 m.

Haunched Beams

Haunched beams are designed by forming a rigid moment connection between the beams and columns. The haunch connections offer restraints to the beam and help reduce midspan moment and deflection. The beams are designed in a manner similar to that of continuous beams. Considerable economy can be gained in sizing the beams using continuous design, which may lead to a reduction in beam depth up to 30% and deflection up to 50%.

The haunch may be designed to develop the required moment, which is larger than the plastic moment resistance of the beam. In this case, the critical section is shifted to the tip of the haunch. The depth of the haunch is selected based on the required moment at the beam-to-column connections. The length of haunch is typically 5 to 7% of the span length for nonsway frames or 7 to 15% for sway frames. Service ducts can pass below the beams (Fig. 51.13).

Haunched composite beams are usually used in the case where the beams frame directly into the major axis of the columns. This means that the columns must be designed to resist the moment transferred from the beam to the column. Thus a heavier column and more complex connection would be required than would be with a structure designed based on the assumption that the connections are pinned. The

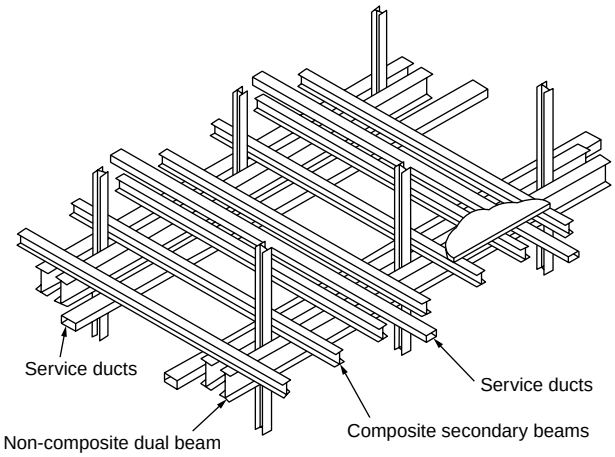

FIGURE 51.14 Parallel composite beam system.

rigid frame action derived from the haunched connections can resist lateral loads due to wind without the need for vertical bracing. Haunched beams offer higher strength and stiffness during the steel erection stage, thus making this type of system particularly attractive for long-span construction. However, haunched connections behave differently under positive and negative moments, as the connection configuration is asymmetrical about the axis of bending.

Parallel Beam System

This system consists of two main beams, with secondary beams running over the top of the main beams (see Fig. 51.14). The main beams are connected to either side of the column. They can be made continuous over two or more spans supported on stubs and attached to the columns. This will help in reducing the construction depth and thus avoid the usual beam-to-column connections. The secondary beams are designed to act compositely with the slab and may also be made to span continuously over the main beams. The need to cut the secondary beams at every junction is thus avoided. The parallel beam system is ideally suited for accommodating large service ducts in orthogonal directions (Fig. 51.14). Small savings in steel weight are expected from the continuous construction because the primary beams are noncomposite. However, the main beam can be made composite with the slab by welding beam stubs to the top flange of the main beam and connecting them to the concrete slab through the use of shear studs (see Stub Girder System below). The simplicity of connections and ease of fabrication make this long-span beam option particularly attractive.

Composite Trusses

Composite truss systems can be used to accommodate large services. Although the cost of fabrication is higher in material cost, truss construction can be cost-effective for very long spans when compared with other structural schemes. One disadvantage of the truss configuration is that fire protection is labor-intensive, and sprayed protection systems cause a substantial mess to the services that pass through the web opening (see Fig. 51.15).

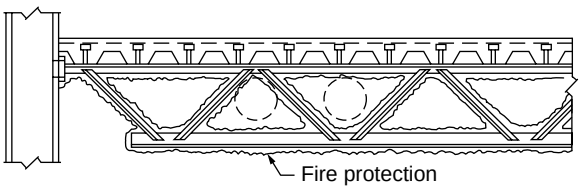

FIGURE 51.15 Composite truss.

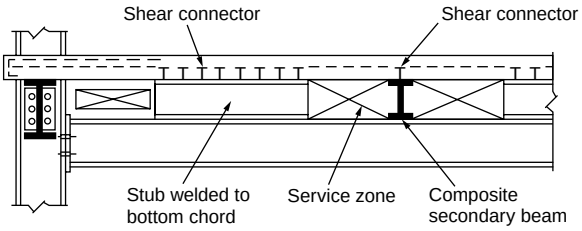

FIGURE 51.16 Stub girder system.

The resistance of a composite truss is governed by: (1) yielding of the bottom chord, (2) crushing of the concrete slab, (3) failure of the shear connectors, (4) buckling of the top chord during construction, (5) buckling of web members, and (6) instability occurring during and after construction. To avoid brittle failures, ductile yielding of the bottom chord is the preferred failure mechanism. Thus the bottom chord should be designed to yield prior to crushing of the concrete slab. The shear connectors should have sufficient capacity to transfer the horizontal shear between the top chord and the slab. During construction, adequate plan bracing should be provided to prevent top chord buckling. When considering composite action, the top steel chord is assumed not to participate in the moment resistance of the truss, since it is located very near to the neutral axis of the composite truss and thus contributes very little to the flexural capacity.

Stub Girder System

The stub girder system involves the use of short beam stubs, which are welded to the top flange of a continuous, heavier bottom girder member and connected to the concrete slab through the use of shear studs. Continuous transverse secondary beams and ducts can pass through the openings formed by the beam stub. The natural openings in the stub girder system allow the integration of structural and service zones in two directions (Fig. 51.16), permitting story height reduction, compared with some other structural framing systems.

Ideally, stub girders span about 12 to 15 m, in contrast to the conventional floor beams, which span about 6 to 9 m. The system is therefore very versatile, particularly with respect to secondary framing spans, with beam depths being adjusted to the required structural configuration and mechanical requirements. Overall girder depths vary only slightly, by varying the beam and stub depths. The major disadvantage of the stub girder system is that it requires temporary props at the construction stage, and these props have to remain until the concrete has gained adequate strength for composite action. However, it is possible to introduce an additional steel top chord, such as a T section, which acts in compression to develop the required bending strength during construction. For span lengths greater than 15 m, stub girders become impractical, because the slab design becomes critical.

In the stub girder system, the floor beams are continuous over the main girders and splices at the locations near the points of inflection. The sagging moment regions of the floor beams are usually designed compositely with the deck slab system, to produce savings in structural steel as well as provide stiffness. The floor beams are bolted to the top flange of the steel bottom chord of the stub girder, and two shear studs are usually specified on each floor beam, over the beam–girder connection, for anchorage to the deck slab system. The stub girder may be analyzed as a Vierendeel girder, with the deck slab acting as a compression top chord, the full-length steel girder as a tensile bottom chord, and the steel stubs as vertical web members or shear panels.

Prestressed Composite Beams

Prestressing of steel girders is carried out such that the concrete slab remains uncracked under working loads and the steel is utilized fully in terms of stress in the tension zone of the girder.

Prestressing of steel beams can be carried out using a precambering technique, as depicted in Fig. 51.17. First, a steel girder member is prebent (Fig. 51.17(a)); then it is subjected to preloading in the direction against the bending curvature until the required steel strength is reached (Fig. 51.17(b)). Second, the

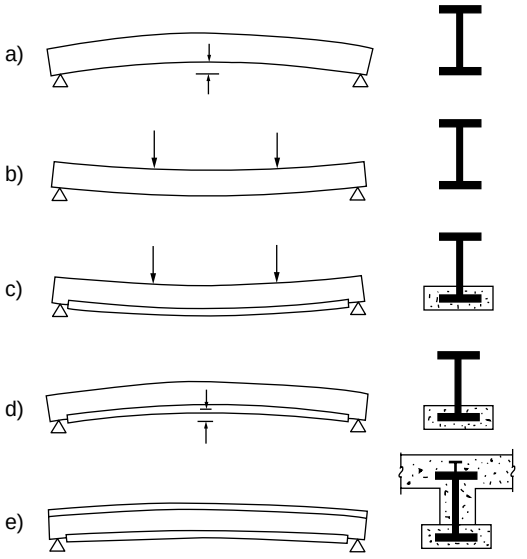

FIGURE 51.17 Process of prestressing using precambering technique.

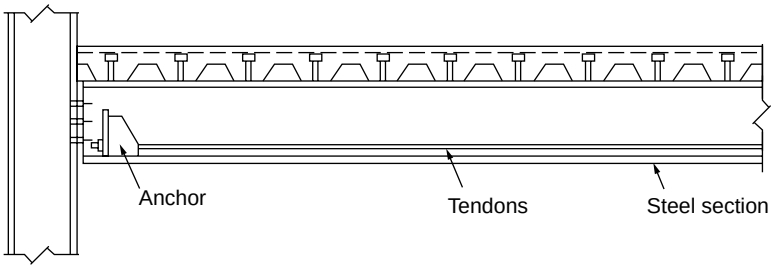

FIGURE 51.18 Prestressing of composite steel girders with tendons.

lower flange of the steel member, which is under tension, is encased in a reinforced concrete chord (Fig. 51.17(c)). The composite action between the steel beam and the concrete slab is developed by providing adequate shear connectors at the interface. When the concrete gains adequate strength, the steel girder is prestressed by stress-relieving the precompressed tension chord (Fig. 51.17(d)). Further composite action can be achieved by supplementing the girder with *in situ* or prefabricated reinforced concrete slabs; this will produce a double composite girder (Fig. 51.17(e)).

The main advantage of this system is that the steel girders are encased in concrete on all sides: no corrosion or fire protection is required for the sections. The entire process of precambering and prestressing can be performed and automated in a factory. During construction, the lower concrete chord cast in the works can act as formwork. If the distance between two girders is large, precast planks can be supported by the lower concrete chord, which is used as a permanent formwork.

Prestressing can also be achieved by using tendons that can be attached to the bottom chord of a steel composite truss or the lower flange of a composite girder to enhance the load-carrying capacity and stiffness of long-span structures (Fig. 51.18). This technique is popular for bridge construction in Europe and the U.S., but it is less common for building construction.

Composite Column Systems

Composite columns have been used for over 100 years, with steel-encased sections similar to that shown in Fig. 51.19(a) being incorporated in multistory buildings in the United States during the late nineteenth

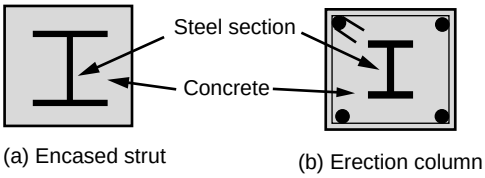

FIGURE 51.19 Encased composite sections.

century [1]. The initial application of composite columns was for fire rating requirements of the steel section [3]. Later developments saw the composite action fully utilized for strength and stability [4,5]. Composite action in columns utilizes the favorable tensile and compressive characteristics of the steel and concrete, respectively. These types of columns are still in use today where steel sections are used as erection columns, with reinforced concrete cast around them as shown in Fig. 51.19(b). One major benefit of this system has been the ability to achieve higher steel percentages than conventional reinforced concrete structures, and the steel erection column allows rapid construction of steel floor systems in steel-framed buildings.

Concrete-filled steel columns, as illustrated in Fig. 51.20, were developed much later during the last century but are still based on the fundamental principle that steel and concrete are most effective in tension and compression, respectively. The major benefits also include constructability issues, whereby the steel section acts as permanent and integral formwork for the concrete. These columns were initially researched during the 1960s, with the use of hot-rolled steel sections filled with concrete considered in Neogi et al. [6] and Knowles and Park [7,8]. These sections, while studied extensively, were essentially expensive, as the steel section itself was designed to be hollow, thus requiring large steel plate thicknesses. This lack of constructional economy has seen the use of concrete-filled steel columns limited in their application throughout the world. Furthermore, restrictive cross section sizes have rendered them unsuitable for application in tall buildings, where demand on axial strength is high.

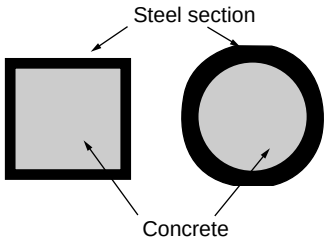

FIGURE 51.20 Concrete-filled steel columns.

Japan has been an exception to the rule in regard to the application of concrete-filled steel columns. Widespread use of thick steel tubes or boxes has been invoked to provide confinement for the concrete and thus achieve greater ductility, which is desirable for cyclic loading experienced during an earthquake. The use of concrete-filled steel columns was initially justified after the Great Kanto Earthquake in 1923, when it was found that existing composite structures were relatively undamaged. This has resulted in more than 50% of the building structures of over five stories in Japan being framed with composite steel–concrete columns, as described by Wakabayashi [9].

Recently in Australia, Singapore, and other developed nations, concrete-filled steel columns have experienced a renaissance in their use. The major reasons for this renewed interest are the savings in construction time, which can be achieved with this method. The major benefits include:

- The steel column acts as permanent and integral *formwork*.
- The steel column provides external *reinforcement*.
- The steel column *supports* several levels of construction prior to concrete being pumped.

A comparison of typical costs of column construction has been compiled by Australian consulting engineers, Webb and Peyton [10], and this is summarized in Table 51.1. This reveals the competitive nature of the concrete- filled steel column with or without reinforcement when compared with conventional reinforced concrete columns for buildings over 30 levels. This statistic will be more favorable for concrete-filled steel columns in buildings of over 50 stories, which are becoming common in many densely populated cities throughout the world [2].

TABLE 51.1 Comparison of Column Costs

Type of Column	Reinforced Concrete	Concrete with Steel Erection Column	Concrete-Encased Steel Strut	Tube Filled with Reinforced Concrete	Steel Tube Filled with Concrete	Full Steel Column
Relative cost, 10 levels	1.0	1.22	1.53	1.14	1.10	2.27
Relative cost, 30 levels	1.0	1.13	1.85	1.11	1.02	2.61

A considerable amount of research has been conducted on this form of column construction, and the main objective has been to reduce the steel plate thickness. The optimization of the steel thickness requires a clear understanding of the behavior during all stages of loading. These aspects will be outlined in this chapter, together with reference to international codes, where design guidance can be provided. In particular, attention is made to fundamental aspects that have not yet been implemented in international codes and that often affect the performance of these members in practice.

51.3 Material Properties

The principal material properties that need to be considered in composite members include structural steel, concrete, reinforcing steel, and profiled steel sheeting, as well as the properties of the shear connectors, which are generally stud shear connectors. Each of these materials will be discussed, and typical pertinent properties used internationally will be described.

Mild Structural Steel

Mild structural steel typical of hot-rolled steel sections exhibits the stress–strain characteristics shown in Fig. 51.21, which shows an elastic region, followed by a plastic plateau, that extends for approximately ten times the yield strain. This is then followed by a strain-hardening region leading to a maximum ultimate stress. The ultimate stress is maintained until the material reaches an ultimate strain, which is sometimes close to 150 times the yield strain, thus exhibiting extremely ductile behavior.

For structural steel of composite sections, the common steel grades as outlined in Eurocode 4 (EC4) [11] are given in Table 51.2. The steel sections may be hot or cold rolled. Nominal values of the yield strength, f_y, and the ultimate tensile strength, f_u for structural steel are presented in Table 51.2.

Other material properties related to steel design are:

- Modulus of elasticity, E_a: 210 kN/mm^2
- Shear modulus, G_a: $E_a/[2(1 + \nu_a)]$
- Poisson's ratio, ν_a: 0.3
- Density, ρ_a: 7850 kg/m^3

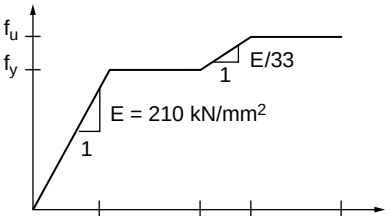

FIGURE 51.21 Idealized stress–strain curve for mild structural steel.

TABLE 51.2 Nominal Values of Strength of Structural Steels to BS EN 10025

Nominal Steel Grade	Nominal Thickness of Element, t (mm)			
	$t \le 40$ mm		40 mm $\le t \le$ 100 mm	
	f_y (N/mm^2)	f_u (N/mm^2)	f_y (N/mm^2)	f_u (N/mm^2)
Fe 360	235	360	215	340
Fe 430	275	430	255	410
Fe 510	355	510	335	490

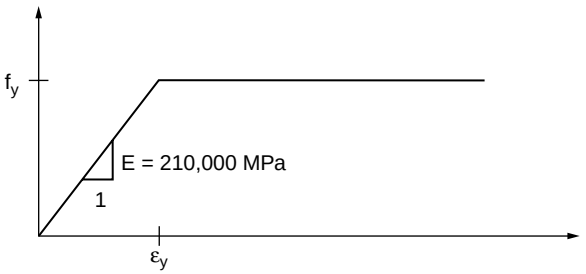

FIGURE 51.22 Idealized stress–strain curve for high strength structural steel.

High-Strength Steel

The idealized stress–strain curve for high-strength structural steel is shown in Fig. 51.22, which shows an elastic range and a plastic plateau with no significant strain hardening occurring for the material. Typical values of yield strengths for high-strength steel are about 700 MPa.

Unconfined Concrete

In composite structures, concrete can be in an unconfined state of stress in compression generally when used as a slab component of a composite beam. In the modeling of these types of structures, it is important to have a model that represents the concrete stress as a function of strain. The Comite Europeen du Beton (CEB-FIP) [13] model for stress–strain has been used in the past and is shown in Fig. 51.23. Other models exist and can be found in most international codes on concrete structures.

Concrete strengths as defined in Eurocode 4 are based on the characteristic cylinder strength, f_{ck}, measured at 28 days. Clause 3.1.2.2 of EC4 also gives the different strength classes and associated cube strengths, as shown in Table 51.3. The classification of concrete, such as C20/25, refers to the cylinder/cube concrete strength at the specified age.

For normal-weight concrete the mean tensile strength, f_{ctm}, and the secant modulus of elasticity, E_{cm}, for short-term loading are also given in Table 51.3. For lightweight concrete, the secant moduli are obtained by multiplying the E_{cm} value by a factor of $(\rho/2400)^2$, where ρ is the density of lightweight concrete.

Confined Concrete

Concrete in composite structures may be confined in a triaxial state of stress when used in applications such as concrete-filled steel sections. A model to consider this behavior for rectangular or square sections

has been developed by Tomii [15]; it is illustrated in Fig. 51.24. Other models also exist for concrete-filled steel tubes and will be discussed in relation to some of the existing international standards.

Reinforcing Steel

Reinforcing steel is often used as tensile reinforcement in the hogging moment regions of continuous composite beams, as well as for crack control in the slabs of simply supported composite beams. For

TABLE 51.4 Characteristic Strengths for Reinforcing Steel according to EC2 and for Modulus of Elasticity, E_s according to EC4-1992

Reinforcing Steel Grades	BS 4449 [17] and BS 4483	BS EN 10080
f_{sk} (N/mm²)	460	500
	250	Not included
Ductility	Not covered	Classes H and N
E_s (N/mm²)	210,000	210,000

Source: Eurocode 4, ENV 1994-1-1, European Committee for Standardization, Brussels, 1992.

continuous composite beams where large rotational capacity is required, ductile reinforcing steel is necessary. Eurocode 4 specifies the types of reinforcing steel that may be used in composite structures.

Standardized grades are defined in EN 10080 [16], which is the product standard for reinforcement. Types of reinforcing steel are classified as follows:

- high (class H) or normal (class N) according to ductility characteristics
- plain smooth or ribbed bars according to surface characteristics

Steel grades commonly used in the construction industry are given in Table 51.4.

Profiled Steel Sheeting

Profiled steel sheeting in composite slabs is often made of cold-formed steel sheeting, which exhibits highly nonlinear stress–strain characteristics, particularly near the proof stress, σ_p. The Ramberg–Osgood [18] model is often used to represent the stress–strain characteristics of cold-formed steel. For this model, stress is represented as a function of strain in the form of

$$\varepsilon = \frac{\sigma}{E} + \varepsilon_p \left(\frac{\sigma}{\sigma_p} \right)^n \tag{51.1}$$

Piecewise linearization is often used in analysis to idealize the stress–strain curves to allow the stress, σ, to be uniquely represented as a function of the strain, ε. However, a proof yield stress is usually used for ultimate strength design.

Shear Connectors

Shear connectors may exist in quite a few varieties, which include headed shear studs, steel angles, and high-strength friction grip bolts. However, it is the headed shear stud connectors that have seen the greatest application, and these will be outlined herein. In the design of the shear connection in composite structures, the designer is mainly interested in the strength that each stud can transfer in shear. Empirical relationships for the shear resistance of headed shear studs exist in various international codes of practice.

The Australian Standard (AS) AS 2327.1-1996 [19] represents the strength of the shear connectors by the lesser of one of the following two expressions:

$$f_{vs} = 0.63 d_{bs}^2 f_{uc} \tag{51.2}$$

$$f_{vs} = 0.31 d_{bs}^2 \sqrt{f'_{cj} E_c} \tag{51.3}$$

where d_{bs} = the diameter of the shank of the stud
f_{uc} = the ultimate strength of the material of the stud

f'_{cj} = the characteristic cylinder strength of the concrete
E_c = the mean value of the secant modulus of the concrete

Equation (51.2) represents the strength of the shear stud if it fails by fracture of the weld collar, whereas Eq. (51.3) represents concrete cone failure surrounding the stud. The design shear resistance of studs in Eurocode 4 for the same failure modes is given by the following:

$$P_{Rd} = 0.8 f_u \left(\pi d^2/4\right) \Big/ \gamma_{Mv} \tag{51.4}$$

$$P_{Rd} = 0.29 \alpha d^2 \left(f_{ck} E_{cm}\right)^{1/2} \Big/ \gamma_{Mv} \tag{51.5}$$

where d = the diameter of the shank of the stud
f_u = the ultimate strength of the material of the stud
f_{ck} = the characteristic cylinder strength of the concrete
E_{cm} = the mean value of the secant modulus of the concrete
h = the overall height of the stud
γ_{Mv} = a partial safety factor (taken as 1.25 for the ultimate limit state)
$\alpha = 0.2[(h/d) + 1]$ for $3 \le h/d \le 4$ and $= 1.0$ for $h/d > 4$

51.4 Design Philosophy

Limit States Design

The design philosophy adopted by most international codes throughout the world is one of limit states. The Australian and North American Standards are limit states design or load resistance factor design approaches, whereas the Eurocodes are based on partial safety factor approaches.

In general structural design requirements relate to corresponding *limit states,* so that the design of a structure that satisfies all the appropriate requirements is termed a *limit states design.*

Structural design criteria may be determined by the designer, or he or she may use those stated or implied in design codes. The stiffness design criteria are usually related to the *serviceability limit state*. These may include excessive deflections, vibration, noise transmission, member distortion, etc.

Strength limit states pertain to possible methods of failure or overload and include yielding, buckling, brittle fracture, or fatigue.

The errors and uncertainties involved in the estimation of loads and on the capacity of structures may be accounted for by using appropriate load factors to increase the nominal loads (S^*) and capacity reduction factors (ϕ) to reduce the member strength (R_u). For strength the generic limit states design equation can be represented in the form

$$S^* \le \phi R_u \tag{51.6}$$

51.5 Composite Slabs

This section will deal with the design of composite slabs in the composite stage. Composite slabs in the noncomposite stage are essentially cold-formed steel structures, and the design of these elements is covered in Chapter 49 "Cold Formed Steel Structures" of this handbook.

Serviceability

Serviceability of composite slabs involves the consideration of the following key issues: deflections, vibrations, and crack control.

Deflections

Deflections of composite slabs are treated very similar to deflections of reinforced concrete slabs. However, this section will reiterate these methods, together with looking at the international standards that already exist in the design of these elements.

In determining the deflections it is important to be able to calculate the effective second moment of area of the composite section. A fully cracked section analysis often overestimates the deformations of a reinforced concrete slab, and subsequently those for a profiled composite slab, for relatively low values of the applied load above the cracking moment of the section. A tension-stiffening model is therefore used here that is related to the transformed cracked and uncracked second moments of area, as well as the ratio of the applied service moment to the cracking moment of the cross section being considered. The model is based on that of Branson [20], except that the uncracked second moment of area I_u replaces this in the following analysis. The effective second moment of area I_{eff} is given by

$$I_{eff} = I_{cr} + \left(I_u - I_{cr}\right)\left(\frac{M_{cr}}{M_s}\right)^3 \tag{51.7}$$

Both BS 5950, Part 4 [21], and ANSI/ASCE 3-91 [22] allow the consideration of a simplified effective second moment of area as

$$I_{eff} = \frac{I_g + I_{cr}}{2} \tag{51.8}$$

where I_g, I_u, and I_{cr} are the gross, uncracked, and cracked second moments of area, respectively. For determining deflections the transformed section properties are required. In the absence of a more rigorous analysis, the effects of creep may be taken into account by using modular ratios for the calculation of flexural stiffness.

$$n = \frac{E_a}{E_c'} \tag{51.9}$$

where E_a = the elastic modulus of structural steel; E_c' = an effective modulus of concrete. $E_c' = E_{cm}$ for short-term effects; $E_c' = E_{cm}/3$ for long-term effects; $E_c' = E_{cm}/2$ for other cases.

Vibrations

For long-span composite slabs, which are those types of slabs with deep troughs, it may be necessary to determine the vibrations of the slab and compare these with acceptable vibrations. Where vibration could cause discomfort or damage the response of long-span composite floors should be considered using SCI Publication 076, "Design Guide on the Vibration of Floors" [23].

Crack Control

Crack control requirements are important criteria for composite slabs, particularly when continuous composite slabs are used. Typical crack control requirements are covered by most international reinforced concrete structures codes, and these are also covered in Chapter 50 "Structural Concrete Design" of this handbook.

Strength

Flexural Failure

A rigid plastic assumption is often used to determine the flexural strength of a composite slab. This method assumes the profiled steel sheeting to be at full yield in tension, with the concrete slab assumed to be fully crushed in compression, as shown in Fig. 51.25.

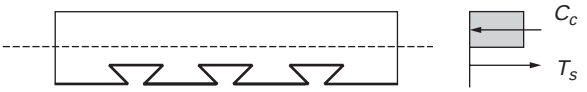

FIGURE 51.25 Ultimate flexural strength of a composite slab.

Assuming the slab is only singly reinforced, the ultimate moment, calculated by summing moments about either the tensile force or compressive force location, is given by

$$M_u = C_c l = T_s l \tag{51.10}$$

where l is the lever arm between the compressive and tensile forces. This method of analysis, based on the rectangular stress block principle, is the method adopted by both the British Standard (BS), BS 5950, Part 4, and the American Standard, ANSI/ASCE 3-91. BS 5950 assumes that the concrete strength is given by 0.4 times the cube strength and the yield strength of the steel is taken. However, this method assumes that there exists a full shear connection between the profiled steel sheeting and the concrete in the tension zone. This is usually the case when a sufficient mechanical and friction bond is developed for the profile in question. Other modes of failure, which may also exist, include longitudinal slip failure and vertical shear failure of the concrete.

Longitudinal Shear Failure

When a composite slab exhibits partial shear connection, slip of the sheeting will occur prior to the steel sheeting yielding and the concrete crushing. The strength of the composite slab is thereby governed by the shear bond capacity between the steel sheeting and the concrete. In many countries throughout the world this is based on manufacturer data, and empirical methods of analysis are often applied. The reader is referred to those methods for a more accurate method of analysis.

Vertical Shear Failure

Composite slabs may fail by vertical shear, in much the same manner as reinforced concrete slabs. For this failure mode the maximum vertical shear capacity can be evaluated, provided sufficient test data are available. The ultimate vertical shear strength as defined by BS 5950 is given as

$$V_u = 0.8A_c\left(m_d p\frac{d_e}{L_v} + k_d\sqrt{f_{cu}}\right) \tag{51.11}$$

where p is the ratio of the cross-sectional area of the profile to that of the concrete A_c per unit width of slab, f_{cu} is the cube strength of the concrete, d_e is the effective slab depth to the centroid of the profile, and L_y is the shear span length, taken as one quarter of the slab span. The constants m_d and k_d are calculated from the slope and intercept, respectively, of the reduced regression line established from the testing of composite slabs.

A similar approach is existent in the American Standard ANSI/ASCE 3-91, which relies on test data and gives an experimentally determined shear strength as

$$V_e = bd\left(\frac{m\rho d}{l_i'} + k\sqrt{f_{ct}'}\right) \tag{51.12}$$

The approach given in Eurocode 4 to determine the vertical shear resistance of a composite slab is

$$V_{v.Rd} = b_o d_p \tau_{Rd} k_v\left(1.2 + 40\rho\right) \tag{51.13}$$

where b_o = the mean width of the concrete ribs
τ_{Rd} = the basic shear strength to be taken as $0.25f_{ctk}/\gamma_c$ (f_{ctk} is the lower 5 percentile confidence limit characteristic strength)
$\rho = A_p/b_o f_p < 0.02$ (A_p is the effective area of the steel sheet in tension)
$k_v = (1.6 - d_p) = 1.0$, with d_p expressed in meters

Ductility

Ductility of composite slabs is also a very important consideration, although it appears that many of the existent international codes throughout the world do not have an inherent ductility clause, which is reflected in the design of reinforced concrete slabs. The codes investigated include BS 5950, EC4, and ANSI/ASCE. It is suggested that in the absence of current recommendations for ductility that the following consideration be given for the design of simply supported composite slabs, which limits the depth of the neutral axis so that

$$d_n \leq 0.4d \tag{51.14}$$

This is the ductility requirement for reinforced concrete slabs used in the Australian Standard for concrete structures, AS 3600 [24], and is thus also assumed to be applicable for composite slabs to ensure adequate ductility.

51.6 Simply Supported Beams

Simply supported composite steel–concrete beams are the original form of composite construction developed early in the 1900s. This section will consider the design of simply supported composite beams for serviceability, strength, and ductility. This section will mainly concentrate on the behavior of the beam in the composite stage, as the behavior of beams in the noncomposite stage is essentially the behavior of a steel beam, which is covered in Chapter 50 "Structural Concrete Design" of this handbook.

Serviceability

Deflections of simply supported composite beams need to incorporate the effects of both creep and shrinkage, in addition to the loading effects. These time-dependent effects are taken into account by generally transforming the concrete slab to an equivalent area of steel using a modular ratio. The modular ratio should include the effects of the disparate elastic moduli, as well as the effects of creep of concrete. Now, since the concrete is in the compression zone of simply supported composite beams in sagging bending, the concrete is considered to be fully effective; however, the effects of shear lag need to be determined using an effective breadth relationship. Effective widths from various international codes are included below

AS 2327.1-1996

The effective width, b_e, of the concrete flange for positive bending in AS 2327.1-1996 for a beam in a regular floor system is determined as the minimum of the following

$$b_e = \min\left(\frac{L_{ef}}{4}, b, b_{sf} + 16D_c\right) \tag{51.15}$$

where L_{ef} is the effective span of the composite beam, b is the width between steel beams, b_{sf} is the width of the steel flange, and D_c is the depth of the concrete slab. For the determination of deflections in AS 2327.1-1996, the modular ratio is determined for immediate deflections using the value (E_s/E_c), while for long term deflections, a modular ratio of 3 is suggested. The effective second moments of area of

composite beams for immediate and long-term deflections, respectively, are calculated in AS 2327.1-1996 as

$$I_{eti} = I_{ti} + 0.6\left(1 - \beta_m\right)\left(I_s - I_{ti}\right) \tag{51.16}$$

$$I_{etl} = I_{tl} + 0.6\left(1 - \beta_m\right)\left(I_s - I_{tl}\right) \tag{51.17}$$

where I_{ti} and I_{tl} are the transformed second moments of area of a composite beam under immediate and long-term loads, respectively; β_m is the level of shear connection, and I_s is the second moment of area of the steel section alone.

BS 5950, Part 3 [25]

The effective width of the concrete flange for a typical internal beam in this code should not be taken as greater than one quarter of the distance between points of contraflexure. The imposed load deflections in each span should be based on the loads applied to the span and the support moments for that span, modified as recommended to allow for pattern loading and shakedown. Provided that the steel beam is uniform without any haunches, the properties of the gross uncracked composite section should be used throughout. (This includes the use of a modular ratio to account for long-term effects.)

Long-Term Effects (Creep and Shrinkage)

Simplified methods for determining the cross section properties in BS 5950, Part 3, involve the use of a modular ratio. An effective modular ratio is expressed as

$$\alpha_e = \alpha_s + \rho_1\left(\alpha_1 - \alpha_s\right) \tag{51.18}$$

where α_1 = the modular ratio for long-term loading
α_s = the modular ratio for short-term loading
ρ_1 = the proportion of the total loading, which is long term

Deflection Due to Partial Shear Connection

The increased deflection under serviceability loads arising from partial shear connection should be determined from the following expressions:

For propped construction,

$$\delta = \delta_c + 0.5\left(1 - \frac{N_a}{N_p}\right)\left(\delta_s - \delta_c\right) \tag{51.19}$$

For unpropped construction,

$$\delta = \delta_c + 0.3\left(1 - \frac{N_a}{N_p}\right)\left(\delta_s - \delta_c\right) \tag{51.20}$$

where δ_s = the deflection of the steel beam acting alone
δ_c = the deflection of a composite beam with a full shear connection for the same loading
N_a = the actual number of shear connectors provided
N_p = the number of shear connectors for full composite action

Vibrations

Where vibration could cause discomfort or damage the response of long-span composite floors should be considered using SCI Publication 076, "Design Guide on the Vibration of Floors" [23].

Eurocode 4

The deflection calculation provisions of Eurocode 4-1994 are given herein. For an internal beam, the effective width of the concrete flange for a typical internal beam in this code should not be taken as greater than one quarter of the distance between points of contraflexure.

Long-Term Effects

In the absence of a more rigorous analysis, the effects of creep may be taken into account by using modular ratios, as given in Section 3.1.4.2, for the calculation of flexural stiffness.

$$n = \frac{E_a}{E_c'} \tag{51.21}$$

where E_a is the elastic modulus of structural steel and E_c' is an effective modulus of concrete. $E_c' = E_{cm}$ for short-term effects, $E_c' = E_{cm}/3$ for long-term effects, and $E_c' = E_{cm}/2$ for other cases.

Deflections of Beams

Deflections of the steel beam shall be calculated in accordance with EC3. Deflections of the composite beam shall be calculated using elastic analysis with corrections. Shear lag can be ignored for deflection calculations, except where $b > L/8$, then shear lag is included by determining the effective width of the flange according to Section 4.2.2.1. The effects of incomplete interaction may be ignored in spans or cantilevers where critical cross sections are either class 3 or 4. The effects of incomplete interaction may be ignored in unpropped construction, provided that shear connectors are designed according to Chapter 6: the shear connection ratio is greater than 0.50 or the forces on the shear connectors do not exceed $0.7P_{rk}$, or in the case of a ribbed slab with ribs transverse to the beam, the height of the ribs does not exceed 80 mm. If these conditions are violated but $N/N_f = 0.4$, then in lieu of testing or accurate analysis, the increased deflection arising from incomplete interaction may be determined from the following equations:

For propped construction,

$$\frac{\delta}{\delta_c} = 1 + 0.5\left(1 - \frac{N}{N_f}\right)\left(\frac{\delta_a}{\delta_c} - 1\right) \tag{51.22}$$

For unpropped construction,

$$\frac{\delta}{\delta_c} = 1 + 0.3\left(1 - \frac{N}{N_f}\right)\left(\frac{\delta_a}{\delta_c} - 1\right) \tag{51.23}$$

where δ_a = the deflection for the steel beam alone
δ_c = the deflection for the composite beam with complete interaction
N/N_f = the degree of shear connection

Strength

The flexural strength of simply supported steel–concrete composite beams in sagging bending is determined using a rigid plastic method of analysis, where the concrete slab is assumed to be fully crushed in compression and the steel beam is assumed to be fully yielded in tension and compression, depending on the location of the plastic neutral axis, as well as the strength of the longitudinal shear connection. The following cases thus may exist.

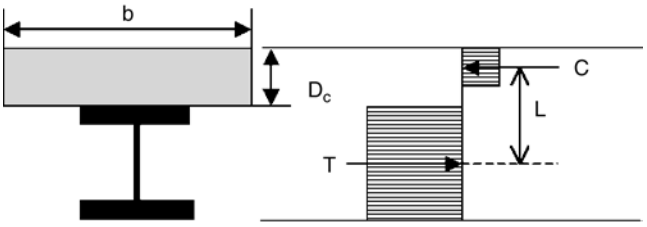

FIGURE 51.26 Ultimate flexural moment, plastic neutral axis in concrete slab (β = 1.0).

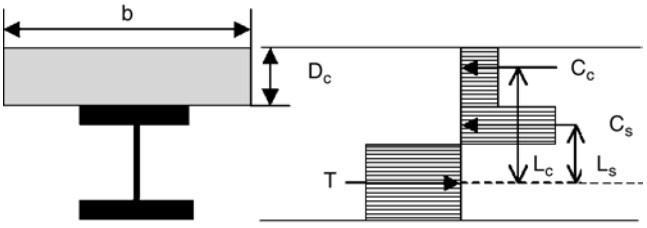

FIGURE 51.27 Ultimate flexural moment, plastic neutral axis in steel beam (β = 1.0).

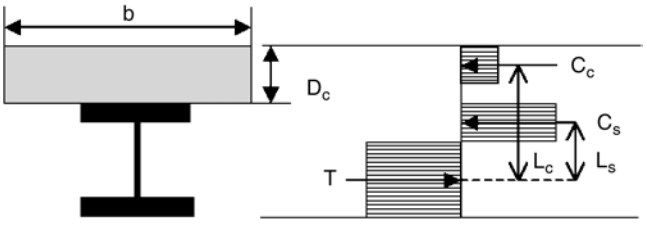

FIGURE 51.28 Ultimate flexural moment, partial shear connection (β < 1.0).

Plastic Neutral Axis in the Concrete Slab (Full Shear Connection, β = 1.0)

When the concrete slab is stronger than the steel beams, the plastic neutral axis will lie within the concrete slab. For the case when the plastic neutral axis lies within the concrete slab, the ultimate flexural strength is determined from a simple couple, as shown in Fig. 51.26.

$$M_u = TL = CL \tag{51.24}$$

Plastic Neutral Axis in the Steel Beam (Full Shear Connection, β = 1.0)

When the steel beam is stronger than the concrete slab, the plastic neutral axis for the beam with a full shear connection will lie within the steel beam. For this case it is more convenient to sum the moments about the centroid of the tension force, as illustrated in Fig. 51.27.

$$M_u = C_c L_c = C_s L_s \tag{51.25}$$

Partial Shear Connection (β < 1.0)

For the case of partial shear connection of composite beams, the shear connection is the weakest element. Again, summing the moments on a convenient point on the cross section will yield the ultimate flexural moment of the beam, as illustrated in Fig. 51.28.

$$M_u = C_c L_c = C_s L_s \tag{51.26}$$

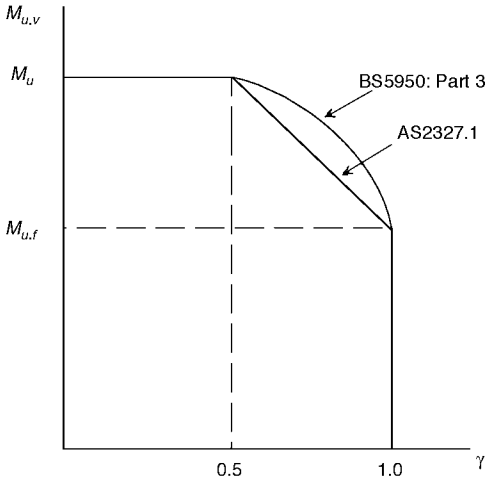

FIGURE 51.29 Influence of shear on ultimate flexural strength of composite beams.

Existing International Standards

Existing international standards that deal with the flexural strength of composite beams include the American Institute of Steel Construction Load and Resistance Design Specification (AISC-LRFD), Australian Standards (AS 2327.1-1996), British Standards (BS 5950, Part 3), and Eurocode 4-1994. While some of these standards have a closed-form solution for the flexural strength determination, it is best left in a more general form, in terms of stress blocks, as shown in Figs. 51.26 to 51.28, and for individuals to refer to the individual regional standards to determine the strength equations and apply the relevant load and capacity reduction factors. The most general manner in which to assess the flexural strength of a composite beam is as

$$M^* \le \phi M_u \tag{51.27}$$

Influence of Shear on Flexural Strength

The influence of shear on the ultimate flexural strength of steel–concrete composite beams can be significant when the relative ratio of applied shear force to shear strength is high. Most of the design methods for this failure mode are based on test data, and an appropriate interaction equation is used by various international standards, such as the Australian and British Standards. The Australian Standard (AS 2327.1-1996) uses a linear relationship for reduction, which is largely based on the steel standard, whereas the British Standard uses a quadratic expression, based on test data. Both of these relationships are shown in Fig. 51.29.

AS 2327.1-1996:

$$M_{u.v} = M_u - \left(M_u - M_{u.f}\right)\left(2\gamma - 1\right) \tag{51.28}$$

BS 5950, Part 3:

$$M_{u.v} = M_u - \left(M_u - M_{u.f}\right)\left(2\gamma - 1\right)^2 \tag{51.29}$$

where γ = the ratio of shear force to shear strength
$M_{u.v}$ = the ultimate flexural strength incorporating shear
M_u = the ultimate flexural strength with zero shear
$M_{u.f}$ = the ultimate flexural strength of the beam considering the flanges only

Ductility

None of the existing international codes have a ductility clause; however, it has been suggested by Rotter and Ansourian [26] that in order to achieve a plastic hinge, strain hardening in the bottom flange must develop, and from a treatment of the mechanics of the problem, they found that ductility can be guaranteed in a simply supported beam if a ductility parameter, χ, is greater than 1. The ductility parameter is determined as

$$\chi = \frac{0.85 f_c b_c \varepsilon_u \left(h_{conc} + h_{steel}\right)}{A_{steel} f_y \left(\varepsilon_u + \varepsilon_{st}\right)} \tag{51.30}$$

where f_c = the characteristic cylinder strength
b_c = the effective slab width
ε_u = the ultimate strain of concrete
h_{conc} = the depth of the slab
h_{steel} = the depth of the steel beam
A_{steel} = the cross-sectional area of the steel section
f_y = the yield strength of the steel
ε_{st} = the strain to cause strain hardening of the section

51.7 Continuous Beams

The design of continuous composite beams requires only an augmentation of the behavior of design of simply supported composite beams. In particular, the salient point in regard to serviceability and strength needs to take into account that composite beams in hogging bending behave completely differently than beams subjected to sagging bending. This is because in hogging bending the concrete slab is subjected to tension, and this will significantly affect both the stiffness and strength of the cross sections in hogging moment regions.

Serviceability

When considering serviceability effects in continuous composite beams, one must include the effects of cracking in the negative moment regions, as well as the effects of creep and shrinkage associated with long-term loading. Since continuous beams are indeterminate, it is difficult to develop a general approach that is amenable for design that reflects the exact behavior. Existing code methods provide a good basis for simplifying the problem to account for the indeterminacy, as well as the nonuniform flexural rigidity, that exists along the length of a beam. These methods will be outlined herein.

BS 5950, Part 3

Calculation of Moments

The calculation of moments for supports can be determined using the following two methods.

Pattern Loading and Shakedown — The support moments required for these cases should be based on an elastic analysis using the properties of the gross uncracked section throughout.

Simplified Method — The moments in continuous composite beams for serviceability may be determined using the coefficients below, provided that the following conditions are satisfied: the steel beam should be of uniform section with no haunches; the steel beam should be of the same section in each span; loading should be uniformly distributed; live loads should not exceed 2.5 times the dead load; no span should be less than 75% of the longest span; end spans should not exceed 115% of the length of adjacent spans; and there should not be any cantilevers.

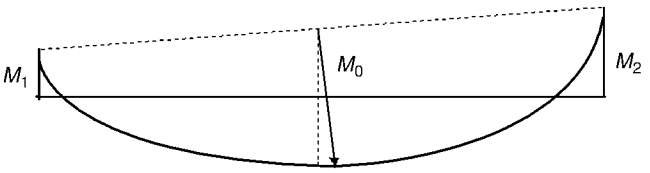

FIGURE 51.30 Bending moment distribution of a continuous beam.

Support moments can then be taken as:

two-span beam: $$\frac{wL^2}{8} \tag{51.31}$$

first support in a multispan beam: $$\frac{wL^2}{10} \tag{51.32}$$

other internal supports: $$\frac{wL^2}{14} \tag{51.33}$$

w is the unfactored uniformly distributed load on the span L. Where the spans on each side of a support differ, the mean value of w is adopted.

Calculation of Deflections

For continuous beams under uniform load or symmetric point loads, the deflection δ_c at midspan may be determined from the expression:

$$\delta_c = \delta_o \left(1 - 0.6 \frac{(M_1 + M_2)}{M_o} \right) \tag{51.34}$$

where δ_o = the deflection of a simply supported beam for the same loading
M_o = the maximum moment in the simply supported beam
M_1 and M_2 = the moments at the adjacent supports (modified as appropriate)

Partial Shear Connection

The increased deflection under serviceability loads arising from a partial shear connection should be determined from the following expressions:

For propped construction,

$$\delta = \delta_c + 0.5 \left(1 - \frac{N_a}{N_p} \right) (\delta_s - \delta_c) \tag{51.35}$$

For unpropped construction,

$$\delta = \delta_c + 0.3 \left(1 - \frac{N_a}{N_p} \right) (\delta_s - \delta_c) \tag{51.36}$$

where δ_s = the deflection of the steel beam acting alone
δ_c = the deflection of a composite beam with a full shear connection for the same loading
N_a = the actual number of shear connectors provided
N_p = the number of shear connectors for a complete interaction

Cracking

Reference is made to BS 8110 [27]. Floors in car park structures are alluded to as being of importance, and additional reinforcement should be provided to avoid these over support regions. No consideration for increased deflections is made due to cracking.

Vibrations

Where vibration could cause discomfort or damage the response of long-span composite floors should be considered using SCI Publication 076, "Design Guide on the Vibration of Floors."

Eurocode 4

Design of continuous composite beams for serviceability in EC4 is covered in Chapter 5, which is on serviceability. Furthermore, relevant sections for internal forces and moments in continuous composite beams are covered in Section 4.5. For stiffness calculations, modular ratios are considered in Section 3.1.4.2.

Scope

This chapter of the code covers the following limit states of deflection control and crack control. Other limit states such as vibration may be important but are not covered in Eurocode 4.

Assumptions

Calculation of stresses and deformations at the serviceability limit state shall take into account shear lag; incomplete interaction; cracking; tension stiffening of concrete in hogging moment regions; creep and shrinkage of concrete; yielding of steel, if any, when unpropped; and yielding of reinforcement in hogging moment regions.

Long-Term Effects

In the absence of a more rigorous analysis, the effects of creep may be taken into account by using modular ratios, as given in Section 3.1.4.2, for the calculation of flexural stiffness.

$$n = \frac{E_a}{E_c'} \tag{51.37}$$

where E_a is the elastic modulus of structural steel and E_c' is an effective modulus of concrete. $E_c' = E_{cm}$ for short-term effects, $E_c' = E_{cm}/3$ for long-term effects, and $E_c' = E_{cm}/2$ for other cases.

Deformations

The effect of cracking of concrete in hogging moment regions may be taken into account by adopting one of the following methods of analysis.

Hogging moments and top-fiber concrete stresses, σ_{ct}, are determined at each internal support using the flexural stiffnesses E_aI_1. For each support at which σ_{ct} exceeds $0.15f_{ck}$, the stiffness should be reduced to the value E_aI_2 over 15% of the length of the span on each side of the support. A new distribution of bending moments is then determined by reanalyzing the beam. At every support where stiffnesses E_aI_2 are used for a particular loading they should be used for all other loadings, as shown in Fig. 51.31.

For beams with classes 1–3, where σ_{ct} exceeds $0.15f_{ck}$, the bending moment at the support is multiplied by a reduction factor f_1 and corresponding increases are made to the bending moments in adjacent spans, as shown in Fig. 51.32. Curve A should be used when loading on all spans is equal and the lengths of all

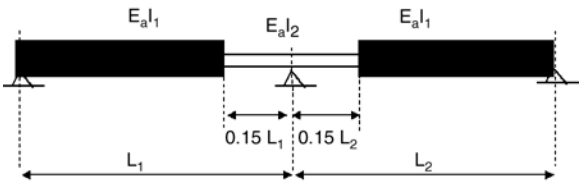

FIGURE 51.31 Distribution of flexural rigidities for a continuous composite beam.

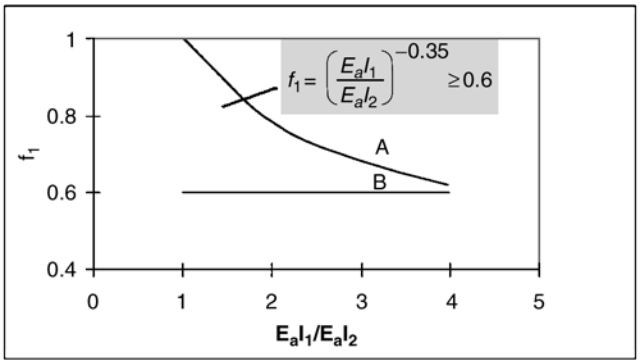

FIGURE 51.32 Reduction factor for bending moment at supports.

spans do not differ by more than 25%. Otherwise, the approximate lower bound $f_1 = 0.60$ should be used (i.e., line B).

In unpropped beams account may be taken of the influence of local yielding over a support by multiplying the bending moments at the support by:

- $f_2 = 0.5$ if f_y is reached before the concrete slab has hardened.
- $f_2 = 0.7$ if f_y is caused by the loading after the concrete has hardened.

Cracking

Some important points to note about cracking in EC4, which are covered in Section 5.3, include: design crack widths should be agreed with the client; minimum reinforcement requirements are specified; maximum steel stresses are specified for bar sizes and required crackwidths; and elastic global analysis is used to ascertain internal forces and moments.

Strength

In the hogging moment region, the moment resistance of the composite beam section depends on the tensile resistance of the steel reinforcement and the compression resistance of the steel beam section. Partial shear connection also exists; however, it depends on the steel reinforcement strength in tension, rather than the concrete slab in compression. The moment resistance depends on the location of the plastic neutral axis as follows.

Plastic Neutral Axis in the Concrete Slab (Full Shear Connection, β = 1.0)

When the steel reinforcing is stronger than the steel beam, the plastic neutral axis will lie within the concrete slab. For the case when the plastic neutral axis lies within the concrete slab, the ultimate flexural strength is determined from a simple couple, as shown in Fig. 51.33.

$$M_u = TL = CL \tag{51.38}$$

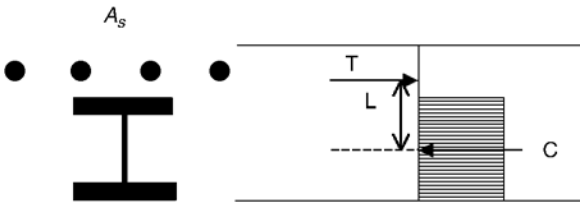

FIGURE 51.33 Ultimate flexural moment, plastic neutral axis in concrete slab (β = 1.0).

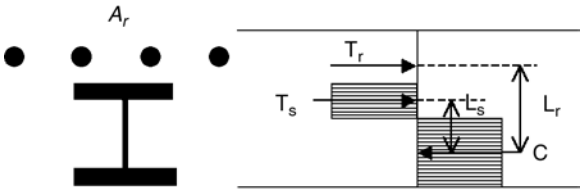

FIGURE 51.34 Ultimate flexural moment, plastic neutral axis in steel beam (β = 1.0).

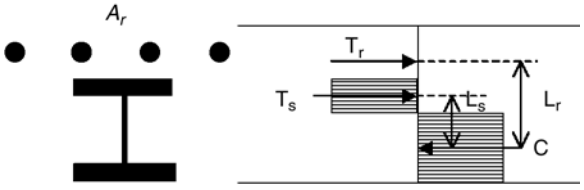

FIGURE 51.35 Ultimate flexural moment, partial shear connection (β < 1.0).

Plastic Neutral Axis in the Steel Beam (Full Shear Connection, β = 1.0)

When the steel beam is stronger than the reinforcing steel, the plastic neutral axis for the beam with full shear connection will lie within the steel beam. For this case it is more convenient to sum the moments about the centroid of the compression force, as illustrated in Fig. 51.34.

$$M_u = T_s L_s + T_r L_r \tag{51.39}$$

Partial Shear Connection (β < 1.0)

Although not generally allowed by international codes of practice, partial shear connection in the negative moment region may need to be considered for special cases. For the case of partial shear connection of composite beams in hogging bending, the shear connection is the weakest. Again, summing the moments on a convenient point on the cross section will yield the ultimate flexural moment of the beam.

$$M_u = T_s L_s + T_r L_r \tag{51.40}$$

Ductility

The assumption of a plastic collapse mechanism in continuous composite beams will generally be dependent on the formation of hinges at both the sagging and hogging regions. Oehlers and Bradford [3] have shown that when the ductility parameter $\chi > 1.6$, a plastic mechanism will be formed. The ductility parameter is determined as

$$\chi = \frac{0.85 f_c b_c \varepsilon_u \left(h_{conc} + h_{steel}\right)}{A_{steel} f_y \left(\varepsilon_u + \varepsilon_{st}\right)} \tag{51.41}$$

51.8 Composite Columns

The design of composite columns requires the consideration of both short-column and slender-column behavior. In addition, bending moments, which may occur about either axis due to imperfections and applied loading, must be considered. This section will consider the existing codes for the design of composite columns. The most comprehensive method is the Eurocode 4 approach, followed by the AISC-LRFD [28] approach. An Australian approach incorporating AS 3600 and AS 4100 [29] will also be considered herein.

Eurocode 4

Resistance of the Cross Section to Compression

The plastic resistance to compression of a composite cross section represents the maximum load that can be applied to a short composite column. It is important to recognize that concrete-filled circular hollow sections exhibit enhanced resistance due to the triaxial containment effects. Fully or partially concrete-encased steel sections and concrete-filled rectangular sections do not achieve such enhancement. Hence these two categories are dealt with separately in EC4.

Encased Steel Sections and Concrete-Filled Rectangular Hollow Sections

The plastic resistance of an encased steel section or a concrete-filled rectangular or square hollow section is given by the sum of the resistances of the components as follows:

$$N_{pl.Rd} = A_a f_y/\gamma_a + \alpha_c A_c f_{ck}/\gamma_c + A_s f_{sk}/\gamma_s \tag{51.42}$$

where A_a, A_c, and A_s = the cross-sectional areas of the structural section, the concrete, and the reinforcing steel, respectively

f_y, f_{ck}, and f_{sk} = the yield strength of the steel section, the characteristic compressive strength of the concrete, and the yield strength of the reinforcing steel, respectively

γ_a, γ_c, and γ_s = the partial safety factors at the ultimate limit state (γ_a = 1.10, γ_c = 1.5, and γ_s = 1.15)

a_c = the strength coefficient for concrete, 1.0 for concrete-filled hollow sections and 0.85 for fully and partially concrete-encased steel sections.

For ease of expression, f_y/γ_a, $a_c f_{ck}/\gamma_c$, and f_{sk}/γ_s are presented as the design strengths of the respective materials, such as f_{yd}, f_{cd}, and f_{sd}. Equation (51.42) can therefore be rewritten as follows:

$$N_{pl.Rd} = A_a f_{yd} + A_c f_{cd} + A_s f_{sd} \tag{51.43}$$

An important design parameter, δ, the steel contribution ratio, is defined as follows:

$$\delta = \frac{A_a f_{yd}}{N_{pl.Rd}} \tag{51.44}$$

The column is classified as composite if the steel contribution ratio falls within the range of $0.2 \le \delta \le 0.9$. If δ is less than 0.2, the column shall be designed as a reinforced concrete column; otherwise, if δ is greater than 0.9, the column shall be designed as a bare steel column.

Concrete-Filled Circular Hollow Sections

For concrete-filled circular hollow sections, the load-bearing capacity of the concrete can be increased due to the confinement effect from the surrounding tube. This effect is shown in Fig. 51.36. When a concrete-filled circular section is subjected to compression, causing the Poisson's expansion of the concrete to exceed that of steel, the concrete is triaxially confined by the axial forces associated with the development of hoop tension in the steel section. The development of these hoop tensile forces in the tube, combined with the compressive axial forces in the steel shell, lowers the effective plastic resistance of the steel section in accordance with the von Mises failure criteria. However, the increase in concrete strength over the normal unconfined cylinder strength often more than offsets any reduction in the resistance of the steel. The net effect is that such columns show an enhanced strength.

The plastic resistance of the cross section of a concrete-filled circular hollow section is given by:

$$N_{pl.Rd} = A_a \eta_2 \frac{f_y}{\gamma_a} + A_c \frac{f_{ck}}{\gamma_c}\left(1 + \eta_1 (t/d)\frac{f_y}{f_{ck}}\right) + A_s \frac{f_{sk}}{\gamma_s} \tag{51.45}$$

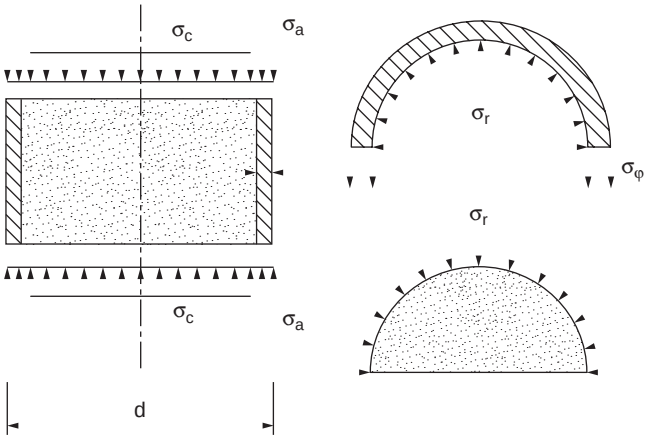

FIGURE 51.36 Effect of concrete confinement.

The concrete enhancement effect is included in the bracket term associated with the concrete component term in Eq. (51.45). The hoop stress effect is reflected by the η_2 factor in the steel component term. Other parameters given in Eq. (51.45) are defined as follows: t is the thickness of the circular hollow section,

$$\eta_1 = \eta_{10}\left(1 - \frac{10e}{d}\right) \tag{51.46}$$

$$\eta_2 = \eta_{20} + \left(1 - \eta_{20}\right)\frac{10e}{d} \tag{51.47}$$

A linear interpolation is carried out for load eccentricity, $e \le d/10$, with the basic values η_{10} and η_{20}, which depend on the relative slenderness λ:

$$\eta_{10} = 4.9 - 18.5\lambda + 17\lambda^2 \qquad \ge 0.0 \tag{51.48}$$

$$\eta_{20} = 0.25\left(3 + 2\lambda\right) \qquad \le 1.0 \tag{51.49}$$

No reinforcement is necessary for concrete infilled sections; however, if the contribution from reinforcement is to be considered in the load-bearing capacity, the ratio of reinforcement should fall within the range of $0.3\% \le A_s/A_c \le 4\%$. Additional reinforcement may be necessary for fire resistance design, but shall not be taken into account if the ratio exceeds 4%.

The effects of triaxial containment tend to diminish as the column length increases. Consequently, this effect may only be considered up to a relative slenderness of $\lambda \le 0.5$. For most practical columns the value of λ of 0.5 corresponds to a length-to-diameter ratio (l/d) of approximately 12. In addition, the eccentricity of the normal force, e, may not exceed the value $d/10$, d being the outer diameter of the circular hollow steel section. If the eccentricity, e, exceeds the value $d/10$, or if the nondimensional slenderness λ exceeds the value 0.5, then $\eta_1 = 0$ and $\eta_2 = 1.0$ must be applied, and Eq. (51.45) reduces to Eq. (51.42).

The eccentricity, e, is defined by:

$$e = \frac{M_{\max,Sd}}{N_{Sd}} \tag{51.50}$$

where $M_{max,Sd}$ = the maximum design moment from first-order analysis
N_{Sd} = the design axial force

Table 51.5 gives the basic values η_{10} and η_{20} for different values of λ. It should be noted that the evaluation of $N_{pl.Rd}$ for concrete-filled circular hollow sections always starts with Clause 4.8.3.3(1), with unity material factors to give λ, and thus it is not an iteration process.

From a numerical study carried out by Bergmann et al. [30], the application of Eqs. (51.45) to (51.49) and its relation to Eq. (51.43) is shown in Table 51.6. The table gives the respective increase in the axial

TABLE 51.5 Basic Values η_{10} and η_{20} to Allow for the Effect of Triaxial Confinement in Concrete-Filled Circular Hollow Sections

TABLE 51.7 Limiting Plate Slenderness Ratios to Avoid Local Buckling

Type of Cross Section	Nominal Steel Grade		
	Fe 360	Fe 430	Fe 510
Concrete-filled circular hollow section (d/t)	90	77	60
Concrete-filled rectangular hollow section (h/t)	52	48	42
Partly encased I section (b/t)	44	41	36

strength of the column caused by the confinement effect for certain ratios of steel-to-concrete strengths, selected values for λ, and certain ratios of e/d and d/t. For the calculation, the longitudinal reinforcement is assumed to be 4%, with a yield strength of 500 N/mm^2. It must be recognized that for higher slenderness and larger eccentricities, the advantage of the confinement effect is very low. Similarly, for higher diameter-to-thickness ratios of the circular hollow section, and smaller steel-to-concrete-strength ratios, the confinement effect decreases. Therefore, in the calculation of axial strength for the column, a significant increase in strength due to the confinement effect is obtained only when the values of λ are less than 0.2 and the eccentricity ratios e/d are less than 0.05.

Local Buckling

Both Eqs. (51.43) and (51.45) are valid, provided that local buckling in the steel sections does not occur. To prevent premature local buckling, the plate slenderness ratios of the steel section in compression must satisfy the following limits:

- $d/t \le 90\varepsilon^2$ for concrete-filled circular hollow sections.
- $h/t \le 52\varepsilon$ for concrete-filled rectangular hollow sections.
- $b/t \le 44\varepsilon$ for partially encased I sections.

where d = the outer diameter of the circular hollow section with thickness, t
h = the depth of the rectangular hollow section with thickness, t
b = the breadth of the I section with a flange thickness, t_f
$\varepsilon = \sqrt{(235/f_y)}$
f_y = the yield strength of the steel section (N/mm^2).

Table 51.7 shows the limit values for the plate slenderness ratio for steel sections in class 2, which have limited rotation capacity. In such cases, plastic analysis, which considers moment redistribution due to the formation of plastic hinges, is not allowed.

For fully encased steel sections, no verification for local buckling is necessary. However, the concrete cover to the flange of a fully encased steel section should not be less than 40 mm or less than one sixth of the breadth, b, of the flange. The cover to reinforcement should be in accordance with Clause 4.1.3.3 of EC2-1990.

Effective Elastic Flexural Stiffness

Elastic flexural stiffness of a composite column is required in order to define the elastic buckling load, which is defined as

$$N_{cr} = \pi^2 (EI)_e / l^2 \tag{51.51}$$

The term $(EI)_e$ is the effective elastic flexural stiffness of the composite column and l is the buckling length of the column.

The buckling length may be determined using EC3 [31] by considering the end conditions due to the restraining effects from the adjoining members.

Special consideration of the effective elastic flexural stiffness of the composite column is necessary, as the flexural stiffness may decrease with time, due to creep and shrinkage of concrete. The design rules for the evaluation of the effective elastic flexural stiffness of composite columns under short-term and long-term loading are described in the following two sections.

Short-Term Loading — The effective elastic flexural stiffness $(EI)_e$ is obtained by adding up the flexural stiffnesses of the individual components of the cross section:

$$(EI)_e = E_a I_a + 0.8 E_{cd} I_c + E_s I_s \tag{51.52}$$

$$E_{cd} = E_{cm}/1.35 \tag{51.53}$$

where I_a, I_c, and I_s = the second moments of area for the steel section, concrete (assumed uncracked), and reinforcement about the axis of bending, respectively
E_a, E_s = the moduli of elasticity of the steel section and the reinforcement, respectively
$0.8\ E_{cd}I_c$ = the effective stiffness of the concrete
E_{cm} = the secant modulus of elasticity of concrete

The simplified design method of EC4 has been developed with a secant stiffness modulus of the concrete of $600 f_{ck}$. In order to have a similar basis like EC2, the secant modulus of the concrete E_{cm} was chosen as the reference value. The transformation led to the factor 0.8 in Eq. (51.52). This factor, as well as the safety factor 1.35 in Eq. (51.53), may be considered as the effect of cracking of concrete under moment action due to the second-order effects. So, if this method is used for a test evaluation of composite columns, which is typically done without any safety factor, the safety factor for the stiffness should be taken into account subsequently, i.e., the predicted member capacity should be calculated using $(0.8E_{cm}/1.35)$. In addition, the value of 1.35 should not be changed, even if different safety factors are used in the country of application.

Long-Term Loading — For slender columns under long-term loading, the creep and shrinkage of concrete will cause a reduction in the effective elastic flexural stiffness of the composite column, thereby reducing the buckling resistance. However, this effect is significant only for slender columns. As a simple rule, the effect of long-term loading should be considered if the buckling length-to-depth ratio of a composite column exceeds 15.

If the eccentricity of loading, as defined in Eq. (51.50), is more than twice the cross section dimension, the effect on the bending moment distribution caused by increased deflections due to creep and shrinkage of concrete will be very small. Consequently, it may be neglected, and no provision for long-term loading is necessary. Moreover, no provision is necessary if the nondimensional slenderness, λ, of the composite column is less than the limiting values given in Table 51.8.

Otherwise, the effect of creep and shrinkage of concrete should be allowed for by employing the modulus of elasticity of the concrete, E_c, instead of E_{cd} in Eq. (51.54), which is defined as follows:

$$E_c = E_{cd}\left[1 - \left(0.5 N_{G.Sd}/N_{Sd}\right)\right] \tag{51.54}$$

where N_{Sd} = the design axial load
$N_{G.Sd}$ = the part of the design load permanently acting on the column

Table 51.8 also allows the effect of long-term loading to be ignored for concrete-filled hollow sections with $\lambda \le 2.0$, provided that d is greater than 0.6 for braced (nonsway) columns and 0.75 for unbraced (sway) columns.

TABLE 51.8 Limiting Values of λ That Do Not Require the Consideration of Long-Term Loading

Type of Cross Section	Braced Nonsway Systems	Unbraced and Sway Systems
Concrete encased	<0.8	<0.5
Concrete filled	$<0.8/(1-\delta)^a$	$<0.5/(1-\delta)^a$

[a] δ is the steel contribution ratio as defined in Eq. (51.44).

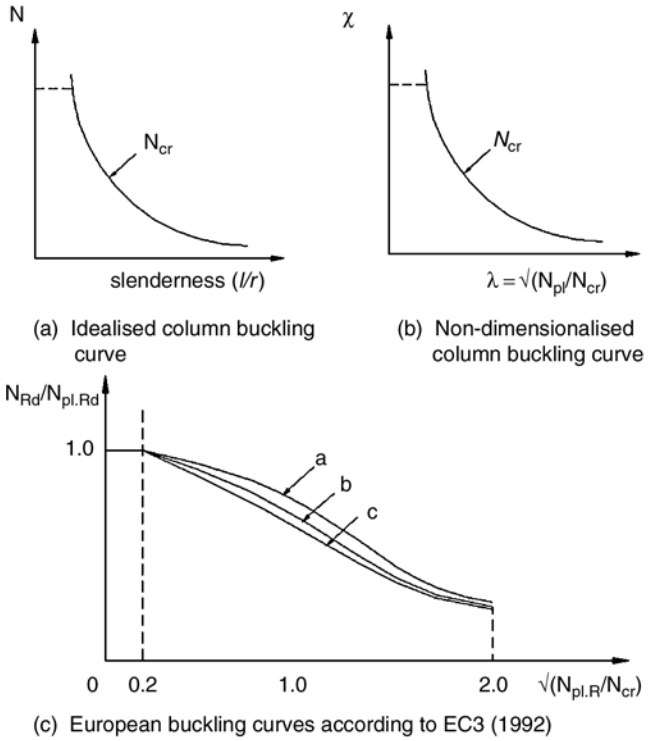

FIGURE 51.37 Slender composite column behavior: (a) idealized column buckling $N_{Rd}/N_{pl.Rd}$ curve, (b) nondimensionalized buckling curve, (c) European buckling curves according to EC3-1992.

Resistance of Members to Axial Compression

The plastic resistance to compression of a composite cross section, N_{pl}, represents the maximum load that can be applied to a short column. For slender columns with low elastic critical loads, overall buckling may be critical.

In a typical buckling curve for a column, as shown in Fig. 51.37(a), the horizontal line represents N_{pl}, while the curve represents N_{cr}, which is a function of the column slenderness. They are the boundaries to the compressive resistance of the column.

In Fig. 51.37(b), the buckling resistance of a column may be expressed as a proportion χ of the plastic resistance to compression, N_{pl}, thereby nondimensionalizing the vertical axis of Fig. 51.37(b). The horizontal axis may be nondimensionalized similarly by N_{cr}, as shown in Fig. 51.37(b).

By incorporating the effects of both residual stresses and geometric imperfections, the multiple column curves may be drawn on this basis, as shown in Fig. 51.37(c). They form the basis of column buckling design for both steel and composite columns.

In order to determine the compressive resistance of a column with the European buckling curves, the nondimensional slenderness of the column should be first evaluated as follows:

$$\lambda = \sqrt{\left(N_{pl.R}/N_{cr}\right)} \tag{51.55}$$

where $N_{pl.R}$ = the plastic resistance of the cross section to compression, according to Eq. (51.42), with $\gamma_a = \gamma_c = \gamma_s = 1.0$

N_{cr} = the elastic critical buckling load, as defined in Eq. (51.51)

Once the nondimensional slenderness of a composite column is established, the buckling resistance to compression of the column may be evaluated.

A composite column has sufficient compression resistance if, for both axes of bending,

$$N_{Sd} \leq \chi\, N_{pl.Rd} \tag{51.56}$$

where N_{Sd} = the design applied load to be resisted
$N_{pl.Rd}$ = the cross section resistance in accordance with Eq. (51.42) or (51.45)
χ = the reduction coefficient due to column buckling and is a function of the nondimensional slenderness of the composite column

The European buckling curves illustrated in Fig. 51.37(c) may be used for composite columns. They are selected according to type of steel section and the axis of bending:

curve *a* for concrete-filled hollow sections
curve *b* for fully or partially concrete-encased I sections buckling about the strong axis of the steel sections
curve *c* for fully or partially concrete-encased I sections buckling about the weak axis of the steel sections

These curves can also be calculated based on the following equation:

$$\chi = 1\Big/\left[\phi + \left(\phi^2 + \lambda^2\right)^{1/2}\right] \leq 1.0 \tag{51.57}$$

where

$$\phi = 0.5\left[1 + \alpha\left(\lambda - 0.2\right) + \lambda^2\right] \tag{51.58}$$

The factor α is used to allow for different levels of imperfections in the columns. It is important to note that the second-order moment due to imperfection, or the imperfection moment, has been incorporated in the method through different buckling curves; no additional consideration is necessary. The various values of α are in Table 51.9.

TABLE 51.9 Imperfection Factors α for the Buckling Curves according to Eurocode 3

European Buckling Curve	*a*	*b*	*c*
Imperfection factor α	0.21	0.34	0.49

Combined Compression and Uniaxial Bending

The design for a composite column under combined compression and bending is carried out in stages as follows:

- The composite column is isolated from the framework, and the end moments that result from the analysis of the system as a whole are taken to act on the column under consideration. Internal moments and forces within the column length are determined from the structural consideration of end moments and axial and transverse loads.
- For each axis of symmetry, the buckling resistance to compression should be checked with the relevant nondimensional slenderness of the composite column.
- In the presence of an applied moment about one particular axis, e.g., the *y-y* axis, the moment resistance of the composite cross section should be checked with the relevant nondimensional slenderness of the composite column, i.e., l_y instead of l_z,although l_z may be larger than and thus more critical than l_y.
- For slender columns, both long-term loading and second-order effects should be included.

In the simplified method of EC4, imperfections within the column length need not be considered, as they are taken into account in the determination of the buckling resistance of the columns.

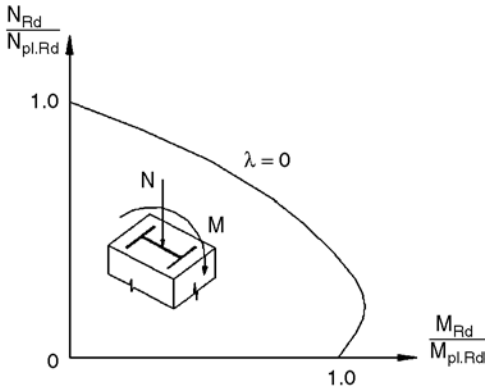

FIGURE 51.38 Interaction curve for compression and uniaxial bending.

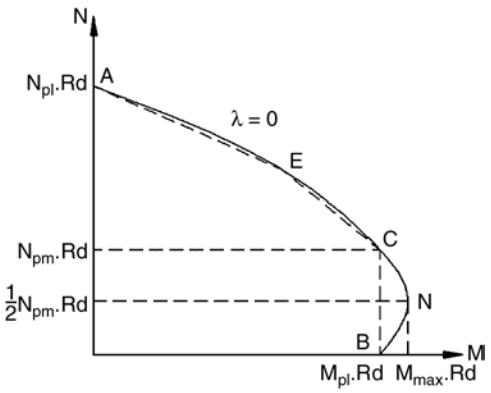

FIGURE 51.39 Interaction curve with polygonal approximation.

Interaction Curve for Compression and Uniaxial Bending

In EC4, the resistance of the composite column to combined compression and bending is determined with the help of an interaction curve. Unlike the interaction diagram for a bare steel section, where the moment resistance undergoes a continuous reduction with increase in axial load, the moment resistance for very short composite columns may be increased by the presence of an axial load. This is because the prestressing effect of an axial load may in certain circumstances prevent cracking, and so make the concrete more effective in resisting moment. Figure 51.38 represents the nondimensional interaction curve for compression and uniaxial bending for a composite cross section.

Such a curve for short composite columns can be determined by considering different positions of the neutral axis over the whole cross section and determining the internal action effects from the resulting stress blocks. This approach can only be carried out by computer analysis.

With the simplified method of EC4, it is possible to calculate by hand four or five points (ACDB and E) of the interaction curve. The interaction curve may be replaced by the polygon ACDB(E) through these points (see Fig. 51.39). The method is applicable to the design of columns with cross sections that are symmetrical about both principal axes.

The simplified design method in EC4 uses the following method to determine points A to E.

Figure 51.40 shows the stress distributions in the cross section of a concrete-filled rectangular hollow section at each point (A, B, C, D, and E) of the interaction curve. It is important to note that:

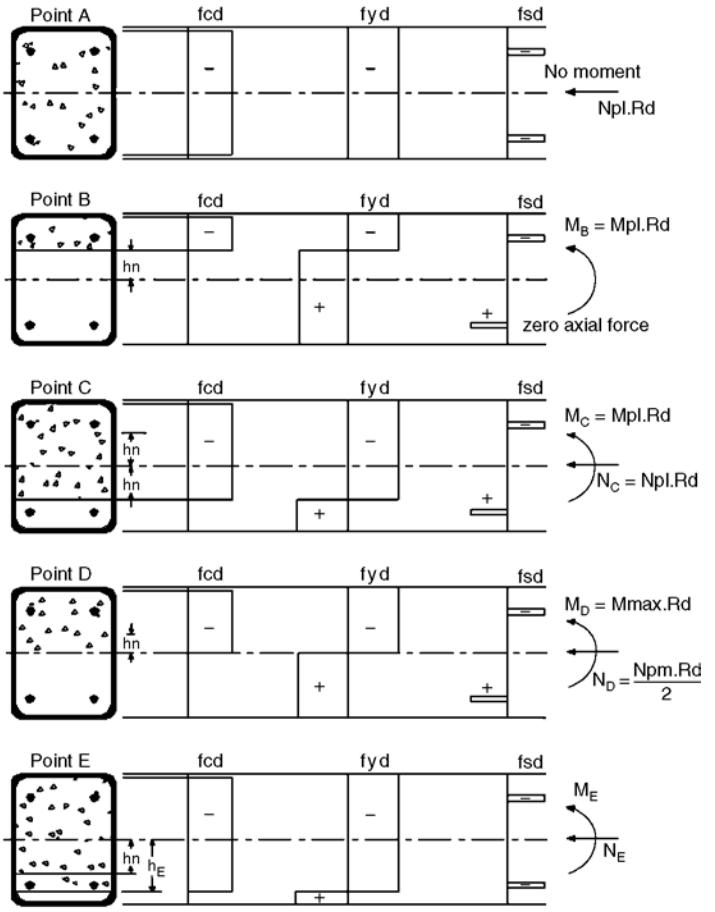

FIGURE 51.40 Stress distribution for the points of the interaction curve for concrete-filled rectangular hollow sections, according to EC4-1992.

- Point A marks the plastic resistance of the cross section to compression:

$$N_{\mathrm{A}} = N_{\mathrm{pl.Rd}}$$

$$M_{\mathrm{A}} = 0$$

- Point B corresponds to the plastic moment capacity of the cross section:

$$N_{\mathrm{B}} = 0$$

$$M_{\mathrm{B}} = M_{\mathrm{pl.Rd}}$$

- Point C, the compressive and moment resistances of the column, are given as follows:

$$N_{\mathrm{C}} = N_{\mathrm{pm.Rd}} = A_{\mathrm{c}} f_{\mathrm{cd}}$$

$$M_{\mathrm{C}} = M_{\mathrm{pl.Rd}}$$

FIGURE 51.41 Initially imperfect column under axial compression.

- The expressions may be obtained by combining the stress distributions of the cross section at points B and C. The compression area of the concrete at point B is equal to the tension area of the concrete at point C. The moment resistance at point C is equal to that at point B, since the stress resultants from the additionally compressed parts nullify each other in the central region of the cross section. However, these additionally compressed regions create an internal axial force, which is equal to the plastic resistance to compression of the concrete alone, $N_{pm.Rd}$.
- At point D, the plastic neutral axis coincides with the centroidal axis of the cross section and the resulting axial force is half of that at point C:

$$N_D = N_{pm.Rd}/2$$

$$M_C = M_{max.Rd}$$

- Point E is midway between points A and C. It is often required for highly nonlinear interaction curves, in order to achieve better approximation. In general, it is not needed for concrete-encased I sections subject to moments about the major axis, or if the design axial force does not exceed $N_{pm.Rd}$. For concrete-filled hollow sections, the use of point E will give more economical design, although much calculation effort is required. For simplicity, point E may be omitted in design.

Analysis of Bending Moments Due to Second-Order Effects

Under the action of a design axial load N_{Sd} on a column with an initial imperfection e_o, as shown in Fig. 51.41, there will be a maximum internal moment of $N_{Sd}(e_o)$. It is important to note that this second-order moment does not need to be considered separately, as its effect on the buckling resistance of the composite column is already accounted for in the European buckling curves, as shown in Fig. 51.37(c).

However, in addition to axial forces, a composite column may be also subjected to end moments as a consequence of transverse loads acting on it, or because the composite column is part of a frame. The moments and displacements obtained initially are referred to as first-order values. For slender columns, the first-order displacements may be significant, and additional or second-order bending moments may be induced under the actions of applied loads. As a simple rule, the second-order effects should be considered if the buckling length-to-depth ratio of a composite column exceeds 15.

The second-order effect on the bending moment for isolated nonsway columns should be considered when both of the following conditions are satisfied:

1. $N_{Sd}/N_{cr} > 0.1$, where N_{Sd} is the design applied load and N_{cr} is the elastic critical load of the composite column.
2. $\lambda > 0.2(2 - r)$, where λ is the nondimensional slenderness of the composite column and r is the ratio of the smaller to the larger end moment. If there is any transverse loading, r should be taken as 1.0.

The second-order effects in an isolated nonsway column may be allowed for by multiplying the maximum first-order bending moment $M_{max.Sd}$ with a correction factor k, which is defined as

$$k = \frac{\beta}{1 - \left(\frac{N_{Sd}}{N_{cr.L}}\right)} \geq 1.0 \tag{51.59}$$

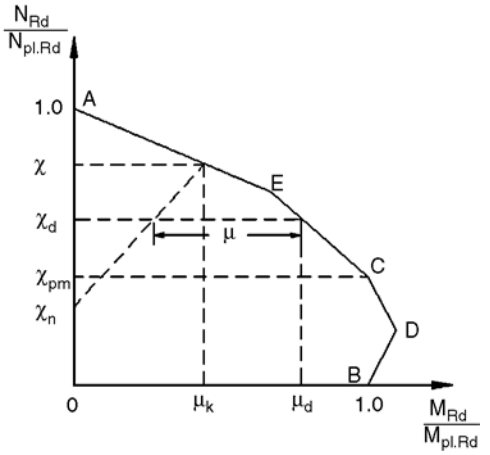

FIGURE 51.42 Interaction curve for compression and uniaxial bending using EC4 method.

where N_{Sd} = the design axial load
$N_{cr.L}$ = the elastic critical load of the composite column based on the system length, L
β = an equivalent moment factor

For columns with transverse loading within the column length, the value for b should be taken as 1.0. For pure end moments, β is determined as follows:

$$\beta = 0.66 + 0.44r \geq 0.44 \tag{51.60}$$

Resistance of Members under Combined Compression and Uniaxial Bending

The principle for checking sections under compression and uniaxial bending is shown graphically in Fig. 51.39 or 51.42. In this method an initial imperfection has been incorporated, so that any additional consideration of geometrical imperfection is unnecessary in the calculations of moments within the column length.

The axial resistance of the composite column in the absence of moment is given by $\chi N_{pl.Rd}$ (refer to Eq. (51.46)). Therefore, at the level $\chi = N_{Rd}/N_{pl.Rd}$, no additional bending moment can be applied to the column. The corresponding value for bending μ_k of the cross section is therefore the moment for imperfection of the column, and the influence of this imperfection is assumed to decrease linearly to the value χ_n. For an axial load ratio less than χ_n, the effect of imperfections is neglected.

It is important to recognize that the value χ_n accounts for the fact that the influences of the imperfections and bending moment do not always act together unfavorably. For columns with end moments, χ_n may be obtained as follows:

$$\chi_n = \chi(1-r)/4 \tag{51.61}$$

If transverse loads occur within the column height, r is taken as unity and χ_n is thus equal to zero.

With a design axial load of N_{Sd}, the axial load ratio χ_d is defined as

$$\chi_d = N_{Sd}/N_{pl.Rd} \tag{51.62}$$

The horizontal distance from the interaction curve, μ, defines the ultimate moment resistance that is still available, having taken account of the influence of second-order effects in the column.

EC4 considers that the design is adequate when the following condition is satisfied:

$$M_{Sd} \leq 0.9\ \mu M_{pl.Rd} \tag{51.63}$$

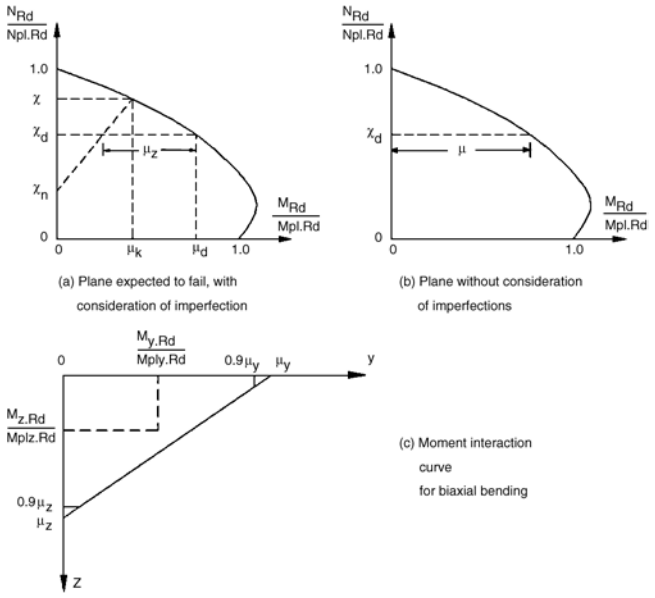

FIGURE 51.43 Design for combined compression and biaxial bending.

where M_{Sd} = the design bending moment, which may be factored to allow for second-order effects, if any
μ = the moment resistance ratio obtained from the interaction curve
$M_{pl.Rd}$ = the plastic moment resistance of the composite cross section

The interaction curve has been determined without considering the strain limitations in the concrete. Hence the moments, including second-order effects if necessary, are calculated using the effective elastic flexural stiffness $(EI)_e$ and taking into account the entire uncracked concrete area of the cross section (i.e., concrete is uncracked). Consequently, a reduction factor of 0.9 is applied to the moment resistance in Eq. (51.63) to allow for the simplifications in the approach.

In certain regions of the interaction curve, the moment resistance ratio is allowed to be greater than the unity in the presence of an axial load. This is due to the fact that in the presence of an axial load, the amount of concrete in tension and thus area of cracked section is reduced, and more concrete is included in the evaluation of the moment resistance. However, if the bending moment and applied load are independent of each other, the value of μ must be limited to 1.0.

For concrete-filled hollow sections, inclusion of point E in the interaction curve, as shown in Fig. 51.42, will give more economical design, especially for columns under a high axial load and low end moments.

Combined Compression and Biaxial Bending

For the design of a composite column under combined compression and biaxial bending, the axial resistance of the column in the presence of the bending moment for each axis must be evaluated separately. In general, it will be obvious which axis is more critical. If not, checks have to be carried out for compression and uniaxial bending for each axis separately. Imperfections should be considered only for the plane in which failure is expected to occur.

After finding the moment resistance ratios μ_y and μ_z for both axes, the interactions of the moments are checked using the moment interaction curve shown in Fig. 51.43. This linear interaction curve is cut off at $0.9\mu_y$ and $0.9\mu_z$. The design moments $M_{y.Sd}$ and $M_{z.Sd}$, related to the respective plastic moment resistances, must lie within the moment interaction curve.

EC4 considers the check adequate when all of the following conditions are satisfied:

$$\frac{M_{y.Sd}}{\mu_y M_{Ply.Rd}} \le 0.9 \tag{51.64}$$

$$\frac{M_{z.Sd}}{\mu_z M_{Plz.Rd}} \le 0.9 \tag{51.65}$$

and

$$\frac{M_{y.Sd}}{\mu_y M_{Ply.Rd}} + \frac{M_{z.Sd}}{\mu_z M_{Plz.Rd}} \le 1.0 \tag{51.66}$$

In columns with a different distribution of moments in both of the main axes, the determination of the position of the critical combination of moments is often very difficult. For the purpose of simplification, the maximum moments of the bending axes may be used in Eq. (51.66).

AISC-LRFD

The concept of applying AISC-LRFD column design methodology to composite columns by the use of modified properties was first presented by Furlong [32]. Modified yield stress F_{my}, modified modulus of elasticity E_m, and modified radius of gyration r_m were incorporated into an allowable stress design procedure that was published by Task Group 20 of the Structural Stability Research Council [33].

Axially Loaded Column

When a column is under axial compression, concrete spalls and fails when longitudinal strain reaches about 0.18 to 0.20%. Cross section strength P_o is the sum of axial load capacities of the materials that make up the cross section. Thus, for steel that yields at strains no greater than 0.2%,

$$P_o = A_s F_y + A_r F_{yr} + 0.85 A_c f_c' \tag{51.67}$$

where A_s = the area of structural shape in the cross section
A_r = the area of longitudinal reinforcement in the cross section
A_c = the concrete in the cross section
F_y = the yield strength of the structural shape steel
F_{yr} = the yield strength of the longitudinal reinforcement
f_c' = the strength of concrete from standard cylinder tests

The design strength of composite columns is determined from the same equations as those applicable to bare steel columns, except that the formulas are entered with modified properties F_{my}, E_m, and r_m. The axial design strength is computed as

$$\phi_c P_n = 0.85 A_s F_{cr} \tag{51.68}$$

where F_{cr} is the critical stress of the column given by Eqs. (51.69) and (51.70). Both equations include the estimate effects of residual stresses and initial of-out-straightness of the members. The factor 0.877 in Eq. (51.70) accounts for the effect of member initial out-of-straightness.

$$F_{cr} = \left(0.658^{\lambda_c^2}\right) F_{my} \qquad \text{for } \lambda_c \le 1.5 \tag{51.69}$$

and

$$F_{cr} = \frac{0.877}{\lambda_c^2} F_{my} \qquad \text{for } \lambda_c > 1.5 \tag{51.70}$$

TABLE 51.10 Numerical Coefficients for Design of Composite Columns

Composite Column Type	Numerical Coefficients		
	c_1	c_2	c_3
Concrete-filled pipe and tubing	1.0	0.85	0.4
Concrete-encased shapes	0.7	0.6	0.2

where F_{my} = the modified yield stress and $\lambda_c = (KL/r_m\pi)\sqrt{(F_{my}/E_m)}$, in which E_m is the modified modulus of elasticity, r_m is the modified radius of gyration about the axis of buckling, K is the effective length factor, and L is the laterally unbraced length of a member.

The modified properties F_{my}, E_m, and r_m account for the effects of concrete and longitudinal reinforcing bars. The modified radius of gyration r_m is the radius of gyration of the steel section, and it shall not be less than 0.3 times the overall thickness of the composite cross section in the plane of buckling. The modified values F_{my} and E_m are given by the following equations:

$$F_{my} = F_y + \frac{c_1 F_{yr} A_r}{A_s} + \frac{c_2 f_c' A_c}{A_s} \tag{51.71}$$

and

$$E_m = E + \frac{c_3 E_c A_c}{A_s} \tag{51.72}$$

where F_y = the yield strength of structural steel, ≤60 ksi (414 MPa)
F_{yr} = the yield strength of longitudinal reinforcement, ≤60 ksi (414 MPa)
E = the modulus of elasticity of steel
E_c = the modulus of elasticity of concrete
c_1, c_2, and c_3 = the numerical coefficients listed in Table 51.10

Coefficients c_1, c_2, and c_3 are higher for filled composite columns than for encased composite columns. With the steel encasement always available to provide lateral confinement to concrete in filled composite columns, there is no uncertainty that the contained concrete will reach at least as much strength as that reached by concrete in unconfined standard concrete cylinders used in determining f_c'. In contrast, there is less uncertainty that an unconfined concrete encasement can attain stress as high as $0.85f_c'$. If the unconfined concrete fails to reach $0.85f_c'$, the longitudinal reinforcement it stabilizes may not reach its yield stress, F_{yr}, either. The values of c_1 and c_2 for encased composite columns are 70% of the values for filled composite columns, reflecting the higher degree of uncertainty.

To account for the uncertainty regarding the contribution of concrete to the buckling strength of a composite column, Eq. (51.72) includes the numerical coefficient c_3, which is equal to 0.4 for filled composite columns and 0.2 for encased composite columns. These coefficients are consistent with values recommended in the ACI building code for flexural stiffness, EI, in estimates of inelastic buckling loads.

Concrete loses stiffness at strains near 0.2% and may not be fully effective for stabilizing steel at strains higher than 0.2%, which translates into steel–stress values of about 60 ksi (414 MPa). The yield stresses of structural steel (F_y) and reinforcing bars (F_{yr}) used in calculating the strength of composite columns should not exceed 60 ksi. It is further recommended that the concrete strength f_c' be limited to 10 ksi (69 MPa) and smaller, since only very few tests are available for composite columns with f_c' in excess of 10 ksi. A lower limit of $f_c' = 2.5$ ksi (17 MPa) is recommended in order to encourage a degree of quality control commensurate with this readily available and familiar grade of structural concrete.

Flexural Strength

The nominal flexural strength, M_n, of a column cross section may be determined from the plastic state of stress or from an analysis of flexural strength at the ultimate state of strain. For simplicity, the

commentary in the AISC-LRFD (Section C-I4) offers an approximate equation for moment capacity of doubly symmetric sections. The sum of flexural capacities for component parts includes the plastic moment capacity of the steel shape, an estimate of the yield moment of reinforcement, and the moment capacity for which compression concrete is considered reinforced at middepth by longitudinal bars and the web of the steel shape.

$$M_n = ZF_y + \frac{1}{3}\left(h_2 - 2C_r\right)A_r F_{yr} + \left(\frac{h_2}{2} - \frac{A_w F_y}{1.7 f_c' h_1}\right)A_w F_y \tag{51.73}$$

where A_w = the web area of steel shape plus any longitudinal bars at the center of the section
Z = the plastic section modulus of the steel shape
h_1 = the concrete width perpendicular to the plane of bending
h_2 = the concrete thickness in the plane of bending
c_r = the thickness of concrete cover from the center of bar to the edge of the section in the plane of bending

Combined Axial Compression and Moments

For composite columns symmetrical about the plane of bending, the interaction of compression and flexure should be limited by the formulas in the following AISC-LRFD equations:

$$\frac{P_u}{\phi_c P_n} + \frac{8}{9}\left(\frac{M_{ux}}{\phi_b M_{nx}} + \frac{M_{uy}}{\phi_b M_{ny}}\right) \le 1 \qquad \text{for } P_u \ge 0.2\phi_c P_n \tag{51.74}$$

and

$$\frac{P_u}{2\phi_c P_n} + \frac{M_{ux}}{\phi_b M_{nx}} + \frac{M_{uy}}{\phi_b M_{ny}} \le 1 \qquad \text{for } P_u < 0.2\phi_c P_n \tag{51.75}$$

where P_u = the required compressive strength
P_n = the nominal compressive strength
M_u = the required flexural strength
M_n = the nominal flexural strength
ϕ_c = the resistance factor for compression, 0.85
ϕ_b = the resistance factor for flexure, 0.90

and subscripts x and y denote the major and minor axes, respectively.

Second-order effects may be considered in the determination of M_u for use in Eqs. (51.74) and (51.75).

The simplicity of AISC-LRFD results in a conservative design. The supporting comparisons with the beam-column test, given in the commentary of AISC-LRFD, included 48 concrete-filled pipes or tubing and 44 concrete-encased steel shapes (see Galambos and Chapuis [34]). The overall mean test-to-prediction ratio was 1.23, and the coefficient of variation was 0.21.

Australian Standards AS 3600 and AS 4100

Strength of Short Columns

The design of a concrete-filled steel column in Australia can be undertaken using a combination of the Australian Standards for concrete and steel structures. Thus the ultimate axial force of a column can be represented as

$$N_u = N_{uc} + N_{us} \tag{51.76}$$

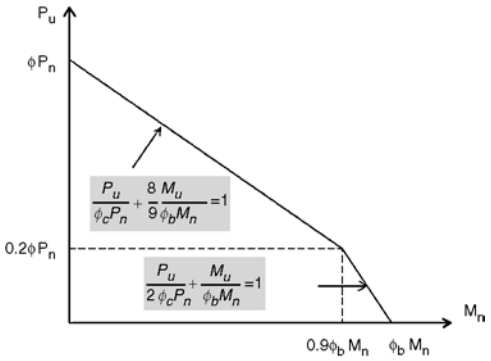

FIGURE 51.44 Column interaction curve using AISC-LRFD (1993).

The Australian Standard for concrete structures, AS 3600, will not allow confinement, as it does not treat the behavior of concrete-filled steel columns directly. The concrete contribution to strength can be determined using Eq. (51.77), where

$$N_{uc} = 0.85A_c f_c \tag{51.77}$$

The Australian Standard for steel structures, AS 4100, suggests a set of slenderness limits that do not allow for the beneficial effect of local buckling. Slenderness limits for inelastic local buckling are as low as $b/t = 30$ for heavily welded sections. However, this standard allows one to use a rational local buckling method to determine the post-local buckling strength. The steel strength can therefore be determined from Eq. (51.78), where

$$N_{uc} = A_{se} f_y \tag{51.78}$$

If one combines the concrete and steel strengths, N_{uc} and N_{us}, respectively, from the AS 3600 and AS 4100 analysis, the resulting ultimate axial strength can be written as

$$N_u = 0.85A_c f_c + A_{se} f_y \tag{51.79}$$

Therefore, while the beneficial effect of the concrete is taken into account for post-local buckling, the effect of concrete confinement is ignored; the initial slenderness limits are too stringent for use in concrete-filled steel columns, which are economical in steel construction.

Local Buckling

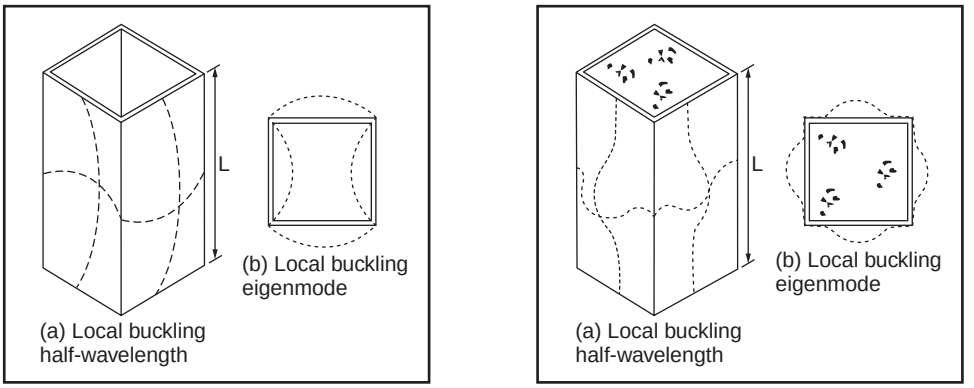
If a composite section has a thin-walled steel section, which is able to buckle locally, then a reduction for the strength of the steel section must be made. The local buckling load and strength of a concrete-filled steel section are significantly higher than those of a hollow steel section, as shown in Fig. 51.45.

The local buckling stress can be determined using Eq. (51.80), where k is determined from a rational local buckling analysis and is given in Table 51.11 for various boundary and fill conditions.

$$\sigma_{ol} = \frac{k\pi^2 E}{12\left(1-\upsilon^2\right)\left(\dfrac{b}{t}\right)^2} \tag{51.80}$$

Post-Local Buckling

Post-local buckling is often predicted using the effective width concept. Effective width models for hot-rolled and fabricated sections have been modified to incorporate residual stresses and initial imperfections by Bradford [35] and Bradford et al. [36], and were adopted in the Australian Standard AS 4100-1990



(a) Hollow steel section (b) Filled steel section

TABLE 51.11 Local Buckling Coefficient, k

Boundary Condition	Type of Section	k
Supported on two longitudinal edges	Hollow	4.0
Supported on two longitudinal edges	Filled	10.31
Supported on one longitudinal edge	Hollow	0.425
Supported on one longitudinal edge	Filled	2.0

TABLE 51.12 Post-Local Buckling Parameter, α

Boundary Condition	Method of Manufacture	α
Supported on two longitudinal edges	Stress relieved	0.84
Supported on two longitudinal edges	Hot rolled	0.84
Supported on two longitudinal edges	Lightly welded	0.74
Supported on two longitudinal edges	Heavily welded	0.65
Supported on two longitudinal edges	Stress relieved	0.91
Supported on two longitudinal edges	Hot rolled	0.91
Supported on two longitudinal edges	Lightly welded	0.86
Supported on two longitudinal edges	Heavily welded	0.80

[29]. This model is based on the Winter formula, which is also present in steel codes in the U.S. and Europe and is of the form

$$\frac{b_e}{b} = \alpha \sqrt{\frac{\sigma_{ol}}{\sigma_y}} \tag{51.81}$$

where α is a parameter used to account for residual stresses and initial geometric imperfections. This parameter varies, depending on the type of section and its method of fabrication. Furthermore, the type of boundary condition also affects the determination of α. Values for this parameter, including all these factors, are summarized in Table 51.12, which was calibrated for steel structures in the Australian Standard AS 4100-1990 [29] and reported by Bradford et al. [36]. These parameters were thus used in calibrating the model with the post-local buckling test results determined by Uy [37] for concrete-filled sections. The results are illustrated in Figs. (51.46) and (51.47).

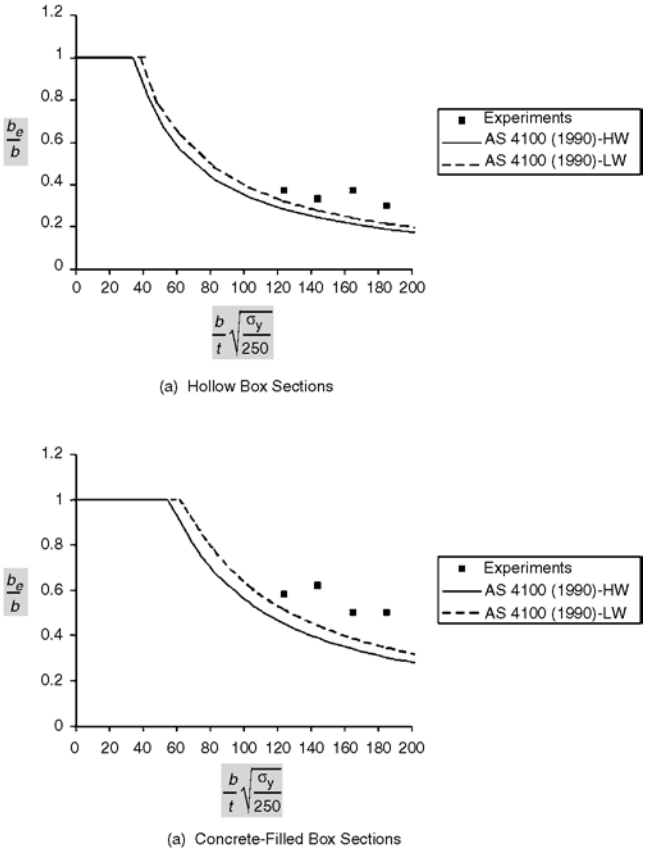

FIGURE 51.46 Post-local buckling comparisons for box sections: (a) hollow box sections, (b) concrete-filled box sections. From Uy, B., *J. Struct. Eng. ASCE,* 127, 666, 2001.

Strength of Slender Columns

Slender composite columns can be analyzed using either the concrete approach, AS 3600, or the steel approach, AS 4100. The approach used by the Eurocode 4 is a useful manner in which to distinguish between the two methods

$$\delta = \frac{A_a f_{yd}}{N_{pl.Rd}} \tag{51.82}$$

The column is classified as composite if the steel contribution ratio falls within the range of $0.2 \le \delta \le 0.9$. If δ is less than 0.2, the column shall be designed as a reinforced concrete column; otherwise, if δ is greater than 0.9, the column shall be designed as a bare steel column.

Concrete Approach, AS 3600

Slender columns are analyzed in the Australian Concrete Structures Code, AS 3600, using a strength interaction diagram and a loading line. The loading line is used to account for nonlinearities and second-order effects.

Steel Approach, AS 4100

The approach of the Australian Standard for steel columns is essentially the same as the approach of EC3 and EC4, which use the column curves with different levels of imperfections and residual stresses. The

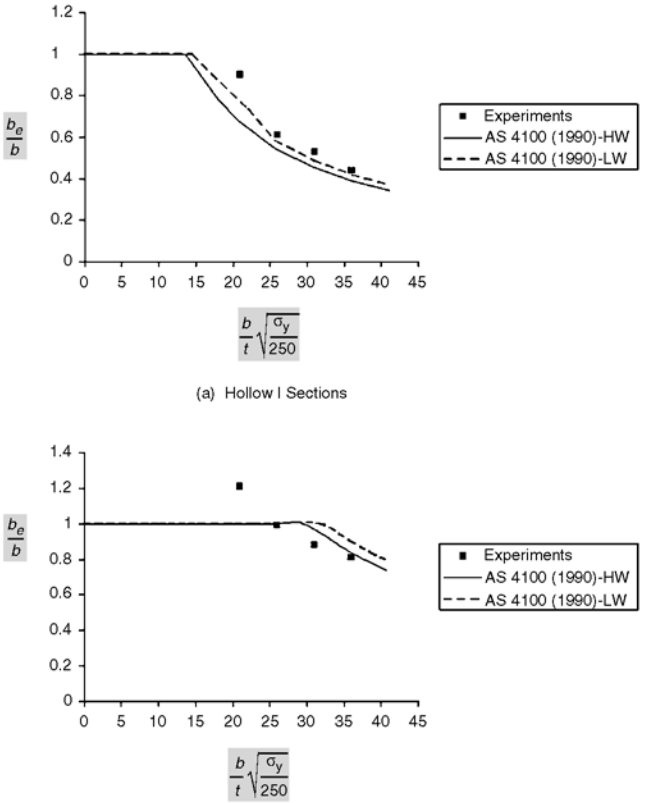

FIGURE 51.47 Post-local buckling comparisons for I sections: (a) hollow I sections, (b) concrete-filled I sections. From Uy, B., *J. Struct. Eng. ASCE,* 127, 666, 2001.

method relies on determining a critical buckling load, N_c, where the critical buckling load depends on both the member slenderness and the level of imperfections and residual stresses:

$$N_c = \alpha_c N_s \tag{51.83}$$

where α_c is the coefficient, which depends on both member slenderness and method of manufacture. N_s is determined based on the section capacity, which can account for local buckling. However, Vrcelj and Uy [38] have developed a more comprehensive method to consider local buckling for concrete-filled steel sections, and to use this method, N_s in Eq. (51.83) is calculated as the member squash load.

Effects of Local Buckling

The slender column buckling load, N_{clb}, which incorporates local buckling, can be represented in the form of Eq. (51.84) in terms of N_c, the column buckling load, which ignores the effects of local buckling.

$$N_{clb} = \alpha_{lb} N_c \tag{51.84}$$

where α_{lb} is the interaction coefficient to account for local buckling and is in the range

$$0 \le \alpha_{lb} \le 1.0 \tag{51.85}$$

and is calculated as

$$\alpha_{lb} = \frac{\left(100 - p_r\right)}{100} \tag{51.86}$$

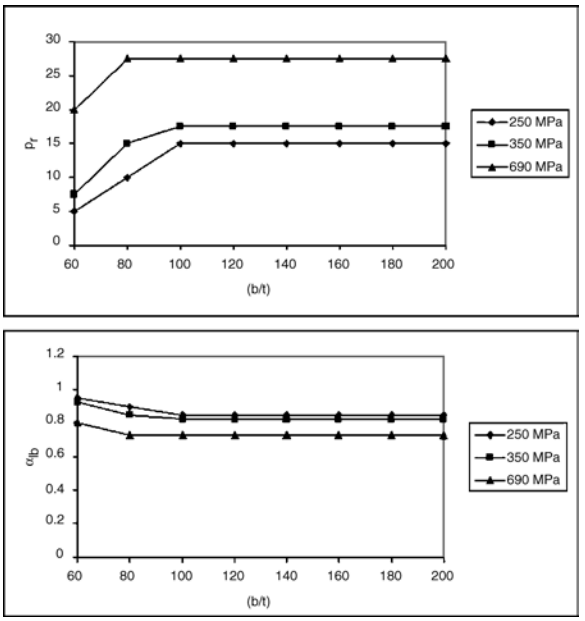

FIGURE 51.48 Interaction buckling of composite columns. From Vrcelj, Z. and Uy, B., J. Construct. Steel Res., 2001.

where the percentage reduction, p_r, is given as

$$p_r = \left(\frac{N_c - N_{clb}}{N_c} \right) * 100 \tag{51.87}$$

By determining N_c using an existing standard, one can include the effects of local buckling by determining α_{lb}. The global buckling load N_{clb} can be determined using Eq. (51.84). The reduction factors may be determined using Fig. 51.48.

51.9 Lateral Load Resisting Systems

This section discusses four classical lateral load resisting systems for multistory building frames. They are the (1) core braced system, (2) moment–truss system, (3) outrigger and belt system, and (4) tube system. Multistory buildings that utilize cantilever action will have higher efficiencies, but the overall structural efficiency depends on the height-to-width ratio. Interactive systems involving a moment frame and vertical truss or core are effective up to 40 stories and represent most building forms for tall structures. Outrigger and belt trusses help to further enhance the lateral stiffness by engaging the exterior frames with the core braces to develop cantilever actions. Exterior framed tube systems with closely spaced exterior columns connected by deep girders mobilize the three-dimensional action to resist lateral and torsional forces. Bundled tubes improve the efficiency of exterior frame tubes by providing internal stiffening to the exterior tube. Finally, by providing diagonal braces to the exterior framework, a superframe is formed and can be used for ultratall megastructures. Further details on the comparison of various framing schemes are reported in Liew et al. [39].

Core Braced Systems

This type of structural system relies entirely on the internal core for lateral load resistance. The basic concept is to provide an internal shear wall core to resist the lateral forces (Fig. 51.49). The surrounding

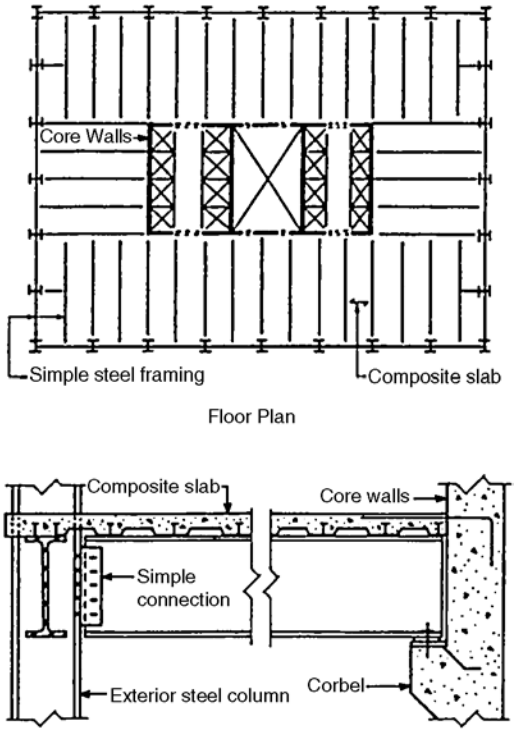

FIGURE 51.49 Core braced frame: (a) internal core walls with simple exterior framing, (b) beam-to-wall and beam-to-exterior column connections.

steel framing is designed to carry a gravity load only if simple framing is adopted. Otherwise, a rigid framing surrounding the core will enhance the overall lateral force resistance of the structure. The steel beams can be simply connected to the core walls by using a typical corbel detail, by bearing in a wall pocket, or by using a shear plate embedded in the core wall through studs. If rigid connection is required, the steel beams should be rigidly connected to the steel columns embedded in the core wall. Rigid framing surrounding the cores is particularly useful in high seismic areas and for very tall buildings that tend to attract stronger wind loads. They act as moment frames and provide resistance to some part of the lateral loads by engaging the core walls in the building.

The core generally provides all torsional and flexural rigidity and strength, with no participation from the steel system. Conceptually, the core system should be treated as a cantilever wall system with punched openings for access. The floor framing should be arranged in such a way that it distributes enough gravity load to the core walls so that their design is controlled by compressive stresses, even under wind loads. The geometric location of the core should be selected so as to minimize eccentricities for lateral load. The core walls need to have adequate torsional resistance for possible asymmetry of the core system, where the center of the resultant shear load is acting at an eccentricity from the center of the lateral force resistance.

A simple cantilever model should be adequate to analyze a core wall structure. However, if the structural form is a tube with openings for access, it may be necessary to perform a more accurate analysis to include the effect of openings. The walls can be analyzed by a finite element analysis using thin-walled plate elements. An analysis of this type may also be required to evaluate torsional stresses when the vertical profile of the core wall assembly is asymmetrical.

The concrete core walls can be constructed using slip-form techniques, where the core walls could be advanced several floors (typically four to six stories) ahead of the exterior steel framing. The core wall system represents an efficient type of structural system up to a certain height premium because of its

cantilever action. However, when it is used alone, the massiveness of the wall structure increases with height, thereby inhabiting the free planning of interior spaces, especially in the core. The space occupied by the shear wall leads to loss of overall floor area efficiency, compared to the tube system, which could otherwise be used.

In commercial buildings where floor space is valuable, the large area taken up by a concrete column can be reduced by the use of an embedded steel column to resist the extreme loads encountered in tall buildings. Sometimes, particularly at the bottom open floors of a high-rise structure, where large open lobbies or atriums are utilized as part of the architectural design, a heavy embedded steel section as part of a composite column is necessary to resist high load and because of the large unbraced length. A heavy steel section in a composite column is often utilized where the column size is restricted architecturally and where reinforcing steel percentages would otherwise exceed the code's maximum allowed values for the design of reinforced concrete columns.

Moment–Truss Systems

Vertical shear trusses located around the inner core in one or both directions can be combined with perimeter moment-resisting frames in the facade of a building to form an efficient structure for lateral load resistance. An example of a building consisting of moment frames with shear trusses located at the center is shown in Fig. 51.50(a). For the vertical trusses arranged in the North–South direction, either the K or X form of bracing is acceptable, since access to lift shafts is not required. However, K trusses

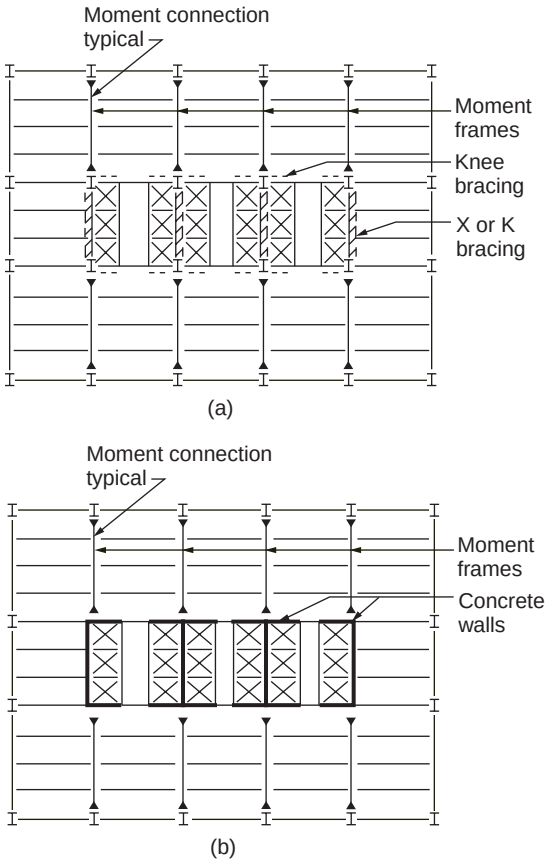

FIGURE 51.50 (a) Moment frame with internal braced trusses. (b) Moment frame with internal core walls.

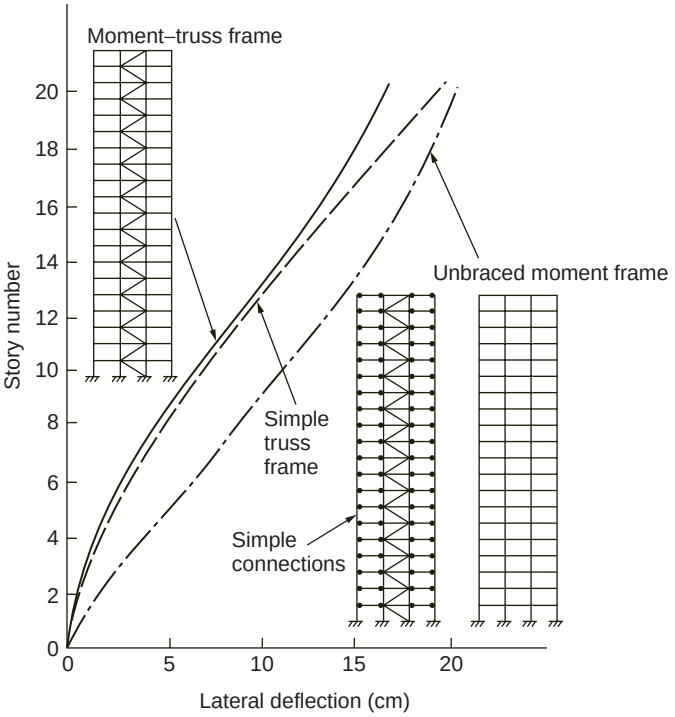

FIGURE 51.51 Sway characteristics of rigid braced, simple braced, and rigid unbraced frames.

are often preferred, because in the case of the X or single-brace form, bracing the influence of gravity loads is rather significant. In the East–West direction, only knee bracing is effective in resisting lateral load.

In some cases internal bracing can be provided using concrete shear walls, as shown in Fig. 51.50(b). The internal core walls substitute the steel trusses in K, X, or single-brace form, which may interfere with openings that provide access to, for example, elevators.

The interaction of shear frames and vertical trusses produces a combination of two deflection curves with the effect of more efficient stiffness. These moment frame–truss interacting systems are considered to be the most economical steel systems for buildings up to 40 stories. Figure 51.51 compares the sway characteristic of a 20-story steel frame subjected to the same lateral forces, but with different structural schemes, namely, (1) unbraced moment frame, (2) simple truss frame, and (3) moment–truss frame. The simple truss frame helps to control lateral drift at the lower stories, but the overall frame drift increases toward the top of the frame. The moment frame, on the other hand, shows an opposite characteristic for side sway, compared with the simple braced frame. The combination of the moment frame and the truss frame provides overall improvement in reducing frame drift; the benefit becomes more pronounced toward the top of the frame. The braced truss is restrained by the moment frame at the upper part of the building, while at the lower part, the moment frame is restrained by the truss frame. This is because the slope of frame sway displacement is relatively smaller than that of the truss at the top, while the proportion is reversed at the bottom. The interacting forces between the truss frame and moment frame, as shown in Fig. 51.52, enhance the combined moment–truss frame stiffness to a level larger than the summation of individual moment frame and truss stiffness.

Outrigger and Belt Truss Systems

Another significant improvement of lateral stiffness can be obtained if the vertical truss and the perimeter shear frame are connected on one or more levels by a system of outrigger and belt trusses. Figure 51.53 shows a typical example of such a system. The outrigger truss leads the wind forces of the core truss to

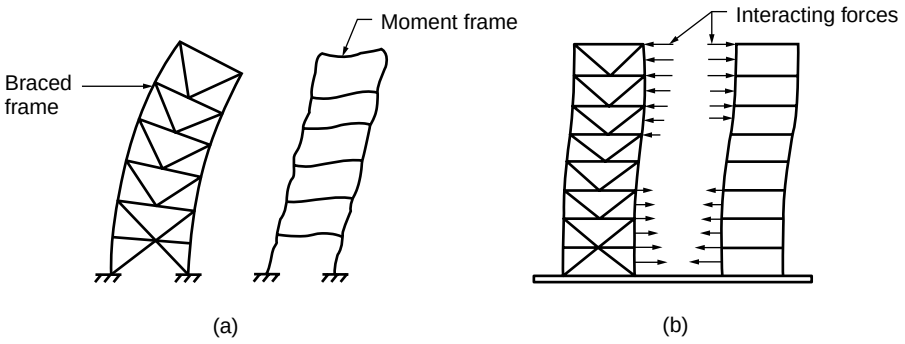

FIGURE 51.52 Behavior of frames subjected to lateral load: (a) independent behavior, (b) interactive behavior.

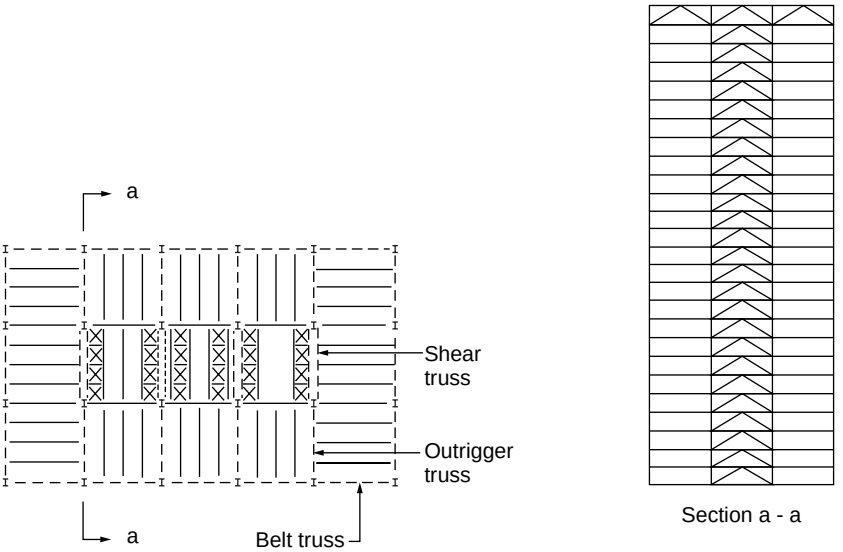

FIGURE 51.53 Outrigger and belt truss system.

the exterior columns, providing cantilever behavior of the total frame system. The belt truss in the facade improves the cantilever participation of the exterior frame and creates a three-dimensional frame behavior.

Figure 51.54 shows a schematic diagram that demonstrates the sway characteristic of the overall building under lateral load. Deflection is significantly reduced by the introduction of the outrigger–belt trusses. Two kinds of stiffening effects can be observed: one is related to the participation of the external columns, together with the internal core, to act in a cantilever mode; the other is related to the stiffening of the external facade frame by the belt truss to act as a three-dimensional tube. The overall stiffness can be increased up to 25%, compared to the shear truss and frame system without such outrigger–belt trusses.

The efficiency of this system is related to the number of trussed levels and the depth of the truss. In some cases the outrigger and belt trusses have a depth of two or more floors. They are located in service floors where there are no requirements for wide open spaces.

Frame Tube Systems

Figure 51.55 shows a typical frame tube system, which consists of a frame tube at the exterior of the building and gravity steel framing at the interior. The framed tube is constructed from large columns

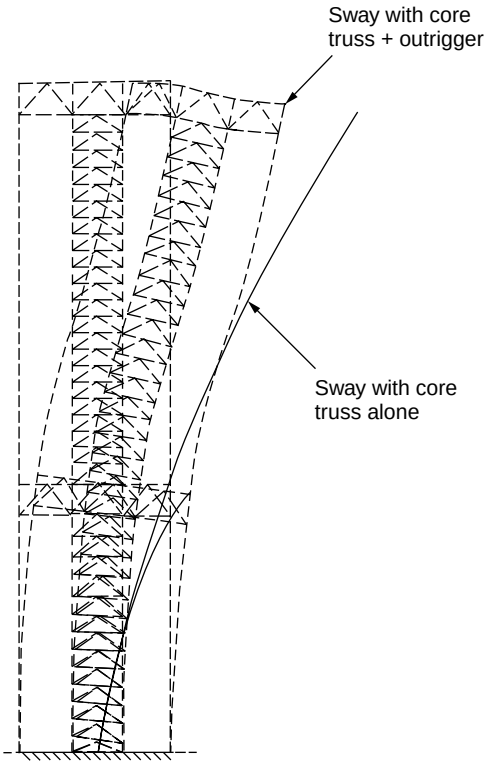

FIGURE 51.54 Improvement of lateral system using outrigger and belt trusses.

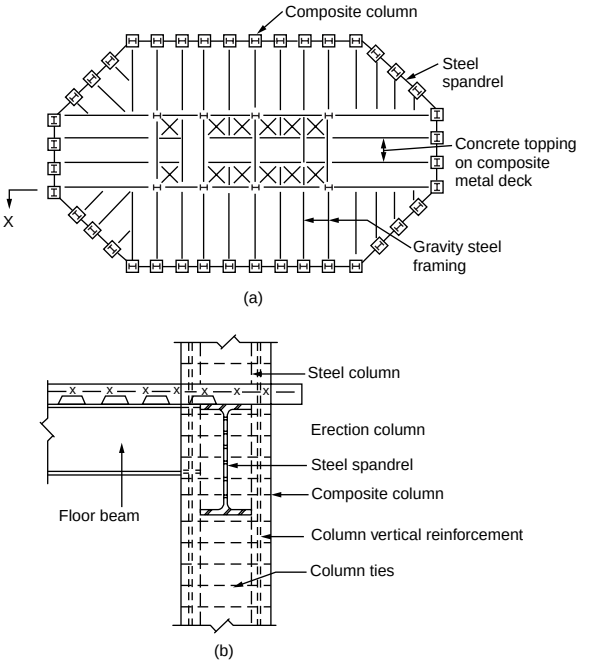

FIGURE 51.55 Composite tube system.

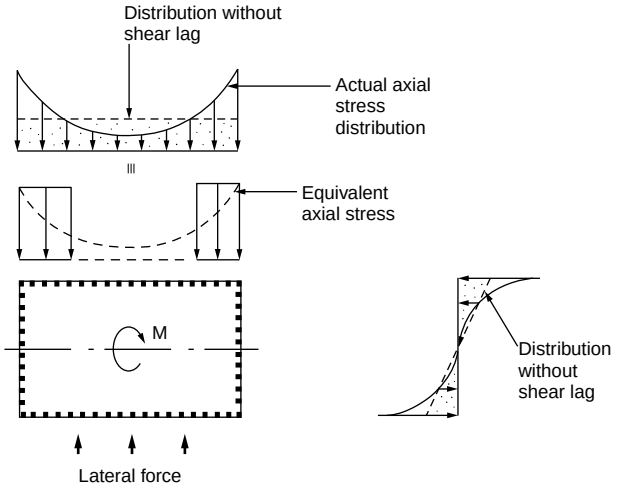

FIGURE 51.56 Shear lag effect in a frame tube system.

placed at close centers connected by deep beams, creating a punched-wall appearance. The exterior frame tube structure resists all lateral loads of wind or earthquake, whereas the simple steel framing in the interior resists only its share of gravity loads. The behavior of the exterior frame tube is similar to that of a hollow perforated tube. The overturning moment under the action of lateral load is resisted by compression and tension of the leeward and windward columns. The shear is resisted by bending of the columns and beams at the two sides of the building parallel to the direction of the lateral load.

Deepening on the shear rigidity of the frame tube, there may exist a shear lag across the windward and leeward sides of the tube. As a result, not all flange columns resist the same amount of axial force. An approximate approach is to assume an equivalent column model, as shown in Fig. 51.56. In the calculation of the lateral deflection of the frame tube it is assumed that only the equivalent flange columns on the windward and leeward sides of the tube and the web frames would contribute to the moment of inertia of the tube.

The use of an exterior framed tube has two distinct advantages: (1) it develops high rigidity and strength for torsional and lateral load resistance, since the structural components are effectively placed at the exterior of the building, forming a three-dimensional closed section; and (2) the massiveness of frame tube system eliminates potential uplift difficulties and produces better dynamic behavior. The use of simple steel framing in the interior has the advantage of flexibility and enables rapid construction.

Composite columns are commonly used in the perimeter of the building where the closely spaced columns are rigidly connected by deep spandrel beams to form a three-dimensional cantilever tube. The exterior frame tube significantly enhances the structural efficiency in resisting lateral loads and thus reduces the shear wall requirements. However, in cases where a higher magnitude of lateral stiffness is required (such as for very tall buildings), internal wall cores and interior columns with floor framing can be added to transform the system into a tube-in-tube system. The concrete core may be strategically located to recapture elevator space and to provide transmission of mechanical ducts from shafts and mechanical rooms.

Steel–Concrete Composite Systems

Steel–concrete composite construction has gained wide acceptance as an alternative to pure steel and pure concrete construction. Composite building systems can be broadly categorized into two forms: one utilizes the core braced system by means of interior shear walls, and the other utilizes exterior framing to form a tube for lateral load resistance. Combining these two structural forms will enable taller buildings to be constructed.

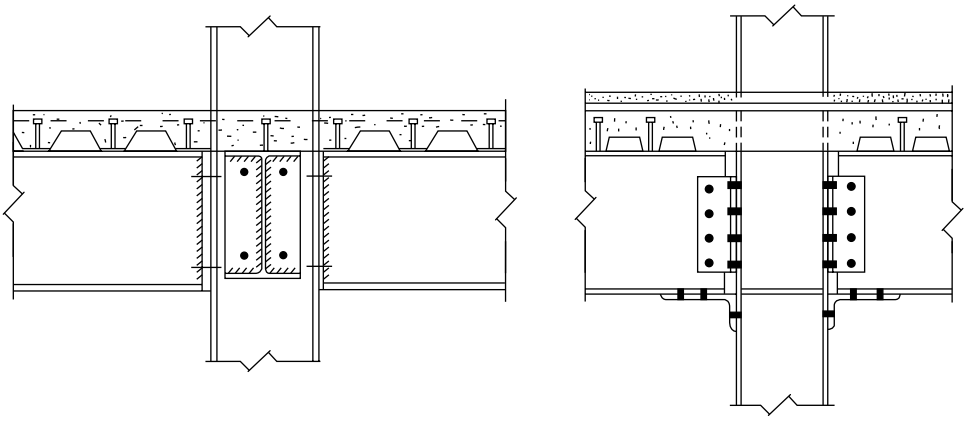

FIGURE 51.57 Composite connections.

For composite frames resisting gravity load only, the beam-to-column connections behave as they do when pinned before the placement of concrete. During construction, the beam is designed to resist concrete dead load and the construction load (to be treated as a temporary live load). At the composite stage, the composite strength and stiffness of the beam should be utilized to resist the full design loads. For simple frames consisting of bare steel columns and composite beams, there is now sufficient knowledge available for the designer to use composite action in the structural element, as well as the semirigid composite joints, to increase design choices, leading to more economical solutions. Practical design guidelines for semicontinuous composite braced frames are given in Liew et al. [40]. Deflection equations are derived, and vibration studies were conducted.

Figure 51.57 shows two typical beam-to-column connections: one using a flushed end plate bolted to the column flange, and the other using a bottom angle with double web cleats. Composite action in the joint is developed based on the tensile forces in the rebars that act with the balancing compression forces transmitted by the lower portion of the steel section that bears against the column flange to form a couple. Properly designed and detailed composite connections are capable of providing moment resistance up to the hogging resistance of the connecting members.

In designing the connections, slab reinforcements placed within a horizontal distance of six times the slab depth are assumed to be effective in resisting the hogging moment. Reinforcement steels that fall outside this width should not be considered in calculating the resisting moment of the connection (see Fig. 51.58). The connections to edge columns should be carefully detailed to ensure adequate anchorage of rebars. Otherwise, they shall be designed and detailed as simply supported. In braced frames a moment connection to the exterior column will increase the moments in the column, resulting in an increase of column size. Although the moment connections restrain the column from buckling by reducing the effective length, this is generally not adequate to offset the strength required to resist this moment.

For an unbraced frame subjected to gravity and lateral loads, the beam is typically bent in double curvature with hogging moment at one end of the beam and sagging moment at the other. The concrete is assumed to be ineffective in tension; therefore, only the steel beam stiffness on the hogging moment region and the composite stiffness on the sagging moment region can be utilized for frame action. The frame analysis can be performed with variable moments of inertia for the beams, and the second-order effect can be included in the advanced analysis [41].

If semirigid composite joints are used in unbraced frames, the flexibility of the connections will contribute to additional drift over that of a fully rigid frame. In general, semirigid connections do not require the column size to be increased significantly over an equivalent rigid frame. This is because the design of frames with semirigid composite joints takes advantage of the additional stiffness in the beams provided by the composite action. The increase in beam stiffness would partially offset the additional flexibility introduced by the semirigid connections.

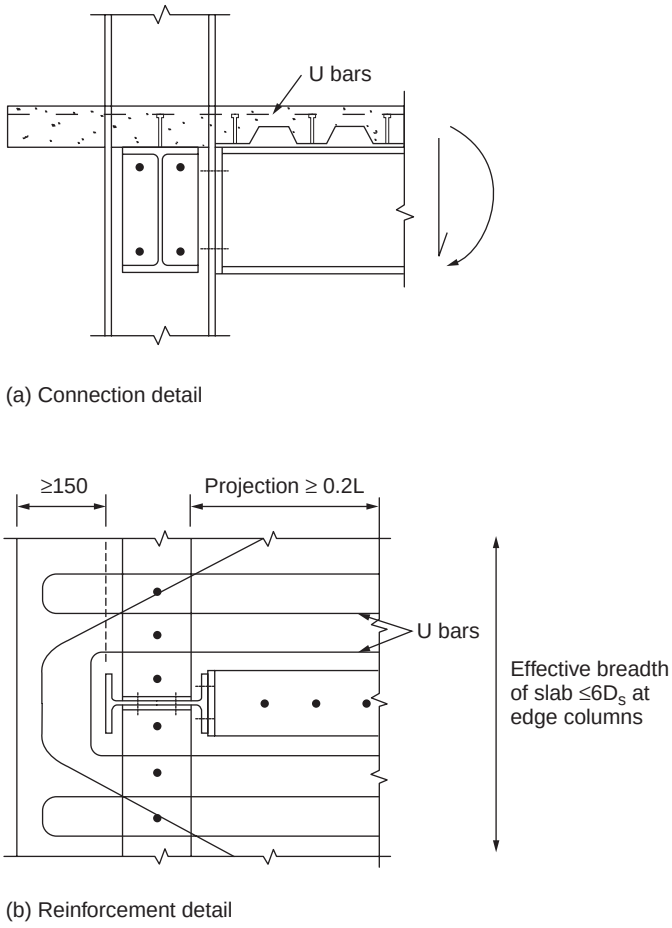

FIGURE 51.58 Transferring of moment through slab reinforcement at perimeter columns.

Methods for an accurate modeling of effective stiffness of composite members in unbraced frames, including second-order effects, are reported in Liew and Uy [42]. Advanced analysis for modeling beam-to-column semirigid connections, steel frames, and concrete core wall interaction is reported in Liew [43]. Further research is required to assess the performance of various types of composite connections used in building structures with mixed systems.

Notation

A_c	Area of concrete
A_r	Area of reinforcement
A_s	Area of steel section
A_w	Web area of steel section
B_1, B_2	Factors used in determining M_n for combined bending and axial forces when elastic, first-order analysis is employed
b	Breadth of steel section
b_c	Overall breadth of composite column
c_1, c_2, c_3	Numerical coefficients
c_r	Thickness of concrete cover
D_o	Outer diameter of circular hollow steel section
d	Depth of steel section

E_a	Modulus of elasticity of steel section
E_c	Modulus of elasticity of concrete for long term
E_{cd}	Modulus of elasticity of concrete for short term
E_{cm}	Secant modulus of the concrete
E_s	Modulus of elasticity of reinforcement
e	Eccentricity of applied loading
e_o	Initial imperfection
$(EI)_e$	Effective elastic flexural stiffness of a composite cross section
F	Force in the element
F_v	Average shear force
f_{cc}	Characteristic strength of concrete due to confinement effect
f_{cd}	Design strength of concrete
f_{ck}	Characteristic cylinder strength of concrete
f_{cu}	Characteristic cube strength of concrete
f_{sd}	Design strength of reinforcement
f_{sk}	Nominal yield strength of reinforcement
f_u	Ultimate strength of the shear connector
f_y	Characteristic strength of reinforcement
f_{yd}	Design strength of steel section
G_a	Shear modulus of steel
h_c	Overall width of composite column
h_1	Concrete width perpendicular to plane of bending
h_2	Concrete thickness in plane of bending
I_a	Second moment of area of steel section
I_c	Second moment of concrete
I_s	Second moment of area reinforcement
L	Length of column
l_e	Effective length of column
$M_{a.Sd}$	Design moment applied to steel section
M_c	Moment capacity of composite section
$M_{cs.Sd}$	Design moment applied to concrete and reinforcement
M_{lt}	Required flexural strength in member due to lateral frame transition
M_n	Required flexural strength of column
M_{nt}	Required flexural strength in member, assuming there is no lateral transiton of frame
$M_{pl.c.Rd}$	Plastic moment resistance of concrete and reinforcement
$M_{pl.Rd}$	Plasic moment resistance of the composite cross section
M_s	Plastic moment capacity of steel beam alone
M_{Sd}	Design moment applied to composite column
M_u	Moment capacity of column
$N_{a.Rd}$	Resistance to compression of steel section
$N_{a.Sd}$	Design axial load applied to steel section
N_{cr}	Elastic buckling load of column
$N_{cr.L}$	Elastic critical load of composite column based on system length
$N_{cs.Sd}$	Design axial load applied to concrete and reinforcement
$N_{G.Sd}$	Part of the design load acting permanently on column
$N_{pl.R}$	Plastic resistance of composite column
$N_{pl.Rd}$	Resistance to compression of composite cross section
N_{Sd}	Design axial force of column
N_u	Squash load of column
P_{Rd}	Design resistance of headed-stud connector
p_y	Design strength of structural steel (N/mm^2)
r_m	Modified radius of gyration of steel shape, pipe, or tubing in composite columns
r_y	Radius of gyration of a member about its minor axis

S_x	Plastic section modulus
t_f	Flange thickness
t_w	Web thickness
t_{wd}	Reduced web thickness
$V_{\text{pl.a.Rd}}$	Shear resistance of steel section
$V_{\text{a.Sd}}$	Design shear force resisted by steel section
W_p	Plastic section modulus
Z_x	Elastic section modulus
α	Imperfection factor
α_c	Strength coefficient of concrete
β	Equivalent moment factor
χ	Reduction factor for buckling
χ_{pm}	Axial resistance ratio due to concrete
δ	Steel contribution ratio
ε	Constant $(275/\rho_y)^{1/2}$
γ_a	Partial factor of safety for steel section
γ_c	Partial factor of safety for concrete
γ_s	Partial factor of safety for reinforcement
λ	Slenderness of column
μ	Moment resistance ratio or coefficient of friction
μ_1, μ_2	Coefficients used for evaluating confinement effect
μ_{10}, μ_{20}	Coefficients used for evaluating confinement effect
ρ	Density of concrete

52.1 Introduction

The principle aim of structural design is the assurance of satisfactory performance within the constraints of economy. A primary complication toward achieving this in practice is imperfect execution and the lack of complete information. The existence of uncertainties in structural engineering has long been recognized and quantitatively accounted for through the use of safety factors in design. Reliability analysis, using probability theory as a tool, provides a rational and consistent basis for determining the appropriate safety margins (Ang and Tang, 1984). Its success is exhibited by the numerous reliability-based provisions developed in recent code revisions to achieve a target reliability range in the design of structural elements (e.g., AISC, ACI, AASHTO). Over the last 20 years, research studies have been carried out to provide similar reliability provisions at the structural systems level, and perhaps they will have a more direct and substantial influence in design specifications over the next decade.

This chapter aims to provide the basic knowledge for structural engineers who have little exposure in this field and to serve as a platform for understanding the basic philosophy behind reliability-based design.

Definition of Reliability

Reliability can be defined as the probabilistic measure of assurance of performance with respect to some prescribed condition(s). A condition can refer to an ultimate limit state (such as collapse) or serviceability limit state (such as excessive deflection and/or vibration).

As a simple illustration, consider a bar with ultimate tensile capacity R (which can be viewed as the supply to the system) that has to resist a tensile load S (which can be viewed as the demand of the system).

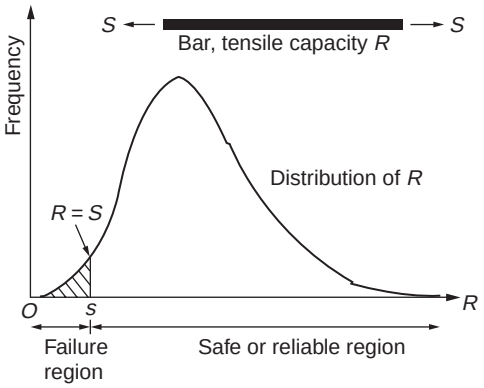

FIGURE 52.1 Distribution of R, failure, and safe regions.

Performance against failure is ensured if $R > S$ (i.e., supply exceeds demand). However, the capacity of this particular bar cannot be known exactly unless it is tested to failure. Nevertheless, some estimates can be obtained based on test results of similar bars, which can be summarized in the form of a distribution. The proportion of bars with strength equal to or above S (assumed deterministic) gives an indication of the reliability of this bar (see Fig. 52.1). Complementary to this, the proportion (shaded region) of bars below S indicates the probability of failure of the system. Hence, reliability can be viewed as a complementary to the *probability of failure*.

The simple example above can be extended to the case where S is not known with certainty. Similarly, one can consider a more complicated function for R, e.g., a reinforced concrete beam where the capacity is a function of many variables, such as the properties of the concrete and reinforcing bars used. One can also look at the reliability of a structure comprising more than one bar or element. An exposition to some basic probability concepts is prerequisite to understanding the complexity and solutions of such problems.

52.2 Basic Probability Concepts

Random Variables and Probability Distributions

For the case of the tensile capacity of the bar mentioned above, its strength can be modeled as a *continuous random variable* and denoted in general as X. Other engineering parameters may take on only discrete values, such as the number of significant earthquakes, and hence modeled as a *discrete random variable*. In either case, a histogram can be constructed once data are available and normalized such that the area under it for the continuous random variable case (or the summation of the ordinates for the discrete case) is unity.

A mathematical expression can be used to describe the distribution represented by the histogram, which for the discrete case is known as the *probability mass function* (PMF), denoted as $p_X(x)$, and for the continuous case as *probability density function* (PDF), denoted as $f_X(x)$.

The cumulative value of the mass or density from the smallest value of X can be described by its *cumulative distribution function* (CDF), commonly denoted as $F_X(x)$ (see Fig. 52.2). Hence, one can write the probability of X taking on values less than or equal to a as

$$P(X \le a) = F_X(a) = \int_{-\infty}^{a} f_X(x)dx \qquad \text{for continuous } X \tag{52.1a}$$

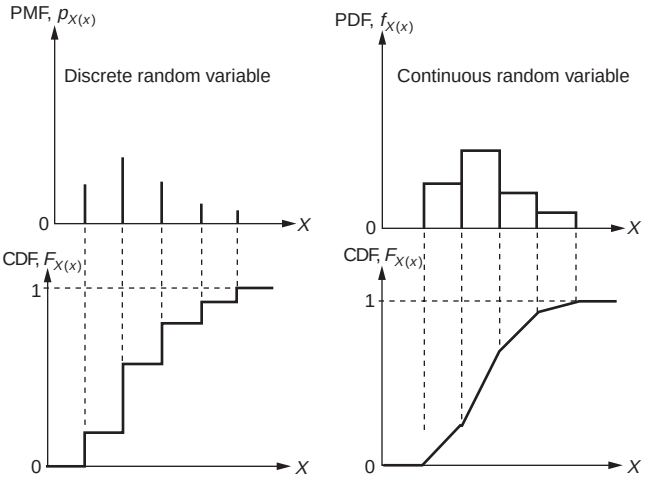

FIGURE 52.2 PMF (discrete random variable), PDF (continuous random variable), and corresponding CDFs.

$$= \sum_{x_i \le a} p_X(x_i) \qquad \textit{for discrete } X \tag{52.1b}$$

Commonly used probability functions related to engineering problems can be found in textbooks on probability and statistics (e.g., Ang and Tang, 1975). Table 52.1 is provided for convenience.

The most common distribution used is the *normal distribution*, with two parameters, namely, mean, μ_X, and standard deviation, σ_X. It cumulative function $F_X(x)$ cannot be expressed in closed form and is often denoted as

$$P(X \le a) = F_X(a) = \int_{-\infty}^{a} \frac{1}{\sigma_X \sqrt{2\pi}} \exp\left[-\frac{1}{2} \left(\frac{x - \mu_X}{\sigma_X} \right)^2 \right] = \Phi\left(\frac{a - \mu_X}{\sigma_X} \right) \tag{52.2}$$

where $\Phi(.)$ denotes the CDF of a normal distribution with a mean equal to 0 and standard deviation equal to 1. Its concise tabulated form is given in Table 52.2.

Another common distribution used, which spans over positive values of X, is the *lognormal distribution*, with parameters λ_X and ζ_X. Note that the transformation $Y = ln\ X$ produces a normal distribution for Y. The CDF of X can be conveniently evaluated as

$$P(X \le a) = F_X(a) = \Phi\left(\frac{\ln a - \lambda_X}{\zeta_X} \right) \tag{52.3}$$

Expectation and Moments

Consider a function $g(X)$ where X is a random variable with PMF $p_X(x)$ or PDF $f_X(x)$. The expected value (also known as *expectation*) of $g(X)$ is defined as

$$E[g(X)] = \int_{-\infty}^{\infty} g(x) f_X(x) dx \qquad \textit{for continuous } X \tag{52.4a}$$

$$= \sum_{all\, x_i} g(x_i) p_X(x_i) \qquad \textit{for discrete } X \tag{52.4b}$$

TABLE 52.1 Some Distribution Type

Distribution	PMF ($p_X(x)$) or PDF ($f_X(x)$)	Mean, $E[X]$	Variance, Var$[X]$
Binomial	$p_X(x)=\binom{n}{x}p^x(1-p)^{n-x}$ $x=0, 1, 2, \ldots, n$	np	$np(1-p)$
Poisson	$p_X(x)=\frac{(\nu t)^x}{x!}e^{-\nu t}$	νt	νt
Normal	$f_X(x)=\frac{1}{\sigma\sqrt{2\pi}}\exp\left[-\frac{1}{2}\left(\frac{x-\mu}{\sigma}\right)^2\right]$ $-\infty < x < \infty$	μ	σ^2
Lognormal	$f_X(x)=\frac{1}{x\zeta\sqrt{2\pi}}\exp\left[-\frac{1}{2}\left(\frac{\ln x-\lambda}{\zeta}\right)^2\right]$ $0 < x < \infty$	$e^{\left(\lambda+\frac{1}{2}\zeta^2\right)}$	$e^{(2\lambda+\zeta^2)}\left[e^{\zeta^2}-1\right]$
Rayleigh	$f_X(x)=\frac{x}{\alpha^2}\exp\left[-\frac{1}{2}\left(\frac{x}{\alpha}\right)^2\right]$ $0 \le x < \infty$	$\alpha\sqrt{\frac{\pi}{2}}$	$\left(2-\frac{\pi}{2}\right)\alpha^2$
Exponential	$f_X(x)=\lambda\exp\left[-\lambda(x-\tau)\right]$ $\tau \le x < \infty$	$\tau+\frac{1}{\lambda}$	$\frac{1}{\lambda^2}$
Gumbel type I maximum	$f_X(x)=\alpha\exp\left[-\alpha(x-u)-e^{-\alpha(x-u)}\right]$ $-\infty < x < \infty$	$u+\frac{0.5772}{\alpha}$	$\frac{\pi^2}{6\alpha^2}$
Fretchet type II maximum	$f_X(x)=\frac{k}{\nu-\tau}\left(\frac{\nu-\tau}{x-\tau}\right)^{k+1}\exp\left[-\left(\frac{\nu-\tau}{x-\tau}\right)^k\right]$ $\varepsilon < x < \infty$	$(\nu-\tau)\Gamma\left(1-\frac{1}{k}\right)+\tau$	$(\nu-\tau)^2\left[\Gamma\left(1-\frac{2}{k}\right)\right]-\Gamma^2\left(1-\frac{1}{k}\right)$
Weibull type III minimum	$f_X(x)=\frac{k}{w-\varepsilon}\left(\frac{x-\varepsilon}{w-\varepsilon}\right)^{k-1}\exp\left[-\left(\frac{x-\varepsilon}{w-\varepsilon}\right)^k\right]$ $\varepsilon < x < \infty$	$(w-\varepsilon)\Gamma\left(1-\frac{1}{k}\right)+\varepsilon$	$(w-\varepsilon)^2\left[\Gamma\left(1-\frac{2}{k}\right)+\Gamma^2\left(1-\frac{1}{k}\right)\right]$

If $g(X) = X$, then Eq. (52.4) gives the *population mean* (denoted as μ_X), which physically describes the central tendency of the distribution of X. The mean is also known as the *first moment* of X.

In general, if $g(X) = X^n$, evaluation of Eq. (52.4) gives the nth moment of X, denoted as $\mu_X^{(n)}$.

If $g(X) = (X - \mu_X)^2$, then Eq. (52.4) gives the *population variance* (denoted as σ_X^2), which measures the spread of data around the mean value. It is also known as the *second central moment* and is related to the second moment and the mean by

$$\sigma_X^2 = E\left[\left(X-\mu_X\right)^2\right] = E\left[X^2\right]-\mu_X^2 \tag{52.5}$$

The square root of variance is the *population standard deviation*, and for $\mu_X \neq 0$, its normalized form is known as the *coefficient of variation*, that is,

$$COV = V_X = \sigma_X/\mu_X \tag{52.6}$$

Note: $\Phi(-Z) = 1 - \Phi(Z)$, e.g., $\Phi(2) = 1 - \Phi(-2)$.

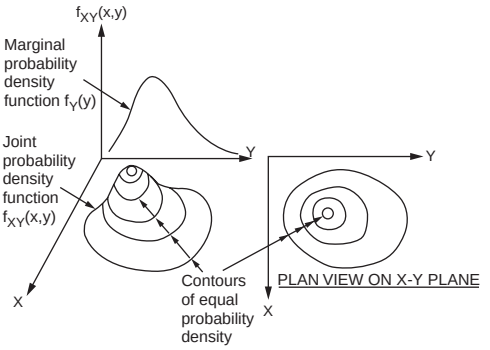

FIGURE 52.3 Joint probability density function.

Higher order central moments can be defined, where $g(X) = (X - \mu_X)^n$. For example, $n = 3$ gives the third central moment and is a measure of the skewness of the distribution, and $n = 4$ gives the fourth central moment and is a measure of the peakedness (or flatness) of the distribution. The third and fourth central moments for a normal distribution are 0 and $3\sigma_x^2$, respectively.

Joint Distribution and Correlation Coefficient

Invariably, all engineering problems involve more than one variable that are random and may be related to one another. To estimate the distribution of multiple random variables, data are jointly collected, from which a multidimensional histogram can be plotted. A suitable *joint probability mass function* or *density function* may be used to represent the spread of data. An example of a joint PDF $f_{XY}(x, y)$ for two random variables, X and Y, is illustrated in Fig. 52.3. The plan view is a two-dimensional contour representation of the three-dimensional plot. Lower probability information can be deduced from the joint probability function; for example, the marginal PDF of Y is given by

$$f_Y(y) = \int_{-\infty}^{\infty} f_{XY}(x, y)dx \tag{52.7}$$

as illustrated in Fig. 52.3.

Consider the random variable Z, which is the sum of two random variables X and Y, that is, $Z = X + Y$. The mean and variance of Z can be expressed as

$$\mu_Z = E[Z] = E[X + Y] = E[X] + E[Y] = \mu_X + \mu_Y \tag{52.8}$$

$$\begin{aligned}\sigma_Z^2 = Var[Z] &= E\left[(Z - \mu_Z)^2\right] = E\left[\left\{(X - \mu_X) + (Y - \mu_Y)\right\}^2\right] \\ &= E\left[(X - \mu_X)^2\right] + E\left[(Y - \mu_Y)^2\right] + 2E\left[(X - \mu_X)(Y - \mu_Y)\right] \\ &= \sigma_X^2 + \sigma_Y^2 + 2Cov[X, Y] = \sigma_X^2 + \sigma_Y^2 + 2\rho_{XY}\sigma_X\sigma_Y\end{aligned} \tag{52.9}$$

where $Cov[X, Y] = E[(X - \mu_X)(Y - \mu_Y)]$ is the *covariance* between X and Y. It is a measure of their linear interdependence, and its normalized form is known as the *correlation coefficient*, given by

$$\rho_{XY} = \frac{Cov[X, Y]}{\sigma_X\sigma_Y} \tag{52.10}$$

When $\rho_{XY} = +1$, X and Y are said to be *perfectly positive correlated*, whereas $\rho_{XY} = -1$ implies *perfect negative correlation* ("negative" meaning that high values of X occur with low values of Y and vice versa). When $\rho_{XY} = 0$, X and Y are said to be uncorrelated.

It is appropriate to mention here that for the special case where X and Y are normally distributed, their sum (and also difference), Z, follows a normal distribution.

Statistical Independence

Practical problems involve more than one random variable with varying degrees of interdependence among them. An extreme case is when the random variables, say X and Y, are *statistically independent*, meaning that the event of one variable taking on some value does not affect the probability of the other variable taking on another value. That is,

$$P\left(X \le a \,|\, Y \le b\right) = P\left(X \le a\right) \tag{52.11}$$

where the symbol | denotes "given that," and the left-hand side of Eq. (52.11) is a *conditional probability*. As a consequence of Eq. (52.11), the probability of the two events, $X \le a$ and $Y \le$ b, happening together (denoted by the intersection symbol $\cap$) can be simplified as

$$P\left(X \le a \cap Y \le b\right) = P\left(X \le a \,|\, Y \le b\right) P\left(Y \le b\right) = P\left(X \le a\right) P\left(Y \le b\right) \tag{52.12}$$

Note that if two variables are statistically independent, they must also be uncorrelated, but the converse is not true in general.

The concept of statistical independence permits simplification in solving complex reliability problems approximately. In fact, a number of real quantities can be reasonably assumed as statistically independent. For example, one would expect dead load to be relatively independent of wind load, the occurrence of tornado to be independent of the occurrence of earthquake, and loads to be independent of structural capacity.

52.3 Assessment of Reliability

A brief exposure is provided here for engineers who wish to have some basic understanding of structural reliability theory. Those interested in a more complete treatment should refer to the many textbooks in this field, such as Ang and Tang (1984), Ditlevsen and Madsen (1996), Madsen et al. (1986), Melchers (1999), and Nowak and Collins (2000).

Fundamental Case

Consider the bar in tension shown in Fig. 52.1 and denote the PDF of R as $f_R(r)$ and the deterministic load as $S = s_1$. Then the probability of failure is given by

$$p_f = P\left(R \le S \,|\, S = s_1\right) = \int_{-\infty}^{s_1} f_{R|S}\left(r \,|\, S = s_1\right) dr \tag{52.13}$$

For the case where S is also random, described by the PDF $f_s(s)$, Eq. (52.13) becomes

$$\begin{aligned} p_f &= \int_{-\infty}^{\infty} P\left(R \le S \,|\, S = s\right) f_S(s)\, ds = \int_{-\infty}^{\infty} \int_{-\infty}^{s} f_{R|S}\left(r \,|\, S = s\right) f_S(s)\, dr\, ds \\ &= \int_{-\infty}^{\infty} \int_{-\infty}^{s} f_{RS}(r, s)\, dr\, ds \end{aligned} \tag{52.14}$$

which is the volume of the joint PDF in the failure region defined by $R \le S$.

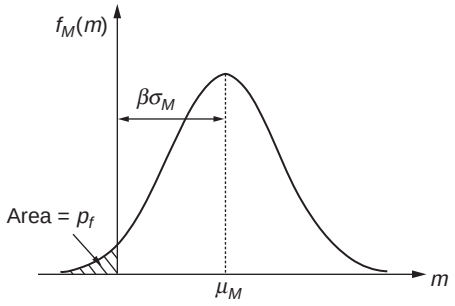

FIGURE 52.4 Probabilistic interpretation of safety margin.

TABLE 52.3 Reliability Indices and Corresponding Failure Probabilities

Reliability Index β	Failure Probability p_f
10^{-1}	1.28
10^{-2}	2.33
10^{-3}	3.10
10^{-4}	3.72
10^{-5}	4.25
10^{-6}	4.75

An equivalent formulation is to define a performance function

$$M = g(R,S) = R - S \tag{52.15}$$

In this case, M can be interpreted as the *margin of safety*, and $g(R, S)$ is a limit state function. The mean μ_M and standard deviation σ_M of M can be computed following Eqs. (52.8) and (52.9). If both R and S are normally distributed, then M is also normally distributed. Equation (52.15) can then be evaluated as

$$p_f = P(M \le 0) = \Phi\left(\frac{0-\mu_M}{\sigma_M}\right) = \Phi\left(-\frac{\mu_R - \mu_S}{\sqrt{\sigma_R^2 + \sigma_S^2 + 2\rho_{RS}\sigma_R\sigma_S}}\right) \tag{52.16}$$

The quantity μ_M/σ_M is denoted as β and is known as the *reliability index*. Its relationship to the safety margin in the probabilistic sense is illustrated in Fig. 52.4. Some β values in the practical range and their corresponding failure probabilities with respect to the normal distribution are given in Table 52.3.

For the case where both R and S can be modeled more accurately by the lognormal distribution, the factor of safety format will result in an easier computation of p_f. That is, define the performance function as

$$M = g(R,S) = R/S \tag{52.17}$$

By taking the natural logarithm and in view of Eq. (52.3), Eq. (52.14) can be simplified as

$$p_f = P(M \le 0) = \Phi\left(-\frac{\lambda_R - \lambda_S}{\sqrt{\zeta_R^2 + \zeta_S^2 + 2\rho_{\ln R \ln S}\zeta_R\zeta_S}}\right) \tag{52.18}$$

where

$$\rho_{\ln R \ln S} = \frac{\ln\left(1+\rho_{RS}V_R V_S\right)}{\zeta_R \zeta_S} \cong \rho_{RS}$$

for small V_R and V_S.

For problems involving n random variables, $\boldsymbol{X} = \{X_1, X_2, X_3, \ldots X_n\}$, with performance function

$$M = g(\boldsymbol{X}) = a_0 + \sum_{i=1}^{n} a_i X_i \tag{52.19}$$

The mean and variance of M in Eq. (52.16) is computed as

$$\mu_M = a_0 + \sum_{i=1}^{n} a_i \mu_{X_i}, \quad \sigma_M^2 = \sum_{i=1}^{n}\sum_{j=1}^{n} a_i a_j \rho_{X_i X_j} \sigma_{X_i} \sigma_{X_j} \tag{52.20}$$

First-Order Second-Moment Index

It should be mentioned here that in the early stage of the development of structural reliability theory, β given in Eq. (52.16) is proposed as the first-order second-moment index, since only the first two moments of the random variables are involved. The failure probability is approximated by Eq. (52.16), which is exact if the random variables are normally distributed and $g(\boldsymbol{X})$ is a linear function.

Hasofer–Lind Reliability Index

Consider the case where R and S are uncorrelated. Define the standardized form of the random variable as $R' = (R - \mu_R)/\sigma_R$ and $S' = (S - \mu_S)/\sigma_S$. The limit state function of Eq. (52.15) can be rewritten as

$$M = g(R,S) = \sigma_R R' - \sigma_S S' + \mu_R - \mu_S = 0 \tag{52.21}$$

If the limit state function is plotted on the $R' - S'$ coordinate system (see Fig. 52.5), then β is the shortest distance from the origin to the limit state function $g(R', S') = 0$, also known as the *Hasofer–Lind reliability index*. The point x^* has the highest probability density value in the failure region and is hence termed the *most likely failure point*.

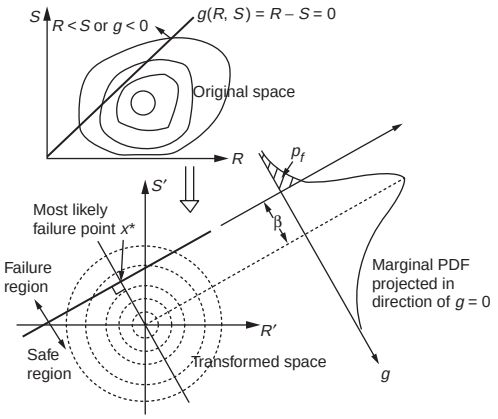

FIGURE 52.5 Hasofer–Lind reliability index and most likely failure point.

Another important set of information that can be extracted from this computation is the sensitivity of each random variable to the reliability index. This is given by the direction cosines, which for this example is

$$\alpha_R = \frac{\sigma_R}{\sqrt{\sigma_R^2 + \sigma_{S'}^2}}, \quad \alpha_S = \frac{-\sigma_S}{\sqrt{\sigma_R^2 + \sigma_S^2}} \tag{52.22}$$

The most likely failure point in the transformed coordinate space is given by

$$\left(r'^*, s'^*\right) = \left(-\alpha_R\beta, -\alpha_S\beta\right) \text{ or } \left(r^*, s^*\right) = \left(\mu_R - \alpha_R\beta\sigma_R, \mu_S - \alpha_S\beta\sigma_S\right) \tag{52.23}$$

Reliability Estimate by FORM

In general, the limit state function can be nonlinear and the distribution of the random variables different from normal or lognormal. The first-order reliability method (FORM) has been developed to evaluate the failure probability with reasonable accuracy and cost for realistic structures. The basic idea of the method can be summarized as follows:

1. For the general case of correlated nonnormal random variables, the *Rosenblatt transformation* can be employed and requires the complete joint PDF (see, e.g., Ditlevsen and Madsen, 1996). In many practical problems, only the marginal distribution functions and the covariance matrix are known. For such cases, approximations using the Nataf distribution can be employed (Der Kiureghian and Liu, 1986). A more approximate but simpler procedure and its variations have been developed. Essentially, the random variables are first transformed into uncorrelated random variables using the correlation matrix (basically finding its eigenvalues and eigenvectors). The *principle of normal tail approximation* (Rackwitz and Fiessler, 1978) is then employed to replace the nonnormal distributions by normal distributions. For the latter, the equivalent normal distribution parameters are determined such that the PDF as well as the CDF values at the most likely failure point corresponding to the actual and the normal distributions are equal.
2. The nonlinear performance function, $g_{NL}(\boldsymbol{X})$, is linearized at the most likely failure point (denoted as $\boldsymbol{X}^*$) in the standardized normal coordinate space. That is, $g_{NL}(\boldsymbol{X})$ is now approximated by Eq. (52.19) with a_i given by the partial differential $\partial g_{NL}(\boldsymbol{X})/\partial X_i$ evaluated at $\boldsymbol{X}^*$. This is basically a first-order Taylor series expansion of the nonlinear performance function. Since $\boldsymbol{X}^*$ is not known apriori, an iterative solution to obtain β is inevitable.

Based on the principle of normal tail approximation and the first-order approximation of $g_{NL}(\boldsymbol{X})$ described above, a simple algorithm to compute β is given by the following steps:

1. Find the eigenvalues λ and corresponding eigenvectors $\boldsymbol{T}$ corresponding to the correlation matrix ρ_{XX}.
2. Assume an initial guess $\boldsymbol{x}^*$ for $\boldsymbol{X}$, satisfying $g_{NL}(\boldsymbol{x}^*) = 0$. This can be achieved by using the mean values for n-1 random variables, with the value for the remaining variable obtained by enforcing the condition $g_{NL}(\boldsymbol{x}^*) = 0$. Next, compute $\partial g_{NL}(\boldsymbol{X})/\partial X_i$ at $\boldsymbol{x}^*$.
3. For each of the nonnormal random variables, say with CDF $F_{X_i}(x)$ and PDF $f_{X_i}(x)$, compute the equivalent normal parameters as follows:

$$\sigma_{X_i}^N = \frac{1}{f_{X_i}\left(x_i^*\right)}\phi\left[\Phi^{-1}\left(F_{X_i}\left(x_i^*\right)\right)\right]$$
$$\mu_{X_i}^N = x_i^* - \sigma_{X_i}^N\left[\Phi^{-1}\left(F_{X_i}\left(x_i^*\right)\right)\right] \tag{52.24}$$

The values for the vector of reduced variates $\boldsymbol{z}^*$ at the failure point can be obtained where

$$\beta = \frac{\mathbf{G}^t\mathbf{T}\lambda^{1/2}\{\mathbf{z}\}}{\sqrt{\mathbf{G}^t\rho_{xx}\mathbf{G}}} \quad \text{where} \quad G_i = -\sigma_{X_i}^N \left.\frac{\partial g_{NL}(\mathbf{X})}{\partial X_i}\right|_{x^*}$$

4. The reliability index, corresponding to the most likely failure point, can be computed using the formula

$$\beta = \frac{\mathbf{G}^t\mathbf{T}\lambda^{1/2}\{\mathbf{z}\}}{\sqrt{\mathbf{G}^t\rho_{xx}\mathbf{G}}} \quad \text{where} \quad G_i = -\sigma_{X_i}^N \left.\frac{\partial g_{NL}(\mathbf{X})}{\partial X_i}\right|_{x^*} \tag{52.25}$$

   where the superscript **t** denotes transpose.
5. The sensitivity factors can be estimated as

$$\alpha = \frac{\lambda^{1/2}\mathbf{T}^t\mathbf{G}}{\sqrt{\mathbf{G}^t\rho_{xx}\mathbf{G}}} \tag{52.26}$$

6. A new set of n-1 random variables can be formulated as

$$x_i^* = \mu_{X_i}^N - \alpha_i\beta\sigma_{X_i}^N \tag{52.27}$$

7. and x_n^* obtained by enforcing the condition $g_{NL}(\boldsymbol{x}^*) = 0$.
8. Steps 3 to 6 are repeated until β and $\boldsymbol{x}^*$ converge. The failure probability is then approximated by $p_f = \Phi(-\beta)$.

Reliability Estimate by Monte Carlo Simulation

The computation of failure probability is equivalent to evaluating the integral

$$p_f = \int\cdots\int_{g(\mathbf{X})\le 0} f_{\mathbf{X}}(\mathbf{X})dx = \int\cdots\int I\left[g(\mathbf{X})\le 0\right]f_{\mathbf{X}}(\mathbf{x})d\mathbf{x} \tag{52.28}$$

where $I[.]$ is a function taking a value of 1 if the condition in the bracket is true, and is assigned zero otherwise. Analytical solution or even numerical integration using quadrature-based techniques is only possible for limited cases. Hence, approximate numerical techniques such as FORM or higher order methods (e.g., second-order reliability method (SORM)) have been developed. Alternatively, numerical integration can be performed using Monte Carlo simulation (MCS) techniques. A brief introduction will be given here. The generation of random numbers can be found in standard textbooks and will not be discussed here.

In essence, MCS involves the random generation of many realizations of a set of random variables, say N realizations, and to count how many of these result in the condition $g(\boldsymbol{X}) \le 0$. The failure probability is estimated as

$$p_f = \frac{1}{N}\sum_{i=1}^{N} I\left[g(\boldsymbol{x}_i)\le 0\right] \tag{52.29}$$

The variance of this estimate can be approximated by (Melchers, 1999)

$$s_{p_f}^2 = \frac{1}{(N-1)}\left(\frac{1}{N}\left[\sum_{i=1}^{N} I^2\left[g(\mathbf{x}_i)\le 0\right]\right] - \left[\frac{1}{N}\sum_{i=1}^{N} I\left[g(\mathbf{x}_i)\le 0\right]\right]^2\right) \tag{52.30}$$

From Eq. (52.29), it is obvious that when p_f is small, N has to be very large to get a reasonable estimate, which makes MCS unattractive. This limitation can be further compounded by cases where the dimension of $\boldsymbol{X}$ is large or $g(\boldsymbol{X})$ is not easy to evaluate (such as the need to perform a finite element computation). In addition, the variance decreases slowly with N. By using additional information to focus the simulation on a more fruitful region, N can be made small and the variance can be significantly reduced. Among the many variance reduction techniques, the *importance sampling technique* is currently one of the most popular in structural reliability and is briefly described below.

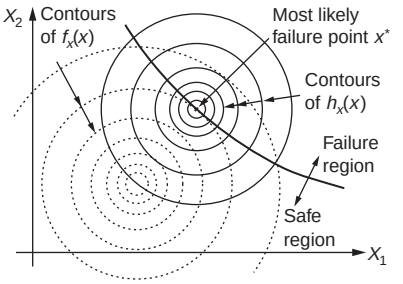

FIGURE 52.6 Concept of importance sampling in MCS.

The region that contributes most to p_f is around the most likely failure point $\boldsymbol{x}^*$. Hence, one can selectively generate the realizations around this vicinity. For example, one can sample from distributions that follow $f_X(\boldsymbol{x})$, but with their means shifted to $\boldsymbol{x}^*$, denoted as $h_X(\boldsymbol{x})$, as proposed by Harbitz (1983). This will result in having an order of $N/2$ points in the failure region (see Fig. 52.6) and should logically reduce the size of N needed, subjected to some conditions being satisfied, such as the nature of the performance function and the suitable choice of $h_X(\boldsymbol{x})$. Equation (52.29), in view of the modified sampling space, becomes

$$p_f = \int \ldots \int I\left[g(\boldsymbol{X}) \le 0\right] \frac{f_X(\boldsymbol{x})}{h_X(\boldsymbol{x})} h_X(\boldsymbol{x}) d\boldsymbol{x}$$
$$\cong \frac{1}{N} \sum_{i=1}^{N} I\left[g(\boldsymbol{x}_i) \le 0\right] \frac{f_X(\boldsymbol{x}_i)}{h_X(\boldsymbol{x}_i)} \tag{52.31}$$

The optimal choice of $h_X(\boldsymbol{x})$ is by no means simple and is the subject of many research papers that cannot be adequately discussed in this brief introduction. Nevertheless, the following points should be noted (Melchers, 1991):

1. $h_X(\boldsymbol{x})$ should not be too flat or skewed. As such, the use of normal distribution has been suggested.
2. $\boldsymbol{x}^*$ may not be unique. The use of multiple $h_X(\boldsymbol{x})$ functions with corresponding weights may be necessary.
3. A highly concave limit state function gives rise to low efficiency, and N may need to be large for such cases. This may be overcome by using multiple $h_X(\boldsymbol{x})$ functions.

52.4 Systems Reliability

Structural engineering design, for the sake of simplicity, is invariably based on satisfying various individual limit state functions. Similarly, a structure is usually designed on member basis, although its optimal performance as an entire structure is desired. Codified optimal design at the structural systems level has been the subject of research for many decades. Classical systems reliability concepts have been employed in various applications, such as nuclear power plants, offshore installations, and bridges. In view of space limitations, only issues closely related to structures will be briefly discussed in this section. A general treatment of systems reliability pertaining to civil engineering can be found in Ang and Tang (1984), whereas that pertaining to structures is fairly well treated by Melchers (1999).

Systems in Structural Reliability Context

Structural reliability problems involving more than one limit state are solved using systems reliability concepts. Hence, in a general sense, a *structural system* can comprise only one element, such as a beam

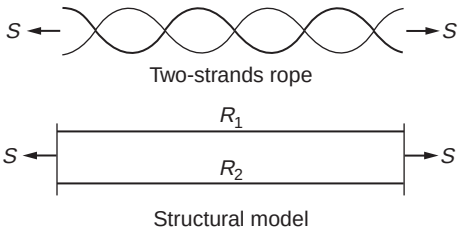

FIGURE 52.7 Model of a two-strand parallel structure.

that involves combined stresses and deflection limit states, or can comprise many elements, as in a truss or frame structure.

As an illustration, consider a simply supported beam of length l and stiffness EI subjected to a uniform load w per unit length and designed with flexural capacity M_u and shear capacity V_u that must satisfy a deflection limit Δ. The limit state equations can be written as follows:

$$\begin{aligned} g_1(\boldsymbol{X}) &= M_u - \frac{1}{8}wl^2, & g_2(\boldsymbol{X}) &= V_u - \frac{1}{2}wl, \\ g_3(\boldsymbol{X}) &= 1 - \left(\frac{wl^2}{8M_u} + \frac{wM_u}{2V_u^2}\right), & g_4(\boldsymbol{X}) &= \Delta - \frac{5wl^4}{384EI} \end{aligned} \tag{52.32}$$

The nonperformance or failure of this system happens when any one of the limit state equations is violated. The failure probability can be formulated as

$$p_f = P\left[\left(g_1(\boldsymbol{X}) \le 0\right) \cup \left(g_2(\boldsymbol{X}) \le 0\right) \cup \left(g_e(\boldsymbol{X}) \le 0\right) \cup \left(g_4(\boldsymbol{X}) \le 0\right)\right] \tag{52.33}$$

where the symbol $\cup$ is the Boolean or operator to denote the *union* of events. For example, $A \cup B$ denotes the occurrence of event A, event B, or both events A and B. Such a system is known as a *series system*.

Another class of systems is the *parallel system*. Consider a simple redundant system comprising a bundle of two steel strands with capacity R_1 and R_2 under a load S, schematically shown in Fig. 52.7. Assume the capacities to be random but correlated with a coefficient denoted as $\rho_{R_1R_2}$. The failure probability of this system can be written as

$$\begin{aligned} p_f &= P\left[\left(g_1(\boldsymbol{X}) \le 0\right) \cap \left(g_2(\boldsymbol{X}) \le 0\right)\right] \\ g_1(\boldsymbol{X}) &= R_1 - S, \qquad g_2(\boldsymbol{X}) = R_2 - S \end{aligned} \tag{52.34}$$

where the symbol $\cap$ is the Boolean and operator to denote the *intersection* of events. For example, $A \cap B$ denotes the occurrence both events A and B. Such a system is known as a parallel system.

The failure region corresponding to the two different systems described by Eqs. (52.33) and (52.34) is best illustrated assuming that there are only two random variables shown in Fig. 52.8. It should be noted that even for cases where the individual $g_i(\boldsymbol{X})$ are linear, the failure region is bounded by piecewise linear boundaries. Hence, the evaluation of Eqs. (52.33) and (52.34) is nonlinear and can be quite formidable.

Note that an equivalent form of Eq. (52.34) can be written by considering the complementary events, such as $g_1(\boldsymbol{X}) > 0$, which is also denoted as $\overline{g_1(\boldsymbol{X}) \le 0}$, where the overbar indicates the complementary of the event under the bar. Since the nonfailure of the two-strand structure implies the nonfailure of at least one strand, one can write

$$p_f = 1 - P\left[\overline{\left(g_1(\mathbf{X}) \le 0\right)} \cup \overline{\left(g_2(\mathbf{X}) \le 0\right)}\right] \tag{52.35}$$

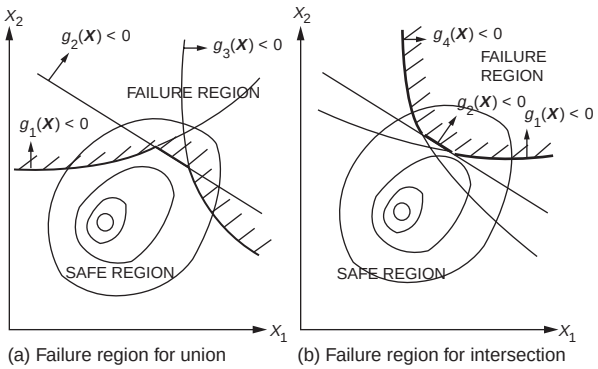

FIGURE 52.8 Failure region for system involving (a) union and (b) intersection of events.

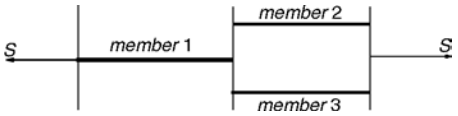

FIGURE 52.9 Model of a simple series–parallel three-bar system.

Based on the same consideration, the equivalence of Eq. (52.33) is

$$p_f = 1 - P\left[\overline{\left(g_1(\mathbf{X}) \le 0\right)} \cap \overline{\left(g_2(\mathbf{X}) \le 0\right)} \cap \overline{\left(g_1(\mathbf{X}) \le 0\right)} \cap \overline{\left(g_2(\mathbf{X}) \le 0\right)}\right] \tag{52.36}$$

The equivalence of the two sets of formulation is basically an application of *De Morgan's rule* in set theory.

In general, a complete system may be cast as a combination of parallel and series subsystems. For example, consider the three-bar system shown in Fig. 52.9. Denote F_i, i = 1, 2, and 3, as the failure of members 1, 2, and 3, respectively. The system cannot withstand the load if member 1 fails or if both members 2 and 3 fail. Thus, the probability of failure of the system can be formulated as

$$p_f = P\left[F_1 \cup \left(F_2 \cap F_3\right)\right] \tag{52.37}$$

The evaluation of equations such as Eq. (52.37) can be a formidable task, and numerical techniques need to be used. As an alternative, first-order and second-order bounds are often computed instead. The bounds for the series and the parallel systems will be considered next, namely,

$$p_{\cup} = P\left[G_1 \cup G_2 \cup G_3 \cup \ldots \cup G_n\right] \tag{52.38}$$

$$p_{\cap} = P\left[G_1 \cap G_2 \cap G_3 \cap \ldots \cap G_n\right] \tag{52.39}$$

First-Order Probability Bounds

One extreme case is to consider all the events in Eq. (52.39) to be mutually independent. Hence, by virtue of Eq. (52.12), Eq. (52.39) becomes

$$p_{\cap indp} = P\left(G_1 \cap G_2 \cap \ldots \cap G_n\right) = P\left(G_1\right)P\left(G_2\right)\ldots P\left(G_n\right) = \prod_{i=1}^{n} P\left(G_i\right) \tag{52.40}$$

Similarly, Eq. (52.39) for mutually independent events is simplified as

$$p_{\cup indp} = 1 - P\left(\overline{G}_1 \cap \overline{G}_2 \cap \ldots \cap \overline{G}_n\right) = 1 - \prod_{i=1}^{n} P\left(\overline{G}_i\right)$$
$$= 1 - \prod_{i=1}^{n}\left[1 - P\left(G_i\right)\right] \le \sum_{i=1}^{n} P\left(G_i\right) \tag{52.41}$$

Note that if $P(G_i)$ is small, as in most practical structural systems, then

$$p_{\cup indp} \approx \sum_{i=1}^{n} P\left(G_i\right).$$

The other extreme is when the G_i are perfect-positively correlated. The corresponding probabilities are

$$p_{\cap ppc} = \min_{i=1}^{n} P\left(G_i\right) \quad \text{and} \quad p_{\cup ppc} = \max_{i=1}^{n} P\left(G_i\right) \tag{52.42}$$

Based on the above, the first-order probability bounds can be summarized as:

$$\max_{i=1}^{n} P\left(G_i\right) \le P\left(\bigcup_{i-1}^{n} G_i\right) \le 1 - \prod_{i=1}^{n}\left[1 - P\left(\overline{G}_i\right)\right] \qquad \text{for } \rho \ge 0$$
$$1 - \prod_{i=1}^{n}\left[1 - P\left(G_i\right)\right] \le P\left(\bigcup_{i-1}^{n} G_i\right) \le \min\left[1, \sum_{i=1}^{n} P\left(G_i\right)\right] \qquad \text{for } \rho \le 0 \tag{52.43}$$

$$\prod_{i=1}^{n} P\left(G_i\right) \le P\left(\bigcap_{i-1}^{n} G_i\right) \le \min_{i=1}^{n} P\left(G_i\right) \qquad \text{for } \rho \ge 0$$
$$0 \le P\left(\bigcap_{i-1}^{n} G_i\right) \le \prod_{i=1}^{n} P\left(G_i\right) \qquad \text{for } \rho \le 0 \tag{52.44}$$

Second-Order Probability Bounds

The probability bounds given by Eqs. (52.43) and (52.44) for some applications can be wide and have limited use. Hence, second-order bounds have been proposed where the joint probability of two events $P(G_iG_j)$ are used in the computation. The probability bounds for the union of events is given by

$$P\left(\bigcup_{i-1}^{n} G_i\right) \le \min\left[1, \sum_{i=1}^{n} P\left(G_i\right) - \sum_{i=2}^{n} \max_{j<i} P\left(G_iG_j\right)\right]$$
$$P\left(\bigcup_{i-1}^{n} G_i\right) \ge P\left(G_1\right) + \sum_{i=2}^{n} \max\left[0, P\left(G_i\right) - \sum_{j=1}^{i-1} P\left(G_iG_j\right)\right] \tag{52.45}$$

where the events G_i are ordered in terms of decreasing probability, as a rule of thumb, for optimal results. The joint probability of two events can be estimated either by numerical integration or by the following approximate bounds:

$$\begin{aligned} &\max\left[P(A),P(B)\right] \le P\left(G_i G_j\right) \le P(A)+P(B) \qquad \text{for } \rho \ge 0 \\ &0 \le P\left(G_i G_j\right) \le \min\left[P(A),P(B)\right] \qquad \text{for } \rho \le 0 \end{aligned} \tag{52.46}$$

where

$$P(A)=\Phi(-\beta_i)\Phi\left(-\frac{\beta_j-\rho_{ij}\beta_i}{\sqrt{1-\rho_{ij}^2}}\right), \quad P(B)=\Phi(-\beta_j)\Phi\left(-\frac{\beta_i-\rho_{ij}\beta_j}{\sqrt{1-\rho_{ij}^2}}\right) \tag{52.47}$$

in which β_i is the reliability index corresponding to $P(G_i \le 0)$ and ρ_{ij} is the correlation coefficient between G_i and G_j. An estimate of the latter is given by

$$\rho_{ij}=\left(\sum_{k=1}^{n}\alpha_{ik}\alpha_{jk}\right)\Bigg/\sqrt{\left(\sum_{k=1}^{n}\alpha_{ik}^2\sum_{k=1}^{n}\alpha_{jk}^2\right)} \tag{52.48}$$

where α_{ik} are the components of the direction cosines $\boldsymbol{\alpha}$ at the most likely failure point corresponding to G_i, given in Eq. (52.26), with n as the number of basic random variables.

For tighter bounds, the use of higher order probabilities has been proposed (e.g., Greig, 1992). This will not be treated here.

Monte Carlo Solution

The concept of MCS in estimating the failure probability for the case of a single limit state function described earlier can be extended directly to that for series and parallel systems. For example, the indicator function in Eqs. (52.28) and (52.31) for series system becomes

$$\begin{aligned} I\left[\bigcup_{i=1}^{n} g_i(x)<0\right]&=1 \qquad \text{if } I[.] \text{ is true} \\ &=0 \qquad \text{otherwise} \end{aligned} \tag{52.49}$$

The difference in the application of importance sampling technique in this case is that the presence of numerous limit state functions (see Fig. 52.8) complicates the choice of $h_x(\boldsymbol{x})$. A simple solution is to consider a multimodal sampling function given by

$$h_X(x)=\sum_{i=1}^{n} w_i h_{Xi}(x) \quad \text{where} \quad \sum_{i=1}^{n} w_i = 1 \tag{52.50}$$

and $h_{xi}(\boldsymbol{x})$ is the sampling distribution determined based on the ith limit state function and w_i is the weight, which is inversely proportional to β_i.

Applications to Structural Systems

Design codes generally try to ensure that actual structural systems fail in ductile modes rather than brittle ones. It is therefore reasonable to assume that the commonly used rigid-plastic model provides a reasonable approximation to structural system behavior (Bjerager, 1984). The dependence of the probability of failure on the load path for such a case is not a significant issue. On the other extreme, there are cases where the actual member behavior can be better idealized as elastic-brittle, where within a structural

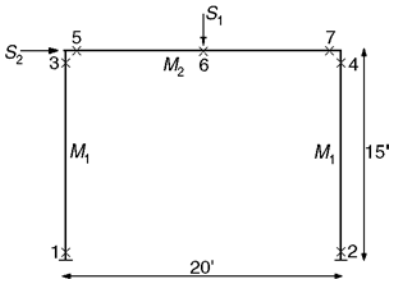

FIGURE 52.10 Simple frame structure with potential plastic hinges (numbered 1 to 7).

TABLE 52.4 Mechanisms, Performance Functions, and Failure Probabilities

Mechanism i	Location of Hinges	Performance Functions G_i	Reliability Index β_i	Failure Probability p_{fi}
1	1, 2, 3, 6	$4M_1 + 2M_2 - 10S_1 - 15S_2$	1.8167	0.03463
2	1, 2, 3, 4	$4M_1 - 15S_2$	2.2123	0.01347
3	1, 2, 5, 6	$2M_1 + 4M_2 - 10S_1 - 15S_2$	2.2589	0.01195
4	5, 6, 7	$4M_2 - 10S_1$	3.0177	0.00127
5	1, 2, 5, 7	$2M_1 + 2M_2 - 15S_2$	3.2276	0.00062
6	3, 4, 6	$2M_1 + 2M_2 - 10S_1$	3.3024	0.00048

system, deformation at zero capacity is possible after the peak capacity has been reached (Quek and Ang, 1986). Real structures will behave somewhat in between these two idealized models and can be too complex for accurate evaluation of the system failure probability. Consequently, one can consider probabilistic upper and lower bound solutions.

For structures that ultimately fail in a ductile manner, the collapse mechanism approach can be employed. As an illustration, consider a simple one-story one-bay frame under concentrated vertical and lateral loads, as shown in Fig. 52.10, with the seven critical sections marked and numbered (Ma and Ang, 1981). The member plastic moment capacities, M_1 and M_2, have mean values of 360 and 480 ft-kips with standard deviations of 54 and 72 ft-kips, respectively. The loads, S_1 and S_2, have mean values of 100 and 50 kips with standard deviations of 10 and 15 kips, respectively. All four random variables are assumed to be independent normal variates. Six physically admissible mechanisms can be generated, with the limit state function corresponding to each given in Table 52.4.

The reliability index and failure probability of each individual performance function can be obtained using Eqs. (52.16) and (52.20) and Table 52.2. For example,

$$P(G_1 \le 0) = \Phi\left(-\frac{4\mu_{M_1} + 2\mu_{M_2} - 10\mu_{S_1} - 15\mu_{S_2}}{\sqrt{16\sigma_{M_1}^2 + 4\sigma_{M_2}^2 + 100\sigma_{S_1}^2 + 225\sigma_{S_2}^2}}\right)$$

$$= \Phi\left(-\frac{650}{\sqrt{128{,}017}}\right) = \Phi(-1.8167) = 0.03463$$

To find the first-order probability bounds, Eq. (52.43) gives $0.03463 \le p_f \le 0.06124$.

To obtain the second-order bounds, the joint probability of pairs of events is needed. It is illustrated using G_1 and G_2. First, the correlation coefficient is computed using Eq. (52.48). The α values for G_1 and G_2 are (0.6037, 0.4025, –0.2795, and –0.6289) and (0.6925, 0, 0, and –0.7214), respectively. Hence, ρ_2= 0.8718. From Eq. (52.47),

$$P(A) = \Phi(-1.8167)\Phi\left(-\frac{2.2123 - 0.8718 * 1.8167}{\sqrt{1 - 0.8718^2}}\right) = 0.003422,$$

$$P(B) = 0.007953$$

Hence, from Eq. (52.46), $0.007953 \le P(G_1G_2) \le 0.011375$. Performing similar computations for other joint probabilities and applying Eq. (52.45) yields the second-order bounds as $0.0367 \le p_f \le 0.0447$.

52.5 Reliability-Based Design

There are two principal considerations in the design of structures: the first is the optimization of the total expected utility of the structure by the designer, and the second is the optimization of the design code by the controlling authority. In the latter, the optimization covers as much as possible the range of practical structures and includes issues such safety, serviceability, and overall cost. A complete practical design code will have to be simple, yet consider all the above factors for the whole family of structures and account for many details, some of which may not have been fully tested. As such, it is natural that code formats and requirements evolved over a long period of time and collective wisdom and consensus of the profession remain significant factors. Such a process is seen to be less formal and has obvious drawbacks when new materials, structural principles, and technological developments are introduced. Nevertheless, previous generation codes still play a major role as guides to new generation codes in the process known as *code calibration*.

Reliability concepts presented in the earlier sections serve as a plausible vehicle for code calibration, where various limit state conditions such as ultimate and serviceability limit states need to be addressed. Based on the calibration results, it is possible in principle when formulating the new code to incorporate the type of failure and the associated consequences of failure through a cost component. To enforce such requirements explicitly will make the codified design procedure for general use unnecessarily too complex a process in the present-day context. Nevertheless, it can be incorporated in the code in a less obvious manner through the numerical factors specified in the code. Reliability analysis is being accepted currently as a practical, consistent, and formal tool for which partial factors can be derived given the safety-checking formats in code formulation.

Load and Resistance Factor Design Format

Before outlining the code calibration and formulation procedure, it is appropriate to briefly mention safety-checking formats. The format for codes of practice differs between countries, and there are attempts to unify such format. For example, all European structural design codes follow the general form specified by the Comite Europeen du Beton (CEB, 1976). Numerous partial factors for both materials and loads are imposed to account for various uncertain components. The Canadian building codes adopted a less complicated format by using only one partial factor to account for material uncertainties (NRCC, 1977). The AISC code in the U.S. uses the load and resistance factor design (LRFD) format, expressed as (Ravindra and Galambos, 1978)

$$\phi R_n = \sum_{k=1}^{i} \gamma_k S_{km} \tag{52.51}$$

where ϕ and γ_k are the resistance and load factors, respectively, R_n the nominal resistance, and S_{km} the mean load effects.

Code Calibration Procedure

Changes or improvements to existing codes can result for reasons of harmonization of different codes or development of a simpler code. The first comprehensive change toward reliability-based design code

TABLE 52.5 Summary of Statistical Data on Resistance

Designation	R/R_n	V_R	Probability Distribution
Reinforced concrete, flexure			
Grade 60	1.05	0.11	Normal
Grade 40	1.14	0.14	Normal
Reinforced concrete, short-tied columns	0.95	0.14	Normal
Reinforced concrete beams, shear, minimum stirrups	1.00	0.19	Normal
Structural steel			
Tension members, yield	1.05	0.11	Lognormal
Compact beam, uniform moment (plastic design)	1.07	0.13	Lognormal
Beam-column (plastic design)	1.07	0.15	Lognormal
Cold-formed steel, braced beams	1.17	0.17	Lognormal
Aluminum, laterally braced beams	1.10	0.08	Lognormal
Unreinforced masonry walls in compression, inspected workmanship	5.3	0.18	Lognormal
Glulam beams			
Live load	1.97	0.18	Weibull
Snow load	1.62	0.18	Weibull

formulation in the United States was the American National Standard A58 on minimum design loads in buildings (Ellingwood et al., 1980). Calibration has been defined as the process of assigning values to the parameters in a design code to achieve a desired level of reliability accounting for practical constraints, resulting in a specific design code. It involves the combination of judgment, fitting to existing design practice, and optimization.

The first step in the code calibration procedure is to define the *scope* of applicability, namely, the class of structures (e.g., bridges), materials (e.g., concrete), failure modes, geographical domain of validity, and geometrical properties. This will result in selecting the range of values for the design variables, such as length, cross-sectional areas, permitted yield stress, and applied loads. For practical computation, discrete zones of such values are used and the corresponding frequency of occurrence corresponding to each zone in actual practice estimated. For example, the dead-to-live load ratios in building structures are usually confined within the range of 0.5 to 2.

In the second step, for each zone the existing structural design code is used to *design* the various elements, such as beams and columns, with specified geometry and load conditions.

The third step involves the specification of *performance functions*. The limit state conditions to be specified in the new code must be defined, such as those related to flexure, shear, local buckling, and deflection. The performance function for each limit state is expressed in terms of the basic variables.

In order to compute the reliability index corresponding to each performance function, in the fourth step, the *statistics of the basic variables* are assumed to be available. These are often compiled from extensive survey data. An example of statistical data on resistance can be found in Galambos et al. (1982) and is reproduced in Table 52.5.

The fifth step involves computing the *reliability indices* of each member designed under the old code using techniques such as FORM. An example of the reliability indices obtained from such a process is shown in Fig. 52.11, reproduced directly from Galambos et al. (1982). It shows the range of reliability indices implied in existing code for gravity loads. If the range is unacceptably wide, further work is needed to obtain a new set of factors satisfying the intended goals.

The specification of the *goal* of the revised or new code is a major step of the process of calibration. The overall goal could be to maximize the expected utility or to achieve a specified failure probability or reliability index taking into consideration the failure consequences. The target reliability index to be used for a revised code can be based on the values obtained in the previous step. For example, a statistically determined value can be chosen, such as the weighted average or some specified percentile value of β

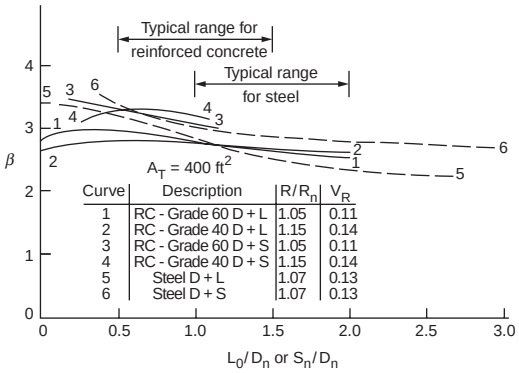

FIGURE 52.11 Reliability index for steel and reinforced concrete beams. (From Galambos, T.V. et al., *J. Struct. Div. ASCE,* 108, 959, 1982.)

based on the occurrence frequency of the various designs encountered in practice. For example, Siu et al. (1975) obtained an average β value of 4.67 for hot-rolled steel columns under compression failure for the 1975 NBCC code. It is unlikely that a single value will be selected as the target for an entire code. For example, failure consequence is a major design consideration, and higher values of β are often imposed for brittle-type failure. To achieve the desired goal, a quantitative measure or objective function must be formulated for example (Ditlevsen and Madsen, 1996),

$$\Delta = \sum_{\substack{\text{materials}}} \sum_{\substack{\text{failure} \\ \text{modes}}} \sum_{\substack{\text{parameters}}} w_i M(\beta_i) \tag{52.52}$$

where w_i are the relative frequencies of occurrences (determined in the first step). The function $M(.)$ can be simply in terms of reliability indices, such as $(\beta_i^* - \beta_i)^2$ where β_i^* is the target reliability indices. This function can take on a more complex form by introducing cost variables (including cost of initial construction and cost of failure consequences).

For a given code safety-checking format, the set of partial factors is determined based on the objective function. First, trial values of partial factors are used for the new format and the respective β_i computed. The objective function is computed using Eq. (52.52). By repeating for different sets of values for the partial factors, the set of values that minimize Eq. (52.52) are adopted. The same procedure is repeated for the various load combinations to be implemented in the new (or revised) code.

Evaluation of Load and Resistance Factors

As an illustration of the computation of the load and resistance factors, a simple example involving only the dead and live loads is considered. The new code format is specified as

$$\phi R_n \geq \gamma_D D_n + \gamma_L L_n \tag{52.53}$$

where R_n, D_n , and L_n are the nominal resistance, dead load, and live load, respectively, and ϕ, γ_D, and γ_L are the corresponding partial factors. Consider the case of a steel member under tension with the performance function expressed as

$$g(\mathbf{X}) = R - D - L \tag{52.54}$$

The statistics of the basic variables are given in Table 52.6. For the specific class of loads corresponding to a mean live-to-dead load ratio $\bar{L}/\bar{D}$ of 1.5, the partial factors are to be computed for a target reliability index of 3.0.

TABLE 52.6 Statistics of Basic Variables

Variables	$\overline{R}/R_n$	Coefficient of Variation, V	Probability Distribution
Resistance, R	1.05	0.11	Lognormal
Dead load, D	1.05	0.10	Normal
Live load, L	1.00	0.25	Type I extreme

The computation can be summarized as follows:

1. To commence the computation, the most likely failure point is assumed, say $r^* = 0.866\overline{R}$, $d^* = 1.03\overline{D}$ and $l^* = 1.99\overline{L}$.
2. The equivalent normal parameters for R and L are next computed. For R, which is lognormal distributed,

$$\sigma_R^N = r^* \varsigma_R = r^* \sqrt{\ln\left(1+V_R^2\right)} = 0.09497\overline{R}$$

$$\mu_R^N = r^* \left(1 - \ln\frac{r^*}{\overline{R}} - \frac{1}{2}\ln\left(1+V_R^2\right)\right) = 0.9854\overline{R}$$

For L, which follows the type I extreme distribution,

$$\alpha_n = \frac{\pi}{\sigma_L\sqrt{6}} = \frac{5.1302}{\overline{L}} = \frac{3.4201}{\overline{D}}$$

$$u_n = L - -\frac{0.5772}{\alpha_n} = 1.3312\overline{D}$$

$$F_L(l^*) = \exp\left[-\exp\left\{-\alpha_n\left(l^* - u_n\right)\right\}\right] = 0.9965$$

$$f_L(l^*) = \alpha_n \exp\left[-\alpha_n\left(l^* - u_n\right) - \exp\left\{-\alpha_n\left(l^* - u_n\right)\right\}\right] = \frac{0.01191}{\overline{D}}$$

$$\sigma_L^N = \frac{\phi\left(\Phi^{-1}\left[F_L(l^*)\right]\right)}{f_L(l^*)} = 0.8821\overline{D}$$

$$\mu_L^N = l^* - \mu_L^N \Phi^{-1}\left[F_L(l^*)\right] = 0.606\overline{D}s$$

3. Based on the performance function and the target reliability index,

$$\beta = \frac{\mu_R^N - \mu_D^N - \mu_L^N}{\sqrt{\sigma_R^{N^2} + \sigma_D^{N^2} + \sigma_L^{N^2}}} = 3.0$$

$$0.8898\overline{R}^2 - 3.9491\overline{R}\overline{D} - 4.5137\overline{D}^2 = 0 \quad \text{or} \quad \overline{R} = 4.6482\overline{D}$$

4. The sensitivity factors at the most likely failure point is given by the direction cosines and computed as

$$\alpha_R^* = \frac{\sigma_R^N}{\sqrt{\sigma_R^{N^2} + \sigma_D^{N^2} + \sigma_L^{N^2}}} = 0.4452$$

$$\alpha_D^* = \frac{-\sigma_D^N}{\sqrt{\sigma_R^{N^2} + \sigma_D^{N^2} + \sigma_L^{N^2}}} = -0.1009$$

$$\alpha_L^* = -0.8897$$

5. The most likely failure point is then updated,

$$r^* = \mu_R^N - \alpha_R^* \sigma_R^N \beta = 0.9854\overline{R} - 0.4452 * 0.09497\overline{R} * 3.0 = 0.8586\overline{R}$$

$$d^* = 1.030\overline{D}$$

$$l^* = 2.960\overline{D} = 1.9736\overline{L}$$

6. If the results in step 5 are significantly different from the values assumed in step 1, then the values in step 5 are used for the next iteration. Steps 2 to 5 are then repeated until convergence. The final solution of the most likely failure point is used to estimate the partial factors.
7. Assuming the values given in step 5 are correct, the mean partial factors of safety are given by

$$\overline{\phi} = r^* / \overline{R} = 0.859$$

$$\overline{\gamma}_D = d^* / \overline{D} = 1.030$$

$$\overline{\gamma}_L = l^* / \overline{L} = 1.974$$

The nominal partial factors of safety are

$$\phi = \frac{r^* * \overline{R}}{\overline{R} * R_n} = 0.859 * 1.05 = 0.902$$

$$\gamma_D = 1.030 * 1.05 = 1.082$$

$$\gamma_L = 1.974 * 1.0 = 1.974$$

Hence the code checking equation can be written as

$$0.90R_n \geq 1.08D_n + 1.97L_n$$

The implied overall mean factor of safety can be estimated as

$$\frac{\overline{R}}{\overline{D} + \overline{L}} \geq \frac{\left(1.03\overline{D} + 1.974\overline{L}\right) / 0.859}{\overline{D} + \overline{L}} = 1.86$$

whereas the overall nominal factor of safety is approximately 1.80.

Acknowledgment

The author expresses his gratitude to Dr. Kok-Kwang Phoon for reading through the manuscript and providing constructive suggestions.

SURVEYING IS ONE OF THE OLDEST ACTIVITIES of the civil engineer, and remains a primary component of civil engineering. It is also one field that continues to undergo phenomenal changes due to technological developments in digital imaging and satellite positioning. These modern surveying tools are not only revolutionizing regular surveying engineering tasks but are also impacting a myriad of applications in a variety of fields where near-real-time positioning is of great value.

Surveying and engineering are closely related professional activities. The area of surveying and mapping is in many countries a discipline by itself, and taken in total, it is almost as broad in scope as civil engineering. In the U.S., surveying engineering has been historically allied to civil engineering. Engineering surveying is defined as those activities involved in the planning and execution of surveys for the

location, design, construction, operation, and maintenance of civil and other engineered projects. Such activities include the preparation of survey and related mapping specifications; execution of photogrammetric and field surveys for the collection of required data, including topographic and hydrographic data; calculation, reduction, and plotting of survey data for use in engineering design; design and provision of horizontal and vertical control survey networks; provision of line and grade and other layout work for construction and mining activities; execution and certification of quality control measurements during construction; monitoring of ground and structural stability, including alignment observations, settlement levels, and related reports and certifications; measurement of material and other quantities for inventory, economic assessment, and cost accounting purposes; execution of as-built surveys and preparation of related maps and plans and profiles upon completion of construction; and analysis of errors and tolerances associated with the measurement, field layout, and mapping or other plots of survey measurements required in support of engineering projects. Engineering surveying may be regarded as a specialty within the broader professional practice of engineering and, with the exception of boundary, right-of-way, or other cadastral surveying, includes all surveying and mapping activities required to support the sound conception, planning, design, construction, maintenance, and operation of engineered projects. Engineering surveying does not include surveys for the retracement of existing land ownership boundaries or the creation of new boundaries.

Modern surveying engineering encompasses several specialty areas, each of which requires substantial knowledge and training in order to attain proper expertise. The most primary area perhaps is plane surveying because it is so widely applied in engineering and surveying practice. In plane surveying, we consider the fundamentals of measuring distance, angle, direction, and elevation. These measured quantities are then used to determine position, slope, area, and volume — the basic parameters of civil engineering design and construction. Plane surveying is applied in civil engineering projects of limited areal extent, where the effects of the earth's curvature are negligible relative to the positional accuracy required for the project.

Geodesy, or higher surveying, is an extensive discipline dealing with mathematical and physical aspects of modeling the size and shape of the earth, and its gravity field. Since the launch of earth-orbiting satellites, geodesy has become a truly three-dimensional science. Terrestrial and space geodetic measurement techniques, and particularly the relatively new technique of satellite surveying using the Global Positioning System (GPS), are applied in geodetic surveying. GPS surveying has not only revolutionized the art of navigation but has also brought about an efficient positioning technique for a variety of users, prominent among them the engineering community. GPS has had a profound impact on the fundamental problems of determining relative and absolute positions on the earth, including improvements in speed, timeliness, and accuracy. It is safe to say that any geometry-based data collection scheme profits to some degree from the full constellation of 24 GPS satellites. In addition to the obvious applications in geodesy, surveying, and photogrammetry, the use of GPS is applied in civil engineering areas such as transportation (truck and emergency vehicle monitoring, intelligent vehicle and highway systems, etc.) and structures (monitoring of deformation of structures such as water dams). Even in other areas such as forestry and agriculture (crop yield management) GPS provides the geometric backbone of modern (geographic) information systems.

Photogrammetry and remote sensing encompass all activities involved in deriving qualitative and quantitative information about objects and environments from their images. Such imagery may be acquired at close range, from aircraft, or from satellites. In addition to large-, medium-, and small-scale mapping, many other applications such as resource management and environmental assessment and monitoring rely on imageries of various types. Close-range applications include such tasks as accident reconstruction, mapping of complex piping systems, and shape determination for parabolic antennas. Large-scale mapping (including the capture of data on infrastructure) remains the primary civil engineering application of photogrammetry. Recent evolution toward working with digital imagery has brought about the increasing acceptance of the digital orthophoto to augment or supplant the planimetric map. Digital image processing tools offer the probability of great increases in mapping productivity through automation. For small- and medium-scale mapping, the increasing availability of satellite image

data offers an alternative to chemical photography. Commercially available satellite data with spatial resolutions of 1 to 3 meters, proposed for the near future, would have a profound impact on all mapping activities within civil engineering. Inclusion of GPS in photogrammetric and remote sensing acquisition platforms will lead to substantial improvements in accuracy, timeliness, and economy.

For centuries, maps have provided layered information in graphical form and have been used as legal documents and as tools to support decision making for applications such as urban planning. Recently, geographic information systems (GIS) have broadened the role played by all types of maps to encompass a total system of hardware, software, and procedures designed to capture, manage, manipulate, and produce information in a spatial context. GIS applications are broad indeed; they include land record management, base mapping, infrastructure maintenance, facilities management, and many others.

A driving force behind the move toward integrating mapping and other spatially oriented data has been the various utility industries and municipalities who need to plan and manage their infrastructure facilities and property assets. This automated mapping/facilities management, or AM/FM, concept is being used successfully today by many cities, counties, and utility industries, who may have embarked on the transition as much as 15 years ago. Successful practitioners of GIS can satisfy the needs of a broad spectrum of users with a single system, minimizing the duplication of resources required to support historically independent user groups.

All other components of surveying engineering contribute to the construction of a GIS. The range of survey methods, from classical to modern geodesic and space-based technologies, provide the required reference framework. Digital mapping provides an efficient technology to populate the GIS with spatial information. Remote sensing techniques applied to the earth and its environment provide the various thematic layers of information.

Scope of This Section of the Handbook

The scope of Section VII, Surveying Engineering, in this handbook is to present the reader with the basic information involved in the performance of different surveying engineering projects. As was mentioned earlier, this is a discipline of many areas, each of which will be covered in a separate chapter. The underlying mathematical concepts used by the different areas of surveying engineering are covered first in Chapter 53, followed by four chapters covering, in sequence, plane surveying, geodesy, photogrammetry and remote sensing, and geographic information systems. Of particular importance is the topic on measurements, their errors, and least squares adjustment of redundant data. Since surveying is fundamentally a measurement science, all phases are covered: preanalysis (design), data acquisition (observations), data preprocessing, data adjustment, and postadjustment analysis of the results (quality assessment). Each engineering surveying project must properly execute these phases.

53.1 Coordinate Systems

Two-Dimensional Systems

Figure 53.1 depicts two commonly used coordinate systems, one polar (r, θ) and the other *Cartesian or rectangular* (x_1, x_2). A point p can be located either by the angle θ, measured from the reference direction x_1, and range r from the reference point 0, or by its two distances from two perpendicular axes, x_1, x_2. The relationships between the two systems are given by

$$x_1 = r\cos\theta$$

$$x_2 = r\sin\theta \tag{53.1}$$

$$r = (x_1^2 + x_2^2)^{1/2}$$

$$\theta = \tan^{-1}(x_2/x_1) \tag{53.2}$$

Three-Dimensional Coordinate Systems

Figure 53.2 shows two systems of three-dimensional coordinates: *spherical* (α, β, r) and Cartesian or rectangular (x_1, x_2, x_3). The Cartesian system depicted in Fig. 53.2 is *right-handed*, since a right-threaded screw rotated by an angle less than 90° from $+x_1$ to $+x_2$ would advance in the direction of $+x_3$. The relations between these two systems are as follows:

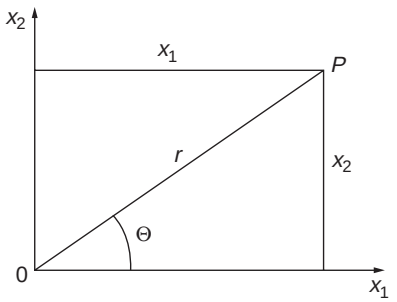

FIGURE 53.1 Two-dimensional coordinate systems.

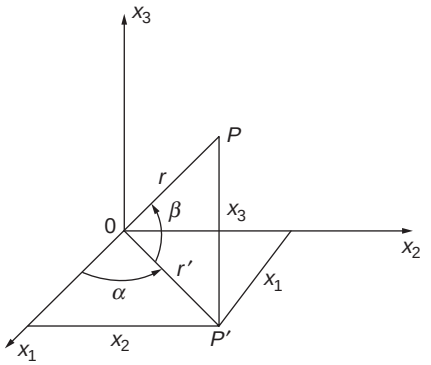

FIGURE 53.2 Three-dimensional right-handed Cartesian coordinate system.

$$r' = r\cos\beta$$

$$x_1 = r'\cos\alpha$$

$$x_2 = r'\sin\alpha$$

$$x_1 = r\cos\alpha\cos\beta$$

$$x_2 = r\sin\alpha\cos\beta \tag{53.3}$$

$$x_3 = r\sin\beta$$

$$r = (x_1^2 + x_2^2 + x_3^2)^{1/2}$$

$$\alpha = \tan^{-1}(x_2/x_1) \tag{53.4}$$

$$\beta = \sin^{-1}(x_3/r)$$

One example of spherical coordinates consists of latitude ϕ, longitude λ, and earth radius R, when the earth is considered as a sphere. A more accurate representation of the earth is an ellipsoid of revolution about its minor (shorter) axis. Coordinates referring to the earth ellipsoid, and other figures, are given in Chapter 55, "Geodesy."

Examples of rectangular systems include the geocentric and local space rectangular (LSR) coordinate systems. The geocentric system has its origin at the center of the earth, Z through the North Pole, X through the point of zero longitude, and the Y completing a right-handed system. The LSR varies with location, with its XY plane either tangent or secant to the ellipsoid and passing through a selected point λ_0, ϕ_0, and its Z along the local zenith.

53.2 Plane Geometry

Distance between Two Points

The distance between two points P_1 and P_2, with coordinates X_1, Y_1 and X_2, Y_2, is given by

$$L_{12} = \sqrt{(X_2 - X_1)^2 + (Y_2 - Y_1)^2} \tag{53.5}$$

Slope of a Line between Two Points

The slope of any line in a plane is the tangent of the angle it makes with the X axis. The slope angle is the counterclockwise angle from the $+X$ axis to the line in a *specified direction*. If the slope angle for the line P_1P_2 is θ_{12}, which is $<90^\circ$, and the slope angle for the line P_2P_1 is θ_{21}, which is $>180^\circ$, then

$$\theta_{21} = \theta_{12} + 180^\circ \tag{53.6}$$

The slope m_{12} of the line P_1P_2 is

$$m_{12} = \tan\theta_{12} = \frac{Y_2 - Y_1}{X_2 - X_1} \tag{53.7}$$

and that for the line P_2P_1 is

$$m_{21} = \tan\theta_{21} = \frac{Y_1 - Y_2}{X_1 - X_2} \tag{53.8}$$

Note that $m_{21} = \tan\theta_{21} = \tan(\theta_{12} + 180°) = \tan\theta_{12}$.

Azimuth

Azimuth is a clockwise angle with a magnitude between 0 and 360°. It is measured either from North (or the $+Y$ axis) or from South (or the $-Y$ axis). Thus, for any line, α_N and α_S designate azimuths from North and from South, respectively. One azimuth angle is obtained from the other by simply adding 180° and dropping 360° whenever the sum exceeds 360°. Thus

$$\begin{aligned} \alpha_S &= \alpha_N + 180° \\ \alpha_N &= \alpha_S + 180° \end{aligned} \tag{53.9}$$

Bearing

Bearing is another form of expressing the direction of a line in surveying. It is always an *acute* angle, with a magnitude between 0 and 90°, and is a positive quantity. The bearing is the angle the line makes with either N (for North) or S (for South). The quadrant is indicated by specifying whether the angle is on the east or west side of the meridian (Y axis). Thus, the bearing angle is preceded by either N or S and succeeded by either E or W. If β designates a bearing, Table 53.1 shows how to convert bearing to azimuth. Table 53.2 shows how to convert azimuth to bearing.

TABLE 53.1 Conversion of Bearing to Azimuth

Bearing	α_N, deg	α_S, deg
$N\ \beta°\ E$	β	$180 + \beta$
$S\ \beta°\ E$	$180 - \beta$	$360 - \beta$
$S\ \beta°\ W$	$\beta + 180$	β
$N\ \beta°\ W$	$360 - \beta$	$180 - \beta$

Source: Tables 53.1 and 53.2 are from Anderson, J.M. and Mikhail, E.M. *Introduction to Surveying,* McGrawHill, Inc., New York, NY, 1985, p. 665. With permission.

TABLE 53.2 Conversion of Azimuth to Bearing

α_N, deg	α_S, deg	β			Bearing
0–90	180–270	α_N	or	$\alpha_S - 180°$	$N\ \beta°\ E$
90–180	270–360	$180° - \alpha_N$	or	$360° - \alpha_S$	$S\ \beta°\ E$
180–270	0–90	$\alpha_N - 180°$	or	α_S	$S\ \beta°\ W$
270–360	90–180	$360° - \alpha_N$	or	$180° - \alpha_S$	$N\ \beta°\ W$

Source: Tables 53.1 and 53.2 are from Anderson, J.M. and Mikhail, E.M. *Introduction to Surveying,* McGrawHill, Inc., New York, NY, 1985, p. 665. With permission.

Relation between Azimuth and Slope Angle

Considering the commonly used azimuth from North, α_N, the slope angle θ is obtained from

$$\theta = 90° - \alpha_N \tag{53.10}$$

Internal and External Division of a Line Segment

Let points I and E divide a line segment in the proportion s_1/s_2, where I is an internal and E is an external point. If (x_1, y_1) and (x_2, y_2) are the coordinates of the ends of the line segment, the coordinates of I and E are given by

$$\begin{aligned} X_1 &= \frac{s_1X_2 + s_2X_1}{s_1 + s_2} \\ Y_1 &= \frac{s_1Y_2 + s_2Y_1}{s_1 + s_2} \end{aligned} \tag{53.11}$$

$$\begin{aligned} X_E &= \frac{s_1X_2 - s_2X_1}{s_1 - s_2} \\ y_E &= \frac{s_1Y_2 - s_2Y_1}{s_1 - s_2} \end{aligned} \tag{53.12}$$

Equation of a Line with Known *X* and *Y* Intercepts

$$\begin{aligned} \frac{X}{X_0} + \frac{Y}{Y_0} &= 1 \\ Y_0X + X_0Y &= X_0Y_0 \end{aligned} \tag{53.13}$$

where X_0 and Y_0 are the X and Y intercepts, respectively.

General Equation of a Line

$$aX + bY + c = 0 \tag{53.14}$$

Since two points define a line, only two of the three coefficients a, b, c are independent. This can be shown by dividing by c, or

$$\frac{a}{c}X + \frac{b}{c}Y + 1 = 0 \quad \text{or} \quad a'X + b'Y + 1 = 0$$

The two intercepts are obtained from Eq. (53.14) as

$$X \text{ intercept} = -\frac{c}{a} \tag{53.15}$$

$$Y \text{ intercept} = -\frac{c}{b}$$

and the slope of the line is given by

$$m = \tan\theta = -\frac{a}{b} \tag{53.16}$$

Lines Parallel to the Axes

The equation of a line parallel to the X axis is simply

$$Y = k_1 \tag{53.17}$$

where k_1 is the distance of the line from the X axis. Similarly, the equation of a line parallel to the Y axis is

$$X = k_2 \tag{53.18}$$

where k_2 is the distance between the Y axis and the line.

Equation of a Line with Given Slope and Y Intercept

$$Y = mX + k \tag{53.19}$$

where m is the slope and k is the Y intercept.

Equation of a Line with a Given Slope Passing through a Given Point

$$Y - Y_p = m(X - X_p) \tag{53.20}$$

where m is the slope and X_p, Y_p are the coordinates of the point. In terms of azimuth α, the equation becomes

$$Y - Y_p = (X - X_p)\cot\alpha \tag{53.21}$$

Equation of a Line Joining Two Points

The equation of a line passing through two points P_1 and P_2 with coordinates X_1, Y_1 and X_2, Y_2 is given by

$$\frac{Y - Y_1}{X - X_1} = \frac{Y_2 - Y_1}{X_2 - X_1} \tag{53.22}$$

Equation of a Line with Given Length and Slope of the Perpendicular from Origin

$$X \cos\theta + Y \sin\theta = p \tag{53.23}$$

where p is the length of the perpendicular from the origin to the line, and θ is the angle it makes with the X axis.

Perpendicular Distance from the Origin to a Line

From the general form of the equation of a line, Eq. (53.14), the length of the perpendicular from the origin to the line is given by

$$p = \left| \frac{c}{\sqrt{a^2 + b^2}} \right| \tag{53.24}$$

Perpendicular Distance from a Point to a Line

$$s = \left| \frac{aX_1 + bY_1 + c}{\sqrt{a^2 + b^2}} \right| \tag{53.25}$$

where X_1, Y_1 are the coordinates of the point, and the line is given by the general equation $aX + bY + c = 0$.

Equation of a Line through a Point and Parallel to Another Line

$$X \cos\theta + Y \sin\theta = p + s \tag{53.26}$$

in which $X \cos\theta + Y \sin\theta = p$ is the equation of the given line and s is the perpendicular distance between the two lines. The value of s cannot be taken as its absolute value; its proper sign must be determined. This is done by realizing that the value of the left-hand side of Eq. (53.14) will always be positive for all points on one side of the line and negative for all points on the other side. (The value is of course zero for points falling on the line.) Thus,

$$\frac{a}{\sqrt{a^2 + b^2}} X + \frac{b}{\sqrt{a^2 + b^2}} Y = -\frac{c}{\sqrt{a^2 + b^2}} + \frac{aX_1 + bY_1 + c}{\sqrt{a^2 + b^2}}$$

which when clearing fractions becomes

$$aX + bY - (aX_1 + bY_1) = 0 \tag{53.27}$$

This is the equation sought, in which a, b belong to the given line and X_1, Y_1 are the coordinates of the given point.

Equation of a Line through a Point and Perpendicular to Another Line

The given line has the general equation $aX + bY + c = 0$, and the given point P has coordinates X_p, Y_p. The slope of the given line is

$$m = -\frac{a}{b}$$

The slope of the line perpendicular to the given line is b/a. Thus,

$$Y - Y_p = \frac{b}{a}(X - X_p)$$

or

$$bX - aY - (bX_p - aY_p) = 0 \tag{53.28}$$

Angle between Two Lines

The angle γ, between two lines is given by

$$\gamma = \theta_2 - \theta_1 \tag{53.29}$$

where θ_1 and θ_2 are the slope angles of the two lines. Then

$$\tan\gamma = \tan(\theta_2 - \theta_1)$$

or

$$\tan\gamma = \frac{\tan\theta_2 - \tan\theta_1}{1 + \tan\theta_1 \tan\theta_2}$$

With the line slopes $m_1 = \tan\theta_1$ and $m_2 = \tan\theta_2$,

$$\tan\gamma = \frac{m_2 - m_1}{1 + m_1 m_2} \tag{53.30}$$

If $\tan\gamma = 0$ or $m_1 = m_2$, the two lines are parallel. On the other hand, if $\tan\gamma = \infty$ or $m_1 m_2 = -1$, the two lines are perpendicular to each other.

Point of Intersection of Two Lines

If the point of intersection of the two lines is q, its coordinates X_q, Y_q satisfy their equations. Then, to get X_q, Y_q we simultaneously solve the two equations of the lines:

$$\begin{aligned} X_q &= \frac{c_1 b_2 - c_2 b_1}{a_1 b_2 - a_2 b_1} \\ Y_q &= \frac{c_1 a_2 - c_2 a_1}{a_1 b_2 - a_2 b_1} \end{aligned} \tag{53.31}$$

Equation of a Circle

Given a circle of radius r and center coordinates X_c, Y_c, its equation is

$$(X - X_c)^2 + (Y - Y_c)^2 = r^2 \tag{53.32}$$

If the circle's center is the origin of the coordinate system, $X_c = Y_c = 0$, its equation reduces to

$$X^2 + Y^2 = r^2 \tag{53.33}$$

Equation (53.32) may be expanded to the form

$$X^2 + Y^2 + 2dX + 2eY + f = 0 \tag{53.34}$$

which represents the general form of the equation of a circle. It contains three coefficients, d, e, f, which represent three geometric elements such as the radius and the two coordinates of its center.

Intersection of a Line and a Circle

In general, a straight line intersects a circle in two points. Given the equations of a circle and a line,

$$X^2 + Y^2 + 2dX + 2eY + f = 0$$

$$Y = mX + k$$

we can eliminate Y and get a general *quadratic* equation in X,

$$AX^2 + BX + C = 0$$

Its two roots are in general given by

$$X_1 = \frac{-B + \sqrt{B^2 - 4AC}}{2A} \quad \text{and} \quad X_2 = \frac{-B - \sqrt{B^2 - 4AC}}{2A}$$

for each of which a value for r is obtained from the equation of the line.

In addition to the case of two points of intersection, two other situations are possible, depending upon the quantity under the radical, $B^2 - 4AC$. If this quantity is zero, or $B^2 = 4AC$, then $X_1 = X_2$ and the line is tangent to the circle at one point. In the second situation, $B^2 < 4AC$, the quantity is negative, which means that one cannot take the square root. (This is usually referred to as the imaginary solution to the quadratic equation.) In this case, the line misses the circle and no intersection takes place.

Areas

Circle.

$$A = \pi r^2 = \frac{\pi d^2}{4} \tag{53.35}$$

where r and d are the radius and diameter of the circle, respectively.

Sector.

$$A = \frac{1}{2} ra = \frac{\pi r^2 \theta^\circ}{360^\circ} \tag{53.36}$$

where r is the radius, a is the arc length, and θ is the angle at the center in degrees.

Segment (Less Than a Semicircle).

$$A = \frac{1}{2} ra - \frac{1}{2} r^2 \sin\theta \tag{53.37}$$

or

$$A = \frac{\pi r^2 \theta^\circ}{360^\circ} - \frac{1}{2} r^2 \sin\theta \tag{53.38}$$

where r, a, and θ are as defined above. If the chord length c is given, then

$$\sin\frac{\theta}{2} = \frac{c}{2r} \tag{53.39}$$

Triangle. For a *general* triangle, the area T is given by

$$T = \frac{1}{2} bh \qquad (h \text{ is perpendicular to } b) \tag{53.40}$$

or

$$T = \frac{1}{2} bc \sin A \tag{53.41}$$

or

$$T = \sqrt{s(s-a)(s-b)(s-c)} \tag{53.42}$$

with

$$s = \frac{1}{2}(a+b+c) \tag{53.43}$$

where a, b, c are the lengths of the sides, h is the height of the triangle (which is perpendicular to the base b), and A, B, C are the interior angles opposite to the side lengths a, b, c, respectively. Other useful relations for a plane triangle are

$$A + B + C = 180° \tag{53.44a}$$

$$\frac{\sin A}{a} = \frac{\sin B}{b} = \frac{\sin C}{c} \tag{53.44b}$$

$$a^2 = b^2 + c^2 - 2bc\cos A \tag{53.44c}$$

$$b^2 = c^2 + a^2 - 2ac\cos B \tag{53.44d}$$

$$c^2 = a^2 + b^2 - 2ab\cos C \tag{53.44e}$$

$$\tan\frac{A}{2} = \frac{1}{s-a}\sqrt{\frac{(s-a)(s-b)(s-c)}{s}} \tag{53.44f}$$

$$\cos\frac{A}{2} = \sqrt{\frac{s(s-a)}{bc}} \tag{53.44g}$$

$$\cos\frac{B}{2} = \sqrt{\frac{s(s-b)}{ca}} \tag{53.44h}$$

$$\cos\frac{C}{2} = \sqrt{\frac{s(s-c)}{ab}} \tag{53.44i}$$

$$\frac{a-b}{a+b} = \frac{\tan(A-B)/2}{\tan(A+B)/2} \tag{53.44j}$$

$$h = \frac{2}{b}\sqrt{s(s-a)(s-b)(s-c)} \tag{53.44k}$$

For an *equilateral* triangle, where sides $a = b = c$ and angles $A = B = C = 60°$, then the area T becomes

$$T = \frac{a^2\sqrt{3}}{4} \qquad \left(with\ h = \frac{a\sqrt{3}}{2}\right) \tag{53.45}$$

Square.

$$A = a^2 \tag{53.46}$$

where a is the side length.

Rectangle.

$$A = ab \tag{53.47}$$

where a and b are its width and length.

Parallelogram. Let a and b be the sides, h the altitude upon side b, C the acute angle, and A the area. Then

$$A = bh = ab \sin C \tag{53.48}$$

Trapezoid. If b_1 and b_2 are the parallel sides, and h is the altitude between them, then the area A is

$$A = \frac{1}{2}h(b_1 + b_2) \tag{53.49}$$

For an *isosceles* trapezoid, if a is the length of one of the two nonparallel sides, and C is the acute angle between a and b_2, then

$$A = \frac{1}{2}a(b_1 + b_2)\sin C \tag{53.50}$$

53.3 Three-Dimensional Geometry

Distance between Two Points

The distance between two points (X_1, Y_1, Z_1) and (X_2, Y_2, Z_2) is

$$d_{12} = [(X_1 - X_2)^2 + (Y_1 - Y_2)^2 + (Z_1 - Z_2)^2]^{1/2} \tag{53.51}$$

Equation of a Plane

The general equation of a plane is given by

$$AX + BY + CZ + D = 0 \tag{53.52}$$

Only three of the four coefficients A, B, C, D are independent, since we can divide by D and get

$$\frac{A}{D}X + \frac{B}{D}Y + \frac{C}{D} + 1 = 0$$

or

$$EX + FY + GZ + 1 = 0 \tag{53.53}$$

Three noncollinear points determine a plane by writing three linear equations and solving them for E, F, G. When D in Eq. (53.52) is zero, or when no 1 is in Eq. (53.53), the plane passes through the origin. (For vector representation of a plane, see "Planes and Lines" in Section 53.4.)

Equation of a Straight Line

Since a straight line is the intersection of two planes, and since a plane is expressed by one linear equation, a straight line in three-dimensional space is represented by two linear equations. The two equations of a line passing through two points (X_1, Y_1, Z_1) and (X_2, Y_2, Z_2) are given by

$$\frac{X - X_1}{X_2 - X_1} = \frac{Y - Y_1}{Y_2 - Y_1} = \frac{Z - Z_1}{Z_2 - Z_1} \tag{53.54}$$

For vector representation of a straight line, see "Planes and Lines" in the following section.

Equation of a Sphere

If (X_c, Y_c, Z_c) represents the center of the sphere and R is its radius, its equation is given by

$$(X - X_c)^2 + (Y - Y_c)^2 + (Z - Z_c)^2 = R^2 \tag{53.55}$$

53.4 Vector Algebra

Definitions

A *vector* is an entity which has a magnitude and direction. In two- and three-dimensional spaces, it is a directed line segment from one point to another. The projections of the vector on the x_1, x_2, and x_3 axes are a_1, a_2, and a_3 and are called the vector components. It is represented by a column:

$$\mathbf{a} = \begin{bmatrix} a_1 \\ a_2 \\ a_3 \end{bmatrix}$$

The *length* of the vector is designated by $|\mathbf{a}|$ and is given by

$$|\mathbf{a}| = (a_1^2 + a_2^2 + a_3^2)^{1/2} \tag{53.56}$$

A vector's *direction* is given either by the angles α, β, γ it makes with the axes or by their cosines. The latter are called *direction cosines* and are given by

$$\cos\alpha = \frac{a_1}{|\mathbf{a}|} \qquad \cos\beta = \frac{a_2}{|\mathbf{a}|} \qquad \cos\gamma = \frac{a_3}{|\mathbf{a}|} \tag{53.57}$$

It is evident that

$$\cos^2\alpha + \cos^2\beta + \cos^2\gamma = 1 \tag{53.58}$$

Generalizing a vector to n dimensions, we write

$$\mathbf{a} = \begin{bmatrix} a_1 \\ a_2 \\ \vdots \\ a_n \end{bmatrix}$$

Vector Operations

Equality.

$$\mathbf{a} = \mathbf{b} \qquad \text{when } a_1 = b_1, a_2 = b_2, \cdots, a_n = b_n$$

Addition/Subtraction.

$$\mathbf{c} = \mathbf{a} \pm \mathbf{b} \qquad \text{or} \qquad c_1 = a_1 \pm b_1, c_2 = a_2 \pm b_2, \cdots, c_n = a_n \pm b_n$$

$$\mathbf{a} + \mathbf{b} = \mathbf{b} + \mathbf{a}$$

$$(\mathbf{a} + \mathbf{b}) + \mathbf{c} = \mathbf{a} + (\mathbf{b} + \mathbf{c})$$

Multiplication by a Scalar. A *scalar* is a quantity which has magnitude but no direction, such as mass, temperature, time, etc., and will be designated by a lowercase Greek letter.

$$\lambda\mathbf{a} = \begin{bmatrix} \lambda a_1 \\ \lambda a_2 \\ \vdots \\ \lambda a_n \end{bmatrix}$$

$$\lambda(\mu\mathbf{a}) = (\lambda\mu)\mathbf{a} = \mu(\lambda\mathbf{a}) \tag{53.59}$$

$$\begin{aligned} (\lambda + \mu)\mathbf{a} &= \lambda\mathbf{a} + \mu\mathbf{a} \\ \lambda(\mathbf{a} + \mathbf{b}) &= \lambda\mathbf{a} + \lambda\mathbf{b} \\ |\lambda\mathbf{a}| &= \lambda|\mathbf{a}| \end{aligned}$$

Any vector a is reduced to a unit vector $\mathbf{a}^\circ$ when dividing its components by its length, which is a scalar, or $\mathbf{a}^\circ = \mathbf{a}/|\mathbf{a}|$. The components of $\mathbf{a}^\circ$ are the direction cosines of **a**. Unit vectors along the coordinate axes are called base or basis vectors and are given by

$$\mathbf{i} = \begin{bmatrix} 1 \\ 0 \\ 0 \end{bmatrix} \qquad \mathbf{j} = \begin{bmatrix} 0 \\ 1 \\ 0 \end{bmatrix} \qquad \mathbf{k} = \begin{bmatrix} 0 \\ 0 \\ 1 \end{bmatrix} \tag{53.60}$$

Any vector in 3-space is uniquely expressed as

$$\mathbf{a} = a_1\mathbf{i} + a_2\mathbf{j} + a_3\mathbf{k} \tag{53.61}$$

The right-handed system introduced in Section 53.1 can be generalized for three vectors **a**, **b**, **c**. If they are not coplanar, and they have the same initial point, then they are said to form a right-handed system if a right-threaded screw rotated through an angle *less than 180°* from **a** to **b** would advance in the direction c.

Vector Products

Dot (or Scalar) Product.

$$\mathbf{a} \cdot \mathbf{b} = \sum_{p=1}^{n} a_p b_p = a_1 b_1 + a_2 b_2 + \cdots + a_n b_n \tag{53.62}$$

This is also called the *inner product*. It is a scalar and has the following properties:

$$
\begin{aligned}
\mathbf{a}\cdot\mathbf{b} &= \mathbf{b}\cdot\mathbf{a}\\
\mathbf{a}\cdot(\mathbf{b}+\mathbf{c}) &= \mathbf{a}\cdot\mathbf{b}+\mathbf{a}\cdot\mathbf{c}\\
\lambda(\mathbf{a}\cdot\mathbf{b}) &= (\lambda\mathbf{a})\cdot\mathbf{b} = \mathbf{a}\cdot(\lambda\mathbf{b}) = (\mathbf{a}\cdot\mathbf{b})\lambda\\
\mathbf{i}\cdot\mathbf{i} &= \mathbf{j}\cdot\mathbf{j} = \mathbf{k}\cdot\mathbf{k} = 1\\
\mathbf{i}\cdot\mathbf{j} &= \mathbf{j}\cdot\mathbf{k} = \mathbf{k}\cdot\mathbf{i} = 0
\end{aligned}
\tag{53.63}
$$

The dot product of a vector with itself is equal to the square of its length, or

$$
\mathbf{a}\cdot\mathbf{a} = a_1^2 + a_1^2 + \cdots a_n^2 = |\mathbf{a}|^2 \tag{53.64}
$$

If θ is the angle between two vectors **a** and **b** (in two- or three-dimensional space), it can be shown that

$$
\mathbf{a}\cdot\mathbf{b} = |\mathbf{a}||\mathbf{b}|\cos\theta \tag{53.65}
$$

It follows that if **a** is perpendicular to **b**, then $\mathbf{a}\cdot\mathbf{b} = 0$.

Cross (or Vector) Product. $\mathbf{a}\times\mathbf{b}$ (read "**a** cross **b**") is another vector **c**, which is perpendicular to both **a** and **b** and in a direction such that **a**, **b**, **c** (in this order) form a right-handed system. The length of **c** is given by

$$
|\mathbf{c}| = |\mathbf{a}\times\mathbf{b}| = |\mathbf{a}||\mathbf{b}|\sin\theta \tag{53.66}
$$

where θ is the angle between **a** and **b**. This quantity is the area of the parallelogram determined by **a** and **b**. If $\mathbf{a} = a_1\mathbf{i} + a_2\mathbf{j} + a_3\mathbf{k}$, and $\mathbf{b} = b_1\mathbf{i} + b_2\mathbf{j} + b_3\mathbf{k}$, then c is given by the determinant

$$
\mathbf{c} = \mathbf{a}\times\mathbf{b} = \begin{bmatrix} \mathbf{i} & \mathbf{j} & \mathbf{k} \\ \mathbf{a_1} & \mathbf{a_2} & \mathbf{a_3} \\ b_1 & b_2 & b_3 \end{bmatrix} \tag{53.67}
$$

It has the following properties

$$
\begin{aligned}
\mathbf{a}\times\mathbf{b} &= -(\mathbf{b}\times\mathbf{a})\\
\mathbf{a}\times(\mathbf{b}+\mathbf{c}) &= \mathbf{a}\times\mathbf{b}+\mathbf{a}\times\mathbf{c} \qquad \text{(observing the order)}\\
\mathbf{a}\cdot(\mathbf{a}\times\mathbf{c}) &= 0\\
|\mathbf{a}\times\mathbf{b}|^2 &= |\mathbf{a}|^2|\mathbf{b}|^2 - (\mathbf{a}\cdot\mathbf{b})^2\\
\mathbf{i}\times\mathbf{i} &= \mathbf{j}\times\mathbf{j} = \mathbf{k}\times\mathbf{k} = 0\\
\mathbf{i}\times\mathbf{j} &= \mathbf{k};\ \mathbf{j}\times\mathbf{k} = \mathbf{i};\ \mathbf{k}\times\mathbf{i} = \mathbf{j}
\end{aligned}
\tag{53.68}
$$

For two nonzero vectors, if $\mathbf{a}\times\mathbf{b} = \mathbf{0}$, then **a** and **b** are parallel.

Scalar Triple Product.

$$
\mathbf{a}\times\mathbf{b}\cdot\mathbf{c} = \begin{vmatrix} a_1 & a_2 & a_3 \\ b_1 & b_2 & b_3 \\ c_1 & c_2 & c_3 \end{vmatrix} \tag{53.69}
$$

is a scalar which is equal to the volume of the parallelepiped determined by **a**, **b**, **c**. If it is zero, then the three vectors are coplanar. It has the following properties:

$$
\begin{aligned}
\mathbf{a}\times\mathbf{b}\cdot\mathbf{c} &= \mathbf{b}\times\mathbf{c}\cdot\mathbf{a} = \mathbf{c}\times\mathbf{a}\cdot\mathbf{b}\\
\mathbf{a}\times\mathbf{b}\cdot\mathbf{c} &= \mathbf{a}\cdot\mathbf{b}\times\mathbf{c}
\end{aligned}
$$

Planes and Lines

If $\mathbf{p_0}$ is a given point in a plane, $\mathbf{n}$ is a nonzero vector normal to the plane, and $\mathbf{p}$ is any point in the plane, then the equation of the plane takes the form

$$(\mathbf{p}-\mathbf{p_0})\cdot\mathbf{n} = 0 \qquad \text{or} \qquad \mathbf{p}\cdot\mathbf{n}-\mathbf{p_0}\cdot\mathbf{n} = 0 \tag{53.70}$$

Let $\mathbf{n} = A\mathbf{i} + B\mathbf{j} + C\mathbf{k}$, $\mathbf{p_0} = X_0\mathbf{i} + Y_0\mathbf{j} + Z_0\mathbf{k}$, and $\mathbf{p} = X\mathbf{i} + Y\mathbf{j} + Z\mathbf{k}$. Then Eq. (53.70) becomes

$$A(X-X_0) + B(Y-Y_0) + C(Z-Z_0) = 0 \tag{53.71}$$

or

$$AX + BY + CZ + D = 0$$

where $D = -(AX_0 + BY_0 + CZ_0)$. Two planes are parallel when they have a common normal vector n, and are perpendicular when their normals are, or $\mathbf{n_1}\cdot\mathbf{n_2} = 0$.

If $\mathbf{p_0}$ represents a given point on a line, $\mathbf{p}$ any other point on the line, and $\mathbf{v}$ is a given nonzero vector parallel to the line, then

$$\mathbf{p} = \mathbf{p_0} + \lambda\mathbf{v} \tag{53.72}$$

is an equation of the line. In component form, it yields three scalar equations describing the parametric form (λ is the *running parameter*):

$$\begin{aligned} X &= X_0 + \lambda v_x \\ Y &= Y_0 + \lambda v_y \\ Z &= Z_0 + \lambda v_z \end{aligned} \tag{53.73}$$

If λ is eliminated, one gets the usual two-equation form of a straight line in space; see Eq. (53.54).

53.5 Matrix Algebra

Definition

A *matrix* is a group of numbers or scalar functions collected in two-dimensional (rectangular) array. A matrix is designated by a boldface capital Roman letter. Thus, an $m \times n$ matrix can be symbolically written as

$$\underset{m,n}{\mathbf{A}} = \begin{bmatrix} a_{11} & a_{12} & \cdots & a_{1n} \\ a_{21} & a_{22} & & a_{2n} \\ \vdots & & \ddots & \vdots \\ a_{m1} & a_{m2} & \cdots & a_{mn} \end{bmatrix}$$

Types of Matrices

Square Matrix. This is a matrix in which the number of rows equals the number of columns. In this case, $\underset{m,m}{A}$ is a square matrix of order m. The *principal* (or *main*) diagonal of a square matrix is composed of all elements a_{ij} for which $i = j$.

Row Matrix.

$$\underset{1,n}{\mathbf{a}} = \begin{bmatrix} a_1 & a_2 & \cdots & a_n \end{bmatrix}$$

Column Matrix or Vector.

$$\underset{m,1}{\mathbf{b}} = \begin{bmatrix} b_1 \\ b_2 \\ \vdots \\ b_m \end{bmatrix}$$

Diagonal Matrix.

$$\mathbf{D} = \begin{bmatrix} d_{11} & 0 & \cdots & 0 \\ 0 & d_{22} & & 0 \\ \vdots & & \ddots & \vdots \\ 0 & 0 & \cdots & d_{mm} \end{bmatrix}$$

That is, $d_{ij} = 0$ for all $i \neq j$.

Scalar Matrix.

$$\mathbf{A} = \begin{bmatrix} a & 0 & \cdots & 0 \\ 0 & a & & 0 \\ \vdots & & \ddots & \vdots \\ 0 & 0 & \cdots & a \end{bmatrix}$$

$$a_{ij} = 0 \qquad \text{for all} \quad i \neq j$$

$$a_{ij} = a \qquad \text{for all} \quad i = j$$

Identity or Unit Matrix.

$$\mathbf{I} = \begin{bmatrix} 1 & 0 & \cdots & 0 \\ 0 & 1 & & 0 \\ \vdots & & \ddots & \vdots \\ 0 & 0 & \cdots & 1 \end{bmatrix}$$

$$a_{ij} = 0 \qquad \text{for all} \quad i \neq j$$

$$a_{ij} = 1 \qquad \text{for all} \quad i = j$$

Null Matrix. A null or zero matrix is a matrix whose elements are all zero. It is denoted by a boldface zero, **0**.

Upper Triangular Matrix.

$$\mathbf{U} = \begin{bmatrix} u_{11} & u_{12} & \cdots & u_{1m} \\ 0 & u_{22} & & u_{2m} \\ \vdots & & \ddots & \vdots \\ 0 & 0 & \cdots & u_{mm} \end{bmatrix}$$

with $u_{ij} = 0$ for $i > j$.

Lower Triangular Matrix.

$$\mathbf{L} = \begin{bmatrix} l_{11} & 0 & \cdots & 0 \\ l_{21} & l_{22} & & 0 \\ \vdots & & \ddots & \vdots \\ l_{m1} & l_{m2} & \cdots & l_{mm} \end{bmatrix}$$

where $l_{ij} = 0$ for $i > j$.

Basic Matrix Operations

Two matrices **A** and **B** are equal if they are of the same dimensions and each element $a_{ij} = b_{ij}$ for all i and j. The sum of two matrices **A** and **B** is possible only if they are of equal dimensions, and the elements of the resulting matrix **C** are $c_{ij} = a_{ij} + b_{ij}$ for all i, j. The following relations apply to addition (and subtraction) of matrices:

$$\begin{aligned} \mathbf{A} + \mathbf{B} &= \mathbf{B} + \mathbf{A} \\ \mathbf{A} + (\mathbf{B} + \mathbf{C}) &= (\mathbf{A} + \mathbf{B}) + \mathbf{C} = \mathbf{A} + \mathbf{B} + \mathbf{C} \\ \mathbf{A} + (-\mathbf{A}) &= \mathbf{0} \end{aligned} \tag{53.74}$$

with **0** being the zero or null matrix, and **–A** is the matrix composed of $-a_{ij}$ as elements.

Multiplication of a matrix by a scalar α results in another $\mathbf{B} = \alpha\mathbf{A}$ whose elements are $b_{ij} = \alpha a_{ij}$ for all i and j.

The following relations hold for scalar multiplication (λ, μ are scalars):

$$\begin{aligned} \lambda(\mathbf{A} + \mathbf{B}) &= \lambda\mathbf{A} + \lambda\mathbf{B} \\ (\lambda + \mu)\mathbf{A} &= \lambda\mathbf{A} + \mu\mathbf{A} \\ \lambda(\mathbf{AB}) + (\lambda\mathbf{A})\mathbf{B} &= \mathbf{A}(\lambda\mathbf{B}) \\ \lambda(\mu\mathbf{A}) &= (\lambda\mu)\mathbf{A} \end{aligned} \tag{53.75}$$

The product of two matrices is another matrix. The two matrices must be *conformable for multiplication*, i.e., the number of columns of the first matrix must equal the number of rows of the second matrix. Thus, if **A** is an $m \times q$ matrix and **B** is a $q \times n$ matrix, the product **AB**, *in that order*, is another matrix **C** with m rows (as in **A**) and n columns (as in **B**). Each element c_{ij} in **C** is obtained by multiplying each one of the q elements in the ith row in **A** by the corresponding element in the jth column in **B** and adding. Algebraically, this is written as

$$c_{ij} = a_{il}b_{1j} + a_{i2}b_{2j} + \cdots + a_{iq}b_{qj} = \sum_{k=1}^{q} a_{ik}b_{kj} \tag{53.76}$$

To illustrate matrix multiplication:

$$\underset{2,1}{\mathbf{C}} = \underset{2,3}{\mathbf{A}} \quad \underset{3,1}{\mathbf{B}} = \begin{bmatrix} 1 & 0 & 2 \\ 2 & 1 & 0 \end{bmatrix} \begin{bmatrix} 1 \\ 5 \\ 3 \end{bmatrix}$$

$$= \begin{bmatrix} (1 \times 1) + (0 \times 5) + (2 \times 3) \\ (2 \times 1) + (1 \times 5) + (0 \times 3) \end{bmatrix} = \begin{bmatrix} 7 \\ 7 \end{bmatrix}$$

Matrix multiplication is not commutative; that is, in general **FG ≠ GF**, even if the dimensions of the matrices allow multiplication in both directions (e.g., $m \times n$ and $n \times m$, or square matrices). The following relationships regarding matrix multiplication hold:

$$\begin{aligned}
\mathbf{AI} &= \mathbf{IA} = \mathbf{A} \qquad \text{in which } \mathbf{I} \text{ is the unit or identity matrix} \\
\mathbf{AB} &\neq \mathbf{BA} \\
\mathbf{A(BC)} &= \mathbf{(AB)C} = \mathbf{ABC} \qquad \text{(associative law)} \\
\mathbf{A(B+C)} &= \mathbf{AB+AC} \qquad \text{(distributive laws)} \\
\mathbf{(A+B)C} &= \mathbf{AC+BC} \qquad \text{(distributive laws)}
\end{aligned} \tag{53.77}$$

$\mathbf{AB} = \mathbf{0}$ is possible without either $\mathbf{A}$ or $\mathbf{B}$ equaling $\mathbf{0}$. Also, $\mathbf{AB} = \mathbf{AC}$ does not imply $\mathbf{B} = \mathbf{C}$.

The transpose of the $m \times n$ matrix $\mathbf{A}$ is an $n \times m$ matrix formed from $\mathbf{A}$ by interchanging rows and columns such that the ith row of $\mathbf{A}$ becomes the ith column of the transposed matrix. We denote the transpose of $\mathbf{A}$ by $\mathbf{A^T}$. If $\mathbf{B} = \mathbf{A^T}$, it follows that $b_{ij} = a_{ji}$ for all i and j. The following relationships apply to the transpose of a matrix:

$$\begin{aligned}
(\mathbf{A}+\mathbf{B})^{\mathrm{T}} &= \mathbf{A}^{\mathrm{T}} + \mathbf{B}^{\mathrm{T}} \\
(\mathbf{AB})^{\mathrm{T}} &= \mathbf{B}^{\mathrm{T}}\mathbf{A}^{\mathrm{T}} \qquad \text{(note reverse order)} \\
(\alpha\mathbf{A})^{\mathrm{T}} &= \alpha\mathbf{A}^{\mathrm{T}} \\
(\mathbf{A}^{\mathrm{T}})^{\mathrm{T}} &= \mathbf{A}
\end{aligned} \tag{53.78}$$

A square matrix $\mathbf{A}$ is *symmetric* if $\mathbf{A^T} = \mathbf{A}$. Diagonal, scalar, and identity matrices are symmetric, since each is equal to its transpose. For any matrix $\mathbf{A}$ (not necessarily square), both $\mathbf{AA^T}$ and $\mathbf{A^TA}$ are symmetric. If $\mathbf{B}$ is a symmetric matrix of suitable dimensions, then for any matrix $\mathbf{A}$, both $\mathbf{ABA^T}$ and $\mathbf{A^T BA}$ are also symmetric.

If $\mathbf{a}$ is a column matrix (or vector), then $\mathbf{a^Ta}$ is a positive scalar which is equal to the sum of the squares of its elements; for example, the square of the vector's length.

A square matrix $\mathbf{A}$ is *skew-symmetric* if $\mathbf{A^T} = -\mathbf{A}$ and $a_{ij} = -a_{ji}$ for all i,j. For any square matrix $\mathbf{A}$, the matrix $(\mathbf{A} + \mathbf{A^T})$ is symmetric and $(\mathbf{A} - \mathbf{A^T})$ is skew-symmetric.

The *trace of a square* matrix is the scalar which is equal to the sum of its main diagonal elements. It is denoted by tr $(\mathbf{A})$; thus $\operatorname{tr}\underset{n,n}{(\mathbf{A})} = a_{11} + a_{22} + \cdots a_{nn}$. The following are properties of the trace:

$$\begin{aligned}
\operatorname{tr}(\mathbf{A}) &= \operatorname{tr}(\mathbf{A}^{\mathrm{T}}) \\
\operatorname{tr}(\lambda\mathbf{A}) &= \lambda\operatorname{tr}(\mathbf{A}^{\mathrm{T}}) \\
\operatorname{tr}(\mathbf{A}+\mathbf{B}) &= \operatorname{tr}(\mathbf{A}) + \operatorname{tr}(\mathbf{B}) \\
\operatorname{tr}(\mathbf{AB}) &= \operatorname{tr}(\mathbf{BA}) \\
\operatorname{tr}(\mathbf{FAF}^{-1}) &= \operatorname{tr}(\mathbf{A}) \qquad (\mathbf{F} \text{ nonsingular matrix})
\end{aligned} \tag{53.79}$$

Matrix Inverse

Division of matrices is not defined. Instead, the *inverse of a square* matrix $\mathbf{A}$, if it exists, is the unique matrix $\mathbf{A^{-1}}$ with the following property:

$$\mathbf{AA}^{-1} = \mathbf{A}^{-1}\mathbf{A} = \mathbf{I} \tag{53.80}$$

where $\mathbf{I}$ is the identity matrix.

The properties of the inverse are

$$\begin{aligned}
(\mathbf{AB})^{-1} &= \mathbf{B}^{-1}\mathbf{A}^{-1} \text{ (note reverse order)} \\
(\mathbf{A}^{-1})^{-1} &= \mathbf{A} \\
(\mathbf{A}^{\mathrm{T}})^{-1} &= (\mathbf{A}^{-1})^{\mathrm{T}} \\
(\lambda\mathbf{A})^{-1} &= \frac{1}{\lambda}\mathbf{A}^{-1}
\end{aligned} \tag{53.81}$$

A square matrix which has an inverse is called *nonsingular*, whereas a matrix which does not have an inverse is called *singular*.

It was stated previously that **AB** can equal **0** without either **A** = **0** or **B** = **0**. If, however, either **A** or **B** is nonsingular, then the other matrix must be a null matrix. Hence, the product of two nonsingular matrices cannot be a null or zero matrix.

Associated with each *square matrix* **A** is a unique scalar called the *determinant* of **A**. It is denoted either by det **A** or by $|\mathbf{A}|$. Thus, for

$$\mathbf{A} = \begin{bmatrix} 3 & 1 \\ 1 & 2 \end{bmatrix}$$

the determinant is expressed as

$$|\mathbf{A}| = \begin{vmatrix} 3 & 1 \\ 1 & 2 \end{vmatrix}$$

The determinant of order n (for an $n \times n$ square matrix) can be defined in terms of determinants of order $n - 1$ and less. The determinant of a 1×1 matrix is defined as the value of that one element, i.e., for $\mathbf{A} = [a_{11}]$, $|\mathbf{A}| = \det \mathbf{A} = a_{11}$.

If **A** is an $n \infty n$ matrix, and one row and one column of **A** are deleted, the resulting matrix is an $(n-1) \times (\mathbf{n} - 1)$ *submatrix* of **A**. The determinant of such a submatrix is called a *minor* of **A**, and it is designated by m_{ij}, where i and j correspond to the deleted row and column, respectively. More specifically, m_{ij} is known as the *minor of the element* a_{ij} in **A**. Thus, each element of **A** has a minor.

The *cofactor* c_{ij} of an element a_{ij} is defined as

$$c_{ij} = (-1)^{i+j} m_{ij} \tag{53.82}$$

The determinant of an $n \times n$ matrix **A** can now be defined as

$$|\mathbf{A}| = a_{11}c_{11} + a_{12}c_{12} + \cdots + a_{1n}c_{1n} \tag{53.83}$$

which states that the determinant of **A** is the sum of the products of the elements of the first row of **A** and their corresponding cofactors. (It is equally possible to define $|\mathbf{A}|$ in terms of any other row or column, but for simplicity we used the first row.) On the basis of this definition, the 2×2 matrix

$$\mathbf{A} = \begin{bmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{bmatrix}$$

has cofactors $c_{11} = |a_{22}| = a_{22}$ and $c_{12} = -|a_{21}| = -a_{21}$, and the determinant of **A** is

$$|\mathbf{A}| = a_{11}c_{11} + a_{12}c_{12} = a_{11}a_{22} - a_{12}a_{21}$$

The *cofactor matrix* **C** of a matrix **A** is the square matrix of the same order as **A** in which each element a_{ij} is replaced by its cofactor c_{ij}.

The *adjoint matrix* of **A**, denoted by adj **A**, is the transpose of its cofactor matrix, i.e.,

$$\text{adj } \mathbf{A} = \mathbf{C}^{\mathrm{T}} \tag{53.84}$$

It can be shown that

$$\mathbf{A}(\text{adj } \mathbf{A}) = (\text{adj } \mathbf{A})\mathbf{A} = |\mathbf{A}|\mathbf{I} \tag{53.85}$$

Comparison of Eqs. (53.80) and (53.85) leads directly to a procedure for evaluating the inverse from the adjoint matrix, namely,

$$\mathbf{A}^{-1} = \frac{\text{adj } \mathbf{A}}{|\mathbf{A}|} \tag{53.86}$$

It is easy to show that for a 2×2 matrix, the adjoint matrix is simply

$$\begin{bmatrix} a_{22} & -a_{12} \\ -a_{21} & a_{11} \end{bmatrix}$$

A square matrix is called orthogonal if its inverse is equal to its transpose, or $\mathbf{A^{-1}} = \mathbf{A^T}$. Thus, a matrix $\mathbf{M}$ is orthogonal when

$$\mathbf{M}^{\mathrm{T}}\mathbf{M} = \mathbf{M}\mathbf{M}^{\mathrm{T}} = \mathbf{I} \tag{53.87}$$

The columns of an orthogonal matrix are mutually orthogonal vectors of unit length. Also,

$$|\mathbf{M}| = \pm 1 \tag{53.88}$$

when $|\mathbf{M}| = +1$, $\mathbf{M}$ is called "proper orthogonal"; otherwise it is termed "improper orthogonal." The product of two orthogonal matrices is also an orthogonal matrix.

Matrix Inverse by Partitioning

Let $\mathbf{A}$ be an $n \times n$ square nonsingular matrix whose inverse is to be evaluated. We *partition* $\mathbf{A}$ in the form

$$\boldsymbol{A} = \begin{matrix} s & m \\ \end{matrix} \begin{bmatrix} \boldsymbol{A}_{11} & \boldsymbol{A}_{12} \\ \boldsymbol{A}_{21} & \boldsymbol{A}_{22} \end{bmatrix} \begin{matrix} s \\ m \end{matrix}$$

where $\mathbf{A}_{11}$ is $s \times s$, $\mathbf{A}_{12}$ is $s \times m$, $\mathbf{A}_{21}$ is $m \times s$, $\mathbf{A}_{22}$ is $m \times m$, and $m + s = n$. The inverse $\mathbf{A}^{-1}$ exists, and we shall denote it, in the correspondingly partitioned form, by

$$\mathbf{A}^{-1} = \mathbf{B} = \begin{bmatrix} \mathbf{B}_{11} & \mathbf{B}_{12} \\ \mathbf{B}_{21} & \mathbf{B}_{22} \end{bmatrix}$$

From the basic definition of an inverse we have $\mathbf{A}\mathbf{A}^{-1} = \mathbf{A}\mathbf{B} = \mathbf{I}$, or in the partitioned form,

$$\begin{bmatrix} \mathbf{A}_{11} & \mathbf{A}_{12} \\ \mathbf{A}_{21} & \mathbf{A}_{22} \end{bmatrix} \begin{bmatrix} \mathbf{B}_{11} & \mathbf{B}_{12} \\ \mathbf{B}_{21} & \mathbf{B}_{22} \end{bmatrix} = \begin{bmatrix} \mathbf{I}_s & \mathbf{0} \\ \mathbf{0} & \mathbf{I}_m \end{bmatrix}$$

which, when multiplied out, leads to four matrix equations in the four $\mathbf{B}_{ij}$ submatrices as unknowns, the solution of which, when $\mathbf{A}_{11}^{-1}$ exists, is given by

$$\begin{aligned} \mathbf{B}_{11} &= \mathbf{A}_{11}^{-1} - \mathbf{A}_{11}^{-1}\mathbf{A}_{12}\mathbf{B}_{21} \\ \mathbf{B}_{12} &= -\mathbf{A}_{11}^{-1}\mathbf{A}_{12}\mathbf{B}_{22} \\ \mathbf{B}_{21} &= -\mathbf{B}_{22}\mathbf{A}_{21}\mathbf{A}_{11}^{-1} \\ \mathbf{B}_{22} &= (\mathbf{A}_{22} - \mathbf{A}_{21}\mathbf{A}_{11}^{-1}\mathbf{A}_{12})^{-1} \end{aligned} \tag{53.89}$$

Alternatively, when $\mathbf{A}_{22}^{-1}$ exists, the solution is

$$\begin{aligned}\mathbf{B}_{11} &= [\mathbf{A}_{11} - \mathbf{A}_{12}\mathbf{A}_{22}^{-1}\mathbf{A}_{21}]^{-1} \\ \mathbf{B}_{12} &= -\mathbf{B}_{11}\mathbf{A}_{12}\mathbf{A}_{22}^{-1} \\ \mathbf{B}_{21} &= -\mathbf{A}_{22}^{-1}\mathbf{A}_{21}\mathbf{B}_{11} \\ \mathbf{B}_{22} &= \mathbf{A}_{22}^{-1} - \mathbf{A}_{22}^{-1}\mathbf{A}_{21}\mathbf{B}_{12}\end{aligned} \tag{53.90}$$

If $\mathbf{A}$ is originally a symmetric matrix, then $\mathbf{A}_{21} = \mathbf{A}_{12}^{\mathrm{T}}$ correspondingly $\mathbf{B}_{21} = \mathbf{B}_{21}^{\mathrm{T}}$.

The *rank* of a matrix is the order of the largest nonzero determinant that can be formed from the elements of the matrix by appropriate deletion of rows or columns (or both). Thus, a matrix is said to be of *rank m* if and only if it has *at least one nonsingular submatrix of order m*, but has no nonsingular submatrix of order more than *m*. A nonsingular matrix of order *n* has a rank *n*. A matrix with zero rank has elements that must all be zero.

The inverse $\mathbf{A}^{-1}$ is defined only for square matrices, and it exists when the rank of $\mathbf{A}$ is equal to its order. A more general inverse may be defined for rectangular matrices with arbitrary rank. It is called the generalized inverse, denoted by $\mathbf{A}^{-}$, and satisfies the relation

$$\mathbf{A}\bar{\mathbf{A}}\mathbf{A} = \mathbf{A} \tag{53.91}$$

This condition is not sufficient to define a unique $\mathbf{A}^{-}$. Additional conditions may be imposed on $\mathbf{A}^{-}$, such as

$$\begin{aligned}\bar{\mathbf{A}}\mathbf{A}\bar{\mathbf{A}} &= \mathbf{A}^{-} \\ (\mathbf{A}\mathbf{A}^{-})^{\mathrm{T}} &= \mathbf{A}\mathbf{A}^{-} \\ (\bar{\mathbf{A}}\mathbf{A})^{\mathrm{T}} &= \mathbf{A}^{-}\mathbf{A}\end{aligned} \tag{53.92}$$

If we impose all four conditions in Eqs. (53.91) and (53.92), the inverse is called the *pseudo inverse* or the Moore–Penrose inverse, and is denoted by $\mathbf{A}^{+}$.

The Eigenvalue Problem

For a square matrix $\mathbf{A}$ of order *n*, we seek a nonzero vector $\mathbf{x}$ and a scalar λ such that

$$\mathbf{A}\mathbf{x} = \lambda\mathbf{x} \tag{53.93}$$

which is called the "eigenvalue problem." A solution λ_0 and $\mathbf{x}_0$ to this problem is called an *eigenvalue* (proper value, characteristic value) and the corresponding *eigenvector* (proper vector, characteristic vector) of the matrix $\mathbf{A}$. An eigenvector, if one exists, can be determined only to a scalar multiplication, for if λ_0, $\mathbf{x}_0$ satisfy Eq. (53.93), then λ_0, $\alpha\mathbf{x}_0$, where α is an arbitrary scalar, will also.

Equation (53.93) can be rewritten as

$$(\mathbf{A} - \lambda\mathbf{I})\mathbf{x} = 0 \tag{53.94}$$

which represents a set of homogenous linear equations. For a nontrivial solution to this set the following condition must be satisfied:

$$|\mathbf{A} - \lambda\mathbf{I}| = 0 \tag{53.95}$$

Equation (53.95) represents a real polynomial equation of degree *n*:

$$b_n(-\lambda)^n + b_{n-1}(-\lambda)^{n-1} + \cdots + b_0 = 0 \tag{53.96}$$

where

$$\begin{aligned} b_n &= 1 \\ b_{n-1} &= a_{11} + a_{22} + \cdots + a_{nn} = \sum_{i=1}^{n} a_{ii} = \text{tr}(\mathbf{A}) = \text{trace of } \mathbf{A} \\ &\vdots \\ b_{n-r} &= \text{sum of all principal minors of order } r \text{ of } \mathbf{A} \\ &\vdots \\ b_0 &= |\mathbf{A}| = \text{determinant of } \mathbf{A} \end{aligned} \tag{53.97}$$

Equation (53.96) is called the *characteristic equation* of **A**, or the *eigenvalue equation*. The matrix $(\mathbf{A} - \lambda\mathbf{I})$ is called the *characteristic matrix*. There are n roots for Eq. (53.96), counting multiplicity. These are the n eigenvalues of **A**, $\lambda_1, \lambda_2, \ldots, \lambda_n$. For an eigenvalue λ_i, we solve the set of (homogeneous) linear equations $(\mathbf{A} - \lambda_i\mathbf{I})\mathbf{x} = 0$ to determine the components of the corresponding eigenvector $\mathbf{x}_i$. In general, λ_i and $\mathbf{x}_i$ are either real or complex numbers and vectors, respectively.

If the matrix A is *symmetric*, then:

1. The eigenvalues are real.
2. The eigenvectors are all mutually orthogonal; that is,

$$\mathbf{x}_i^{\mathrm{T}}\mathbf{x}_j = \mathbf{x}_j^{\mathrm{T}}\mathbf{x}_i = 0$$

Bilinear and Quadratic Forms

If **A** is a square matrix of order n and **x** and **y** are two arbitrary n vectors, then the scalar

$$u = \mathbf{x}^{\mathrm{T}}\mathbf{A}\mathbf{y} \tag{53.98}$$

is called a *bilinear form*. If, however, the matrix **A** is also *symmetric*, then

$$v = \mathbf{x}^{\mathrm{T}}\mathbf{A}\mathbf{x} \tag{53.99}$$

is called a *quadratic form* with the kernel **A**.

The matrix **A** is called *positive definite* if $v > 0$ for all $\mathbf{x} \neq \mathbf{0}$, and we write $\mathbf{A} > \mathbf{0}$. If $v \geq 0$ for all **x** and there exists a nonzero vector **x** for which equality holds, we say **A** is *positive semidefinite* (or *nonnegative definite*) and write $\mathbf{A} \geq \mathbf{0}$. There are corresponding definitions for *negative definite* (or *nonpositive definite*). If there exist vectors $\mathbf{x}_1$ and $\mathbf{x}_2$ such that $\mathbf{x}_1^{\mathrm{T}}\mathbf{A}\mathbf{x}_1 > 0$ and $\mathbf{x}_2^{\mathrm{T}}\mathbf{A}\mathbf{x}_2 < 0$, we say **A** is *indefinite*.

For a positive definite matrix **A** it is necessary and sufficient that

$$a_{11} > 0, \quad \begin{vmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{vmatrix} > 0, \quad \cdots, \quad |\mathbf{A}| > 0$$

A quadratic form represents, in general, a conic section of some kind. Considering the two-dimensional case for simplicity, we write

$$\mathbf{x}^{\mathrm{T}}\mathbf{A}\mathbf{x} = b \qquad \text{with } \mathbf{A} \text{ symmetric} \tag{53.100}$$

or

$$a_{11}x_1^2 + 2a_{12}x_1x_2 + a_{22}x_2^2 = b$$

which is the equation of an ellipse.

53.6 Coordinate Transformations

Linear Transformations

A general *linear transformation* of a vector **x** to another vector **y** takes the form

$$\mathbf{y} = \mathbf{M}\mathbf{x} + \mathbf{t} \tag{53.101}$$

Each element of the **y** vector is a linear combination of the elements of **x** plus a translation or shift represented by an element of the **t** vector. The matrix **M** is called the *transformation matrix*, which is in general rectangular, and **t** is called the translation vector. For our use we restrict **M** to being square nonsingular; thus, the inverse relation exists, or

$$\mathbf{x} = \mathbf{M}^{-1}(\mathbf{y} - \mathbf{t}) \tag{53.102}$$

in which case it is called *affine transformation*. Although both Eqs. (53.101) and (53.102) apply to higher-dimension vectors, we will limit our discussions, without loss of generality, to the more practical two- and three-dimensional spaces, where the elements of the transformations can be depicted geometrically.

Two-Dimensional Linear Transformations

There are six *elementary* transformations, each representing a single effect, which are geometrically represented in Fig. 53.3. Initially, four vectors (1,3) (1,5), (3,3) (3,5) representing the corners of a square (solid lines in Fig. 53.3) are referred to the x_1, x_2 coordinate system. Each of the six elementary transformations operates on the square, and the resulting y_1, y_2 coordinates are plotted to show the effect on the location, orientation, size, and shape of the square after the transformation (dashed lines in Fig. 53.3). In displaying the effects of the transformations, we either display the new figure (dashed lines) in the same coordinate system, or we change the coordinate system. It is easier for the student to visualize these transformations if the new figure is drawn without changing the coordinate system, which we did in Fig. 53.3. However, as we discuss each elementary transformation, we will comment on the second interpretation when appropriate.

1. **Translation**

$$\mathbf{y} = \mathbf{x} + \mathbf{t} \qquad \text{where } \mathbf{M} = \mathbf{I} \tag{53.103}$$

   The square is shifted 3 units in x_1 direction and 1 unit in x_2 direction, as shown in Fig. 53.3(a). Alternatively, the solid square remains and the coordinate axes shifted (in the opposite direction and shown in dashed lines).

2. **Uniform Scale**

$$\mathbf{y} = \mathbf{M}\mathbf{x} \qquad \mathbf{M} = \mathbf{U} = \begin{bmatrix} u & 0 \\ 0 & u \end{bmatrix} = u\mathbf{I} \tag{53.104}$$

   The (dotted) square is enlarged by the uniform scale u (= 1.5 in Fig. 53.3(b)), which results from all four point coordinate pairs multiplied by u. Alternatively, the solid square is referred to the same coordinate system, except that the units along the axes are now $1/u$ of the original units.

3. **Rotation**

$$\mathbf{y} = \mathbf{M}\mathbf{x} \quad \mathbf{M} = \mathbf{R} = \begin{bmatrix} \cos\beta & \sin\beta \\ -\sin\beta & \cos\beta \end{bmatrix} \tag{53.105}$$

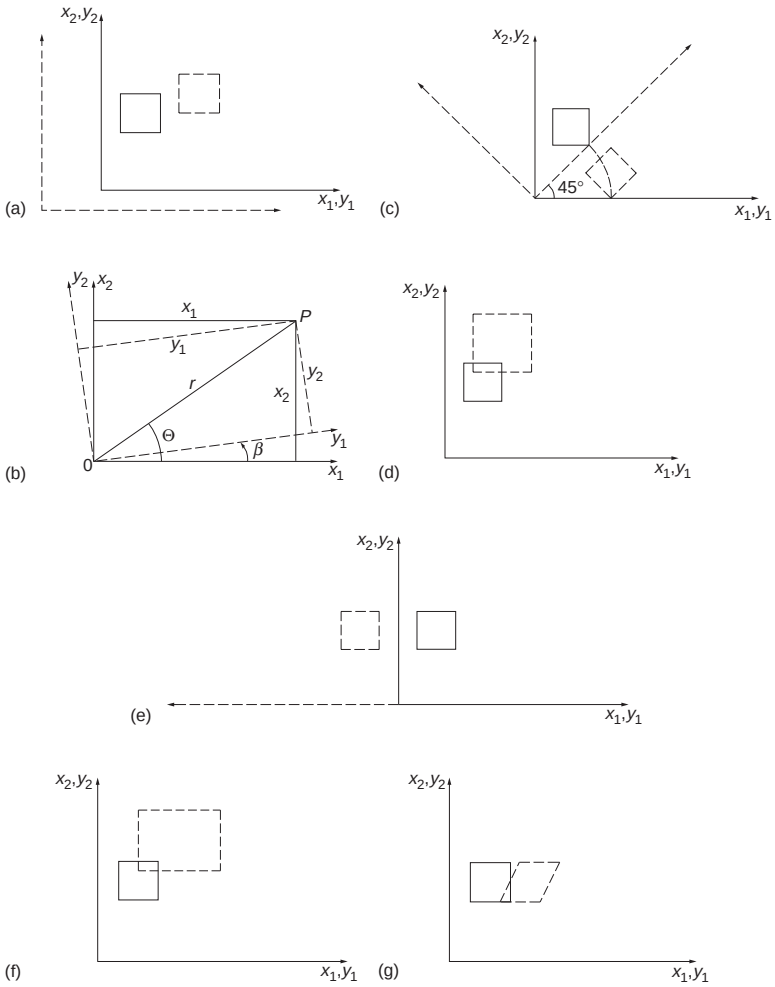

FIGURE 53.3 (a) Translation. (b) Uniform scale. (c) Rotation. (d) Rotation of a two-dimensional coordinate system. (e) Reflection. (f) Stretch (nonuniform scale). (g) Skew (nonperpendicularity of axes).

The square retains its shape, but is rotated through β about the origin of the coordinate system. In Fig. 53.3(c), the coordinate system is also rotated (45°). The elements of **R** are derived from Fig. 53.3(d) as follows:

$$y_1 = r\cos(\theta-\beta) = r\cos\theta\cos\beta + r\sin\theta\sin\beta$$
$$y_2 = r\sin(\theta-\beta) = r\sin\theta\cos\beta - r\cos\theta\sin\beta$$

or

$$y_1 = x_1\cos\beta + x_2\sin\beta$$
$$y_2 = -x_1\sin\beta + x_2\cos\beta$$

or

$$\begin{bmatrix} y_1 \\ y_2 \end{bmatrix} = \begin{bmatrix} \cos\beta & \sin\beta \\ -\sin\beta & \cos\beta \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \end{bmatrix} \tag{53.106}$$

The matrix **R** is proper orthogonal, $\mathbf{R}^{-1} = \mathbf{R}^{\mathrm{T}}$ and $|\mathbf{R}| = +1$. Rotation matrices do not change the length of the vector, i.e., $|\mathbf{x}| = |\mathbf{y}|$. Considering the square of the vector length,

$$\mathbf{y}^{\mathrm{T}}\mathbf{y} = (\mathbf{M}\mathbf{x})^{\mathrm{T}}\mathbf{M}\mathbf{x} = \mathbf{x}^{\mathrm{T}}\mathbf{M}^{\mathrm{T}}\mathbf{M}\mathbf{x}^{\mathrm{T}} = \mathbf{x}^{\mathrm{T}}\mathbf{x}$$

or

$$\mathbf{x}^{\mathrm{T}}(\mathbf{M}^{\mathrm{T}}\mathbf{M} - \mathbf{I})\mathbf{x} = \mathbf{0}$$

which for a nontrivial solution means that $\mathbf{M}^{\mathrm{T}}\mathbf{M} = \mathrm{I}$, thus showing that **M** is an orthogonal matrix.

4. **Reflection**

$$\mathbf{y} = \mathbf{M}\mathbf{x} \qquad \mathbf{M} = \mathbf{F} = \begin{bmatrix} -1 & 0 \\ 0 & 1 \end{bmatrix}$$

Figure 53.3(e) shows reflection of the x_1 axis (i.e., about the x_2 axis). **F** is improper orthogonal, $\mathbf{F}^{-1} = \mathbf{F}^{\mathrm{T}} = \mathbf{F}$ and $|\mathbf{F}| = -1$.

5. **Stretch (Two Scale Factors)**

$$\mathbf{y} = \mathbf{M}\mathbf{x} \qquad \mathbf{M} = \mathbf{S} = \begin{bmatrix} s_1 & 0 \\ 0 & s_2 \end{bmatrix} \tag{53.107}$$

The square is transformed into a rectangle as shown in Fig. 53.3(f), in which

$$\mathbf{S} = \begin{bmatrix} 2 & 0 \\ 0 & 1.5 \end{bmatrix}$$

6. **Skew (Shear)**

$$\mathbf{y} = \mathbf{M}\mathbf{x} \qquad \mathbf{M} = \mathbf{K} = \begin{bmatrix} 1 & k \\ 0 & 1 \end{bmatrix} \tag{53.108}$$

The square is transformed into a parallelogram as shown in Fig. 53.3(g), where

$$\mathbf{K} = \begin{bmatrix} 1 & 0.5 \\ 0 & 1 \end{bmatrix}$$

From these elementary transformations several affine transformations may be constructed using various sequences. The following are two of the commonly used transformations in photogrammetry.

Four-Parameter Transformation.

$$\begin{bmatrix} y_1 \\ y_2 \end{bmatrix} = \begin{bmatrix} u & 0 \\ 0 & u \end{bmatrix} \begin{bmatrix} \cos\beta & \sin\beta \\ -\sin\beta & \cos\beta \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \end{bmatrix} + \begin{bmatrix} t_1 \\ t_2 \end{bmatrix} \tag{53.109a}$$

or

$$\begin{aligned} y_1 &= ux_1\cos\beta + ux_2\sin\beta + t_1 \\ y_2 &= -ux_1\sin\beta + ux_2\cos\beta + t_2 \end{aligned} \tag{53.109b}$$

or

$$\begin{aligned} y_1 &= ax_1 + bx_2 + c \\ y_2 &= -bx_1 + ax_2 + d \end{aligned} \tag{53.109c}$$

or

$$\begin{bmatrix} y_1 \\ y_2 \end{bmatrix} = \begin{bmatrix} a & b \\ -b & a \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \end{bmatrix} + \begin{bmatrix} c \\ d \end{bmatrix} \tag{53.109d}$$

The inverse transformation is given by

$$\begin{bmatrix} x_1 \\ x_2 \end{bmatrix} = \frac{1}{u} \begin{bmatrix} \cos\beta & -\sin\beta \\ \sin\beta & \cos\beta \end{bmatrix} \begin{bmatrix} y_1 - c \\ y_2 - d \end{bmatrix} \tag{53.109e}$$

or

$$\begin{bmatrix} x_1 \\ x_2 \end{bmatrix} = \frac{1}{a^2 + b^2} \begin{bmatrix} a & -b \\ b & a \end{bmatrix} \begin{bmatrix} y_1 - c \\ y_2 - d \end{bmatrix} \tag{53.109f}$$

This transformation has four parameters: a uniform scale, a rotation, and two translations. It is a conformal transformation.

Six-Parameter Transformation.

$$\begin{bmatrix} y_1 \\ y_2 \end{bmatrix} = \begin{bmatrix} s_1 & 0 \\ 0 & s_2 \end{bmatrix} \begin{bmatrix} 1 & k \\ 0 & 1 \end{bmatrix} \begin{bmatrix} \cos\beta & \sin\beta \\ -\sin\beta & \cos\beta \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \end{bmatrix} + \begin{bmatrix} t_1 \\ t_2 \end{bmatrix} \tag{53.110a}$$

or

$$\begin{bmatrix} y_1 \\ y_2 \end{bmatrix} = \begin{bmatrix} a & b \\ d & e \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \end{bmatrix} + \begin{bmatrix} c \\ f \end{bmatrix} \tag{53.110b}$$

The six parameters of this transformation consist of two scales, one skew factor (lack of perpendicularity of the axes), one rotation, and two shifts. The inverse transformation is given by

$$\begin{bmatrix} x_1 \\ x_2 \end{bmatrix} = \frac{1}{ae - bd} \begin{bmatrix} e & -b \\ -d & a \end{bmatrix} \begin{bmatrix} y_1 - c \\ y_2 - f \end{bmatrix} \tag{53.110c}$$

Three-Dimensional Linear Transformations

As in the two-dimensional case, affine transformation in three dimensions can be factored out in several elementary transformations: translation, uniform scale, nonuniform scale, rotations, reflections, etc. Consideration, however, is limited to the seven-parameter transformation, which is composed of a uniform scale change, three translations, and three rotations.

We first consider rotations in three-dimensional space.

Rotations of a Three-Dimensional Coordinate System. There are three elementary rotations, one about each of the three axes. They are frequently performed in sequence one after the other. A set of three of these is as follows, where $\mathbf{x}$ is the original system, $\mathbf{x}'$ is once rotated, and $\mathbf{x}''$ is twice rotated:

1. β_1 about x_1 axis, positive rotation advances $+x_2$ to $+x_3$
2. β_2 about x_2' axis, positive rotation advances $+x_3'$ to $+x_1'$
3. β_3 about x_3'' axis, positive rotation advances $+x_1''$ to $+x_2''$

Each of the three elementary rotations is represented in matrix form by

$$\begin{bmatrix} x_1' \\ x_2' \\ x_3' \end{bmatrix} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & \cos\beta_1 & \sin\beta_1 \\ 0 & -\sin\beta_1 & \cos\beta_1 \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \\ x_3 \end{bmatrix} = \mathbf{M}_{\beta_1} \begin{bmatrix} x_1 \\ x_2 \\ x_3 \end{bmatrix} \tag{53.111a}$$

where x_1, x_2, x_3 are the coordinates before rotation and x_1', x_2', x_3' are the coordinates after rotation. Similarly, rotations of $+\beta_2$ about the x_2' axis and $+\beta_3$ about the x_3'' axis are given by

$$\begin{bmatrix} x_1'' \\ x_2'' \\ x_3'' \end{bmatrix} = \begin{bmatrix} \cos\beta_2 & 0 & -\sin\beta_2 \\ 0 & 1 & 0 \\ \sin\beta_2 & 0 & \cos\beta_1 \end{bmatrix} \begin{bmatrix} x_1' \\ x_2' \\ x_3' \end{bmatrix} = \mathbf{M}_{\beta_2} \begin{bmatrix} x_1 \\ x_2 \\ x_3 \end{bmatrix} \tag{53.111b}$$

$$\begin{bmatrix} y_1 \\ y_2 \\ y_3 \end{bmatrix} = \begin{bmatrix} x_1''' \\ x_2''' \\ x_3''' \end{bmatrix} = \begin{bmatrix} \cos\beta_3 & \sin\beta_3 & 0 \\ -\sin\beta_3 & \cos\beta_3 & 0 \\ 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} x_1'' \\ x_2'' \\ x_3'' \end{bmatrix} = \mathbf{M}_{\beta_3} \begin{bmatrix} x_1'' \\ x_2'' \\ x_3'' \end{bmatrix} \tag{53.111c}$$

The three rotations in Eq. (53.111) are often referred to as *elementary* rotations, since they may be used to construct any required set of sequential rotations. By successive substitution, the total rotation matrix is obtained:

$$\mathbf{y} = \mathbf{x}''' = \mathbf{M}_{\beta_3}\mathbf{M}_{\beta_2}\mathbf{M}_{\beta_1}\mathbf{x} = \mathbf{M}\mathbf{x} \tag{53.112}$$

in which $\mathbf{M}$ is now a function of the three rotation angles β_1, β_2, β_3. The most commonly used set of sequential rotations (in photogrammetry) is given the symbols ω, ϕ, κ where $\omega \equiv \beta_1$; $\phi \equiv \beta_2$; $\kappa \equiv \beta_3$. In this case, the matrix $\mathbf{M}$ which rotates the object coordinate system (X, Y, Z) parallel to the photo coordinate system (x, y, z) is given by

$$\mathbf{M} = \left[\begin{array}{c|c|c} \cos\phi\cos\kappa & \cos\omega\sin\kappa + \sin\omega\sin\phi\cos\kappa & \sin\omega\sin\kappa - \cos\omega\sin\phi\cos\kappa \\ -\cos\phi\sin\kappa & \cos\omega\cos\kappa - \sin\omega\sin\phi\sin\kappa & \sin\omega\cos\kappa + \cos\omega\sin\phi\sin\kappa \\ \sin\phi & -\sin\omega\cos\phi & \cos\omega\cos\phi \end{array}\right] \tag{53.113}$$

in which ω is about the X axis, ϕ is about the once-rotated Y axis, and κ is about the twice-rotated Z axis. The matrix $\mathbf{M}$ is orthogonal, since $\mathbf{M}_\omega$, $\mathbf{M}_\phi$, and $\mathbf{M}_\kappa$ are each orthogonal.

Seven-Parameter Transformation. This transformation contains seven parameters: a uniform scale change u, three rotations β_1, β_2, β_3, and three translations t_1, t_2, t_3. It takes the general form

$$\mathbf{y} = u\mathbf{M}\mathbf{x} + \mathbf{t} \tag{53.114}$$

The orthogonal matrix $\mathbf{M}$ is a function of only three independent parameters, in this case the angles β_1, β_2, β_3. This transformation is useful for different applications, such as absolute orientation, model connection, etc.

The orthogonal matrix $\mathbf{M}$ may be constructed by other methods besides sequential rotations. Two such methods follow.

Constructing M by One Rotation about a Line. This is also often referred to as the *solid body rotation*. Given a three-dimensional object in two different orientations, there exists a line in space about which the object may be rotated by a finite angle to change it from one orientation to the other. If the said line has λ, μ, ν as direction cosines and the angle of rotation is designated by α, the rotation matrix is given by

$$\mathbf{M} = \left[\begin{array}{c|c|c} \lambda^2(1-\cos\alpha)+\cos\alpha & \lambda\mu(1-\cos\alpha)-\nu\sin\alpha & \lambda\nu(1-\cos\alpha)+\mu\sin\alpha \\ \lambda\mu(1-\cos\alpha)+\nu\sin\alpha & \mu^2(1-\cos\alpha)+\cos\alpha & \mu\nu(1-\cos\alpha)-\lambda\sin\alpha \\ \lambda\nu(1-\cos\alpha)-\mu\sin\alpha & \mu\nu(1-\cos\alpha)+\lambda\sin\alpha & \nu^2(1-\cos\alpha)+\cos\alpha \end{array}\right] \tag{53.115}$$

A Purely Algebraic Derivation of M. The following skew-symmetric matrix contains only three parameters a, b, c:

$$\mathbf{S} = \begin{bmatrix} 0 & -c & b \\ c & 0 & -a \\ -b & a & 0 \end{bmatrix} \tag{53.116a}$$

An orthogonal matrix **M** can be obtained from **M** using

$$\mathbf{M} = (\mathbf{I}+\mathbf{S})(\mathbf{I}-\mathbf{S})^{-1} = (\mathbf{I}-\mathbf{S})^{-1}(\mathbf{I}+\mathbf{S}) \tag{53.116b}$$

in which **M** is the identity matrix. Then

$$\begin{aligned} \mathbf{M} &= (\mathbf{I}-\mathbf{S})^{-1}(\mathbf{I}+\mathbf{S}) \\ &= \frac{1}{1+a^2+b^2+c^2}\begin{bmatrix} 1+a^2-b^2-c^2 & 2ab-2c & 2ac+2b \\ 2ab+2c & 1-a^2+b^2-c^2 & 2bc-2a \\ 2ac-2b & 2bc+2a & 1-a^2-b^2+c^2 \end{bmatrix} \end{aligned} \tag{53.117}$$

Nonlinear Transformations

In addition to the linear transformations discussed so far, we use nonlinear transformations both in two and three dimensions. In two dimensions we have the following two transformations:

Eight-Parameter Transformation. The equations

$$\begin{aligned} y_1 &= \frac{a_1x_1+b_1x_2+c_1}{a_0x_1+b_0x_2+1} \\ y_2 &= \frac{a_2x_1+b_2x_2+c_2}{a_0x_1+b_0x_2+1} \end{aligned} \tag{53.118a}$$

represent the projective transformation from the **x** to the **y** coordinate systems, with the eight transformation parameters being $a_0, b_0, a_1, \ldots, c_2$. Its inverse is given by

$$\begin{aligned} x_1 &= \frac{(c_1-y_1)(b_0y_2-b_2)-(c_2-y_2)(b_0y_1-b_1)}{(a_0y_1-a_1)(b_0y_2-b_2)-(a_2y_2-a_2)(b_0y_1-b_1)} \\ x_2 &= \frac{(a_0y_1-a_1)(c_2-y_2)-(a_0y_2-a_2)(c_1-y_1)}{(a_0y_1-a_1)(b_0y_2-b_2)-(a_0y_2-a_2)(b_0y_1-b_1)} \end{aligned} \tag{53.118b}$$

These equations describe the central projectivity between two planes.

Two-Dimensional General Polynomials.

$$\begin{aligned} y_1 &= a_0 + a_1x_1 + a_2x_2 + a_3x_1x_2 + a_4x_1^2 + a_5x_2^2 + \cdots \\ y_2 &= b_0 + b_1x_1 + b_2x_2 + b_3x_1x_2 + b_4x_1^2 + b_5x_2^2 + \cdots \end{aligned} \tag{53.119a}$$

These polynomials can obviously be extended to higher powers in x_1, x_2. A special case of these is the conformal form given in the following section.

Two-Dimensional Conformal Polynomials. The conformal property preserves the angles between intersecting lines after the transformation. If we impose the two conditions

$$\frac{\partial y_1}{\partial x_1} = \frac{\partial y_2}{\partial x_2} \qquad \text{and} \qquad \frac{\partial y_1}{\partial x_2} = -\frac{\partial y_2}{\partial x_1} \tag{53.119b}$$

on the general polynomials in Eq. (53.119a), we get

$$\begin{aligned} y_1 &= A_0 + A_1x_1 + A_2x_2 + A_3(x_1^2 - x_2^2) + A_4(2x_1x_2) + \cdots \\ y_2 &= B_0 - A_2x_1 + A_1x_2 - A_4(x_1^2 - x_2^2) + A_3(2x_1x_2) + \cdots \end{aligned} \tag{53.119c}$$

Note that the first three terms after the equal signs are the same as those in the four-parameter transformation given in Eq. (53.109c). Equation (53.119c) can also be derived using complex numbers by writing

$$(y_1 + y_2i) = (a_0 + b_0i) + (a_1 + b_1i)(x_1 + x_2i) + (a_3 + b_3i)(x_1 + x_2i)^2 + \cdots$$

in which $i = \sqrt{-1}$. Expanding and equating y_1 to the real part and y_2 to the imaginary part (multiplier of i) on the right-hand side leads to Eq. (53.119c).

Three-dimensional General Polynomials.

$$\begin{aligned} y_1 &= a_0 + a_1x_1 + a_2x_2 + a_3x_3 + a_4x_1^2 + a_5x_2^2 + a_6x_1x_2 + a_7x_2x_3 + a_8x_1x_3 + \cdots \\ y_2 &= b_0 + b_1x_1 + b_2x_2 + b_3x_3 + b_4x_1^2 + b_5x_2^2 + b_6x_1x_2 + b_7x_2x_3 + b_8x_1x_3 + \cdots \\ y_3 &= c_0 + c_1x_1 + c_2x_2 + c_3x_3 + c_4x_1^2 + c_5x_2^2 + c_6x_1x_2 + c_7x_2x_3 + c_8x_1x_3 + \cdots \end{aligned} \tag{53.120a}$$

We can extend these polynomials to higher order. Unlike the two-dimensional case, conformal transformation does not exist in three dimensions beyond the first-order (or linear) case given by the seven-parameter transformation, Eq. (53.114). A close approximation, which exists for only second-degree terms, is derived by imposing conditions similar to those in Eq. (53.119b) on every pair of coordinates in Eq. (53.120a). This makes the projections of the 3-space onto each of the three planes conformal. Thus, imposing the following on the general polynomials in Eq. (53.120a)

$$\begin{aligned} &\frac{\partial y_1}{\partial x_1} = \frac{\partial y_2}{\partial x_2} = \frac{\partial y_3}{\partial x_3} \\ &\frac{\partial y_1}{\partial x_2} = -\frac{\partial y_2}{\partial x_1}; \quad \frac{\partial y_2}{\partial x_3} = -\frac{\partial y_3}{\partial x_2}; \quad \frac{\partial y_1}{\partial x_3} = -\frac{\partial y_3}{\partial x_1} \end{aligned} \tag{53.120b}$$

leads to

$$\begin{aligned} y_1 &= A_0 + Ax_1 + Bx_2 - Cx_3 + E(x_1^2 - x_2^2 - x_3^2) + 0 + 2Gx_3x_1 + 2Fx_1x_2 + \cdots \\ y_2 &= B_0 - Bx_1 + Ax_2 + Dx_3 + F(-x_1^2 + x_2^2 - x_3^2) + 2Gx_2x_3 + 0 + 2Ex_1x_2 + \cdots \\ y_3 &= C_0 + Cx_1 - Dx_2 + Ax_3 + G(-x_1^2 - x_2^2 + x_3^2) + 2Fx_2x_3 + 2Ex_3x_1 + 0 + \cdots \end{aligned} \tag{53.120c}$$

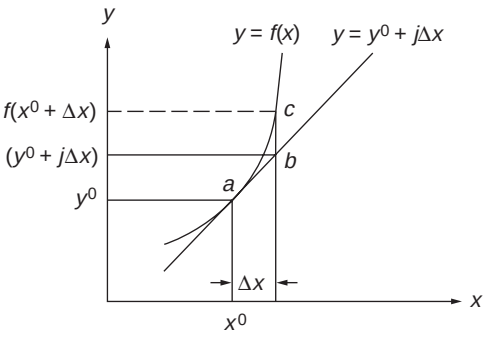

FIGURE 53.4 Linearization.

53.7 Linearization of Nonlinear Functions

Frequently, the equations expressing the geometric and physical conditions of a problem are nonlinear, which makes their direct solution difficult and uneconomical. We linearize these equations using series expansion, usually Taylor's series, which in general is given by the following for $y = f(x)$:

$$y = f(x^0) + \left.\frac{df}{dx}\right|_{x^0} \Delta x + \frac{1}{2!}\left.\frac{d^2y}{dx^2}\right|_{x^0} (\Delta x)^2 + \cdots + \frac{1}{n!}\left.\frac{d^ny}{dx^n}\right|_{x^0} (\Delta x)^n + \cdots \tag{53.121}$$

This gives the value of y at $(x^0 + \Delta x)$, given the value of the function $f(x^0)$ at x^0. Equation (53.121) includes still higher-order terms, and therefore we usually drop the second- and higher-order terms and use the approximation

$$y \approx f(x^0) + \left.\frac{dy}{dx}\right|_{x^0} \Delta x \approx y^0 + j\Delta x \tag{53.122}$$

with obvious correspondence in terms.

The technique of linearization is demonstrated in Fig. 53.4. The curve represents the original nonlinear function $f(x)$, whereas the straight line represents the linearized form, Eq. (53.122).

That line is tangent to the curve at the given point a, (x^0, y^0). When Δx is given (or evaluated), the value of the function would be approximated by point b, whose ordinate is $(y^0 + j\Delta x)$, and the exact value from the nonlinear function is point c, with ordinate $f(x^0 + \Delta x)$. The error arising from using the linear form is the line segment bc.

One Function of Two Variables

$$\begin{aligned} y &= f(x_1, x_2) \\ &= f(x_1^0, x_2^0) + \left.\frac{\partial y}{\partial x_1}\right|_{x_1^0, x_2^0} \Delta x_1 + \left.\frac{\partial y}{\partial x_2}\right|_{x_1^0, x_2^0} \Delta x_2 \\ &\quad + \frac{1}{2!}\left.\frac{\partial^2 y}{\partial x_1^2}\right|_{x_1^0, x_2^0} (\Delta x_1)^2 + \frac{1}{2!}\left.\frac{\partial^2 y}{\partial x_2^2}\right|_{x_1^0, x_2^0} (\Delta x_2)^2 \\ &\quad + \left.\frac{\partial y}{\partial x_1}\right|_{x_1^0, x_2^0} \left.\frac{\partial y}{\partial x_2}\right|_{x_1^0, x_2^0} (\Delta x_1)(\Delta x_2) + \cdots \end{aligned} \tag{53.123}$$

For the linearized form, Eq. (53.123) is truncated to

$$y = y^0 + j_1 \Delta x_1 + j_2 \Delta x_2 \tag{53.124}$$

where

$$y^0 = f(x_1^0, x_2^0) \qquad j_1 = \left.\frac{\partial y}{\partial x_1}\right|_{x_1^0, x_2^0} \qquad j_2 = \left.\frac{\partial y}{\partial x_2}\right|_{x_1^0, x_2^0}$$

Equation (53.124) can be rewritten in matrix form as

$$y = y^0 + [j_1 \quad j_2] \begin{bmatrix} \Delta x_1 \\ \Delta x_2 \end{bmatrix}$$

or

$$y = y^0 + \mathbf{J}_{yx} \Delta \mathbf{x} \tag{53.125}$$

where

$$\mathbf{J}_{yx} = \frac{\partial y}{\partial \mathbf{x}} = \begin{bmatrix} \frac{\partial y}{\partial x_1} & \frac{\partial y}{\partial x_2} \end{bmatrix}$$

is the Jacobian of y with respect to **x**.

Two Functions of One Variable

$$\begin{aligned} y_1 &= f_1(x) \approx y_1^0 + j_1 \Delta x \\ y_2 &= f_2(x) \approx y_2^0 + j_2 \Delta x \end{aligned} \tag{53.126}$$

or

$$\mathbf{y} = \mathbf{y}^0 + \mathbf{J}_{yx} \Delta x$$

with

$$\begin{aligned} y_1^0 &= f_1(x^0) \\ y_2^0 &= f_2(x^0) \\ \mathbf{J}_{yx} &= [j_1 \quad j_2]^{\mathrm{T}} = \left[\left.\frac{dy_1}{dx}\right|_{x^0} \left.\frac{dy_2}{dx}\right|_{x^0} \right]^{\mathrm{T}} \end{aligned}$$

Two Functions of Two Variables Each

$$\begin{aligned} y_1 &= f_1(x_1, x_2) \approx y_1^0 + j_{11} \Delta x_1 + j_{12} \Delta x_2 \\ y_2 &= f_2(x_1, x_2) \approx y_2^0 + j_{21} \Delta x_1 + j_{22} \Delta x_2 \end{aligned} \tag{53.127a}$$

or

$$\begin{bmatrix} y_1 \\ y_2 \end{bmatrix} \approx \begin{bmatrix} y_1^0 \\ y_2^0 \end{bmatrix} + \begin{bmatrix} j_{11} & j_{12} \\ j_{21} & j_{22} \end{bmatrix} \begin{bmatrix} \Delta x_1 \\ \Delta x_2 \end{bmatrix} \tag{53.127b}$$

or

$$\mathbf{y} = \mathbf{y}^0 + \mathbf{J}_{yx} \Delta \mathbf{x} \tag{53.127c}$$

where

$$\mathbf{y}^0 = \begin{bmatrix} y_1^0 \\ y_2^0 \end{bmatrix} = \begin{bmatrix} f_1(x_1^0, x_2^0) \\ f_2(x_1^0, x_2^0) \end{bmatrix}$$

and

$$\mathbf{J}_{xy} = \frac{\partial \mathbf{y}}{\partial \mathbf{x}} = \begin{bmatrix} \dfrac{\partial y_1}{\partial x_1} & \dfrac{\partial y_1}{\partial x_2} \\ \dfrac{\partial y_2}{\partial x_1} & \dfrac{\partial y_2}{\partial x_2} \end{bmatrix}$$

evaluated at x_1^0, x_2^0.

General Case of *m* Functions of *n* Variables

$$\begin{aligned} y_1 &= f_1(x_1, x_2, \ldots, x_n) \\ y_2 &= (x_1, x_2, \ldots, x_n) \\ &\vdots \qquad\qquad \vdots \\ y_m &= f_m(x_1, x_2, \ldots, x_n) \end{aligned} \tag{53.128a}$$

With the auxiliaries,

$$\mathbf{y}^0 = \begin{bmatrix} y_1^0 \\ y_2^2 \\ \vdots \\ y_m^0 \end{bmatrix} = \begin{bmatrix} f_1(x_1^0, x_2^0, \ldots, x_n^0) \\ f_2(x_1^0, x_2^0, \ldots, x_n^0) \\ \vdots \qquad \vdots \\ f_m(x_1^0, x_2^0, \ldots, x_n^0) \end{bmatrix}$$

$$\mathbf{J}_{yx} = \frac{\partial \mathbf{y}}{\partial \mathbf{x}} = \begin{bmatrix} \dfrac{\partial y_1}{\partial x_1} & \dfrac{\partial y_1}{\partial x_2} & \cdots & \dfrac{\partial y_1}{\partial x_n} \\ \vdots & & \ddots & \vdots \\ \dfrac{\partial y_m}{\partial x_1} & \dfrac{\partial y_m}{\partial x_2} & \cdots & \dfrac{\partial y_m}{\partial x_n} \end{bmatrix} \text{ evaluated at } \mathbf{x}^0$$

$$\Delta \mathbf{x} = \begin{bmatrix} \Delta x_1 \\ \Delta x_2 \\ \vdots \\ \Delta x_n \end{bmatrix}$$

the linearized form of Eq. (53.128a) becomes

$$\mathbf{y} \approx \mathbf{y}^0 + \mathbf{J}_{yx} \Delta \mathbf{x} \tag{53.128b}$$

which represents the general form, with $\mathbf{y}$, $\mathbf{y}^0$ being $m \times 1$ vectors, $\mathbf{J}$ an $m \times n$ Jacobian matrix, and $\Delta \mathbf{x}$ an $n \times 1$ vector. Equations (53.122), (53.125), and (53.127c) are special cases of Eq. (53.128b).

Differentiation of a Determinant

The partial derivative of a $p \times p$ determinant with respect to a scalar is composed of the sum of p determinants, each having the elements of only one row or one column replaced by their derivatives. Thus, given the determinant $d = |\mathbf{D}_1\ \mathbf{D}_2 \cdots\ \mathbf{D}_p|$ in which $\mathbf{D}_i, i = 1, 2 \cdots p$ represents its p columns, then

$$\frac{\partial d}{\partial x} = \left|\frac{\partial \mathbf{D}_1}{\partial x}\mathbf{D}_2 \cdots\ \mathbf{D}_p\right| + \left|\mathbf{D}_1\frac{\partial \mathbf{D}_2}{\partial x} \cdots\ \mathbf{D}_\mathbf{P}\right| + \cdots + \left|\mathbf{D}_1\mathbf{D}_2 \cdots\ \frac{\partial \mathbf{D}_p}{\partial x}\right| \tag{53.129}$$

An expression similar to Eq. (53.129) can be written in which rows instead of the columns of d are partially differentiated.

Differentiation of a Quotient

The partial derivative of $g = U/W$ with respect to a variable x is given by

$$\frac{\partial g}{\partial x} = \frac{1}{W}\left[\frac{\partial U}{\partial x} - \frac{U}{W}\frac{\partial W}{\partial x}\right] \tag{53.130}$$

Both U and W can be general functions, including determinants, of several variables.

53.8 Map Projections

Map projection is concerned with the theory and techniques of proper representation of the curved earth surface on the plane of a map. When the map is of such large scale as to represent a very limited area, the earth curvature is insignificant, and field survey measurements can be directly represented on the map. On the other hand, as the surface area of the earth gets larger, this curvature becomes significant and must be dealt with. The earth is an ellipsoid and is also sometimes approximated by a sphere; neither of these surfaces can accurately be developed into a plane. Therefore, all map projection methods must by necessity contain some distortion. Various methods are selected to fit best the shape of the area to be mapped and to minimize the effects of particular distortions.

Locations on the earth are represented by meridians of longitude, λ, and parallels of latitude, ϕ. On the map these are represented by scaled linear distances X, Y, using the dimensions of the earth ellipsoid and selected criteria which the specific map projection must satisfy. These are obtained from transformation equations taking the general functional form of

$$\begin{aligned} X &= f_x(\lambda, \phi) \\ Y &= f_y(\lambda, \phi) \end{aligned} \tag{53.131}$$

Although all modern map projections are performed by computer programs, several are based on geometric projection of the earth onto one of three surfaces: a plane, a cylinder, or a cone. It is clear that the cylinder and cone are chosen because they can be developed into a plane — that of the map. When a plane is used, it is tangent to the earth's surface at a point and the projection center is either the center of the earth, as in the *gnomonic* projection shown in Fig. 53.5(a), or the point diametrically opposite to the tangent point, as in the *stereographic* projection shown in Fig. 53.5(b). If the projection lines are perpendicular to the plane, we have an *orthographic* projection, Fig. 53.5(c).

A cone is usually selected with its axis coincident with the earth's polar axis. It may be tangent to the earth at one small circle, called *standard parallel*, or intersect it in two standard parallels. When developed, the scale will be true (i.e., without any distortion or error) at the standard parallels; see Fig. 53.6. Polyconic projections use a series of frustums of cones, each from a separate cone.

Like a cone, a cylinder may be selected to be tangent to the earth or secant to it. It may be *regular*, with its axis being the polar axis as in Fig. 53.7(a); *transverse*, with one tangent meridian as in Fig. 53.7(b); *secant*, with two meridians of intersection; or *oblique* cylindrical, shown in Fig. 53.7(c).

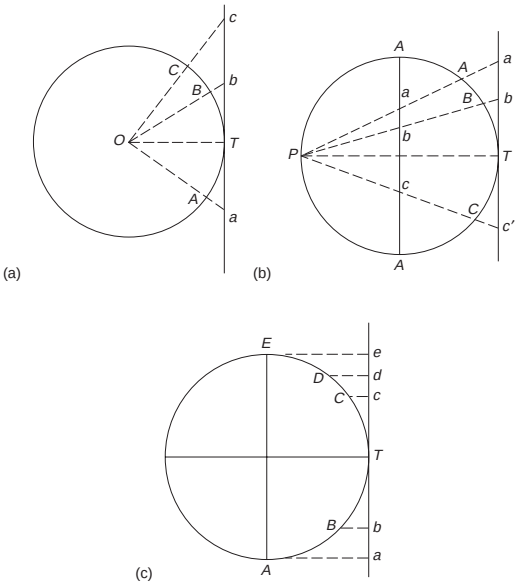

FIGURE 53.5 (a) Gnomonic projection. (b) Stereographic projection. (c) Orthographic projection.

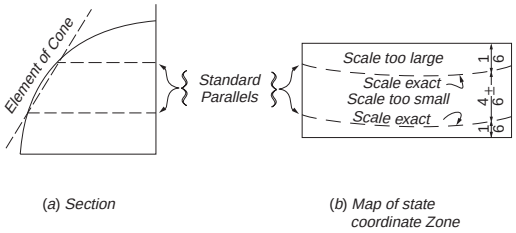

FIGURE 53.6 Lambert conformal conic projection. (Source: Davis, R. E., Foote, F. S., Anderson, J. M., and Mikhail, E. M. 1981. *Surveying: Theory and Practice,* 6th ed., p. 570. McGraw-Hill, New York. With permission.)

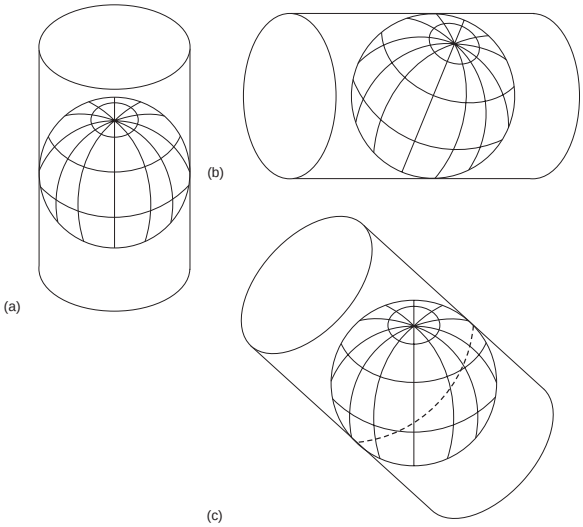

FIGURE 53.7 (a) Vertical cylinder. (b) Transverse horizontal cylinder. (c) Oblique cylinder.

Equation (53.131) will produce a *perfect* map — without any distortions — if it satisfies *all* of the following conditions:

1. All distances and areas have correct relative magnitudes.
2. All azimuths and angles are correctly represented on the map.
3. All great circles are shown on the map as straight lines.
4. Geodetic longitudes and latitudes are correctly shown on the map.

No one map projection can satisfy *all* these conditions. However, each class can satisfy some selected conditions. The following are four classes:

1. **Conformal** or **orthomorphic projection** results in a map showing the correct angle between any pair of short intersecting lines, thus making small areas appear in correct *shape*. As the scale varies from point to point, the shapes of larger areas are incorrect.
2. An **equal-area projection** results in a map showing all areas in proper relative *size*, although these areas may be much out of shape and the map may have other defects.
3. In an **equidistant projection** distances are correctly represented from one central point to other points on the map.
4. In an **azimuthal projection** the map shows the correct *direction* or azimuth of any point relative to one central point.

For conformal mapping, a new latitude, ψ, called the isometric latitude, is used in place of ϕ, where

$$\psi = \ln\left[\left(\frac{1 - e\sin\phi}{1 + e\sin\phi}\right)^{e/2} \tan\left(\frac{\pi}{4} + \frac{\phi}{2}\right)\right] \tag{53.132}$$

in which $e^2 = (a^2 - b^2)/a^2$, with a, b being the semimajor and semiminor axes of the earth ellipsoid, respectively. Then, Eq. (53.131) is replaced by

$$\begin{aligned} X &= f_1(\lambda, \psi) \\ Y &= f_2(\lambda, \psi) \end{aligned} \tag{53.133}$$

In order for the mapping in Eq. (53.133) to be conformal, the following Cauchy–Riemann conditions must be satisfied:

$$\frac{\partial X}{\partial \lambda} = \frac{\partial Y}{\partial \psi} \qquad \text{and} \qquad \frac{\partial X}{\partial \psi} = -\frac{\partial Y}{\partial \lambda} \tag{53.134}$$

Two commonly used conformal projections are the Lambert conformal conic projection and the transverse Mercator projection. A figure of the former is shown in Fig. 53.6, where the projection cone intersects the ellipsoid in two standard parallels. It is very widely used in the U.S., particularly as a State Plane Coordinate System for those states, or zones thereof, with greater east–west extent than north–south. The transverse Mercator projection is shown in Fig. 53.8, where the cylinder is either tangent or secant to the ellipsoid. When it is tangent, the scale at the central meridian is 1:1. But when it is not, the scale at the central meridian is less than 1:1, as shown in Fig. 53.8. The central meridian is the origin of the map X coordinate, while the origin of the map Y coordinate is the equator. This projection is used as a State Plane Coordinate System for states with greater north–south extent.

An extensively used map projection system is the *Universal* Transverse Mercator, or UTM, schematically shown in Fig. 53.9. It is in 6° wide zones, with the scale at each central meridian of a zone being 0.9996. A false easting for each central meridian is 500,000 m. A transverse Mercator projection with 3° wide zones is possible, where the scale at the central meridian is improved to 0.9999.

53.9 Observational Data Adjustment

Mathematical Model for Adjustment

In surveying engineering, measurements are rarely used directly as the required information. They are frequently used in subsequent operations to derive other quantities, often computationally, such as directions, lengths, relative positions, areas, shapes, and volumes. The relationships applied in the computational effort are the mathematical representations of the geometric and physical conditions of the problem, which, together with the quality of the measurements, are called the *mathematical model*.

This mathematical model is composed of two parts: a functional model and a stochastic model. The *functional model* is the part which describes the geometric or physical characteristics of the survey problem and the resulting mathematical relationships. The *stochastic model* is the part of the mathematical model that describes the statistical properties of all the elements involved in the functional model. It designates which parts are the observables, which are constants, and which are unknown parameters to be estimated in the **adjustment**. It also provides the information necessary to properly describe the quality of the observations to be used in the adjustment.

As a simple example, consider the size and shape of a plane triangle. While the shape depends only on angles, its size requires at least one side. Therefore, this model has three angular elements, the interior angles, and three linear (or distance) elements, the triangle sides. Two angles and one side will be the minimum number of measurements necessary to uniquely fix the triangle. If more measurements than these three are obtained, *redundancy* will exist, thus leading to inconsistency, which is resolved through an adjustment technique. Once the number of measurements is decided upon, the required set of independent condition equations can be written to express the functional model. The stochastic model will denote those elements (of the total of six) which are observed, and the quality of the observations.

The *a priori* quality of an observed angle or distance is usually expressed by a *standard deviation*, σ, or its square, the *variance*, σ^2. Correlation between observations is represented by the *covariance*. Thus, for two observables, or *random variables*, say $\bar{x}$ and $\bar{y}$, the variances, σ_x^2 and σ_y^2, and the covariance, σ_{xy}, are collected in a single square symmetric matrix called the variance-covariance matrix, or simply the covariance matrix:

$$\Sigma = \begin{bmatrix} \sigma_x^2 & \sigma_{xy} \\ \sigma_{xy} & \sigma_y^2 \end{bmatrix} \tag{53.135}$$

where the variances are along the main diagonal and the covariance off the diagonal. The concept of the covariance matrix can be extended to the multidimensional case by considering n random variables $\bar{x}_1, \bar{x}_2, \ldots, \bar{x}_n$ and writing

$$\Sigma_{xx} = \begin{bmatrix} \sigma_1^2 & \sigma_{12} & \cdots & \sigma_{1n} \\ \sigma_{12} & \sigma_2^2 & & \sigma_{2n} \\ \vdots & & \ddots & \vdots \\ \sigma_{1n} & \sigma_{2n} & \cdots & \sigma_n^2 \end{bmatrix} \tag{53.136}$$

which is an $n \times n$ square symmetric matrix.

Often in practice, the variances and covariances are not known in absolute terms but only to a scale factor. The scale factor is given the symbol σ_0^2 and is termed the *reference variance*, although other names, such as "variance factor" and "variance associated with weight unity," have also been used. The square

root σ_0, of σ_0^2, is called the "reference standard deviation" and was classically known as the "standard error of unit weight." The relative variances and covariances are called *cofactors* and are given by

$$\mathbf{q}_{ii} = \frac{\sigma_i^2}{\sigma_0^2} \qquad \text{and} \qquad \mathbf{q}_{ij} = \frac{\sigma_{ij}}{\sigma_0^2} \tag{53.137}$$

Collecting the cofactors in a square symmetric matrix produces the *cofactor matrix* **Q**, with the obvious relationship with the covariance matrix.

$$\mathbf{Q} = \frac{1}{\sigma_0^2}\Sigma \tag{53.138}$$

When **Q** is nonsingular, its inverse is called the *weight matrix* and designated by **W**; thus,

$$\mathbf{W} = \mathbf{Q}^{-1} = \sigma_0^2\Sigma^{-1} \tag{53.139}$$

If σ_0^2 is equal to 1, or, in other words, if the covariance matrix is known, the weight matrix becomes its inverse.

Design/Preanalysis

Engineering *design* is more frequently known as *preanalysis* in surveying engineering. It refers to the task of determining the observations to be made and their required accuracy so that the required accuracy of the final product is met. This is usually done by an iterative procedure, often using interactive graphics, and applying the established mathematical model of the problem. The physical limitations of the project, such as visibility and accessibility problems, are first imposed on the design. Next, what is considered to be an adequate set of measurements, with suitable accuracy estimates, is input in a design program to estimate the required unknown parameters and their expected accuracy. The overall accuracy of the estimated parameters is reflected by the posterior covariance matrix $\sum$. (This is why preanalysis is equivalent to *covariance analysis* used in the mathematical literature.) From $\sum$, individual confidence measures, such as **error ellipses** and **ellipsoids**, are computed and compared to the design requirements. If they are too large, additional observations or measurements of increased quality are attempted and the process repeated. On the other hand, if they are too small (i.e., too good), reduced observations or observations of decreased quality (using less expensive equipment/techniques) are attempted instead. The procedure is iterated until an optimum design results.

Data Acquisition

The results of preanalysis provide the information required to set up the specifications for data acquisition, particularly the quantities to be measured and their required accuracy. This leads to deciding on equipment to be used and observational techniques to be applied. It is important that the selected instruments be properly calibrated and in good working order, and that the procedures specified be rigorously followed. Good field practices must be followed to minimize blunders. In fact, all field activities are carefully planned and monitored so that the following operation, preprocessing of data, can be effectively carried out to yield the most suitable data entering the adjustment.

Data Preprocessing

Preprocessing of survey data involves the elimination of *blunders* and the correction for all known systematic errors. The resulting preprocessed measurements should have essentially nothing but random errors before they are used in the adjustment. Any uncorrected systematic errors known to still exist in the measurements must then be modeled mathematically and accounted for during the adjustment.

Because of the significant cost of the field operations, it is becoming more of a requirement to perform preprocessing in the field so as to minimize the cost of any remeasurement. Progressively more sophisticated preprocessing programs are available for use with portable computers in conjunction with electronic data collectors.

There are several techniques for checking the observations which apply to the different types of surveys, such as triangulation, trilateration, traverse, leveling, etc. These techniques depend on the shape of the network and various minimum combinations of observations.

Data Adjustment

When redundant measurements exist, an *adjustment* of the observed data becomes necessary in order to resolve the inconsistency between the observations and the model. As an illustration, consider the size and shape of a plane triangle in which the three interior angles A, B, C and two sides a, b (opposite to A and B, respectively) are measured. Suppose that we are interested in the length of the side c. We obviously have more information than needed, since any one side, a or b, and any two angles suffice to solve the triangle and hence determine c. However, due to random measurement errors, every combination selected would be expected to lead to a slightly different value for c. A choice from all possible combinations would be essentially arbitrary. More important is the fact that one should take advantage of using *all* the available information in one operation, in which each measurement contributes relative to its role in the mathematical model and commensurate with its quality (variance) relative to the quality of all other measurements. One of the most commonly used techniques of adjustment of redundant survey data is the method of **least squares**.

Least Squares Adjustment

Although least squares is an estimation procedure, it has been traditionally referred to in surveying as an *adjustment* technique. This stems from the fact that after the adjustment the original observations are replaced by a set of *adjusted* observations that *are* consistent with the model. Thus, after least squares adjustment the five observations in the triangle example are replaced by a consistent set, $\hat{A}$, $\hat{B}$, $\hat{C}$, $\hat{a}$, $\hat{b}$, in that *any* minimum combination of these would yield the *same* triangle solution. Each adjusted observation is the sum of the original measurement and a *residual*, v, which is calculated in the adjustment.

The method of least squares is based on the observational residuals. If all the residuals in a given set of n observations, **l** are denoted by the vector $\boldsymbol{v}$, and the weight matrix associated with these observations is **W**, the least squares criterion is given by

$$\phi = \boldsymbol{v}^{\mathrm{T}}\mathbf{W}\boldsymbol{v} \rightarrow \text{ minimum} \tag{53.140}$$

Note that ϕ is a scalar, for which a minimum is obtained by equating to zero its partial derivatives with respect to v. In Eq. (53.140) the weight matrix of the observations, **W**, may be full, implying that the observations are correlated. If the observations are uncorrelated, **W** will be a diagonal matrix, and the criterion simplifies to

$$\phi = \sum_{i=1}^{n} w_i v_i^2 = w_1 v_1^2 + w_2 v_2^2 + \cdots w_n v_n^2 \rightarrow \text{minimum} \tag{53.141}$$

which says that the sum of the weighted squares of the residuals is a minimum. Another and simpler case involves observations which are uncorrelated and of equal weight (precision), for which **W** = **I**, and ϕ becomes

$$\phi = \sum_{i=1}^{n} v_1^2 = v_i^2 + v_2^2 + \ldots v_n^2 \rightarrow \text{minimum} \tag{53.142}$$

The case covered by Eq. (53.142) is the oldest and may have accounted for the name "least squares," since it seeks the "least" sum of the squares of the residuals.

If we denote by n_0 the minimum number of independent variables needed to determine the selected model uniquely, then the *redundancy*, r, is given by

$$r = n - n_0 \tag{53.143}$$

As illustrations, consider the following examples.

1. The shape of a plane triangle is uniquely determined by a minimum of two interior angles, or $n_0 = 2$. If three interior angles are measured, then, with $n = 3$, redundancy is $r = 1$.
2. The size and shape of a plane triangle require a minimum of three observations, at least one of which is the length of one side, or $n_0 = 3$. If three interior angles and two side lengths are available, then with $n = 5$ the redundancy is $r = 2$.

After the redundancy r is determined, the adjustment proceeds by writing equations that relate the model variables in order to reflect the existing redundancy. Such equations will be referred to either as *condition equations* or simply as *conditions*. The number of independent conditions, c, will be equal to r if only observational variables and constants are involved. In many situations, however, additional unknown variables, called *parameters*, are carried in the adjustment. In such a case, if the number of unknown parameters is u, then a total of

$$c = r + u \tag{53.144}$$

independent condition equations in terms of both the n observations and u parameters must be written. In order for the parameter to be functionally independent, number, u, should not exceed the minimum number of variables, n_0, necessary to specify the model. Hence, the following relation must be satisfied:

$$0 \leq u \leq n_0 \tag{53.145}$$

Similarly, for the formulated condition equations to be independent, their number, c, should not be larger than the total number of observations n. Hence,

$$r \leq c \leq n \tag{53.146}$$

Techniques of Least Squares

Although there is only one least squares criterion, there are several techniques by which least squares may be applied. Regardless of which technique is applied, the results of an adjustment of a given set of measurements associated with a specified model *must* be the same. The choice of a technique, therefore, is mostly a matter of convenience and computational economy. The first technique is called *adjustment of observations only*. The condition equations take the form

$$\underset{r,n}{\mathbf{A}} \quad \underset{n,1}{\mathbf{v}} \quad = \quad \underset{r,1}{\mathbf{f}} \tag{53.147}$$

For linear adjustment problems the vector $\mathbf{f}$ is given by

$$\mathbf{f} = \mathbf{d} = \mathbf{A1} \tag{53.148}$$

in which $\mathbf{d}$ is a vector of numerical constants and $\mathbf{1}$ is the vector of given numerical values of the measurements.

Let the cofactor matrix of the observations be denoted by $\mathbf{Q}(=\mathbf{W}^{-1})$. Then

$$\mathbf{k} = (\mathbf{AQA}^{\mathrm{T}})^{-1}\mathbf{f} = \mathbf{Q}_e^{-1}\mathbf{f} = \mathbf{W}_e\mathbf{f} \tag{53.149}$$

$$\mathbf{v} = \mathbf{QA}^{\mathrm{T}}\mathbf{k} \tag{53.150}$$

$$\hat{\mathbf{l}} = \mathbf{l} + \mathbf{v} \tag{53.151}$$

Error propagation:

$$\mathbf{Q}_{vv} = \mathbf{QA}^{\mathrm{T}}\mathbf{W}_e\mathbf{AQ} \tag{53.152}$$

$$\mathbf{Q}_{\hat{l}\hat{l}} = \mathbf{Q} - \mathbf{Q}_{vv} \tag{53.153}$$

$$\hat{\sigma}_0^2 = \frac{\mathbf{v}^{\mathrm{T}}\mathbf{Wv}}{r} \tag{53.154}$$

The second technique is called *adjustment of indirect observations*. The condition equations are of the general (nonlinear) form:

$$\mathbf{l} + \mathbf{v} + \mathbf{F}(\mathbf{x}) = 0 \tag{53.155}$$

When linearized at approximations x^0 for the $u = n_0$ parameters x, they become

$$\mathbf{v} + \mathbf{B\Delta} = \mathbf{f} \tag{53.156}$$

where Δ is a vector of unknown parameter corrections, $\mathbf{B} = \left.\frac{\partial \mathbf{F}}{\partial \mathbf{x}}\right|_{x^0}$ is an n by u coefficient matrix, and $\mathbf{f} = -\mathbf{F}(\mathbf{x}^0) - 1$. With $\mathbf{W} = \mathbf{Q}^{-1}(=\Sigma^{-1}$ if $\sigma_0 = 1)$ as the weight matrix of the observations, then

$$\mathbf{N} = \mathbf{B}^{\mathrm{T}}\mathbf{WB} \tag{53.157}$$

$$\mathbf{t} = \mathbf{B}^{\mathrm{T}}\mathbf{Wf} \tag{53.158}$$

$$\Delta = \mathbf{N}^{-1}\mathbf{t} \tag{53.159}$$

$$\hat{\mathbf{x}} = \mathbf{x}^0 + \mathbf{\Sigma\Delta} \qquad \text{(iterate)} \tag{53.160}$$

Error propagation:

$$\mathbf{Q}_{\hat{x}\hat{x}} = \mathbf{Q}_{\Delta\Delta} = \mathbf{N}^{-1} \tag{53.161}$$

$$\mathbf{Q}_{vv} = \mathbf{BN}^{-1}\mathbf{B}^{\mathrm{T}} \tag{53.162}$$

$$\mathbf{Q}_{\hat{l}\hat{l}} = \mathbf{Q} - \mathbf{Q}_{vv} \tag{53.163}$$

$$\hat{\sigma}_0^2 = \frac{\mathbf{v}^{\mathrm{T}}\mathbf{Wv}}{r} \tag{53.164}$$

In the preceding technique, the largest number allowed for the parameters, $u = n_0$, must be carried in the adjustment so that each condition equation contains one and only one observation. In many applications,

it is more economical to carry in the adjustment only the parameters of interest, which are fewer in number: $u < n_o$. This technique is called *combined adjustment of observations and parameters*. The general (nonlinear) condition equations are of the form

$$\mathbf{F}(\mathbf{l}, \mathbf{x}) = \mathbf{0} \tag{53.165}$$

which in linearized form becomes

$$\mathbf{A}\mathbf{v} + \mathbf{B}\boldsymbol{\Delta} = \mathbf{f} \tag{53.166}$$

where

$$\mathbf{A} = \left.\frac{\partial \mathbf{F}}{\partial \mathbf{l}}\right|_{l^0, x^0} \qquad \mathbf{B} = \left.\frac{\partial \mathbf{F}}{\partial \mathbf{x}}\right|_{l^0, x^0}$$

and

$$\mathbf{f} = -[\mathbf{F}(\mathbf{l}^0, \mathbf{x}^0) + \mathbf{A}(\mathbf{l} - \mathbf{l}^0)] \tag{53.167}$$

Then

$$\mathbf{Q}_e = \mathbf{A}\mathbf{Q}\mathbf{A}^{\mathrm{T}} \tag{53.168}$$

$$\mathbf{W}_e = \mathbf{Q}_e^{-1} = (\mathbf{A}\mathbf{Q}\mathbf{A}^{\mathrm{T}})^{-1} \tag{53.169}$$

$$\mathbf{N} = \mathbf{B}^{\mathrm{T}}\mathbf{W}_e\mathbf{B} \tag{53.170}$$

$$\mathbf{t} = \mathbf{B}^{\mathrm{T}}\mathbf{W}_e\mathbf{f} \tag{53.171}$$

$$\boldsymbol{\Delta} = \mathbf{N}^{-1}\mathbf{t} \tag{53.172}$$

$$\hat{\mathbf{x}} = \mathbf{X}^0 + \Sigma\boldsymbol{\Delta} \qquad \text{(iterate)} \tag{53.173}$$

$$\mathbf{v} = \mathbf{Q}\mathbf{A}^{\mathrm{T}}\mathbf{W}_e(\mathbf{f} - \mathbf{B}\boldsymbol{\Delta}) \tag{53.174}$$

$$\hat{\sigma}_0^2 = \frac{\mathbf{v}^{\mathrm{T}}\mathbf{W}\mathbf{v}}{r} \tag{53.175}$$

Error propagation:

$$\mathbf{Q}_{\hat{x}\hat{x}} = \mathbf{Q}_{\Delta\Delta} = \mathbf{N}^{-1} \tag{53.176}$$

$$\mathbf{Q}_w = \mathbf{Q}\mathbf{A}^T(\mathbf{W}_e - \mathbf{W}_e\mathbf{B}\mathbf{Q}_{\Delta\Delta}\mathbf{B}^{\mathrm{T}}\mathbf{W}_e)\mathbf{A}\mathbf{Q} \tag{53.177}$$

$$\mathbf{Q}_{\hat{l}\hat{l}} = \mathbf{Q} - \mathbf{Q}_{vv} \tag{53.178}$$

The linear set $\mathbf{N}\boldsymbol{\Delta} = \mathbf{t}$ is called the *normal equations*.

In the three techniques above, the parameters $\mathbf{x}$ are functionally independent. In many surveying engineering applications, functions may exist between the parameters in the adjustment. Examples include points on geometric forms (lines, planes, surfaces), known distances, angles, etc., to be fixed in the adjustment. These functions are called *constraint equations* or simply *constraints*, to distinguish them from conditions. They are characterized by not containing any observations. The technique when constraints exist is called *adjustment with functional constraints*; of course, the condition equations to be

combined with the constraints can take any of the three situations discussed. It is more general to consider the combined adjustment technique, thus:

$$\mathbf{F}(\mathbf{l}, \mathbf{x}) = \mathbf{0} \tag{53.179}$$

$$\mathbf{G}(\mathbf{x}) = \mathbf{0} \tag{53.180}$$

are the general (nonlinear) conditions and constraints. The linearized form is

$$\mathbf{A}\mathbf{v} + \mathbf{B}\boldsymbol{\Delta} = \mathbf{f} \tag{53.181}$$

$$\boldsymbol{C}\boldsymbol{\Delta} = \boldsymbol{g} \tag{53.182}$$

where $\mathbf{C} = \left.\dfrac{\partial \mathbf{G}}{\partial \mathbf{x}}\right|_{\mathbf{x}^0}$ and $\mathbf{g} = -\mathbf{G}(\mathbf{x}^0)$

$$\mathbf{N} = \mathbf{B}^{\mathrm{T}}\mathbf{W}_e\mathbf{B} \qquad \mathbf{t} = \mathbf{B}^{\mathrm{T}}\mathbf{W}_e\mathbf{f} \tag{53.183}$$

$$\mathbf{M} = \mathbf{C}\mathbf{N}^{-1}\mathbf{C}^{\mathrm{T}} \tag{53.184}$$

$$\mathbf{k}_c = \mathbf{M}^{-1}(\mathbf{g} - \mathbf{C}\mathbf{N}^{-1}\mathbf{t}) \tag{53.185}$$

$$\boldsymbol{\Delta} = \mathbf{N}^{-1}(\mathbf{t} + \mathbf{C}^{\mathrm{T}}\mathbf{k}_c) \tag{53.186}$$

$$\mathbf{x} = \mathbf{x}^0 + \boldsymbol{\Sigma}\boldsymbol{\Delta} \qquad \text{(iterate)} \tag{53.187}$$

$$\mathbf{Q}_{\Delta\Delta} = \mathbf{N}^{-1}(\mathbf{I} - \mathbf{C}^{\mathrm{T}}\mathbf{M}^{-1}\mathbf{C}\mathbf{N}^{-1}) \tag{53.188}$$

The quantities v, $\hat{\sigma}_0^2$, $\mathbf{Q}_{vv}$, and $\mathbf{Q}_{\eta}$ are as given by Eqs. (53.174), (53.175), (53.177), and (53.178), respectively.

Another technique is to perform the adjustment sequentially. For a fixed number of parameters, both the inverse of the normal equations coefficient matrix **N** and the constant terms vector **t** are sequentially updated due to either addition or deletion of a set of condition equations. The relations for *sequential adjustment* are as follows:

$$\mathbf{A}_i\mathbf{v}_i + \mathbf{B}_i\Delta = \mathbf{f}_i \quad \text{with} \quad \mathbf{Q}_i \tag{53.189}$$

are the conditions to be added or subtracted. Let $\mathbf{N}_{I-1}$, $\mathbf{t}_{I-1}$ and $\mathbf{N}_I$, $\mathbf{t}_I$ designate the matrices *before* and *after*, respectively, incorporating the effects of Eq. (53.189). Then

$$\mathbf{N}_I^{-1} = \mathbf{N}_{I-1}^{-1}[\mathbf{I} \mp \mathbf{B}_i^{\mathrm{T}}(\mathbf{Q}_{e_i} \pm \mathbf{B}_i\mathbf{N}_{I-1}^{-1}\mathbf{B}_i^{\mathrm{T}})^{-1}\mathbf{B}_i\mathbf{N}_{I-1}^{-1}] \tag{53.190}$$

$$\mathbf{t}_I = \mathbf{t}_{I-1} \pm \mathbf{B}_i^{\mathrm{T}}\mathbf{W}_{e_i}\mathbf{f}_i \tag{53.191}$$

in which $\mathbf{Q}_{e_i} = \mathbf{A}_i\mathbf{Q}_i\mathbf{A}_i^{\mathrm{T}}$ and $\mathbf{W}_{e_i} = \mathbf{Q}_{e_i^{-1}}$. In Eqs. (53.190) and (53.191) the *upper signs* refer to condition *addition* and the *lower signs* to condition *deletion*.

Finally, a very flexible technique is used in which all the variables in the *mathematical model are considered as observables*. This requires *a priori* estimates for all model variables, but more importantly, estimates of their *a priori* weights. The *a priori* weights provide the mechanism for effectively distinguishing between different groups of variables in the model. Very large weights leave a variable essentially as a constant in the adjustment, while very small or even zero weight leaves it as an unknown parameter that can freely adjust. This is referred to as the *unified least squares* technique and applies to *all* of the techniques presented above. As an example, we consider the combined adjustment of observations and

parameters with the linear (or linearized) conditions: $\mathbf{Av} + \mathbf{B}\Delta = \mathbf{f}$. Let $\mathbf{x}$ be the prior estimates of the parameters and $\mathbf{W}_{xx}$ its corresponding prior weight matrix. The solution given by Eqs. (53.168) to (53.178) essentially apply, except that

$$\Delta = (\mathbf{N} + \mathbf{W}_{xx})^{-1}(\mathbf{t} - \mathbf{W}_{xx}\mathbf{f}_x) \tag{53.192}$$

$$\mathbf{f}_x = \mathbf{x}^0 - \mathbf{x} \tag{53.193}$$

$$\mathbf{Q}_{\Delta\Delta} = (\mathbf{N} + \mathbf{W}_{xx})^{-1} \tag{53.194}$$

Assessment of Adjustment Results

After least squares adjustment it is quite important in surveying to analyze the results and provide a statement regarding the quality of the estimates. This operation is often referred to as *postadjustment analysis*, which applies various statistical techniques.

Test on Reference Variance

The first test is on the estimated reference variance, $\hat{\sigma}_0^2$. Let the *a priori* reference variance be σ_0^2; let r be the degrees of freedom (redundancy) in the adjustment, and assume that the residuals v_i are normally distributed. The statistic $r\hat{\sigma}_0^2/\sigma_0$ has a χ^2 distribution with r degrees of freedom. The two-tailed $100(1-\alpha)$ confidence region for σ_0^2 is given by

$$(r\hat{\sigma}_0^2/\chi^2_{r,\,\alpha/2}) < \sigma_0^2 < (r\sigma_0^2/\chi^2_{r,\,1-\alpha/2}) \tag{53.195}$$

If σ_0^2 is incorrect or the mathematical model used is improper or incomplete (does not adequately account for systematic errors), then σ_0^2 will fall outside this interval.

Test for Blunders or Outliers

If v_i is the ith residual and σ_{v_i} is its standard deviation, then

$$\bar{v}_i = v_i/\sigma_{v_i} \tag{53.196}$$

is called the *standardized residual*. Frequently, the effort involved in computing $\mathbf{\Sigma}_{vv}$ is quite extensive, and therefore an approximate estimate of σ_{v_i} may be obtained from

$$\hat{\sigma}_{v_i} = [(n-u)/n]^{1/2}\hat{\sigma}_0\sigma_{l_i}/\sigma_0 \tag{53.197}$$

in which n is the number of observations, u is the number of parameters (thus $n - u = r$, the redundancy), and σ_{l_i} is the *a priori* standard deviation of observation l_i. When σ_0^2 is known, $\bar{v}_i$ has a probability density function, or pdf, $N(0, \sigma_{v_i^2})$ and

$$\bar{v}_i = \left|\frac{v_i}{\sigma_{v_i}}\right| < N_{1-\alpha/2} \tag{53.198}$$

If σ_0^2 is not known, then

$$\bar{v}_i = \left|v_i/\hat{\sigma}_{v_i}\right| < \tau_{r,\,1-\alpha/2} \tag{53.199}$$

in which $\hat{\sigma}_{v_i}$ is computed from Eq. (53.197), and τ_r has a Tau pdf with r degrees of freedom. If r is large, as in surveying, photogrammetric, or geodetic nets with extensive observations, τ_r may be replaced by Student t_r pdf or even normal pdf.

Confidence Region for Estimated Parameters

The covariance matrix for the parameters as evaluated from the least squares is given by (see, for example, Eq. (53.161))

$$\Sigma_{\hat{x}\hat{x}} = \sigma_0^2 N^{-1} \tag{53.200}$$

It can be shown that a region of constant probability is bounded by a u-dimensional hyperellipsoid centered at $\hat{\mathbf{x}}$, if the parameters are assumed to have a multivariate normal pdf. The function

$$k^2 = (\mathbf{x} - \hat{\mathbf{x}})^T \sum_{\hat{x}\hat{x}}^{-1} (\mathbf{x} - \hat{\mathbf{x}}) \tag{53.201}$$

describes the hyperellipsoid. The quadratic k^2 has a χ_u^2 distribution, with the probability for a point estimate being

$$P(\chi_u^2 < k^2) = 1 - \alpha$$

For the two-dimensional case (error ellipses), typical values are

p	0.394	0.500	0.900	0.950	0.990
k	1.000	1.177	2.146	2.447	3.035

and for the three-dimensional case, they are

P	0.199	0.500	0.900	0.950	0.990
k	1.000	1.538	2.500	2.700	3.368

when $k = 1$, we usually call it the *standard* region, *standard error ellipse* (for 2-D), or *standard error ellipsoid* (for 3-D). The standard regions for several dimensions are

Dimension	1	2	3	4	5	6
P	0.683	0.394	0.199	0.090	0.037	0.014

Given Σ, for example, for a point in a plane, the semimajor axis, a, and semiminor axis, b, of the standard error ellipse are computed from the eigenvalues and eigenvectors (see the discussion of "Basic Matrix Operations," in Section 53.5). If one is interested in the 90% confidence region (i.e., significance level of $\alpha = 0.10$), the a, b are multiplied by 2.146. For the standard regions, there is a 0.683 probability that an adjusted point falls in a one-dimensional interval, a 0.394 probability that it falls inside the standard error ellipse, and only a 0.199 probability that it falls within the standard error ellipsoid.

Applications in Surveying Engineering

Level Net

Let l_{ij} represent the observed difference in elevation between two points whose (unknown) elevations are x_i and x_j. If l_{ij} is from point i to point j, then the condition equation is given by

$$x_i + l_{ij} + v_{ij} - x_j = 0$$

or

$$v_{ij} + x_i - x_j = -l_{ij} \tag{53.202}$$

This condition equation is in the form of adjustment of indirect observations. At least one benchmark (a point of known elevation) is needed for any given level net.

Traverse

There are two conditions, one for a measured angle α_i, and one for a measured distance d_{ij}. If α_i is at station i from the line $i - 1$ to i clockwise to the line from i to $i + 1$, then

$$\alpha_i = A_{i,\,i+1} - A_{i,\,i-1}$$

or

$$v_i + \tan^{-1}\left(\frac{x_{i-1} - x_i}{y_{i-1} - y_i}\right) - \tan^{-1}\left(\frac{x_{i+1} - x_i}{y_{i+1} - y_i}\right) = -\alpha_i \tag{53.203}$$

where **A** represents the azimuth and $(x, y)_{i-1,\,i,\,i+1}$ are the coordinates of the three points involved. The distance condition is given by

$$v_{ij} - [(x_i - x_j)^2 + (y_i - y_j)^2]^{1/2} = -d_{ij} \tag{53.204}$$

Again, this is in the form of adjustment of indirect observations. If any of the points involved is a fixed point (i.e., with known coordinates), its coordinates are not carried as unknown parameters in the adjustment.

Trilateration

This is the operation in which *only* distances are measured in the network. Therefore, the only condition used is that given by Eq. (53.204).

Triangulation

This is the operation in which chains of triangles are connected together. The fundamental measurement is the angle, and the adjustment unit is the triangle. The single condition for one triangle is

$$\sum l_i - \pi = 0 \tag{53.205}$$

where l_i represents all the measured angles inside a single triangle. For a quadrilateral, there is another condition called the *side condition*, the composition of which can be found in the literature.

Defining Terms

Adjustment of observations — The mathematical technique used to resolve the inconsistency between the measurements collected and the underlying mathematical model when *redundancy* exists, or when the measurements exceed the minimum necessary to uniquely define the model.

Azimuthal projection — A map projection that yields a map where correct *direction* or *azimuth* of any point relative to one central point is shown.

Conformal or orthomorphic projection — A map projection technique that preserves *angles* between short intersecting lines, thus making small areas appear in their correct *shape* on the map. Scale varies from point to point, and thus larger areas are incorrect.

Equal-area projection — A map projection technique that results in a map showing all areas in proper relative *size*; however, they may be distorted in *shape*.

Equidistant projection — A map projection technique in which distances are correctly represented from one central point to other points on the map.

Error ellipses and ellipsoids — Confidence regions about estimated survey points in two dimensions (ellipses) or three dimensions (ellipsoids) for specified probabilities.

Error propagation — The general technique of determining the covariance matrix of a set of quantities, which are estimated from functions of another set of quantities of known values and covariance matrix.

Least squares adjustment — The most common adjustment technique used in surveying engineering; it is based on minimizing the sum of the weighted squares of the observational residuals.

Map projection — The theory and techniques of proper representation of the curved earth surface on the plane of a map.

54.1 Introduction

The roots of surveying are contained in plane-surveying techniques that have developed since the very first line was measured. Though the fundamental processes haven't changed, the technology used to make the measurements has improved tremendously. The basic methods of distance measurement, angle measurement, determining elevation, etc., are becoming easier, faster, and more accurate.

Even though electronic measurement is becoming commonplace, distances are still being taped. While many transits and optical theodolites are still being used for layout purposes, electronic instruments are rapidly becoming the instruments of choice by the engineer for measurement of angles. Although establishing elevations on the building site is still being performed using levels, the laser is everywhere. It is the responsibility of the engineer in the field to choose the measuring method and the technology that most efficiently meet the accuracy needed.

The requirements of construction layout are more extensive than ever, with the complex designs of today's projects. The engineer must be exact in measurement procedures and must check and double-check to ensure that mistakes are eliminated and errors are reduced to acceptable limits to meet the tolerances required.

This chapter is directed to the engineer who will be working in the field on a construction project. Often that individual is called the *field engineer,* and that term will be used throughout this chapter. The field engineer should be aware of fundamental measuring techniques as well as advances in the technology of measurement.

Although measurement concepts and calculation procedures are introduced and discussed in this chapter, only the basics are presented. It is the responsibility of the field engineer to review other sources for more detailed information to become more competent in these procedures. See the further information and references at the end of this chapter.

54.2 Distance Measurement

Distance may be measured by indirect and direct measurement procedures. Indirect methods include odometers, optical rangefinders, and tacheometry. Direct methods include pacing, taping, and electronic distance measurement.

When approximate distances are appropriate, pacing can be used over short distances and odometers or optical rangefinders can be used over longer or inaccessible distances. These methods can yield accuracies in the range of 1 part in 50 to 1 part in 100 over modest distances. The accuracy of pacing and optical distance measuring methods decreases rapidly as the distance increases. However, these approximate methods can be useful when checking for gross blunders, narrowing search areas in the field, and making preliminary estimates for quantities or future surveying work. Applications where these lower-order accuracy methods can be used to obtain satisfactory distance observations occur regularly in surveying, construction and engineering, forestry, agriculture, and geology.

Tacheometry

Tacheometry uses the relationship between the angle subtended by a short base distance perpendicular to the bisector of the line and the length of the bisecting line. Stadia and subtense bar are two tacheometric methods capable of accuracies in the range of 1 part in 500 to 1 part in 1000.

In the stadia method the angle is fixed by the spacing of the stadia cross hairs (i) on the telescope reticule and the focal length (f) of the telescope. Then the distance on the rod (d) is observed, and the distance is computed by

$$\frac{D}{d} = \frac{f}{i}$$

$$D = d\left(\frac{f}{i}\right)$$

When the telescope is horizontal, as in a level, a horizontal distance is obtained. When the telescope is inclined, as in a transit or theodolite, a slope distance is obtained. Stadia may be applied with level or transit, plane table and alidade, or self-reducing tacheometers.

The subtense bar is a tacheometric method in which the base distance, d, is fixed by the length of the bar and the angle, α, is measured precisely using a theodolite. The horizontal distance to the midpoint of the bar is computed by

$$\tan\frac{\alpha}{2} = \frac{d/2}{D}$$

$$D = \frac{d}{2\tan\left(\frac{\alpha}{2}\right)}$$

Since a horizontal angle is measured, this method yields a horizontal distance and no elevation information is obtained.

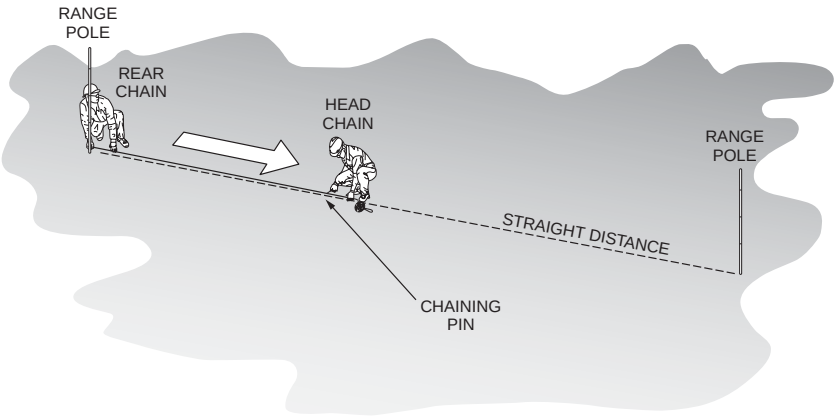

FIGURE 54.1 Taping on level terrain.

Taping

Taping is a direct method of measuring distance in which a tape of known length and graduated at intervals throughout its length is stretched along the line to be measured. Figure 54.1 illustrates taping on level terrain. Low-order accuracy measurements can be obtained using tapes made of cloth or fiberglass material. These tapes are available in a variety of lengths, and they may be graduated in feet, meters, or both. Accurate taped distances are obtained using calibrated metal ribbon tapes made of tempered steel. Tapes made of invar steel for temperature stability are also available. Table 54.1 summarizes the sources of errors and the procedures required to measure distances accurately.

TABLE 51.1 Taping Errors and Procedures

Error	Source	Type	Makes Tape	Importance	Procedure to Eliminate
Tape length	Instrumental	Systematic	Long or short	Direct impact to recorded measurement, always check.	Calibrate tape and apply adjustment.
Temperature	Natural	Systematic or random	Long or short	For a chain standardized at 68°, 0.01 per 15° per 100 ft chain.	Observe temperature of chain, calculate, and apply adjustment.
Tension	Personal	Systematic or random	Long or short	Often not important.	Apply the proper tension. When in doubt, PULL HARD!
Tape not level	Personal or natural	Systematic	Short	Negligible on slopes less than 1%; must be calculated for greater than 1%.	Break chain by using a hand level and plumb bob to determine horizontal; or correct by formula for slope or elevation difference.
Alignment	Personal	Systematic	Short	Minor if less than 1 ft off of line in 100 ft; major if 2 or more ft off of line.	Stay on line; or determine amount off of line and calculate adjustment by formula.
Sag	Natural or personal	Systematic	Short	Large impact on recorded measurement.	Apply proper tension; or calculate adjustment by formula.
Plumbing	Personal	Random	Long or short	Direct impact to recorded measurement.	Avoid plumbing if possible; or plumb at one end of chain only.
Interpolation	Personal	Random	Long or short	Direct impact to recorded measurement.	Check and recheck any measurement that requires estimating a reading.
Improper marking	Personal	Random	Long or short	Direct impact to recorded measurement.	Mark all points so that they are distinct.

TABLE 54.2 Tape Corrections for Systematic Errors

Systematic Error	Correction Formula	0.01-ft Correction Caused by
Tape length	$C_l = \dfrac{L_{\text{tape}} - 100.00}{100.00}$	0.01 per 50-ft tape length
Tension	$C_p = \dfrac{(P - P_0)L}{AE}$	±9 lb
Temperature	$C_t = \alpha(T - T_0)L$	±15°F
Sag	$C_s = \dfrac{-w^2 L_s^3}{24P^2}$	−5 lb in 100-ft tape length
Alignment	$C_a = -\dfrac{h}{2L}$	±1.4 ft

Accuracy in taping requires a **calibrated** tape that has been compared to a length standard under known conditions. A tape calibration report will include the true length of the tape between marked intervals on the tape. The tape is calibrated when it is fully supported throughout its length at a specified pull or tension applied to the tape and at a specified temperature of the tape. The calibration report should also include the cross-sectional area of the tape, the weight of the tape per unit length, the modulus of elasticity for the tape material, and the coefficient of thermal expansion for the tape material. When a distance is observed in the field and the conditions of tape support, alignment, temperature, and tension are recorded, the **systematic errors** affecting the measurement can be corrected and a true distance obtained. The tape correction formulas are summarized in the following example.

Example 54.1

A typical 100-foot surveyor's steel tape is calibrated while supported throughout its length. The calibration report lists the following:

$$\text{True length, 0-ft to 100-ft mark} \quad L_0 = 99.98 \text{ ft}$$

Other length intervals may also be reported (and the tape characteristic constants):

Tension	$P_0 = 25$ lb
Temperature	$T_0 = 68$°F
Cross-sectional area	$A = 0.003$ in.^{2}
Weight	$w = 0.01$ lb/ft
Coefficient of thermal expansion	$\alpha = 0.00000645$/°F
Modulus of elasticity	$E = 29(10^6)$ lb/in.^{2}

Systematic errors in taping, the correction formula, and the change required to cause a 0.01-foot tape correction in a full 100-foot length of the example tape are summarized in Table 54.2. When a distance is measured directly by holding the tape horizontal, the effect of alignment error is present in both the alignment of the tape along the direction of the line to be measured and the vertical alignment necessary to keep the tape truly horizontal.

Normal taping procedures require that the tape be held horizontal for each interval measured. When taping on sloping terrain or raising the tape to clear obstacles, a plumb bob is required to transfer the tape mark to the ground. Steadying the hand-held tape and plumb bob will be the largest source of **random error** in normal taping. Accuracies of 1 part in 2000 to 1 part in 5000 can be expected.

Precise taping procedures eliminate the use of the plumb bob by measuring a slope distance between fixed marks that either are on the ground or are supported on tripods or taping stands. Taping the slope distance, S, will require that the horizontal distance, H, be computed by

$$H = S\cos\alpha = S\sin z$$

where α = **vertical** angle of the tape and z = **zenith** angle of the tape, or by

$$H = \sqrt{S^2 - h^2}$$

where h = difference in elevation between the ends of the tape. If all tape corrections are carefully applied, accuracies of 1 part in 10,000 to 1 part in 20,000 can be obtained.

Electronic Distance Measurement

Distance can be measured electronically if the velocity and travel time of electromagnetic energy propagated along a survey line are determined. Terrestrial electronic distance measurement instruments (EDMIs) measure the travel time by comparing the phase of the outgoing measurement signal to the phase of the signal returning from the remote end of the line. The phase difference is thus a function of the double path travel of the measurement signal. The distance is given by

$$D = \frac{VT}{2}$$

where V = the velocity of electromagnetic energy in the atmosphere and T = the double path travel time determined using the phase difference.

If $\Delta\phi$ is the phase difference observed for the fine or shortest wavelength measurement signal, then the total travel time is found from the equation

$$T = k\left(\frac{1}{f}\right) + \frac{\Delta\phi}{2\pi}\left(\frac{1}{f}\right)$$

where f = the frequency of the measurement signal and k = the integer number of full cycles in the double path distance. The integer k is ambiguous for the fine measurement since the phase difference only determines the fractional part of the last cycle in the double path distance, as illustrated in Fig. 54.2. The value of k can be determined by measuring the phase difference of one or more coarse- or long-wavelength signals to resolve the distance to the nearest full cycle of the fine wavelength.

EDMIs may be classified by type of energy used to carry the measurement signal or by the maximum measurement range of the system. Visible (white) light, infrared light, laser (red) light, and microwaves have been used as carrier energy.

The velocity of electromagnetic energy in the atmosphere is given by the expression

$$V = \frac{c}{n}$$

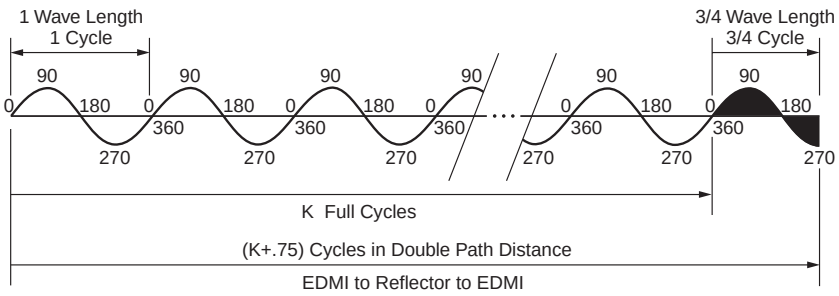

FIGURE 54.2 Phase shift principle of distance measurement.

where c is the velocity in a vacuum, 299,792,158 meters/second, and n is the atmospheric index of refraction for the conditions at the time of observation. The atmospheric index of refraction is a function of the wavelength of the electromagnetic energy propagated and the existing conditions of atmospheric temperature, pressure, and water vapor pressure. For EDMIs using visible, laser, or infrared light carrier wavelengths, the effect of water vapor pressure is negligible, and it is often ignored. For EDMIs using microwave carrier wavelengths, the effect of water vapor pressure is more significant.

Refraction causes a scale error in the observation. The correction is usually expressed in terms of parts per million, ppm, of the distance measured.

$$D_{\text{corrected}} = D + S\left(\frac{D}{10^6}\right)$$

The ppm correction for electro-optical instruments can be expressed in the form

$$S = A + \frac{Bp}{t + 273.2}$$

where p is the atmospheric pressure and t is the atmospheric temperature. The constants A and B are functions of the wavelength of the carrier and the precise frequency used for the highest-resolution measuring signal. The values of A and B can be obtained from the instrument manufacturer. Typically, the ppm value, S, is determined graphically using pressure and temperature read in the field, and the value is entered into the EDMI. On many modern digital instruments, the pressure and temperature readings can be entered directly, and the instrument computes and applies the refraction correction.

The measurement accuracy of an EDMI is expressed as

$$\sigma = \pm (c + s_{\text{ppm}})$$

In this expression, c is a constant that represents the contribution of uncertainty in the offset between the instrument's measurement reference point and the geometric reference point centered over the survey station. The ppm term is a distance-dependent contribution representing the uncertainty caused by measurement frequency drift and atmospheric refraction modeling. An EDMI should be checked periodically to verify that it is operating within its specified error tolerance, σ. A quick check can be done by measuring a line of known length or at least a line that has been measured previously to see if the observed distance changes. When a more rigorous instrument calibration is warranted, use a calibrated base line and follow the procedures recommended in *NOAA Technical Memorandum NOS NGS-10* [Fronczek, 1980]. EDMIs should be sent to the manufacturer for final calibration and adjustment.

54.3 Elevation Measurement

Elevation is measured with respect to a datum surface that is everywhere perpendicular to the direction of gravity. The datum surface most often chosen is called the *geoid*. The geoid is an equipotential surface that closely coincides with **mean sea level.** Elevations measured with respect to the geoid are called orthometric heights. The relationships between the mean sea level geoid, a level surface, and a horizontal line at a point are illustrated in Fig. 54.3.

Benchmark (BM)

A benchmark is best described as a permanent, solid point of known elevation. Benchmarks can be concrete **monuments** with a brass disk in the middle, iron stakes driven into the ground, or railroad spikes driven into a tree, etc.

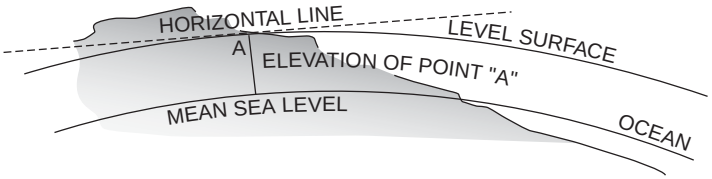

FIGURE 54.3 Elevation datum and level surface.

Turning Point (TP)

A turning point is a point used in the differential leveling process to temporarily transfer the elevation from one setup to the next.

Types of Instruments

Elevation may be measured by several methods. Some of these methods measure elevation directly, whereas some measure the difference in elevation from a reference benchmark to the point to be determined. Many types of instruments have been used for leveling purposes. The instruments have ranged from water troughs and hoses to instruments such as the barometer, dumpy level, automatic level, and laser. The field engineer should realize how each of these can be used to determine elevations for vertical control and construction.

Altimeters

Surveying altimeters are precise aneroid barometers that are graduated in feet or meters. As the altimeter is raised in elevation, the barometer senses the atmospheric pressure drop. The elevation is read directly on the face of the instrument. Although the surveying altimeter may be considered to measure elevation directly, best results are obtained if a difference in elevation is observed by subtracting readings between a base altimeter kept at a point of known elevation and a roving altimeter read at unknown points in the area to be surveyed. The difference in altimeter readings is a better estimate of the difference in elevation because local weather changes, temperature, and humidity that affect altimeter readings are canceled in the subtraction process. By limiting the distance between base and roving altimeters, accuracies of 3 to 5 feet are possible. Other survey configurations utilizing low and high base stations, and/or leap-frogging roving altimeters, can yield good results over large areas.

Level Bubble Instruments

Level bubble instruments include the builder's transit level, the transit, and the dumpy level. Each of these instruments contains a level vial with a bubble that must be centered to be used for leveling. Each instrument consists of three main components: a four-screw leveling head, a level vial attached to the telescope, and a telescope for magnification of the objective.

Instruments that use a level bubble to orient the axes to the direction of gravity depend on the bubble's sensitivity for accuracy. Level bubble sensitivity is defined as the central angle subtended by an arc of one division on the bubble tube. The smaller the angle subtended, the more sensitive the bubble is to dislevelment. A bubble division is typically 2 millimeters long, and bubble sensitivity typically ranges from 60 seconds to 1 second.

Builder's Level. The builder's level is one of the most inexpensive and versatile instruments that is used by field engineers. In addition to being able to perform leveling operations, it can be used to turn angles, and the scope can be tilted for sighting. Many residential builders use this instrument because it serves their purpose of laying out a building. See Fig. 54.4.

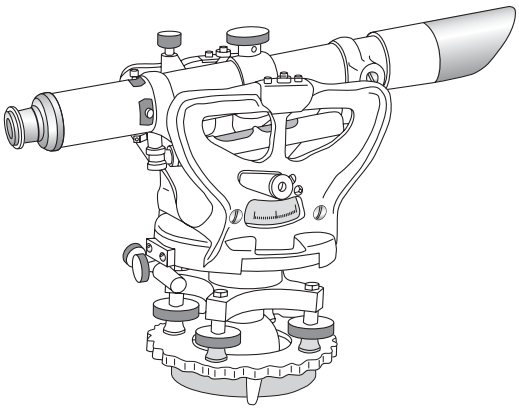

FIGURE 54.4 Builder level.

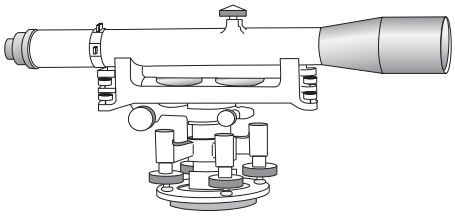

FIGURE 54.5 Engineer's dumpy level.

Transit. Although the primary functions of the transit are for angle measurement and layout, it can also be used for leveling because there is a bubble attached to the telescope. In fact, many construction companies who don't have both an angle measuring instrument and a dumpy or automatic level will do all of their leveling work with a transit. Some people prefer to use the transit for leveling because they are comfortable with its operation. However, the field engineer should be aware that the transit may not be as sensitive and stable as a quality level.

Dumpy Level. The engineer's dumpy level shown in Fig. 54.5 has been the workhorse of leveling instruments for more than 150 years. It has been used extensively for many of the great railroad, canal, bridge, tunnel, building, and harbor projects for the last century and a half. Even with advancements in other leveling instruments such as the automatic level and the laser, the dumpy is still the instrument of choice for a number of persons in construction because of its stability. On any type of project where there is going to be a great deal of vibration — such as pile driving, heavy-equipment usage, or high-rise construction — the dumpy may be the best choice for a leveling instrument.

Automatic Compensator Instruments

Compensator instruments illustrated in Fig. 54.6 were developed about 50 years ago. Although each manufacturer may have developed a unique compensator, all compensators serve the same purpose — maintaining a fixed relationship between the line of sight and the direction of gravity. If the instrument is in adjustment, the line of sight will be maintained as a horizontal line. The operation of a compensator is illustrated in Fig. 54.7. Compensator instruments are extremely fast to set up and level. An experienced person can easily have an automatic level ready for a backsight in less than ten seconds, compared to a minute or more with a bubble-based leveling system. Compensators are available in several styles. Some are constructed

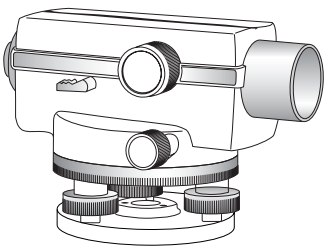

FIGURE 54.6 Automatic level.

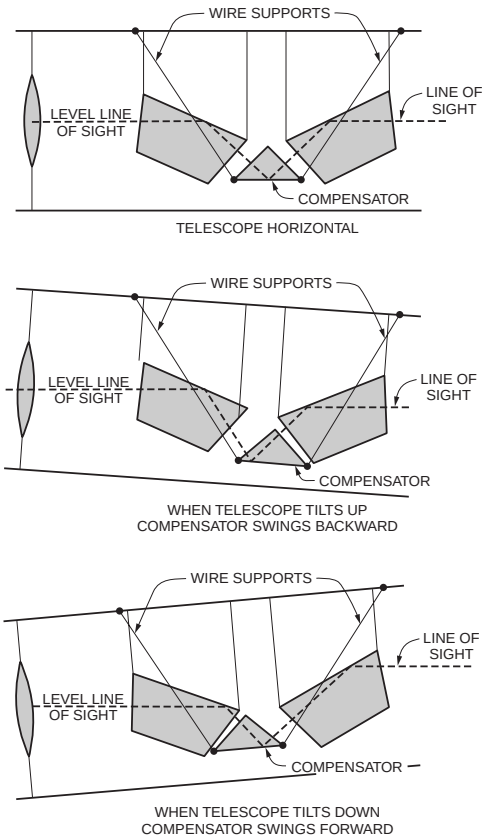

FIGURE 54.7 Leveling the line of sight by compensator.

by suspending a prism on wires. Some have a prism that is contained within a magnetic dampening system. Note that the instrument must be manually leveled to within the working range of the compensator by centering a bull's-eye bubble.

Laser Levels

A laser level uses a laser beam directed at a spinning optical reflector. The reflector is oriented so that the rotating laser beam sweeps out a horizontal reference plane. The level rod is equipped with a sensor to detect the rotating beam. By sliding the detector on the rod, a vertical reading can be obtained. Laser levels are especially useful on construction sites. As the laser beam continuously sweeps out a constant elevation reference plane, anyone with a detector can get a rod reading to set or check grade elevations. Laser levels can be equipped with automatic leveling devices to maintain level orientation. The spinning optics can also be oriented to produce a vertical reference plane.

Digital Levels

Digital levels are electronic levels that can be used to more quickly obtain a rod reading and make the reading process more reliable. The length scale on the level rod is replaced by a bar code. The digital level senses the bar code pattern and compares it to a copy of the code held in its internal memory. By matching the bar code pattern, a rod-reading length can be obtained.

Level Rods

In addition to the leveling instrument, a level rod is required to be able to transfer elevations from one point to another. The level rod is a graduated length scale affixed to a rod and held vertically on a turning

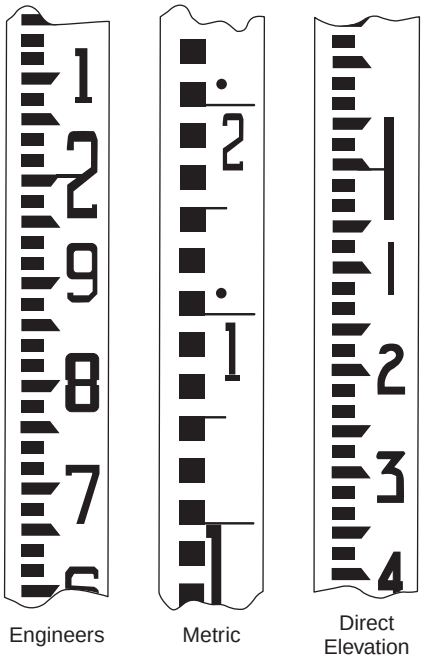

FIGURE 54.8 Typical level rod graduations.

point or benchmark. The scale is read by the person at the instrument. The reading taken is the vertical distance from the point to the line of sight.

Level rods are available in many sizes, shapes, and colors. They are made of wood, fiberglass, metal, or a combination of these materials. There are one-piece rods, two-piece rods, three-piece rods, six-piece rods, etc. Some have a square cross section and others are round or oval. Some are less than 10 feet long, while others are up to 30 feet long. Practically whatever type of rod a field engineer needs is available. Level rods have been named after the cities where they have been manufactured. The Philadelphia rod, for example, is a two-piece rod that can be extended to approximately 13 feet. It is a popular rod used in leveling surveys.

A popular rod that doesn't seem to have a proper name is the telescoping rod. Because a telescoping rod is 25 or 30 feet long, it is the rod of choice for field engineers working on projects where there is a great deal of change in elevation. Great rod lengths increase the elevation difference that can be transferred at one time. It has been argued that these types of rods wear rapidly and therefore aren't as accurate as the more traditional rods. If telescoping rods are well cared for, they are excellent for construction use.

Level rods are graduated in feet, inches, and fractions; feet, tenths, and hundredths; or meters and centimeters. The method of representing units of measurement onto the face of the rod also varies. Typical level rod graduations are shown in Fig. 54.8. The field engineer should, after studying the graduations on the face of the rod, be able to use any rod available. The rod illustrated on the left in Fig. 54.8 shows the markings on a typical "engineer's rod" that is widely used on the construction site. Note that the rod is graduated to the nearest foot with large numbers that are usually painted red. The feet are then graduated to the nearest tenth from 1 to 9. Each tenth is then graduated to the nearest one hundredth, which is the width of the smallest mark on the rod.

Rod Targets

Rod targets are useful devices for several purposes. The rod target can be used as a target by the person looking through the instrument to help locate the rod when visibility conditions are poor. If the rod target has a vernier, it can also be used to obtain a reading on the rod to the nearest thousandth of a foot. In this case the instrument person communicates to the rod person to move the target until it has

centered on the horizontal cross hair. The rod person can then read the rod and the vernier to obtain thousandths of a foot. This accuracy is sometimes required on very precise leveling work.

Rod Levels

Rod levels are used to keep the level rod plumb while the reading is being taken. Rod levels are simple devices made of metal or plastic and have a bull's-eye bubble attached. They are held along the edge of the level rod while the level rod is moved until the bubble is centered. If the rod level is in proper adjustment, the rod is plumb. When a rod level is not used, the rod person should slowly rock the rod through the vertical position. The instrument person watches the cross hair appear to move on the rod and records the lowest reading — the point when the rod was vertical.

Turning Point Pin

If a solid natural point is not available during the leveling process to be used as a turning point, then the field engineer will have to create one. This is accomplished by carrying something such as a railroad spike, piece of rebar, wooden stake, or plumb bob that can be inserted solidly into the ground. The rod is placed on top of the solid point while the foresight and backsight readings are taken. These solid points are removed after each backsight to be used the next time a solid turning point is needed.

Fundamental Relationships

All level instruments are designed around the same fundamental relationships and lines. The principal relationships among these lines are described as follows:

- The **axis of the level bubble** (or compensator) should be perpendicular to the vertical axis.
- The **line of sight** should be parallel to the axis of the level bubble.

When these instrument adjustment relationships are true and the instrument is properly set up, the line of sight will sweep out a horizontal plane that is perpendicular to gravity at the instrument location. However, several effects must be considered if the instrument is to be used for differential leveling.

Earth Curvature

The curved shape of the earth means that the level surface through the telescope will depart from the horizontal plane through the telescope as the line of sight proceeds to the horizon. This effect makes actual level rod readings too large by

$$C = 0.0239D^2$$

where D is the sight distance in thousands of feet.

Atmospheric Refraction

The atmosphere refracts the horizontal line of sight downward, making the level rod reading smaller. The typical effect of refraction is equal to about 14% of the effect of earth curvature. Thus, the combined effect of curvature and refraction is approximately

$$(C - r) = 0.0206D^2$$

Instrument Adjustment

If the geometric relationships defined above are not correct in the leveling instrument, the line of sight will slope upward or downward with respect to the horizontal plane through the telescope. The method of testing the line of sight of the level to ensure that it is horizontal is called the *two-peg test*. It requires setting up the level exactly between two points about 200 feet apart and subtracting readings taken on the points to determine the true difference in elevation between them. The instrument is then moved and placed adjacent to one of the points, and rod readings are again taken on the two points. If the line

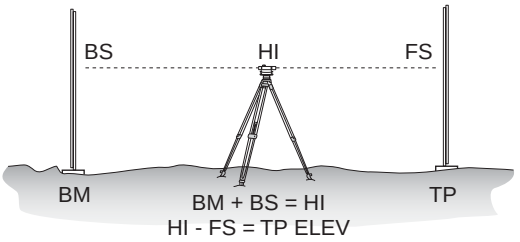

FIGURE 54.9 Differential leveling.

of sight of the instrument is truly horizontal, the difference in elevation obtained from the two setups will be the same. If the line of sight is inclined, the difference in elevation obtained from the two setups will not be equal. Either the instrument must be adjusted, or the slope of the line of sight must be calculated. The slope is expressed as a collimation factor, *C*, in terms of rod-reading correction per unit sight distance. It may be applied to each sight by

$$\text{Corrected rod reading} = \text{Rod reading} + (C_{\text{Factor}} \cdot D_{\text{Sight}})$$

In ordinary differential leveling discussed next, these effects are canceled in the field procedure by always setting up so that the backsight distance and foresight distance are equal. The errors are canceled in the subtraction process. If long unequal sight distances are used, the rod readings should be corrected for curvature and refraction and for collimation error.

Ordinary Differential Leveling

Determining or establishing elevations is, at times, the most essential activity of the field engineer. Elevations are needed to set slope stakes, grade stakes, footings, anchor bolts, slabs, decks, sidewalks, curbs, etc. Just about everything located on the project requires elevation. Differential leveling is the process used to determine or establish those elevations.

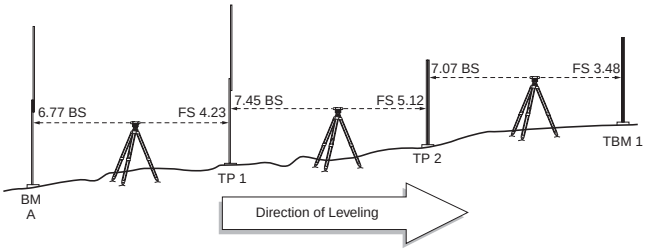
Differential leveling is a very simple process based on the measurement of vertical distances from a horizontal line. Elevations are transferred from one point to another through the process of using a leveling instrument to read a rod held vertically on, first, a point of known elevation and, then, on the point of unknown elevation. Simple addition and subtraction are used to calculate the unknown elevations.

A single-level setup is illustrated in Fig. 54.9. A backsight reading is taken on a rod held on a point of known elevation. That elevation is transferred vertically to the line of sight by reading the rod and then adding the known elevation and the backsight reading. The elevation of the line of sight is the height of instrument, *HI*. By definition, the line of sight is horizontal; therefore, the line of sight elevation can then be transferred down to the unknown elevation point by turning the telescope to the foresight and reading the rod. The elevation of the foresight station is found by subtracting the rod reading from the height of instrument. Note that the difference in elevation from the backsight station to the foresight station is determined by subtracting the foresight rod reading from the backsight rod reading.

A level route consists of several level setups, each one carrying the elevation forward to the next foresight using the differential-leveling method. Figure 54.10 shows a short level route and illustrates the typical format used in the field for differential level notes.

Leveling Closure

Level route **closure** is obtained by taking the last foresight on a benchmark of known elevation. If a second benchmark is not available near the end of the level route, the route should be looped back to the starting benchmark to obtain closure. At the closing benchmark,



BM A TO TBM 1

POINT	BS	HI	FS	SS	ELEVATION
BM A					5280.00
INST 1	6.77	5286.77			
TP 1			4.23		5282.54
INST 2	7.45	5289.99			
TP 2			5.12		5284.87
INST 3	7.07	5291.94			
TBM 1			3.48		5288.46

FIGURE 54.10 Level route and field note form.

$$\text{Closure} = \text{Computed elevation} - \text{Known elevation}$$

Since differential leveling is usually performed with approximately equal setup distances between turning points, the level route is adjusted by distributing the closure equally to each setup:

$$\text{Adjustment} = \left(-\frac{\text{Closure}}{n}\right)\text{per setup}$$

where n is the number of setups in the route. When a network of interconnected routes is surveyed, a **least-squares** adjustment is warranted.

Precise Leveling

Precise leveling methods are required for engineering work that requires extreme accuracy. The process requires that special equipment and methods be used. Instruments used in precise leveling are specifically designed to obtain a high degree of accuracy in leveling. Improved optics in the telescope, improved level sensitivity, and carefully calibrated rod scales are all incorporated into the differential-leveling process. Methods have been developed to ensure that mistakes are eliminated and errors are minimized.

Typically when performing precise leveling, a method of leveling called *three-wire leveling* is used. This involves reading the center cross hair as well as the upper and lower "stadia" cross hairs. The basic process of leveling is the same, except that the three cross hair readings are averaged to improve the **precision** of each backsight and foresight value.

Another method that can be used to improve the precision of the level rod reading involves using an optical micrometer on the telescope. The optical micrometer is a rotating parallel-plate prism attached in front of the objective lens of the level. The prism enables the observer to displace the line of sight parallel with itself and set the horizontal cross hair exactly on the nearest rod graduation. The observer

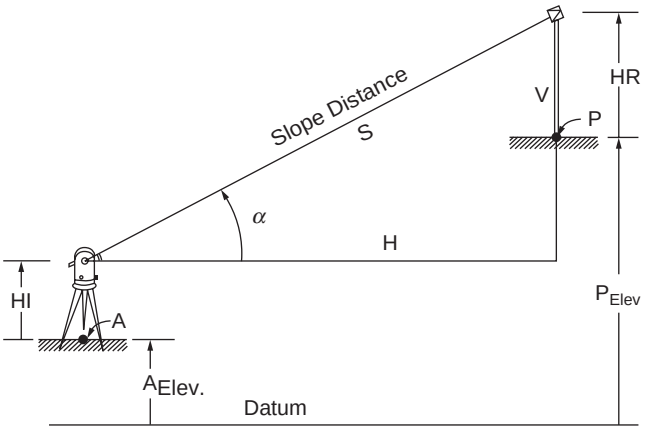


FIGURE 54.11 Trigonometric leveling in plane surveying.

adds the middle cross hair rod reading and the displacement reading on the micrometer to obtain a rod reading precise to the nearest 0.1 millimeter.

When long precise level routes are surveyed, it is necessary to account for the fact that the level surfaces converge as the survey proceeds north. The correction to be applied for convergence of level surfaces at different elevations can be calculated by

$$\text{Correction} = -0.0053 \sin 2\phi H \Delta\phi_{\text{rad}}$$

where ϕ is the latitude at the beginning point, H is the elevation at the beginning point, and $\Delta\phi$ is the change in latitude from beginning point to end point in radians.

Trigonometric Leveling

Trigonometric leveling is a method usually applied when a total station is used to measure the slope distance and the vertical angle to a point. This method is illustrated in Fig. 54.11. Assuming the total station is set up on a station of known elevation, the elevation of the unknown station is

$$V = S \sin\alpha$$
$$P_{\text{Elev}} = A_{\text{Elev}} + HI + V - HR$$

The precision of trigonometric elevations is determined by the uncertainty in the vertical angle measurement and the uncertainty in the atmospheric refraction effects. For long lines the effects of earth curvature and atmospheric refraction must be included.

54.4 Angle Measurement

Horizontal and Vertical Angles

The angular orientation of a line is expressed in terms of horizontal angles and vertical angles. Survey angles illustrated in Fig. 54.12 are defined by specifying the plane that contains the angle, the reference line or plane where the angle starts, the direction of turning, and the terminal line or plane where the angle ends.

Field angles that are measured in the horizontal plane include clockwise angles, counterclockwise angles, and deflection angles. The clockwise angle or "angle to the right," shown in Fig. 54.13, is measured from a backsight line, clockwise in the horizontal plane, to a foresight line. All transits or theodolites

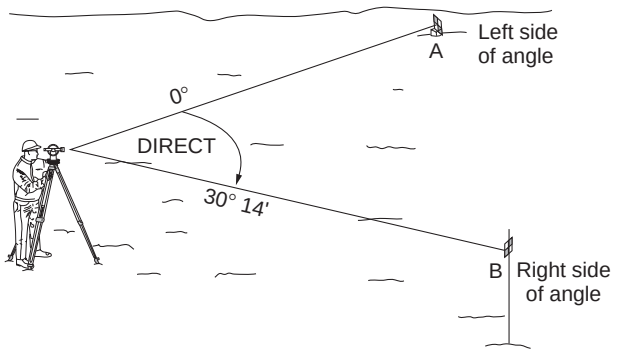

FIGURE 54.12 Horizontal survey angle.

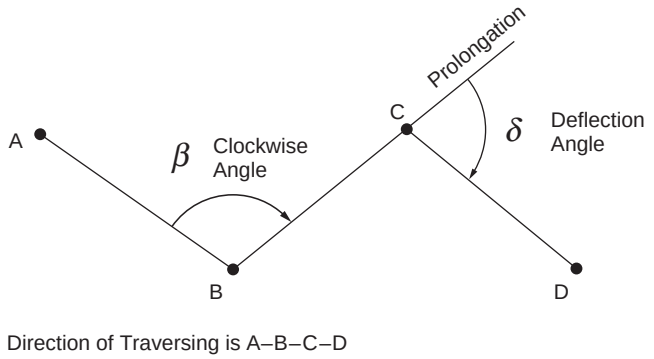

FIGURE 54.13 Horizontal field angles.

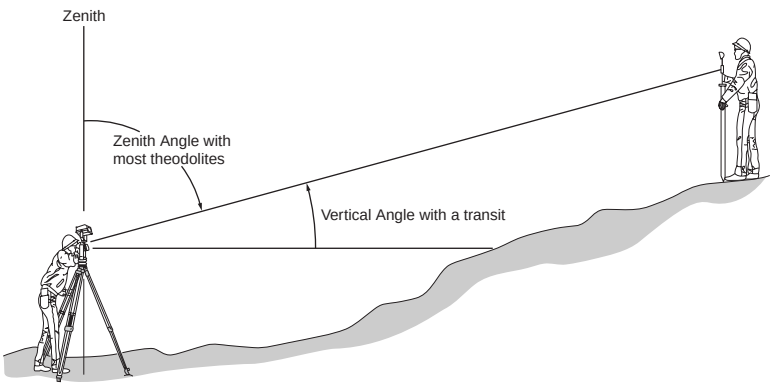

FIGURE 54.14 Vertical field angles.

have horizontal circles marked to read clockwise angles. Transits used to stake out projects typically include counterclockwise markings to facilitate laying out angles to either side of a reference line. A deflection angle, also shown in Fig. 54.13, is measured from the prolongation of the backsight line either left or right to the foresight line. It is commonly used in route centerline surveys.

Vertical angles are measured in the vertical plane as shown in Fig. 54.14. An instrument with a vertical circle graduated to measure vertical angles reads 0° when the instrument is level and the telescope is in the horizontal plane. The vertical angle increases to +90° above the horizontal and to −90° below the

horizontal plane. Many instruments today have vertical circles graduated to measure the zenith angle. Zero degrees is at the zenith point directly overhead on the vertical axis. The zenith angle will increase from 0° at the zenith to 90° at the horizon. The zenith angle is greater than 90° if the telescope is pointing below the horizon. The circle graduations continue to 180° at the nadir, to 270° at the horizon with the telescope reversed, and to 360° closing the circle at the zenith.

Direction Angles

Direction angles are horizontal angles from a north–south reference meridian to a survey line. Direction angles that are computed from field angles include bearings and azimuths. A bearing, as shown in Fig. 54.15, is the acute angle from the reference meridian to the survey line. It always includes the quadrant designation. An azimuth, as shown in Fig. 54.16, is the angle from the north end of the reference meridian clockwise to the survey line. It can have a magnitude from 0° to 360°, and a quadrant designation is not necessary.

Several different meridians can be used as a reference for direction. The direction of north at a point can be defined as any of the following:

- Astronomic north
- Geodetic north
- Magnetic north
- Grid north
- Assumed north

The first three types of meridians converge to their respective north poles on the earth. Therefore, they do not form the basis for a Cartesian coordinate system to be used for plane surveying. There is only a small angular difference between astronomic and geodetic north, but astronomic north is typically taken to be synonymous with the term "true north."

Magnetic north is the direction of the earth's magnetic field at a point. A declination angle measured from the geodetic meridian to the magnetic meridian defines the relationship between the two systems. However, since the direction of magnetic north changes with time, proper use of magnetic north must account for variation in the magnetic declination angle.

Grid north is used in plane surveying. The grid should be defined on an appropriate map projection, such as the state plane coordinate systems available in each state. Then a defined relationship exists between the geodetic and grid meridians.

Assumed north may be used for preliminary surveys, but it is not recommended for permanent work. If the stations on the ground are lost or destroyed, the basis of direction is lost and the survey cannot be retraced.

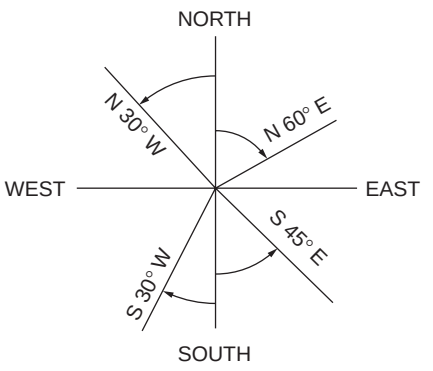

FIGURE 54.15 Bearing direction angles.

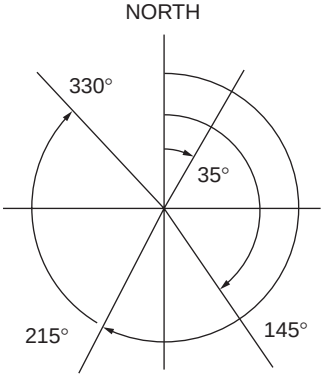

FIGURE 54.16 Azimuth direction angles.

Types of Instruments

There are many types of angle-measuring instruments used in surveying and construction. They include transits, theodolites, digital theodolites, and total stations. Even though the names are different, they look different, and the operation is slightly different, they all are used for the same purpose — angle measurement and layout.

Although there are a number of differences in the construction and features of transits, optical theodolites, and digital theodolites, the major difference is in the method of reading angles. Instruments are often classified according to the smallest interval, or so-called least count, that can be read directly in the instrument. The least count may range from 1 minute for a construction transit to 0.1 seconds for a first-order theodolite. Least counts from 10 seconds to 1 second are common in surveying and engineering instruments. The field engineer should become familiar with the instrument being used on the project.

Transit

The transit was developed to its present form during the 1800s. It has been used on construction projects from railroads across the wild west to the skyscrapers of the modern city. A good, solid, and reliable instrument, the transit is still used by many contractors today. However, optical theodolite technology, and now digital electronic technology, have passed it by. The major companies who manufactured transits have dropped them from their product line. They are slower to use than modern instruments, and they are not as easily adaptable to having an EDMI attached to them. Its major contribution to the field engineer today is that it is a good tool for learning the fundamentals of angle measurement. Its parts are exposed, making it easier to see what is going on in the manipulation of the clamps during the angle measurement process. By understanding the transit, one can easily move on to any other type of angle-measuring equipment.

Repeating Optical Theodolite

The repeating theodolite contains the same upper and lower clamp system as the transit; however, the reading of the angle is different because of the optical-reading capability. *Optical theodolite* is a term that was originally applied in Europe to instruments similar to the transit. However, as instrument technology progressed, *theodolite* became synonymous with a style of instrument that was enclosed, used a magnified optical system to read the angles, had a detachable tribrach with an optical plummet, used a three-screw leveling system, and was more precise than the transit. These features have made it much easier to use than the transit. The better optical theodolites have been "delicate" workhorses since they were introduced. That is, if they are properly cared for, they seem as though they will last forever because of their excellent construction and quality materials. However, they must be handled gently and carefully. A typical optical theodolite may have as many as 20 prisms or lenses as part of the optical angle-reading system. With a sharp bump, these can get out of alignment, which may render the instrument unusable. As with any surveying instrument, the theodolite cannot be exposed to inclement weather because of the optical system.

Scale-Reading Optical Theodolite. The typical scale-reading theodolite has a glass circle with a simple scale that is read directly. The scale is read where it is intersected by the degree readings from the circle. See Fig. 54.17 for an example scale reading. Simply read the degree that shows up in the window and observe where the degree index mark intersects the scale. Both the horizontal circle and the vertical circle are generally observed at the same time.

Micrometer-Reading Optical Theodolite. The micrometer-reading instrument also has a glass circle, but it does not have a scale. An adjustable micrometer is used to precisely read the circle and subdivide the degree intervals into minutes and seconds. See Fig. 54.18 for an example micrometer reading. The operator points the instrument and then uses the micrometer to align the degree index marks. The readings from the degree window and the micrometer window are added together to obtain the angle.

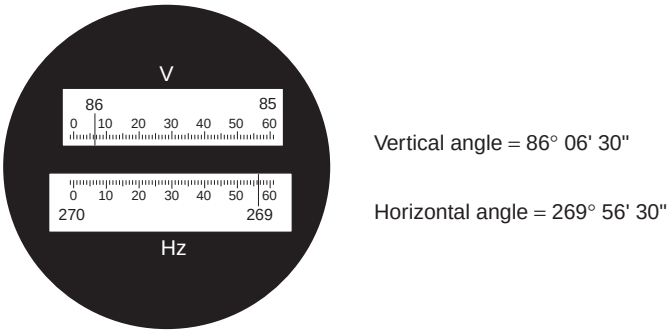

FIGURE 54.17 Scale angle reading display.

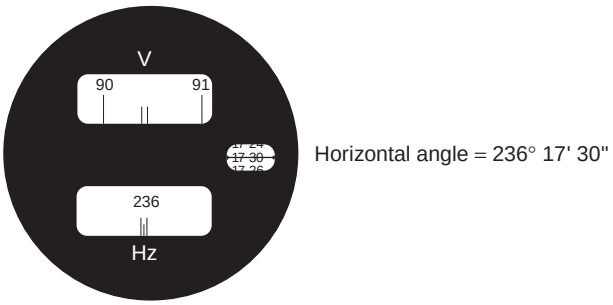

FIGURE 54.18 Micrometer angle reading display.

Directional Optical Theodolite

The directional theodolite is different from other instruments because it does not have a lower motion clamp and tangent screw. Directions (circle readings) are observed and recorded, and then the directions are subtracted to obtain the angle between the backsight and foresight lines of sight. This type of system has generally been used only on the most precise instruments. Zero is usually not set on the instrument. A micrometer is used to optically read the circle. Optical theodolites are excellent instruments, but, just like the transit, they are being surpassed by the technology of electronics.

Digital Theodolite

Digital electronics has recently entered the area of surveying instruments. Angles are no longer read optically, they are displayed on a screen in degree, minute, and second format. The micrometer has been replaced with electronic sensors that determine the angle quickly and precisely. The digital theodolite has the appearance of an optical theodolite in size and overall shape. The telescope, the clamping system, the tribrach, and the optical plummet are the same. Only the angle-measuring and -reading system is different. Digital theodolites are easy to read and fewer reading and recording blunders occur in the field. Because it is electronically based, the digital theodolite is like other electronic equipment — it either works or it doesn't work. If a circuit goes out or the battery is not charged, the instrument is unusable.

Most digital theodolites are designed to be interfaced with top-mounted EDMIs. This essentially has the impact of turning them into what are commonly called *semitotal stations,* which measure distances and angles and can be connected to a data collector for recording measurements. Sighting by both the instrument telescope and the EDMI scope are accomplished separately with this configuration.

Total Stations

The electronic total station is the ultimate in surveying measurement instruments. It is a combination digital theodolite and EDMI that allows the user to measure distances and angles electronically, calculate

coordinates of points, and attach an electronic field book to collect and record the data. Since the total station is a combination digital theodolite and EDMI, its cost is quite high compared to a single instrument. However, its capabilities are simply phenomenal in comparison to the way surveyors and engineers had to measure just a few years ago. Total stations with data collectors are especially effective when a large number of points are to be located in the field, as in topographic mapping. The data collector can be used to transfer the points to a computer for final map preparation. Conversely, complex projects can be calculated on a computer in the office and the data uploaded to the data collector. The data collector is then taken to the field and connected to the total station, where hundreds of points can be rapidly established by radial layout methods.

Instrument Components

Although there are differences between the transit, optical theodolite, and electronic theodolite, the construction and operation of all these instruments is basically the same. The three major components of any instrument are illustrated, using a transit, in Fig. 54.19. The upper plate assembly or the alidade, the lower plate assembly or the horizontal circle, and the leveling head are shown.

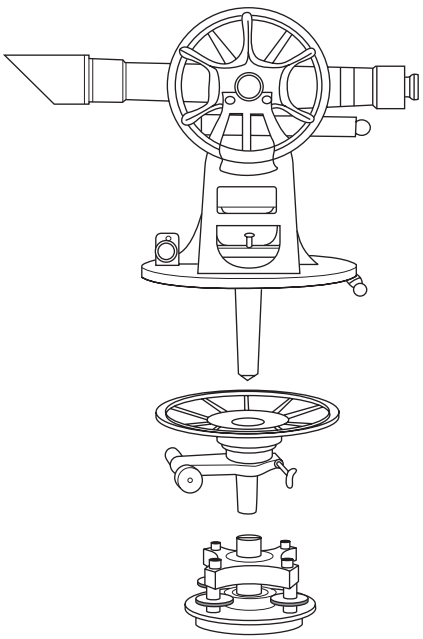

FIGURE 54.19 Transit or theodolite components.

Alidade Assembly

The alidade assembly consists of the telescope, the vertical circle, the vertical clamp and vertical tangent, the standards or structure that holds everything together, the verniers, plate bubbles, telescope bubble, and the upper tangent screw. A spindle at the bottom of the assembly fits down into a hollow spindle on the horizontal circle assembly.

Horizontal Circle Assembly

The horizontal circle assembly comprises the horizontal circle, the upper clamp that clamps the alidade and horizontal circle together, and the hollow spindle that accepts the spindle from the alidade and fits into the leveling head.

Leveling Head

The leveling head is the foundation that attaches the instrument assemblies to the tripod. It consists of leveling screws, the lower clamp that clamps the horizontal circle and the leveling head together, and a threaded bracket for attaching to the tripod.

Fundamental Relationships

All transit or theodolite instruments are designed around the same fundamental relationships and lines. These lines are shown in Fig. 54.20, again illustrated with a standard transit. The principal relationships between these lines are described as follows:

- The axis of the plate level(s) should be perpendicular to the vertical axis.
- The line of sight should be perpendicular to the horizontal axis.
- The horizontal axis should be perpendicular to the vertical axis.
- The vertical circle should read 0° when the instrument is leveled and the telescope is horizontal.

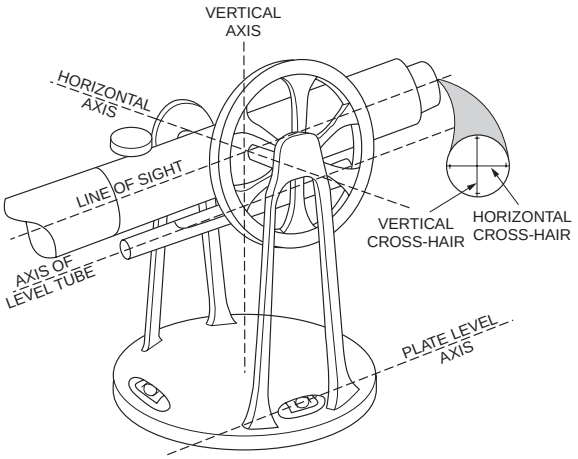

FIGURE 54.20 Principal adjustment relationships.

These four relationships are necessary to measure horizontal and vertical angles correctly. If the instrument will be used as a level, then the following must also be true: The axis of the telescope level should be parallel to the line of sight. Incorrect instrument adjustment in any of the relationships above will be readily apparent during field use of the instrument. Less apparent will be errors in the following relationships:

- The line of sight should be coincident with the telescope optical axis.
- The circles should be mounted concentrically on the axis of rotation.
- The circles should be accurately graduated throughout their circumference.
- The optical plummet should correctly position the instrument vertically over the field station.
- The vertical crosshair should lie in a vertical plane perpendicular to the horizontal axis.

Instrument Operation

The fundamental principle in using any transit or theodolite is the principle of reversion. That is, all operations should be performed in pairs, once with the telescope in the direct position and again with the telescope inverted on the horizontal axis or the reverse position. The correct value is the average of the two observations. Instrument operators should always use the double-centering ability of the instrument to eliminate the instrumental errors listed above. All of the principal instrument adjustment errors — except the vertical axis not being truly vertical — will be compensated for by averaging direct and reversed pairs of observations.

Prolonging a Straight Line

Prolonging a straight line from a backsight station through the instrument station to set a foresight station is a basic instrument operation that illustrates the principle of reversion. Often referred to as double centering, the steps to be performed are outlined as follows:

- Set up and level on the instrument station. With the telescope in the direct position, sight to the backsight station and clamp all horizontal motions.
- Rotate the telescope on the horizontal axis to the reverse position. Sight and set a point P_1 in the foresight direction as illustrated in Fig. 54.21.
- Revolve the instrument on the vertical axis and sight the backsight station again. The telescope will be in the reverse position.

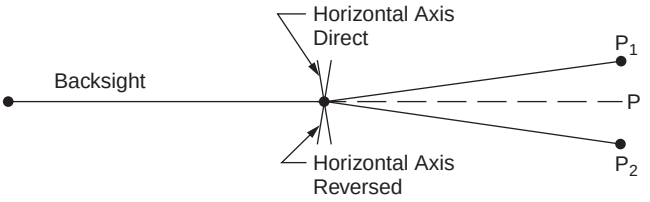

FIGURE 54.21 Double-centering to prolong a straight line.

- Rotate the telescope on the horizontal axis to the direct position. Sight and set a point P_2 in the foresight direction.
- Set the final point, *P*, on the true extension of the backsight line at the midpoint between P_1 and P_2.

If the stations are on nearly level terrain, the instrument error apparent in the distance between P_1 and P_2 is the line of sight not being perpendicular to the horizontal axis. When an instrument is severely out of adjustment, it is inconvenient to use it in the field. The instrument should be cleaned and adjusted periodically by a qualified instrument service technician.

Horizontal Angles by Repetition

The clamping system is probably the most important feature on an instrument because it determines the angle measurement procedures that can be used with the instrument. Transits and some optical theodolites have two horizontal motion clamps. They are commonly called the *upper motion* and *lower motion*. These types of instruments are called *repeating instruments* since the angle can be repeated and accumulated on the instrument circle. A procedure for measuring angles by repetition is outlined below.

1. Set the horizontal angle to read zero with the upper clamp and upper tangent screws. This is for convenience and any initial angle can be used.
2. Point on the backsight station with the telescope in the direct position using the lower motion. Check the circle reading and record the value in the notes.
3. Loosen the upper clamp (the lower clamp remains fixed), turn the instrument to the foresight station, and point using the upper motion clamp and upper tangent screw.
4. Note the circle reading. An approximate value of the angle can be obtained from this first turning.
5. Loosen the lower clamp, keeping the angle reading on the circle, and repeat steps 2 and 3. The number of repetitions must be an even number with half of the turnings with the telescope in the direct position and half of the turnings with the telescope in the reversed position.
6. With each turning, the circle reading will be incremented by the value of the angle. Thus, the average angle can be determined quickly by dividing the total angle read from the circle by the number of times the angle was measured.

Horizontal Angles by Direction

Many theodolites have only the upper horizontal motion clamp and the fine adjustment screw for pointing. A backsight cannot be made while holding an angle on the circle because there is no lower-motion fine adjustment for pointing. These types of instruments are called *direction instruments* since the circle reading is a clockwise direction angle from an arbitrary orientation of the 0° mark on the circle. A procedure for measuring angles by reading directions is outlined below.

1. Set the horizontal circle to read approximately 0° when pointed toward the backsight point with the telescope in the direct position.
2. Point on the backsight station with the telescope in the direct position using the upper-motion clamp and tangent screw. Read the horizontal circle and record the value in the notes.
3. Loosen the upper clamp and turn the instrument to point on the foresight station using the upper-motion clamp and tangent screw. Read the horizontal circle and record the value in the notes.

4. The clockwise angle is the difference between the foresight reading and the backsight reading.
5. Invert the telescope to the reversed position and repeat steps 2, 3, and 4. The circle readings should be exactly 180° from the telescope direct readings if there are no instrument adjustment, pointing, and reading errors. Of course the direct and reversed angles should agree closely and be averaged.
6. The direct and reversed pointings and the average angle constitute one position. Observe several positions and average the results to improve the precision of the final average angle. Advance the horizontal circle approximately between positions in order to distribute the readings around the circle.

54.5 Plane Survey Computations

Plane surveys use a three-dimensional Cartesian coordinate system as shown in Fig. 54.22. The horizontal components of distance, angle, and direction are assumed to be in the plane defined by the *X* and *Y* axes. The vertical components are along the *Z* axis or "up axis" in a vertical plane perpendicular to the horizontal *XY* plane.

Plane surveys referenced to such an orthogonal Cartesian coordinate system ignore the effect of earth curvature, the fact that the actual level surface is perpendicular everywhere to the direction of gravity. Such a computation scheme is suitable only for local project surveys of limited extent. Plane survey computations can be used for horizontal control surveys over a large areal extent if all observations and positions are properly referenced to a grid system using an appropriate map projection. State plane coordinate systems, defined for each state, are an example of this technique.

Traverse

A traverse is an efficient and flexible method of field surveying used to connect points of interest and establish horizontal and/or vertical coordinate reference values for project control. A traverse consists of interconnected straight lines along a traverse route. The straight lines meet at angle points that must be permanently marked by a traverse station monument. The length of each line is measured by field survey and then reduced to the horizontal reference plane. At each traverse station a horizontal angle is measured that will relate the directions of each line to one another in the horizontal plane. The elevation of each traverse station may also be determined if required for the purpose of the survey. Elevation can be

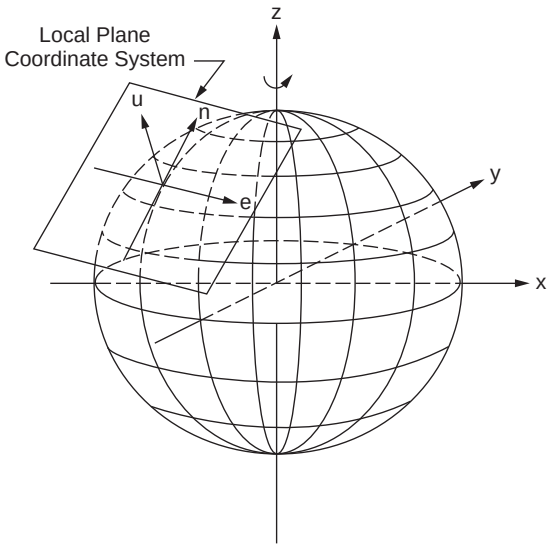

FIGURE 54.22 Local tangent plane coordinate system.

determined by trigonometric leveling as part of the traverse measurements or by differential leveling as a separate survey operation.

Traverses are characterized as open or closed. An open traverse has no check on computed direction or position at the end of the route. It is used only for preliminary and uncontrolled work. Whenever traverse stations are to be used to control subsequent engineering or surveying work, the route should be designed to close on the beginning traverse station or to close on another known point of equal or higher-order accuracy. The closed linear traverse between known control stations is preferred since it can best detect length measurement errors that affect the scale of a survey.

Traverse design is influenced by the purpose of the survey and the terrain through which the survey must progress. The overriding factor in determining where to locate traverse stations is the purpose of the station. In general, a traverse station becomes a reference system control point that is used for one or more of the following purposes:

1. Provide control for mapping by field survey or photogrammetric methods.
2. Provide control for construction layout.
3. Locate property boundaries.
4. Connect lines within the traverse and secondary traverses that may be added to the survey network.

The traverse station must be located so that it is accessible for its intended purpose. Secondary to the purpose of the survey, the traverse station should be located in an area where the monument will be stable and undisturbed for the intended useful life of the station.

The traverse survey route is flexible and generally follows the path of least resistance so that clear lines of sight from traverse station to traverse station are obtained. However, several guidelines should be kept in mind when planning a traverse route. First, avoid lines of sight that pass close to the intervening terrain between stations where atmospheric refraction will seriously degrade measurement accuracy. Second, avoid short lines of sight where setup errors and pointing errors can be the dominant measurement error source. Third, the traverse route should proceed along a generally straight path between terminal stations of a linear closed traverse. A useful rule of thumb is that the deviation of the route, as measured perpendicular to the straight-line path, should not exceed approximately one-third of the straight-line path length.

Accuracy standards for traversing are chosen to match the purpose of the survey. Specifications for the survey process are then developed to meet the required accuracy standards. For control surveys the accuracy standards and specifications developed by the Federal Geodetic Control Committee (FGCC) are often adopted. Surveys may be required to meet **first-**, **second-**, or **third-order accuracy.**

Surveying standards and specifications for surveys intended for other purposes may be available from a variety of sources, such as state statutes or licensing board rules regulating the type of survey, professional societies, or the agency contracting for the survey. For example, standards and specifications developed by ALTA/ACSM are often the requirements adopted for property surveys.

Traverse computations for local plane surveys are outlined in the following conventional procedure:

1. Draw a complete sketch of the traverse.
2. Compute the angular closure. If angle closure is equal to or less than allowable limit, adjust the angles; if angle closure is not acceptable, remeasure angles. The allowable closure is typically specified in the following form:

$$\text{Allowable closure} = c = k\sqrt{n}$$

   where
   c = allowable error in a series of measurements
   k = a value specified for the accuracy order of the survey
   n = number of angles measured
3. Compute the direction (azimuths or bearings) of all lines.

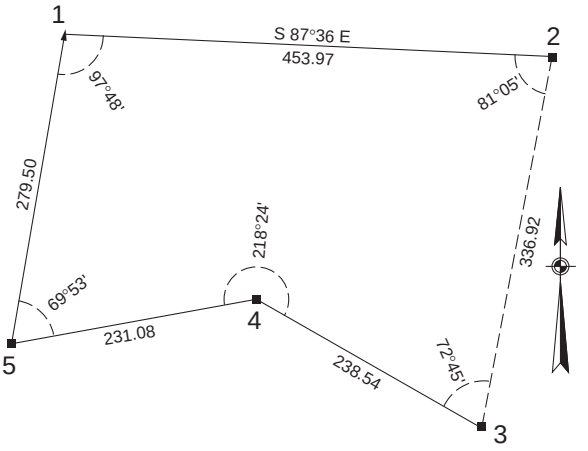

FIGURE 54.23 Sketch of sample traverse.

4. Compute the latitude and departure (relative nothing and relative easting components) for each course. Set up the computations in tabular form.

$$\text{Latitude} = L\cos\alpha$$
$$\text{Departure} = L\sin\alpha$$

5. Compute the traverse misclosure.

$$c = \sqrt{(\text{Latitude error})^2 + (\text{Departure error})^2}$$

6. Compute the traverse precision ratio.

$$\text{Precision} = \frac{\text{Closure error}}{\text{Perimeter}} = \frac{1}{?}$$

7. If the precision ratio is equal to or better than the allowable precision specified for the accuracy order of the survey, then distribute the error of closure throughout the traverse by an appropriate rule or by a least-squares adjustment.
8. Compute the coordinates of the traverse stations using the balanced latitudes and departures.
9. Determine the adjusted traverse course lengths and directions using an inverse computation from the adjusted coordinates or latitudes and departures.
10. Compute the area of a closed loop traverse.

The traverse shown in Fig. 54.23 is used to illustrate conventional plane survey traverse computations. The measured horizontal distance of each line is given, and horizontal angles are measured as interior angles on the closed loop traverse. The orientation of the traverse is defined by the azimuth given for line 1-2. The coordinate system is defined by known coordinates at station of 1000.00N, 500.00E.

1. Draw a complete sketch.
2. Compute the angular closure.

$$\begin{aligned}\text{Field angle closure} &= (97°48' + 81°05' + 72°45' + 218°24' + 69°53') \\ &\quad - (5-2)180° \\ &= 539°55' - 540°00' \\ &= .05'\end{aligned}$$

Assuming the angular error of closure is less than the maximum allowable, apply an equal correction to each angle.

$$\text{Correction per angle} = \frac{05'}{5 \text{ angles}} = 0°01' \text{ to be added to each angle}$$

3. Compute bearings or azimuths. Use the adjusted angles. In this example the azimuth of each line is computed beginning from the given azimuth for line 1-2.
   Azimuth 1 to 2 = given = 92°24′
   Azimuth 2 to 3 = 92°24′ + 180° – 81°06′ = 191°18′
   Azimuth 3 to 4 = 191°18′ + 180° – 72°46′ = 298°32′
   Azimuth 4 to 5 = 298°32′ + 180° – 218°25′ = 260°07′
   Azimuth 5 to 1 = 260°07′ – 180° – 69°54′ = 10°13′
   Azimuth 1 to 2 = 10°13′ + 180° – 97°49′ = 92°24′
   Note that the azimuth of the first line is computed at the end to verify that the computations close on the given azimuth. The adjusted angles and azimuths are shown in Fig. 54.24.
4. Compute the latitude and departure of each course, as shown in Table 54.3.

TABLE 54.3 Computed Latitudes and Departures.

Course	Length (L)	Azimuth α	Latitude $= L \cos \alpha$	Departure $= L \sin \alpha$
1-2	453.97	92°24′	–19.010	453.572
2-3	336.92	191°18′	–330.389	– 66.018
3-4	238.54	298°32′	113.943	– 209.567
4-5	231.08	260°07′	–39.663	– 227.651
5-1	279.50	10°13′	275.068	49.575
Sum =	1540.01	Error =	– 0.051	– 0.089
		Correction	+0.051	+0.089

5. Compute the traverse misclosure.

$$c = \sqrt{(-0.051)^2 + (-0.089)^2} = 0.102 \text{ ft}$$

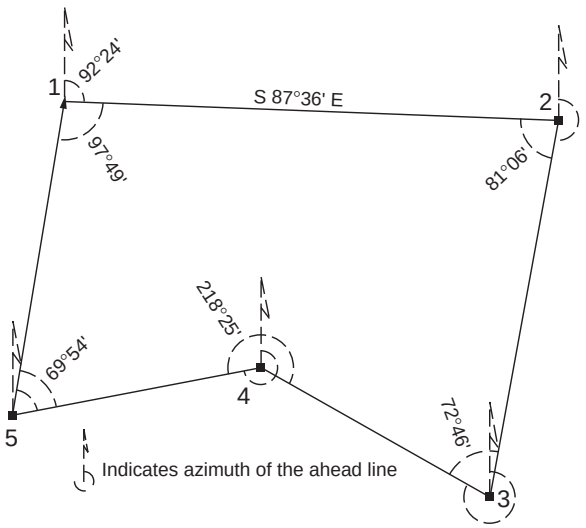

FIGURE 54.24 Adjusted angles and azimuths.

6. Compute the traverse precision.

$$\text{Precision} = \frac{0.102}{1540.01} = \frac{1}{15{,}100}$$

7. Distribute the error of closure. We will assume this precision is sufficient for the particular survey we are carrying out. Adjust the traverse by the compass rule:

$$C_{\text{lat}} = \frac{+\,0.051}{1540.01}\,(\text{Course length})$$

$$C_{\text{dep}} = \frac{+\,0.089}{1540.01}\,(\text{Course length})$$

8. Compute the balanced latitudes and departures by applying the corrections, and then calculate coordinates for all of the traverse stations, as shown in Table 54.4.

TABLE 54.4 Compass Rule Adjustment

	Applying Corrections		Balanced		Coordinates	
Station	Latitude	Departure	Latitude	Departure	North (Y)	East (X)
1					1000.00	500.00
	−19.010	453.572				
	+.015	+.026	−18.995	+453.598	−19.00	+453.60
2					981.00	953.60
	−330.389	−66.018				
	+.011	+.020	−330.378	−65.998	−330.38	−66.00
3					650.62	887.60
	113.943	−209.567				
	+.008	+.014	+113.951	−209.553	+113.95	−209.55
4					764.57	678.05
	−39.663	−227.651				
	+.008	+.013	−39.655	−227.638	−39.65	−227.64
5					724.92	450.41
	275.068	49.575				
	+.009	+.016	+275.077	+49.591	+275.08	+49.59
1					1000.00	500.00
		Total =	0.000	0.000	Check	Check

9. Adjusted traverse line lengths and directions are computed by an inverse computation using the adjusted latitudes and departures or adjusted coordinates, as shown in Table 54.5.

$$\text{Length} = \sqrt{Dep^2 + Lat^2}$$

$$= \sqrt{(X_j - X_i)^2 + (Y_j - Y_i)^2}$$

$$\text{Azimuth}_{ij} = \tan^{-1}\left[\frac{Dep_{ij}}{Lat_{ij}}\right] = \tan^{-1}\left[\frac{X_j - X_i}{Y_j - Y_i}\right]$$

10. Compute the area. Traverse areas are typically computed using the coordinate method, as shown in Table 54.6.

$$\text{Area} = \frac{\left|\sum_1^n X_i Y_{i-1} - \sum_1^n X_i Y_{i+1}\right|}{2}$$

TABLE 54.5 Adjusted Lengths and Azimuths

Station	Coordinates North (Y)	Coordinates East (X)	Adjusted Length	Adjusted Azimuth
1	1000.00	500.00		
			454.00	92°23′53″
2	981.00	953.60		
			336.90	191°17′50″
3	650.62	887.60		
			238.53	298°32′12″
4	764.57	678.05		
			231.07	260°07′05″
5	724.92	450.41		
			279.51	10°13′10″
1	1000.00	500.00		

TABLE 54.6 Coordinate Method for Area

Station	Coordinates North (Y)	Coordinates East (X)	Double Area —	Double Area 0
1	1000.00	500.00	490,500	
2	981.00	953.60	620,431	953,600
3	650.62	887.60	678,632	870,736
4	764.57	678.05	491,532	441,153
5	724.92	450.41	450,410	344,370
1	1000.00	500.00		362,460
		Total =	2,731,505	2,972,319

The traverse area equals one-half of the difference between the totals of the double-area columns.

$$\text{Traverse area} = \left|\frac{2{,}731{,}505 - 2{,}972{,}319}{2}\right| = 120{,}407 \text{ ft}^2 = 2.764 \text{ acres}$$

Partitioning Land

Partitioning land is a problem that can usually be classified according to one of two types of dividing line — a line of known direction or a line through a known point. A preliminary line is often required that satisfies the given condition. Then the line is translated parallel to itself in the first condition or pivoted about the known point in the second condition to obtain the required area.

As an illustration of these methods, partition the adjusted traverse of the previous section so that 65,000 square feet lie west of a true north line. A preliminary cutoff line bearing true north can be constructed through station 4, as shown in Fig. 54.25. The area west of the preliminary line is 50,620 square feet. The line is translated true east a distance X so that 14,380 square feet will be added to the west parcel. The parcel added is a trapezoid as shown in Fig. 54.25, and the area can be expressed by

$$14{,}380 = 227.97X - \frac{1}{2}X(X \tan\theta_1) + \frac{1}{2}X(X \tan\theta_2)$$

where $\theta_1 = 2°23'53''$ and $\theta_2 = 28°32'12''$. Rearranging this expression results in a quadratic equation, and the solution for X is found to be 59.22 feet. Then the following distances can be determined for the final cutoff line:

6-7 = 59.27 feet
4-8 = 67.41 feet
7-8 = 257.69 feet

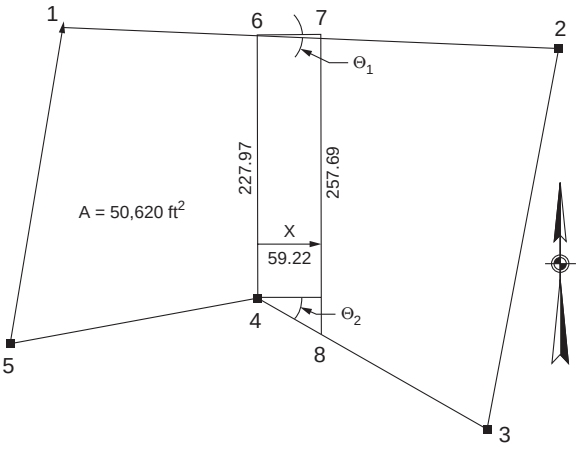

FIGURE 54.25 Partition by sliding a line.

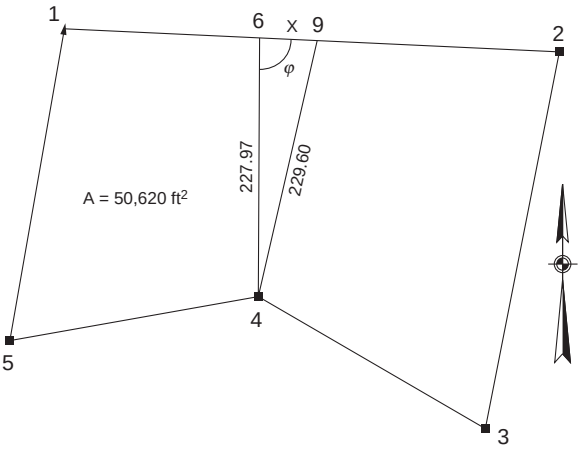

FIGURE 54.26 Partition by pivoting a line.

Next, partition the adjusted traverse so that 55,000 square feet lie west of a line through station 4. The same preliminary cutoff line can be used. The line is pivoted easterly about station 4 so that 4380 square feet is added to the west parcel. The parcel added is a triangle as shown in Fig. 54.26, and the area can be expressed by

$$4380 = \frac{1}{2}227.97X \sin\phi$$

where $\phi = 87°36'07''$. The solution for X is found to be 38.46 feet, and the final cutoff line is

$$4\text{-}9 = 229.60 \text{ feet, } 9°38'05'' \text{ azimuth}$$

54.6 Horizontal Curves

Horizontal curves are used in route projects to provide a smooth transition between straight-line tangent sections. These curves are simple circular curves. The components of a circular curve are illustrated in Fig. 54.27. The design of a circular curve requires that two curve elements be defined and then the

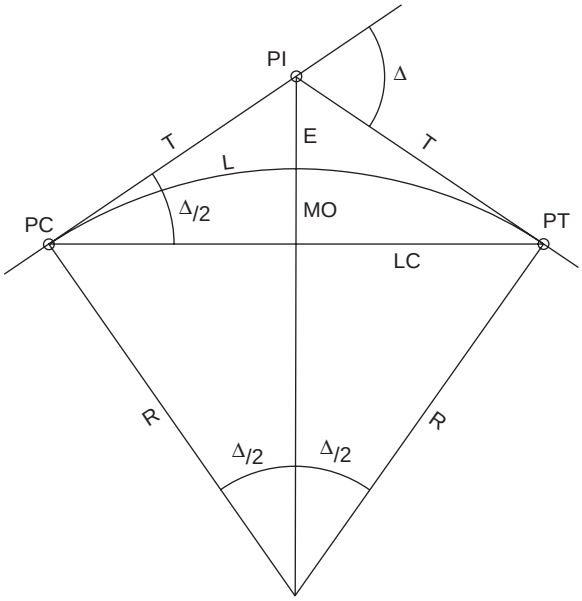

FIGURE 54.27 Circular horizontal curve components.

remaining elements are determined by computation. In the typical case the intersection angle of the tangents is determined by field survey and the curve radius is chosen to meet design specifications such as vehicle speed and minimum sight lengths. The principal relationships between curve elements are

$$T = R \tan\frac{\Delta}{2}$$

$$LC = \frac{1}{2}R \sin\frac{\Delta}{2}$$

$$E = R\left(\sec\frac{\Delta}{2} - 1\right)$$

$$MO = R\left(1 - \cos\frac{\Delta}{2}\right)$$

$$L = R\frac{\pi}{180°}\Delta$$

Important angle relationships used when solving circular curve problems are illustrated in Fig. 54.28.

When a circular curve is staked out in the field, the most common method is to lay off deflection angles at the PC station. Field layout notes are prepared for a theodolite set up at the PC. A backsight is taken along the tangent line to the PI, and foresights are made to specific stations on the curve using the computed deflection angles. If a total station instrument is used the chord distance from the PC to the curve station can be used to set the station. If a tape is used the chord distance measured from the previous station on the curve is intersected with the line of sight to locate the curve station.

The following example illustrates both types of distances used to lay out a horizontal curve. Determine the field information necessary to stake out the horizontal curve shown in Fig. 54.29. First determine the stationing of the PC and PT. The tangent distance is

$$T = R \tan\left(\frac{\Delta}{2}\right) = 572.96 \quad \tan 40°00' = 503.46 \text{ ft}$$

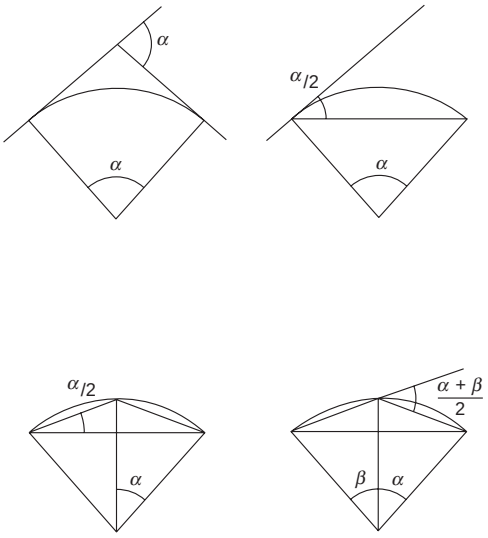

FIGURE 54.28 Angle relationships for circular curves.

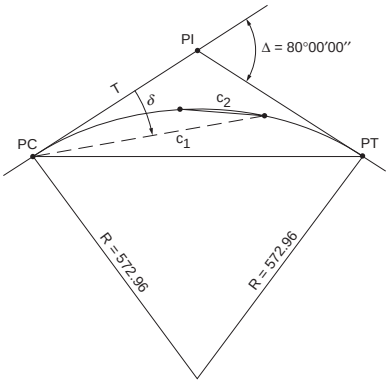

FIGURE 54.29 Horizontal curve layout.

so the PC station is

$$\text{PC sta.} = \text{PI sta.} - T = 100 + 50.00 - 5 + 03.46 = 95 + 46.54 \text{ ft}$$

The arc length of the curve is

$$L = R\left(\frac{\pi}{180^\circ}\right)\delta = 800.00 \text{ ft}$$

so the PT station is

$$\text{PT sta.} = \text{PC sta.} + L = 95 + 46.54 + 8 + 00.00 = 103 + 46.54 \text{ ft}$$

The central angle subtended per station of arc length is

$$D^\circ \text{ per sta} = \frac{\Delta}{L} = \frac{80^\circ 00'}{800.00} = 10^\circ 00'$$

TABLE 54.7 Deflection Angles and Chords for Layout of a Horizontal Curve

Station	Deflection Angle δ	Arc Length from PC	Chord Length C_1	Chord Length C_2
PC 95 + 46.54				
		53.46	53.44	53.44
96 + 00.00	2°40′23″			
		153.46	153.00	99.87

PT 103 + 46.54	Δ/240°00′00″			

The deflection angle is one-half of the central angle or

$$\delta \text{ per sta} = \frac{D}{2} = 5°00'$$

$$\delta \text{ per ft} = \frac{D}{200} = 0°03'$$

Recall the equation for a chord

$$C = 2R \sin\left(\frac{d}{2}\right)$$

where d is the central angle of the chord. The full stations falling on the curve are determined, and the values in Table 54.7 are computed for an instrument set up on the PC and oriented by a backsight on the PI. Note that C_1 denotes the chord measured from the PC and that C_2 denotes the chord measured from the previous station on the curve.

Alternative methods for staking out a curve include tangent offsets, chord offsets, middle ordinates, and radial staking out from the radius point of the curve or from the PI station.

54.7 Vertical Curves

Vertical curves are used in vertical alignments of route projects to provide a smooth transition between grade lines. These curves are usually equal-tangent parabolic curves. The point of vertical intersection, PVI, of the entrance and exit grade lines always occurs at the midpoint of the length of curve. The length of curve and all station distances are measured in the horizontal plane. Figures 54.30 and 54.31 illustrate the geometry of a sag and crest vertical curve, respectively. Note the following relationships between the curves in Figs. 54.30 and 54.31. The top curve is the elevation curve. The middle curve is the grade curve; it is the derivative of the elevation curve. The bottom curve is the rate of change of grade curve; it is the derivative of the grade curve. The rate of change of grade is always a constant, r, for a parabolic vertical curve.

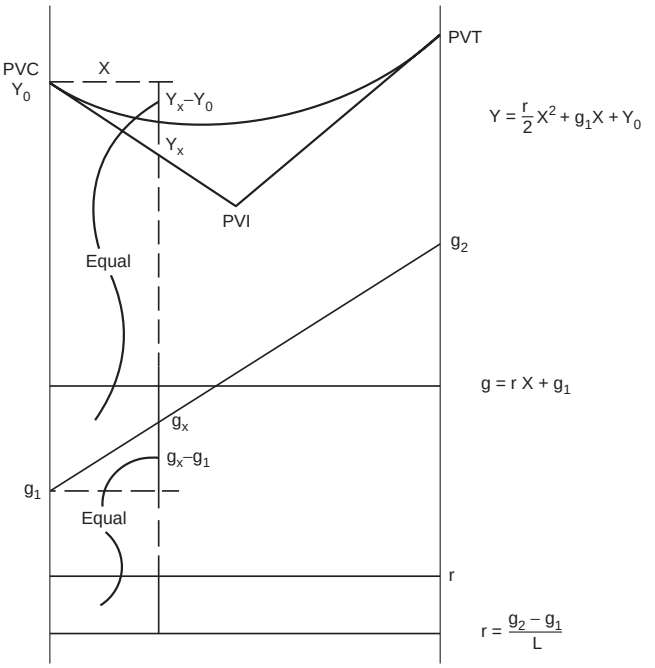

FIGURE 54.30 Sag vertical curve.

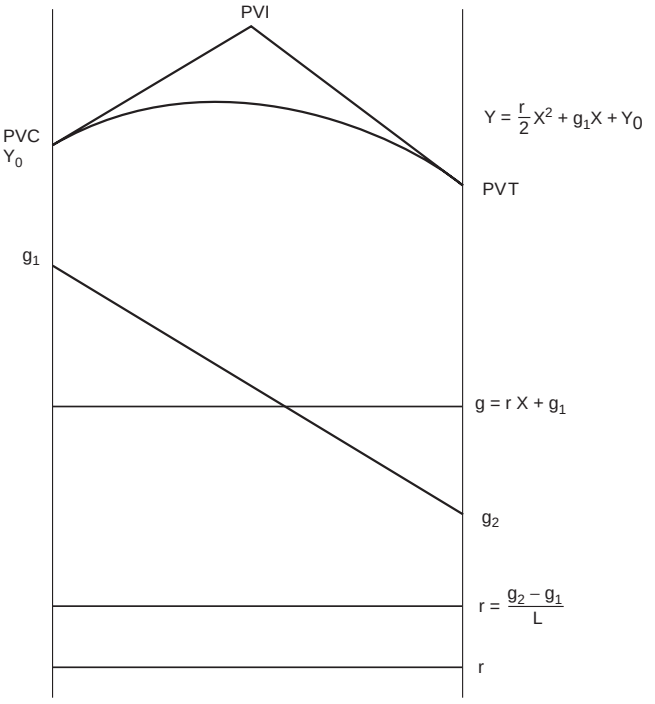

FIGURE 54.31 Crest vertical curve.

Since the curves are related by the derivative/integration operation, the change in an ordinate value on one curve is equal to the area under the next lower curve. Therefore, in Fig. 54.30, the change in elevation on the curve from the PVC to a point at a distance X on the curve is equal to the trapezoidal area under the grade curve

$$Y_x - Y_0 = X\left(\frac{g_x + g_1}{2}\right)$$

The change in grade over the same interval X is the rectangular area under the rate of change of grade curve.

$$g_x - g_1 = Xr$$

These relationships can be used to calculate design values for vertical curves.

For example, suppose it is necessary to find the elevation and station of the high point for the crest curve in Fig. 54.31. Let X equal the distance to the high point that occurs at the point where the grade curve crosses the zero line. The change in grade must be equal to the area under the rate of change of grade curve.

$$\begin{aligned} g_{\text{high}} &= 0 \\ 0 - g_1 &= X(-r) \\ X &= \frac{-g_1}{-r} \end{aligned}$$

Note that r is negative for a crest value. Then the station of the high point is

$$P_{\text{high}} = \text{PC} + X$$

The elevation of the high point can be found by evaluating the elevation equation at the known value of X or by calculating the area under the grade curve:

$$\begin{aligned} Y_x - Y_0 &= X\left(\frac{g_1 + 0}{2}\right) \\ Y_x &= Y_0 + X\left(\frac{g_1}{2}\right) \end{aligned}$$

The design of a vertical curve involves choosing the length of the curve that will satisfy design speed considerations, earthwork considerations, and sometimes geometric constraints. As an example of a constrained design, suppose a PVC is located at station 150 + 40.00 and elevation 622.45 feet. The grade of the back tangent is –3.00% and the grade of the forward tangent is –7.00%. It is required that a vertical curve between these tangents must pass through station 152 + 10.00 at elevation 619.05 feet. Since this is a sag vertical curve, refer to Fig. 54.30. The value of r can be expressed as

$$r = \frac{(+7) - (-3)}{L} = +\frac{10}{L}$$

The distance X from the PVC to the known station on the curve is

$$X = (152 + 10.00) - (150 + 40.00) = 1.70000 \text{ stations}$$

The grade at the known station is then found from

$$g_x = (-3) + \left(\frac{10}{L}\right)1.7 = \frac{17}{L} - 3$$

The change in elevation from the PVC to the known station can be set equal to the trapezoidal area under the grade curve.

$$619.05 - 622.45 = 1.70000 \left[\frac{\left(\frac{17}{L} - 3\right) + (-3)}{2} \right]$$

Solving this expression for L, we obtain

$$L = 8.5000 \text{ stations} = 850.00 \text{ ft}$$

The design elevation at each full station along this curve can be evaluated from the parabolic equation. First the station and elevation of the PVI is

$$\text{PVI sta} = \text{PVC sta} + \frac{L}{2} = 150 + 40.00 + 4 + 25.00 = 154 + 65.00 \text{ ft}$$

$$\text{PVI elev} = \text{PVC elev} + g_1 \frac{L}{2} = 622.45 + (-3)(4.25) = 609.70 \text{ ft}$$

and the station and elevation of the PVT is

$$\text{PVT sta} = \text{PVI sta} + \frac{L}{2} = 154 + 65.00 + 4 + 25.00 = 158 + 90.00 \text{ ft}$$

$$\text{PVT elev} = \text{PVI elev} + g_1 \frac{L}{2} = 609.70 + (+7)(4.25) = 639.45 \text{ ft}$$

Then the elevation of any point on the curve is found from

$$Y = \left(\frac{r}{2}\right) X^2 + g_1 X + Y_0 = \left(\frac{10}{17}\right) X^2 - 3X + 622.45$$

A tabular solution for each full station along the curve is given in Table 54.8.

54.8 Volume

The determination of volume is necessary before a project begins, throughout the project, and at the end of the project. In the planning stages, volumes are used to estimate project costs. After the project is started, volumes are determined so the contractor can receive partial payment for work completed. At the end, volumes are calculated to determine final quantities that have been removed or put in place to make final payment. The field engineer is often the person who performs the field measurements and calculations to determine these volumes. Discussed here are the fundamental methods used by field engineers.

General

To compute volumes, field measurements must be made. This typically involves determining the elevations of points in the field by using a systematic approach to collect the needed data. If the project is a roadway, cross-sectioning is used to collect the data that are needed to calculate volume.

If the project is an excavation for a building, borrow-pit leveling will be used to determine elevations of grid points to calculate the volume. Whatever the type of project, the elevation and the location of

TABLE 54.8 Vertical Curve Elevations

Station	X sta	$(r/2)X^2$	g_1X	Elevation Y ft
PVC 150 + 40.00				Y_0 622.45
	0.6000	0.21	−1.80	
151 + 00.00				620.86
	1.6000	1.50	−4.80	
152 + 00.00				619.15
	2.6000	3.98	−7.80	
153 + 00.00				618.83
	3.6000	7.62	−10.80	
154 + 00.00				619.27
	4.6000	12.45	−13.80	
155 + 00.00				621.10
	5.6000	18.45	−16.80	
156 + 00.00				624.10
	6.6000	25.62	−19.80	
157 + 00.00				628.27
	7.6000	33.98	−22.80	
158 + 00.00				633.63
	8.5000	42.50	−25.50	
PVT 158 + 90.00				639.45

points will need to be determined. It is the responsibility of the field engineer to determine the most efficient method of field measurement to collect the data.

However, it should be mentioned that sometimes volumes can be determined using no field measurements at all. In some situations the contractor may be paid for the number of truckloads removed. Keeping track of the number of trucks leaving the site is all that may be necessary. However, this isn't a particularly accurate method since the soil that is removed expands or swells and takes up a larger amount of space than the undisturbed soil. Depending on how the project is bid, it is sometimes accurate enough.

Field Measurements for Volume Computations

Measurements for volume are nothing more than applying basic distance and elevation measurements to determine the locations and elevations of points where the volume is to be determined. It usually is not practical to take the time to collect data everywhere there is a slight change in elevation. Therefore, it must be understood that volume calculations do not give exact answers. Typically, approximations must be made and averages determined. The field engineer will analyze the data and make decisions that result in the best estimate of the volume.

Area

The key to volume calculation is the determination of area. Most volume calculation formulas contain within them the formula for an area, which is simply multiplied by the height to determine the volume. For instance, the area of a circle is pi times the radius squared. The volume of a cylinder is the area of the circle times the height of the cylinder. If an area can be determined, it is generally easy to determine the volume.

Counting Squares

Approximation is possible by plotting the figure to scale on cross-sectional paper and counting the squares. Each square represents x number of square feet. Incomplete squares along the edges of the cross section are visually combined and averaged.

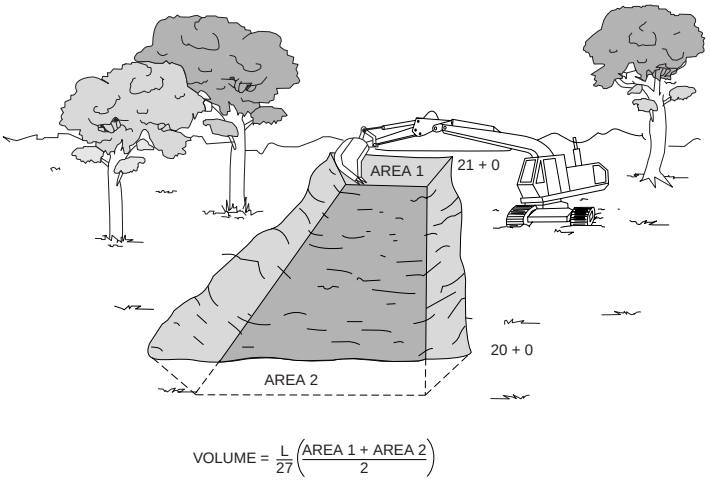

FIGURE 54.32 Average end area method.

Planimeter

The electromechanical digital planimeter is a quick method of determining the area of irregularly shaped figures. The irregular shape is drawn to scale and the planimeter is used to trace the outline of the shape. Inputting a scale factor into the planimeter results in a digital readout of the area.

Geometric Formula

Although a shape at first may seem irregular, it is often possible to break it into smaller regular shapes such as squares, rectangles, triangles, trapezoids, etc., that will allow the use of standard geometric formulas to determine the area. This method may be cumbersome because of all the shapes that may need to be calculated.

Cross-Section Coordinates

If cross-sectional field data are available, use of this data is the recommended method of calculating volume. Once understood, this process is fast and the most accurate way of determining area. Cross section data collected on a project represent elevation and location information for points on the ground. These points can be used as coordinates to determine area.

Volume Computations — Road Construction

In road construction the shape of the ground must be changed to remove the ups and downs of the hills and valleys for the planned roadway. Often mountains of dirt must be moved to create a gentle grade for the roadway. Payment for the removal and placement of dirt is typically on a unit cost basis. That is, the contractor will be paid per cubic yard of soil and will receive a separate price per cubic yard of rock. It can be seen that accurate determination of the volume moved is critical to the owner and to the contractor. Each wants an accurate volume so payment for the work is correct.

For road projects, cross sections of the ground elevations are measured at the beginning of the project, during the project, and at the end of the project. Comparisons between final cross sections and original cross sections are used to determine the volume moved. Areas of the cross sections are most easily determined by using the elevations of the points and their locations from the centerline (coordinates).

The average end area method uses the end areas of adjacent stations along a route and averages them. Refer to Fig. 54.32. This average is then multiplied by the distance between the two end areas to obtain the volume between them. In formula form the process is as follows:

$$\text{Volume} = \frac{L}{27}\left(\frac{\text{Area 1} + \text{Area 2}}{2}\right)$$

where L represents the distance between the cross-sectional end areas being used in the formula, and 27 represents the number of cubic feet in 1 cubic yard. Dividing cubic feet by 27 converts to cubic yards.

Volume Computations — Building Excavation

A method known as *borrow-pit leveling* can be used effectively to determine volume on building projects. A grid is established by the field engineer and elevations on the grid points are determined both before the excavation begins and when the work is complete.

The borrow-pit method uses a grid and the average depth of the excavation to determine the volume. Before the excavating begins the field engineer creates a grid over the entire area where the excavation is to occur. Elevation data are collected at each of the grid points and recorded for future reference. At any time during the excavating, the field engineer can reestablish the grid and determine new elevations for each of the field points. Using the average height formula shown below, the volume of soil removed from each grid area can be determined. Refer to Fig. 54.33. The smaller the grid interval, the more accurate the volume.

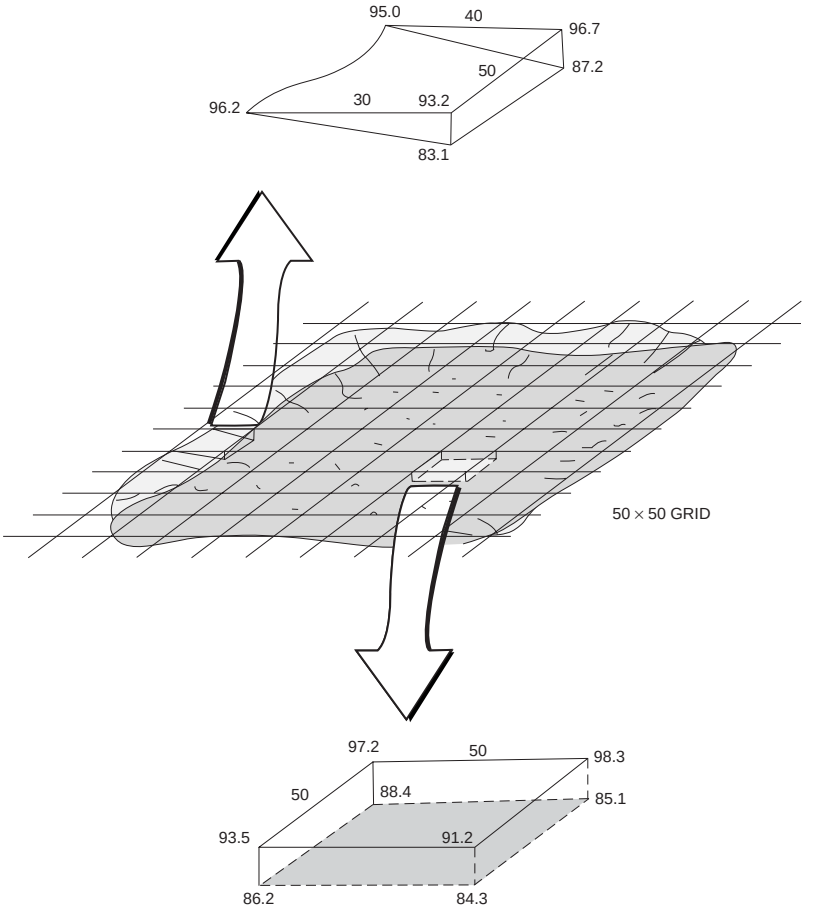

FIGURE 54.33 Borrow-pit method.

Summary

Only two general methods of calculating volumes have been presented here. There are many others that are very specific for the particular situation. For example, when determining volumes along a roadway, there is a constant transition from cut to fill to cut to fill, etc. To more accurately compute the volume, a prismoidal formula is used. The field engineer should check with textbooks that discuss in detail route surveying and earthwork for additional information.

Defining Terms

Accuracy — Refers to the degree of perfection obtained in measurements. It is a measure of the closeness to the true value.

Accuracy (first-order) — The highest accuracy required for engineering projects such as dams, tunnels, and high-speed rail system.

Accuracy (second-order) — The accuracy required for large engineering projects such as highways, interchanges, and short tunnels.

Accuracy (third-order) — The accuracy required for small engineering projects and topographic mapping control.

Accuracy ratio — The ratio of error of closure to the distance measured for one or a series of measurements.

Axis of level bubble — The line tangent to the top inner surface of a spirit level at the center of its graduated scale, and in the plane of the tube and its center of curvature.

Calibration — The process of comparing an instrument or chain with a standard.

Closure — The amount by which a value of a quantity obtained by surveying fails to agree with a value (of the same quantity) determined. It is also called *misclosure* or *error of closure*.

Datum — A reference elevation such as mean sea level or, in the case of some construction projects, a benchmark with elevation 100.00.

Horizontal axis — The axis about which the telescope rotates vertically.

Least squares — A mathematical method for the adjustment of observations based on the theory of probability.

Line of sight — The line extending from an instrument along which distinct objects can be seen. The straight line between two points.

Mean sea level — The average height of the surface of the sea measured over the complete cycle of high and low tides (a period of 18.6 years).

Monument — A physical structure that marks the location of a survey point.

Nadir — The point directly under the observer. The direction that a plumb bob points.

Precision — The closeness of one measurement to another. The degree of refinement in the measuring process. The repeatability of the measuring operation.

Random errors — Errors that are accidental in nature and always exist in all measurements. They follow the laws of probability and are equally high or low.

Refraction — The bending of light rays as they pass through the atmosphere.

Systematic error — Those errors that occur in the same magnitude and the same sign for each measurement of a distance, angle, or elevation. Can be eliminated by mechanical operation of the instrument or by mathematical formula.

Vertical — The direction in which gravity acts.

Zenith — The point directly above a given point on earth.

55.1 Introduction

This chapter covers the basic mathematical and physical aspects of modeling the size and shape of the earth and its gravity field. Terrestrial and space geodetic measurement techniques are reviewed. Extra attention is paid to the relatively new technique of satellite surveying using the Global Positioning System (GPS). GPS surveying has not only revolutionized the art of navigation, but also brought about an efficient positioning technique for a variety of users, engineers not the least. It is safe to say that any

geometry-based data collecting scheme profits in some sense from the full constellation of 24 GPS satellites. Except for the obvious applications in geodesy, surveying, and photogrammetry, the use of GPS is applied in civil engineering areas such as transportation (truck and emergency vehicle monitoring, intelligent vehicle and highway systems, etc.) and structures (monitoring of deformation of such structures as water dams). Even in areas such as forestry and agriculture (crop yield management), GPS provides the geometric backbone to the (geographic) information systems.

Modern geodetic measurement techniques, using signals from satellites orbiting the earth, necessitate a new look at the science of geodesy. Classical measurement techniques divided the theoretical problem of mapping small or large parts of the earth into a horizontal issue and a vertical issue. Three-dimensional measurement techniques "solve" the geodetic problem at once. However, careful interpretation of these three-dimensional results is still warranted, probably even more so than before. This chapter will center around this three-dimensional approach. Less attention has been devoted to classical issues such as the computation of a geodesic on an ellipsoid of revolution. Although this issue still has some importance, the reader is referred to the textbooks listed at the end of this chapter.

More than in classical texts, three-dimensional polar (spherical) coordinate representations are used, because the fundamental issues pertaining to various geodetic models are easier to illustrate by spherical coordinates than by ellipsoidal coordinates. Moreover, the increased influence of the satellite techniques in everyday surveying revives the use of three-dimensional polar coordinate representations, because the three-dimensional location of a point is equally accurately represented by Cartesian, spherical, or ellipsoidal coordinates.

Throughout this chapter all coordinate frames are treated as right-handed orthogonal trihedrals. Because this also applies to curvilinear coordinates, the well-known geographic coordinates of latitude and longitude are presented in the following order:

1. Longitude (positive in east direction), λ
2. Latitude, ψ or ϕ
3. Height, h

In short, $\{\lambda, \psi, h\}$ or $\{\lambda, \phi, h\}$. Local Cartesian and curvilinear coordinates are treated in a similar fashion.

55.2 Coordinate Representations

For a detailed discussion on coordinate frames and transformations, the reader is referred to Chapter 53.

Two-Dimensional

In surveying and mapping, two-dimensional frames are widely used. The different representations are all dependent, because only two numbers suffice to define the location of a point in 2-space. Cartesian frames consist of two often perpendicular reference axes, denoted as x and y, or e (easting) and n (northing). Points in two-dimensional frames are equally well represented by polar coordinates r (distance from an origin) and α (polar angle, counted positive counterclockwise from a reference axis).

We have

$$\begin{aligned} x &= r\cos\alpha \\ y &= r\sin\alpha \end{aligned} \tag{55.1}$$

The polar coordinates $\{r, \alpha\}$ are expressed in terms of the Cartesian counterparts by

$$\begin{aligned} r &= \sqrt{x^2 + y^2} \\ \alpha &= \arctan\left(y/x\right) \end{aligned} \tag{55.2}$$

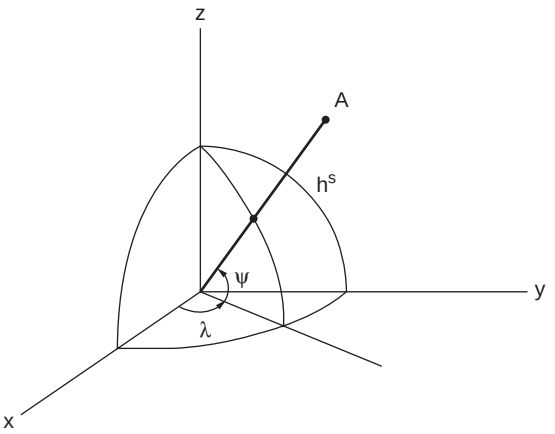

FIGURE 55.1 (Geographic) spherical coordinates: longitude λ, latitude ψ, and height *h*.

Three-Dimensional

Three-Dimensional Cartesian Coordinates

There are various ways to represent points in a three-dimensional space. One of the most well known is the representation by the so-called Cartesian coordinates *x*, *y*, *z*; we represent the position of a point *A* through three distances *x*, *y*, *z* (coordinates) to three perpendicular planes, the *yz*-, *xz*-, *xy*-planes, respectively. The intersecting lines between the three planes are the perpendicular coordinate axes. The position of point *A* is thought to be represented by the vector x with elements {*x*, *y*, *z*}:

$$\mathrm{x} = \begin{pmatrix} x \\ y \\ z \end{pmatrix} \tag{55.3}$$

Three-Dimensional Polar Coordinates: Spherical

We may want to represent the position of these points with respect to a sphere with radius *R*. We make use of so-called spherical coordinates. The earth's radius is about $R = 6371.0$ km.

The sphere is intersected by two perpendicular planes, both of which pass through the center *O* of the sphere: a reference *equatorial plane* (perpendicular to the rotation axis) and a reference *meridian plane* (through the rotation axis). The angle between the vector and the reference equatorial plane is called *latitude,* ψ. The angle between the reference meridian plane (through Greenwich) and the local meridian plane (through *A*) is called *longitude,* λ (positive east). The distance to the surface of the sphere we call *height, h*. Consequently, the position of a point *A* is represented by {λ, ψ, *h*} or {λ, ψ, *r*} or {λ, ψ, $R + h$}; see Fig. 55.1.

Three-Dimensional Polar Coordinates: Ellipsoidal

The earth is flattened at the poles, and the average ocean surface has about the shape of an ellipsoid. For this reason, ellipsoidal coordinates are more often used in geodesy than spherical coordinates. We express the coordinates with respect to an ellipsoid of revolution with an equatorial semimajor axis *a* and a polar semiminor axis *b*. The semimajor axis thus represents the equatorial radius, and *b* is the distance between the ellipsoidal origin and the poles. The equation of such an ellipsoid of revolution is

$$\frac{x^2}{a^2} + \frac{y^2}{a^2} + \frac{z^2}{b^2} = 1 \tag{55.4}$$

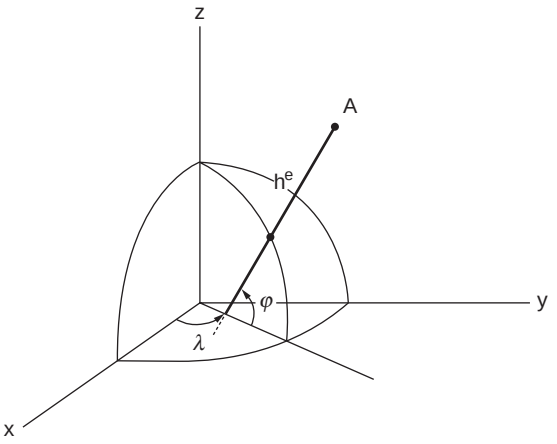

FIGURE 55.2 (Geodetic) ellipsoidal coordinates: longitude λ, latitude ϕ, and height *h*.

For the earth we have a semimajor axis $a = 6378.137$ km and a semiminor axis $b = 6356.752$ km. This means that the poles are about 21.4 km closer to the center of the earth than the equator.

The flattening of the earth is expressed by f and the (first) eccentricity by e:

$$f = \frac{a-b}{a}\left(\approx 1/298.257\right) \tag{55.5}$$

$$e^2 = \frac{a^2-b^2}{a^2}\left(\approx 0.00669438\right) \tag{55.6}$$

See also Fig. 55.2.

Coordinate Transformations

We have to distinguish between two classes of transformations:

- Transformations between dissimilar coordinate representations. An example would be the transformation between Cartesian coordinates and curvilinear coordinates, such as the ellipsoidal (geodetic) coordinates.
- Transformations between similar coordinate frames. An example is the relation between geocentric Cartesian coordinates and topocentric Cartesian coordinates.

The latter group is to be discussed subsequently in this section, after we consider transformations between dissimilar coordinate representations.

Transformations of Different Kind

If the *xy*-plane coincides with the equator plane and the *xz*-plane with the reference meridian plane, then we have the following:

From spherical to Cartesian:

$$\begin{pmatrix} x \\ y \\ z \end{pmatrix} = \left(R+h\right)\begin{pmatrix} \cos\psi\cos\lambda \\ \cos\psi\sin\lambda \\ \sin\psi \end{pmatrix} \tag{55.7}$$

From Cartesian to spherical:

$$\begin{pmatrix} \lambda \\ \psi \\ h \end{pmatrix} = \begin{pmatrix} \arctan\left(y/x\right) \\ \arctan\left(z/\sqrt{x^2+y^2}\right) \\ \sqrt{x^2+y^2+z^2}-R \end{pmatrix} \tag{55.8}$$

From ellipsoidal to Cartesian:

$$\begin{pmatrix} x \\ y \\ z \end{pmatrix} = \begin{pmatrix} \left[N \quad +h\right]\cos\phi\cos\lambda \\ \left[N \quad +h\right]\cos\phi\sin\lambda \\ \left[N\left(1-e^2\right)+h\right]\sin\phi \end{pmatrix} \tag{55.9}$$

with

$$N = \frac{a}{W} \tag{55.10}$$

and

$$W = \sqrt{1-e^2\sin^2\phi} \tag{55.11}$$

In these equations the variable N has a distinct geometric significance: it is the radius of curvature in the prime vertical plane. This plane goes through the local normal and is perpendicular to the meridian plane. In other words, N describes the curvature of the curve obtained through the intersection of the prime vertical plane and the ellipsoid. The curve formed through the intersection of the meridian plane and the ellipsoid is given by M; see Fig. 55.3.

The varying radius of curvature M of the elliptic meridian is given by

$$M = \frac{a\left(1-e^2\right)}{W^3} \tag{55.12}$$

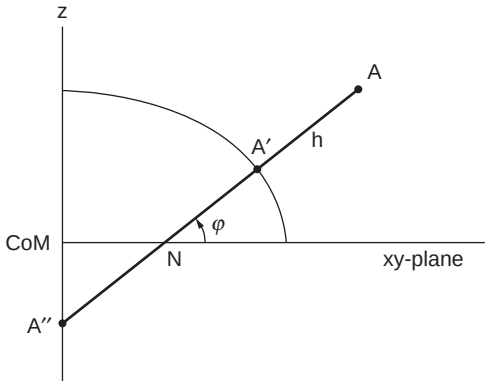

FIGURE 55.3 Meridian plane through point *A*.

From Cartesian to ellipsoidal:

$$\lambda = \arctan\left(y/x\right) \tag{55.13}$$

The geodetic latitude ϕ can be obtained by the following iteration scheme, starting with an approximate value for the geodetic latitude ϕ_0:

$$\begin{aligned} \phi_0 &= \arctan\left[z\Big/\sqrt{x^2+y^2}\right] \\ N_0 &= a\Big/\sqrt{1-e^2\sin^2\phi_0} \\ \phi &= \arctan\left[\left(z+N_0e^2\sin\phi_0\right)\Big/\sqrt{x^2+y^2}\right] \end{aligned} \tag{55.14}$$

If $|\phi - \phi_0| > \varepsilon$, then set ϕ_0 equal to ϕ and go back to the computation of N. After the iteration, h can be computed directly:

$$h = \sqrt{[x^2+y^2+\left(z+Ne^2\sin\phi\right)^2]} - N \tag{55.15}$$

Through more cumbersome expressions an analytical solution for the geodetic latitude ϕ as a function of the Cartesian coordinates $\{x, y, z\}$ is possible.

Transformations of Same Kind

Orthogonal Transformations: Translation and Rotation

When groups of points are known in their relative position with respect to each other, the use of Cartesian coordinates ($3n$ in total) becomes superfluous. As a matter of fact there are 6° of freedom, since the position of the origin with respect to the group is arbitrary, as is the orientation of the frame axes. Two groups of identical points or, for that matter, one and the same group of points expressed in two arbitrary but different coordinate frames may be represented by the following orthogonal transformation:

$$\mathbf{x}' = \mathbf{R}\mathbf{x} + \mathbf{t}' \tag{55.16}$$

or

$$\mathbf{x}' = \mathbf{R}\left(\mathbf{x} - \mathbf{t}\right) \tag{55.17}$$

The vector $\mathbf{t}$ represents a translation. In Eq. (55.16) $\mathbf{t}'$ represents the vector of the old origin in the new frame ($\mathbf{x}' - \mathbf{t}' = \mathbf{R}\mathbf{x}$); in Eq. (55.17) $\mathbf{t}$ represents the coordinates of the origin of the new frame in the old coordinate frame. The relation between the two translation vectors is represented by

$$\mathbf{t}' = -\mathbf{R}\mathbf{t} \tag{55.18}$$

The rotation matrix describes the rotations around the frame axes. In Eq. (55.16) $\mathbf{R}$ describes a rotation around axes through the origin of the $\mathbf{x}$ frame; in Eq. (55.17) $\mathbf{R}$ describes a rotation around axes through the origin of the $\mathbf{x}'$ frame. We define the sense of rotations as follows: the argument angle of the rotation matrix is taken positive if one views the rotation as counterclockwise from the positive end of the rotation axis looking back to the origin. For an application relating coordinates in a local frame to coordinates in a global frame, see Section 55.3.

In the above equations we assume three consecutive rotations, first around the z axis with an argument angle γ, then around the y axis around an argument angle β, and finally around the x axis with the argument angle α. So we have

$$\mathbf{R} = \mathbf{R}_1\left(\alpha\right)\mathbf{R}_2\left(\beta\right)\mathbf{R}_3\left(\gamma\right) \tag{55.19}$$

$$\boldsymbol{R} = \begin{pmatrix} \cos\beta & \cos\beta\sin\gamma & -\sin\beta \\ -\cos\alpha\sin\gamma + \sin\alpha\sin\beta\cos\gamma & \cos\alpha\cos\gamma + \sin\alpha\sin\beta\sin\gamma & \sin\alpha\cos\beta \\ \sin\alpha\sin\gamma + \cos\alpha\cos\beta\cos\gamma & -\sin\alpha\cos\gamma + \cos\alpha\sin\beta\sin\gamma & \cos\alpha\cos\beta \end{pmatrix} \quad (55.20)$$

One outcome of these orthogonal transformations is an inventory of variables that are invariant under these transformations. Without any proof, these include lengths, angles, sizes and shapes of figures, and volumes — important quantities for the civil or survey engineer.

Similarity Transformations: Translation, Rotation, Scale

In the previous section we saw that the relative location of n points can be described by fewer than $3n$ coordinates: $3n - 6$ quantities (for instance, an appropriate choice of distances and angles) are necessary but also sufficient. Exceptions have to be made for so-called critical configurations such as four points in a plane. The 6 is nothing else than the 6° of freedom supplied by the orthogonal transformation: three translations and three rotations.

A simple but different reasoning leads to the same result. Imagine a tetrahedron in a three-dimensional frame. The four corner points are connected by six distances. These are exactly the six necessary but sufficient quantities to describe the form and shape of the tetrahedron. These six sides determine this figure completely in size and shape. A fifth point will be positioned by another three distances to any three of the four previously mentioned points. Consequently, a field of n points (in three-dimensional) will be necessarily but sufficiently described by $3n - 6$ quantities. We need these types of reasoning in three-dimensional geometric satellite geodesy.

If we just consider the *shape* of a figure spanned by n points (we are not concerned any more about the *size* of the figure), then we need even one quantity fewer than $3n - 6$ (i.e., $3n - 7$); we are now ignoring the scale, in addition to the position and orientation of the figure. This constitutes just the addition of a seventh parameter to the six-parameter orthogonal transformation: the scale parameter σ. So we have

$$\mathbf{x}' = \sigma\mathbf{R}\mathbf{x} + \mathbf{t}' \quad (55.21)$$

or

$$\mathbf{x}' = \sigma\mathbf{R}(\mathbf{x} - \mathbf{t}) \quad (55.22)$$

Here also the vector $\mathbf{t}$ represents a translation. In Eq. (55.21) $\mathbf{t}'$ represents the vector of the old origin in the new scaled and rotated frame ($\mathbf{x}' - \mathbf{t}' = \sigma\mathbf{R}\mathbf{x}$); in Eq. (55.22) $\mathbf{t}$ represents the coordinates of the origin of the new frame in the old coordinate frame. The relation between the two translation vectors is represented by

$$\mathbf{t}' = -\sigma\mathbf{R}\mathbf{t} \quad (55.23)$$

One outcome of these similarity transformations is an inventory of invariant variables under these transformations. Without any proof, these include length ratios, angles, shapes of figures, and volume ratios, which are important quantities for the civil or survey engineer. The reader is referred to Leick and van Gelder [1975] for other important properties.

Curvilinear Coordinates and Transformations

One usually prefers to express coordinate differences in terms of the curvilinear coordinates on the sphere or ellipsoid or even locally, rather than in terms of the Cartesian coordinates. This approach also facilitates the study of effects due to changes in the adopted values for the reference ellipsoid (so-called *datum transformations*).

Curvilinear Coordinate Changes in Terms of Cartesian Coordinate Changes

Differentiating the transformation formulas in which the Cartesian coordinates are expressed in terms of the ellipsoidal coordinates (see Eq. (55.9)), we obtain a differential formula relating the Cartesian total differentials $\{dx, dy, dz\}$ as a function of the ellipsoidal total differentials $\{d\lambda, d\phi, dh\}$:

$$\begin{pmatrix} dx \\ dy \\ dz \end{pmatrix} = \mathbf{J} \begin{pmatrix} d\lambda \\ d\phi \\ dh \end{pmatrix} \tag{55.24}$$

The projecting matrix $\mathbf{J}$ is nothing else than the Jacobian of partial derivatives:

$$\mathbf{J} = \frac{\partial(x, y, z)}{\partial(\lambda, \phi, h)} \tag{55.25}$$

Carrying out the differentiation, one finds

$$\mathbf{J} = \begin{bmatrix} -(N+h)\cos\phi\sin\lambda & -(M+h)\sin\phi\cos\lambda & \cos\phi\cos\lambda \\ (N+h)\cos\phi\cos\lambda & -(M+h)\sin\phi\sin\lambda & \cos\phi\sin\lambda \\ 0 & (M+h)\cos\phi & \sin\phi \end{bmatrix} \tag{55.26}$$

On inspection, this Jacobian $\mathbf{J}$ is simply a product of a rotation matrix $\mathbf{R}(\lambda, \phi)$ and a metric matrix $\mathbf{H}(\phi, h)$ [Soler, 1976]:

$$\mathbf{J} = \mathbf{RH} \tag{55.27}$$

or, in full,

$$\mathbf{R} = \begin{bmatrix} -\sin\lambda & -\sin\phi\cos\lambda & \cos\phi\cos\lambda \\ \cos\lambda & -\sin\phi\sin\lambda & \cos\phi\sin\lambda \\ 0 & \cos\phi & \sin\phi \end{bmatrix} \tag{55.28}$$

$$\mathbf{H} = \begin{bmatrix} (N+h)\cos\phi & 0 & 0 \\ 0 & (M+h) & 0 \\ 0 & 0 & 1 \end{bmatrix} \tag{55.29}$$

It turns out that the rotation matrix $\mathbf{R}(\lambda, \phi)$ relates the local $\{e, n, u\}$ frame to the geocentric $\{x, y, z\}$ frame; see further the discussion of earth-fixed coordinates in Section 55.3. The metric matrix $\mathbf{H}(\phi, h)$ relates the curvilinear coordinates' longitude, latitude, and height in radians and meters to the curvilinear coordinates, all expressed in meters.

The formulas just given are the simple expressions relating a small arc distance ds to the corresponding small angle $d\alpha$ through the radius of curvature. The radius of curvature for the longitude component is equal to the radius of the local parallel circle, which in turn

$$\begin{pmatrix} d\lambda_m \\ d\phi_m \\ dh_m \end{pmatrix} = \mathbf{H}(\phi, h) \begin{pmatrix} d\lambda_{\text{rad}} \\ d\phi_{\text{rad}} \\ dh_m \end{pmatrix} \tag{55.30}$$

equals the radius of curvature in the prime vertical plane times the cosine of the latitude.

The power of this evaluation is more apparent if one realizes that the inverse Jacobian, expressing the ellipsoidal total differentials $\{d\lambda, d\phi, dh\}$ as a function of the Cartesian total differentials $\{dx, dy, dz\}$, is easily obtained, whereas an analytic solution expressing the geodetic ellipsoidal coordinates in terms of the Cartesian coordinates is extremely difficult to obtain. So, we have

$$\begin{pmatrix} d\lambda \\ d\phi \\ dh \end{pmatrix} = \mathbf{J}^{-1} \begin{pmatrix} dx \\ dy \\ dz \end{pmatrix} \tag{55.31}$$

With the relationship in Eq. (55.27) $\mathbf{J}^{-1}$ becomes simply

$$\mathbf{J}^{-1} = \left(\mathbf{RH}\right)^{-1} = \mathbf{H}^{-1}\mathbf{R}^{\mathbf{T}} \tag{55.32}$$

or, in full,

$$\mathbf{J}^{-1} = \begin{bmatrix} \dfrac{\sin\lambda}{(N+h)\cos\phi} & \dfrac{\cos\lambda}{(N+h)\cos\phi} & 0 \\ \dfrac{-\sin\phi\cos\lambda}{M+h} & \dfrac{-\sin\phi\sin\lambda}{M+h} & \dfrac{\cos\phi}{M+h} \\ \cos\phi\cos\lambda & \cos\phi\sin\lambda & \sin\phi \end{bmatrix} \tag{55.33}$$

This equation gives a simple analytic expression for the inverse Jacobian, whereas the analytic expression for the original function is virtually impossible.

Curvilinear Coordinate Changes Due to a Similarity Transformation

Differentiating Eq. (55.21) with respect to the similarity transformation parameters α, β, γ, t'_x, t'_y, t'_z, and σ, one obtains

$$\begin{pmatrix} dx \\ dy \\ dz \end{pmatrix}_7 = \mathbf{J}_7 \begin{pmatrix} d\alpha \\ d\beta \\ d\gamma \\ dt'_x \\ dt'_y \\ dt'_z \\ d\sigma \end{pmatrix} \tag{55.34}$$

with

$$\mathbf{J}_7 = \frac{\partial(x, y, z)}{\partial(\alpha, \beta, \gamma, t'_x, t'_y, t'_z, \sigma)} \tag{55.35}$$

The Jacobian $\mathbf{J}_7$ is a matrix that consists of seven column vectors

$$\mathbf{J}_7 = \left[\mathbf{j}_1 \middle| \mathbf{j}_2 \middle| \mathbf{j}_3 \middle| \mathbf{j}_4 \middle| \mathbf{j}_5 \middle| \mathbf{j}_6 \middle| \mathbf{j}_7\right] \tag{55.36}$$

with

$$\begin{aligned}\mathbf{j}_1 &= \sigma\mathbf{L}_1\mathbf{R}_1(\alpha)\mathbf{R}_2(\beta)\mathbf{R}_3(\gamma)\mathbf{x}\\ &= \sigma\mathbf{L}_1\mathbf{R}\mathbf{x}\\ &= \mathbf{L}_1\mathbf{x}'\end{aligned} \tag{55.37}$$

$$\mathbf{j}_2 = \sigma\mathbf{R}_1(\alpha)\mathbf{L}_2\mathbf{R}_2(\beta)\mathbf{R}_3(\gamma)\mathbf{x} \tag{55.38}$$

$$\begin{aligned}\mathbf{j}_3 &= \sigma\mathbf{R}_1(\alpha)\mathbf{R}_2(\beta)\mathbf{R}_3(\gamma)\mathbf{L}_3\mathbf{x}\\ &= \sigma\mathbf{R}\mathbf{L}_3\mathbf{x}\end{aligned} \tag{55.39}$$

$$\left[\mathbf{j}_4\middle|\mathbf{j}_5\middle|\mathbf{j}_6\right] = \mathbf{I} \qquad (3\times 3)\text{ identity matrix} \tag{55.40}$$

$$\begin{aligned}\mathbf{j}_7 &= \mathbf{R}_1(\alpha)\mathbf{R}_2(\beta)\mathbf{R}_3(\gamma)\mathbf{x}\\ &= \mathbf{R}\mathbf{x}\\ &= (\mathbf{x}' - \mathbf{t}')/\sigma\end{aligned} \tag{55.41}$$

since

$$\partial\mathbf{R}_1/\partial\alpha = \mathbf{L}_1\mathbf{R}_1(\alpha) = \mathbf{R}_1(\alpha)\mathbf{L}_1 \tag{55.42}$$

$$\partial\mathbf{R}_2/\partial\beta = \mathbf{L}_2\mathbf{R}_2(\beta) = \mathbf{R}_2(\beta)\mathbf{L}_2 \tag{55.43}$$

$$\partial\mathbf{R}_3/\partial\gamma = \mathbf{L}_3\mathbf{R}_3(\gamma) = \mathbf{R}_3(\gamma)\mathbf{L}_3 \tag{55.44}$$

and

$$\mathbf{L}_1 = \begin{pmatrix}0 & 0 & 0\\ 0 & 0 & 1\\ 0 & -1 & 0\end{pmatrix} \tag{55.45}$$

$$\mathbf{L}_2 = \begin{pmatrix}0 & 0 & -1\\ 0 & 0 & 0\\ 1 & 0 & 0\end{pmatrix} \tag{55.46}$$

$$\mathbf{L}_3 = \begin{pmatrix}0 & 1 & 0\\ -1 & 0 & 0\\ 0 & 0 & 0\end{pmatrix} \tag{55.47}$$

The advantage of these **L** matrices is that in many instances the derivative matrix (product) can be written as the original matrix pre- or postmultiplied by the corresponding **L** matrix [Lucas, 1963].

Curvilinear Coordinate Changes Due to a Datum Transformation

Differentiating Eq. (55.9) with respect to the semimajor axis a and the flattening f, one obtains

$$\begin{pmatrix} dx \\ dy \\ dz \end{pmatrix}_{a,f} = \mathbf{J}_{a,f} \begin{pmatrix} da \\ df \end{pmatrix} \tag{55.48}$$

with (see Soler and van Gelder [1987])

$$\mathbf{J}_{a,f} = \frac{\partial(x, y, z)}{\partial(a, f)} \tag{55.49}$$

and

$$\mathbf{J}_{a,f} = \begin{bmatrix} \cos\phi\cos\lambda/W & a(1-f)\sin^2\phi\cos\phi\cos\lambda/W^3 \\ \cos\phi\sin\lambda/W & a(1-f)\sin^2\phi\cos\phi\sin\lambda/W^3 \\ (1-e^2)\sin\phi/W & (M\sin^2\phi - 2N)(1-f)\sin\phi \end{bmatrix} \tag{55.50}$$

Also see Soler and van Gelder [1987] for the second-order derivatives.

Curvilinear Coordinate Changes Due to a Similarity and a Datum Transformation

The curvilinear effects of a redefinition of the coordinate frame due to a similarity transformation and a datum transformation are computed by adding Eqs. (55.34) and (55.48) and substituting them into

$$\begin{pmatrix} d\lambda \\ d\phi \\ dh \end{pmatrix} = \mathbf{J}^{-1} \begin{pmatrix} dx \\ dy \\ dz \end{pmatrix} \tag{55.51}$$

with

$$\begin{pmatrix} dx \\ dy \\ dz \end{pmatrix} = \begin{pmatrix} dx \\ dy \\ dz \end{pmatrix}_7 + \begin{pmatrix} dx \\ dy \\ dz \end{pmatrix}_{a,f} \tag{55.52}$$

55.3 Coordinate Frames Used in Geodesy and Some Additional Relationships

Earth-Fixed

Earth-Fixed Geocentric

From the moment satellites were used to study geodetic aspects of the earth, one had to deal with modeling the motion of the satellite (a point mass) around the earth's center of mass (CoM). The formulation of the equations of motion is easiest when referred to the CoM. This point became almost naturally the origin of the coordinate frame in which the earthbound observers were situated. For the orientation of

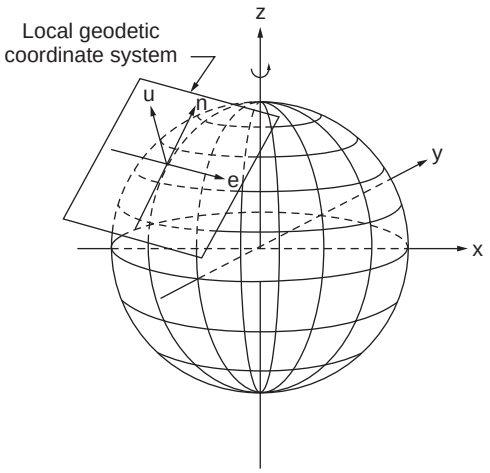

FIGURE 55.4 A geocentric and a local Cartesian coordinate frame.

the x and z axes, see the discussion of spherical three-dimensional polar coordinates in Section 55.2 and the discussion of polar motion in this section.

Earth-Fixed Topocentric Cartesian

An often used local frame is the earth-fixed topocentric coordinate frame. The origin resides at the position of the observer's instrument. Although in principle arbitrary, one often chooses the x axis pointing east, the y axis pointing north, and the z axis pointing up. This e, n, u frame is again a right-handed frame. With respect to the direction of the local z or u axis, various choices are possible: the u axis coincides with the negative direction of the local gravity vector (the first axis of a leveled theodolite) or along the normal perpendicular to the surface of the ellipsoid.

An Important Relationship Using an Orthogonal Transformation

The transformation formulas between a geocentric coordinate frame and a local coordinate frame are (see Fig. 55.4):

$$\begin{pmatrix} x \\ y \\ z \end{pmatrix} = \mathbf{R}_3\left(-\lambda_a - \frac{\pi}{2}\right)\mathbf{R}_1\left(+\phi_a - \frac{\pi}{2}\right)\begin{pmatrix} e \\ n \\ u \end{pmatrix} + \begin{pmatrix} \left[N_a + h_a\right]\cos\phi_a \cos\lambda_a \\ \left[N_a + h_a\right]\cos\phi_a \sin\lambda_a \\ \left[N_a\left(1-e^2\right) + h_a\right]\sin\phi_a \end{pmatrix} \tag{55.53}$$

One should realize that this transformation formula is of the orthogonal type shown in Eq. (55.16):

$$\mathbf{x}' = \mathbf{R}\mathbf{x} + \mathbf{t}' \tag{55.54}$$

whereby $\mathbf{x}'$ = the geocentric Cartesian vector
$\mathbf{R} = \mathbf{R}_3(-\lambda_a - \pi/2)\mathbf{R}_1(\phi_a - \pi/2)$
$\mathbf{t}'_a$ = the location of a in the (new) geocentric frame and is equal to:

$$\mathbf{t}'_a = \begin{pmatrix} \left[N_a + h_a\right]\cos\phi_a \cos\lambda_a \\ \left[N_a + h_a\right]\cos\phi_a \sin\lambda_a \\ \left[N_a\left(1-e^2\right) + h_a\right]\sin\phi_a \end{pmatrix} \tag{55.55}$$

The rotation matrix $\mathbf{R} = \mathbf{R}_3(-\lambda_a - \pi/2)\mathbf{R}_1(\phi_a - \pi/2)$ is given in Section 55.2 as Eq. (55.28).

Given the geocentric coordinates $\{x, y, z\}$ of an arbitrary point (e.g., a satellite), if one wants to compute the local coordinates $\{e, n, u\}$ of that point, the local frame being centered at a, then one obtains for the inverse relationship

$$\begin{pmatrix} e \\ n \\ u \end{pmatrix} = \mathbf{R}_1\left(-\phi_a + \frac{\pi}{2}\right)\mathbf{R}_3\left(+\lambda_a + \frac{\pi}{2}\right)\left[\begin{pmatrix} x \\ y \\ z \end{pmatrix} - \begin{pmatrix} \left[N_a + h_a\right]\cos\phi_a \cos\lambda_a \\ \left[N_a + h_a\right]\cos\phi_a \sin\lambda_a \\ \left[N_a\,(1-e^2) + h_a\right]\sin\phi_a \end{pmatrix}\right] \tag{55.56}$$

The rotation matrix $\mathbf{R}_1 = (-\phi_a + \pi/2)\mathbf{R}_3(+\lambda_a + \pi/2)$ is the transpose of the matrix given in Section 55.2 as Eq. (55.28).

Earth-Fixed Topocentric Spherical

Satellites orbit the earth at finite distances. For such purposes as visibility calculations, one relates the local e, n, u coordinates to local spherical coordinates El (elevation or altitude angle), Az (azimuth, clockwise positive from the north), and Sr (slant range to the object):

$$\begin{pmatrix} e \\ n \\ u \end{pmatrix} = \mathrm{Sr}\begin{pmatrix} \cos\mathrm{El}\sin\mathrm{Az} \\ \cos\mathrm{El}\cos\mathrm{Az} \\ \sin\mathrm{El} \end{pmatrix} \tag{55.57}$$

The inverse relationships are

$$\begin{pmatrix} \mathrm{El} \\ \mathrm{Az} \\ \mathrm{Sr} \end{pmatrix} = \begin{pmatrix} \arctan\left[u \Big/ \sqrt{e^2 + n^2}\right] \\ \arctan\left(e/n\right) \\ \sqrt{e^2 + n^2 + u^2} \end{pmatrix} \tag{55.58}$$

Note again that El, Az, and Sr form themselves a right-handed (curvilinear) frame.

Some Important Relationships Using Similarity and Datum Transformations

Increasing measurement accuracies and improved insights in the physics of the earth often cause reference frames to be reviewed. For instance, if coordinates of a station are given in an old frame, then with current knowledge of similarity transformation parameters relating the old $\mathbf{x}$ frame to the new $\mathbf{x}'$ frame, the new coordinates can be computed according to

$$\mathbf{x}' = \sigma\mathbf{R}\mathbf{x} + \mathbf{t}' \tag{55.59}$$

In many instances the translation and rotation transformation parameters are small, and the scale parameter σ deviates little from 1, so we introduce the following new symbols:

$$\begin{aligned} \sigma &= 1 + \delta\sigma \\ \alpha &= \delta\epsilon \\ \beta &= \delta\psi \end{aligned} \tag{55.60}$$

$$\gamma = \delta\omega$$

$$t'_x = \Delta x$$

$$t'_y = \Delta y$$

$$t'_z = \Delta z$$

Neglecting second-order effects, the rotation matrix **R** can be written as the sum of an identity matrix **I** and a skew-symmetric matrix $\delta\mathbf{R}$:

$$\mathbf{R} = \mathbf{R}_1(\delta\in)\mathbf{R}_2(\delta\psi)\mathbf{R}_3(\delta\omega) \tag{55.61}$$

$$= \mathbf{I} + \delta\mathbf{R} \tag{55.62}$$

with

$$\delta\mathbf{R} = \begin{pmatrix} 0 & \delta\omega & -\delta\psi \\ -\delta\omega & 0 & \delta\varepsilon \\ \delta\psi & -\delta\in & 0 \end{pmatrix} \tag{55.63}$$

Equation (55.59) becomes

$$\mathbf{x}' = (1+\delta\sigma)(\mathbf{I}+\delta\mathbf{R})\mathbf{x} + \Delta\mathbf{x} \tag{55.64}$$

or, neglecting second-order effects,

$$\mathbf{x}' = \mathbf{x} + \mathbf{dx} \tag{55.65}$$

with

$$\mathbf{dx} = \delta\sigma\mathbf{x} + \delta\mathbf{R}\mathbf{x} + \Delta\mathbf{x} \tag{55.66}$$

See Section 55.8 for a variety of parameter sets relating the various reference frames and datum values.

Inertial and Quasi-Inertial

Inertial Geocentric Coordinate Frame

For the derivation of the equations of motion of point masses in space we need so-called inertial frames. These are frames where Newton's laws apply. These frames are nonrotating, where point masses either have uniform velocity or are at rest. Popularly speaking, in these frames the stars or, better, extragalactic points or quasars, are "fixed" (i.e., not moving in a rotational sense). Since the stars are at such large distances from the earth, it is often sufficient in geodetic astronomy to consider the inertial directions. Instead of the inertial coordinates of the stars we consider the vector **d**, consisting of the three direction cosines. One has to realize that these direction cosines are dependent on only two angles. Consequently, only two direction cosines contain independent information because the three direction cosines squared sum up to 1.

The two angles are (see Fig. 55.5)

α right ascention

δ declination

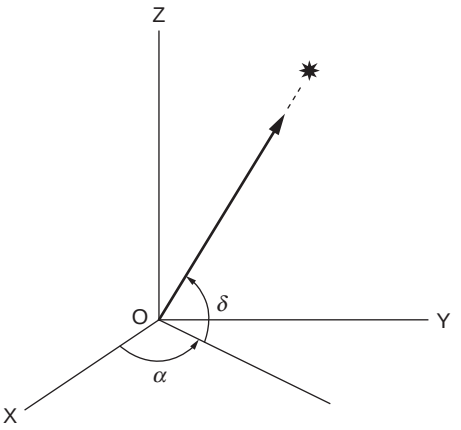

FIGURE 55.5 Direction to a satellite or star: right ascension, α, and declination, δ.

$$\begin{pmatrix} X \\ Y \\ Z \end{pmatrix} = l\mathbf{d} \tag{55.67}$$

with

$$\mathbf{d} = \begin{pmatrix} \cos\delta & \cos\alpha \\ \cos\delta & \sin\alpha \\ \sin\delta & \end{pmatrix} \tag{55.68}$$

The right ascension is counted counterclockwise positive from the *X* axis and is defined as the intersection of the earth's equatorial plane and the plane of the earth's orbit around the sun. One of the points of intersection is called the *vernal equinox:* it is that point in the sky among the stars where the sun appears as viewed from earth at the beginning of spring in the northern hemisphere. The declination is counted from the equatorial plane in the same manner as the latitude; see Fig. 55.6.

Quasi-Inertial Coordinate Frame

In the previous section the position of the origin was not defined yet: the origin of the inertial frame is not to coincide with the center of mass of the earth; since the earth itself orbits around the sun, the center of mass of the earth is subject to accelerations. Similarly, the center of mass of the sun and all its planets is rotating around the center of our galaxy, and the galaxy experiences gravitational forces from other galaxies. A continuation of this reasoning will improve the quality of "inertiality" of the coordinate frame, but the practical application for the description of the motion of earth-orbiting satellites has been completely lost.

In Section 55.5 a practical solution is presented: in orientation the frame is as inertial as possible, but the origin has been chosen to coincide with the earth's center of mass. Such frames are called *quasi-inertial* frames. The apparent forces caused by the (small) accelerations of the origin have to be accounted for later.

Relation between Earth-Fixed and Inertial

Satellite equations of motion are easily dealt with in an inertial frame, but we observers are likely to model our positions and relatively slow velocities in an earth-fixed frame. The relationship between these two frames has to be dealt with.

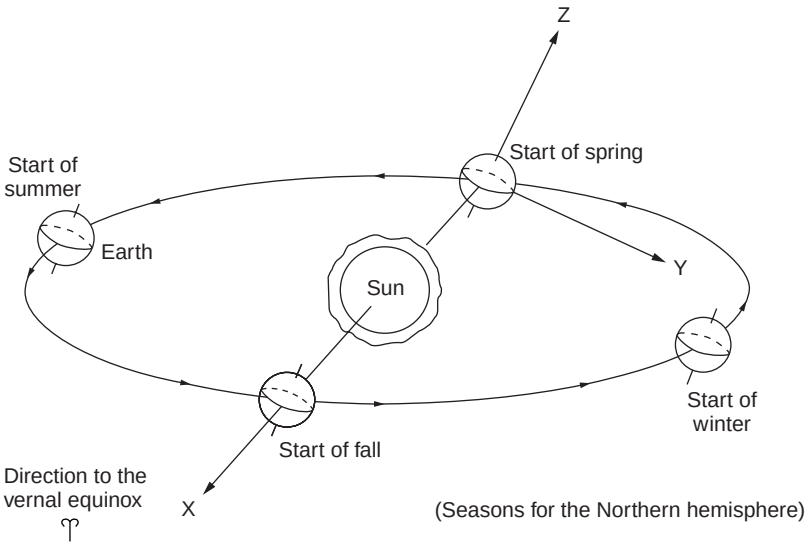

FIGURE 55.6 The (quasi-)inertial reference frame with respect to sun and earth.

Time and Sidereal Time

The diurnal rotation of the earth is given by its average angular velocity:

$$\omega_e = 7.292115 \times 10^{-5} \text{ rad/s} \tag{55.69}$$

This inertial angular velocity results in an average day length of

$$T = \frac{2\pi}{\omega_e} = 86164.1 \text{sec} \tag{55.70}$$

This *sidereal day*, based on the earth's spin rotation with respect to the fixed stars, deviates from our 24 x 60 x 60 = 86,400-sec day by 3 min, 55.9 sec. That is why we see an arbitrary star constellation in the same position in the sky each day about 4 min earlier. Our daily lives are based on the earth's spin with respect to the sun, the *solar day*. Since the earth advances about 1° per day in its orbit around the sun, the earth has not completed a full spin with respect to the sun when it completes one full turn with respect to the stars; see Fig. 55.7.

For practical purposes the angular velocity must include the effect of precession; see the next section. We have

$$\omega_c^* = 7.2921158553 * 10^{-5} \text{ rad/s} \tag{55.71}$$

The angle between the vernal equinox and the Greenwich meridian as measured along the equator is *Greenwich apparent sidereal time* (GAST). This angle increases in time by ω_c^* per second. With the help of the formula of Newcomb, we are able to compute GAST [IERS, 1992]:

$$\text{GAST}(t) = a + bT_u + cT_u^2 + dT_u^3 + \text{ee} \tag{55.72}$$

with

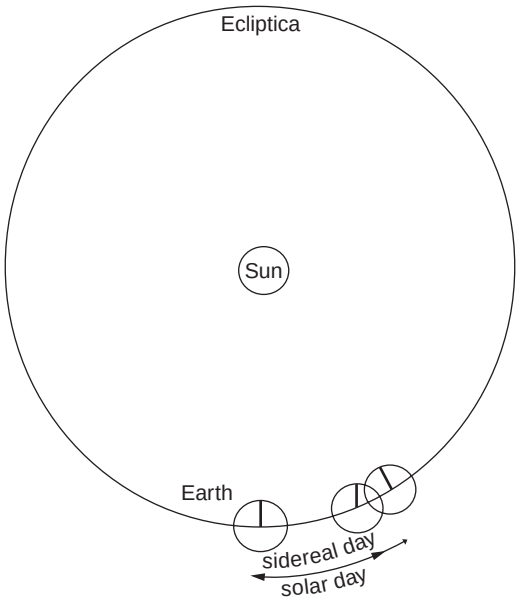

FIGURE 55.7 The earth's orbit around the sun: sidereal day and solar day.

$$
\begin{aligned}
a &= 18\,h\ 41\ \text{min}\ 50.54841\ \text{s} \\
b &= 8{,}640{,}184.812866\ \text{s}/\text{century}^3 \\
c &= 0.093104\ \text{s}/\text{century}^3 \\
d &= -0.0000062\ \text{s}/\text{century}^3 \\
\text{ee} &= \text{the equation of the equinoxes}
\end{aligned}
\tag{55.73}
$$

T_u is measured in Julian centuries of 36,525 universal days, since 1.5 January 2000 (JD_0 = 2,451,545.0). This means that T_u, until the year 2000, is negative. T_u can be computed from

$$
T_u = \frac{\left(\text{JD} - 2{,}451{,}545.0\right)}{36{,}525} \tag{55.74}
$$

when the Julian day number, *JD*, is given.

Polar Motion

Polar motion, or on a geological time scale "polar wandering," represents the motion of the earth's spin axis with respect to an earth-fixed frame. Polar motion changes our latitudes, since if the *z* axis were chosen to coincide with the instantaneous position of the spin axis, our latitudes would change continuously.

Despite the earth's nonelastic characteristics, excitation forces keep polar motion alive. Polar motion is the motion of the instantaneous rotation axis, or celestial ephemeris pole (CEP), with respect to an adopted reference position, the conventional terrestrial pole (CTP) of the conventional terrestrial reference frame (CTRF). The adopted reference position, or conventional international origin (CIO), was the main position of the CEP between 1900 and 1905. Since then the mean CEP has drifted about 10 m away from the CIO in a direction of longitude 280°.

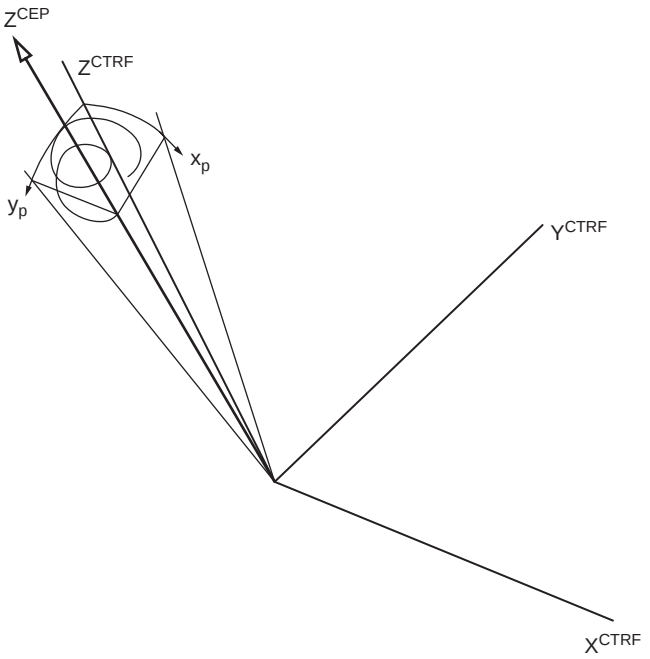

FIGURE 55.8 Local curvilinear pole coordinates x_p, y_p with respect to the conventional terrestrial reference frame.

The transformation from the somewhat earth-fixed frame $\mathbf{x}_{\text{CEP}}$ to $\mathbf{x}_{\text{CTRF}}$ is

$$\mathbf{x}_{\mathbf{CTRF}} = \mathbf{R}_2\left(-x_p\right)\mathbf{R}_1\left(-y_p\right)\mathbf{x}_{\mathbf{CEP}} \tag{55.75}$$

The position of the pole is expressed in local curvilinear coordinates that have their origin in the CIO. The angle x_p (radians) increases along the Greenwich meridian south, whereas the angle y_p increases along the meridian $\lambda = 270°$ south; see Fig. 55.8. As we saw in the previous subsection, the earth rotates daily around its (moving) CEP axis. Expanding the transformation of Eq. (55.75) but now also including the sidereal rotation of the earth, we obtain the following relationship between an inertial reference frame and the CTRF:

$$\mathbf{x}_{\mathbf{CEP}} = \mathbf{R}_3(\text{GAST})\mathbf{x}_{\mathbf{in}} \tag{55.76}$$

This relationship is shown in Fig. 55.9. Combining Eqs. (55.75) and (55.76), we have

$$\mathbf{x}_{\mathbf{CTRF}} = \mathbf{R}_2\left(-x_p\right)\mathbf{R}_1\left(-y_p\right)\mathbf{R}_3(\text{GAST})\mathbf{x}_{\mathbf{in}} \tag{55.77}$$

or, in short,

$$\mathbf{x}_{\mathbf{CTRF}} = \mathbf{R}_S\mathbf{x}_{\mathbf{in}} \tag{55.78}$$

where $\mathbf{R}_S$ represents the combined earth rotation due to polar motion and diurnal rotation (length of day).

Two main frequencies make up the polar motion: the Chandler wobble of 435 days (14 months, more or less) and the annual wobble of 365.25 days. A prediction model for polar motion is

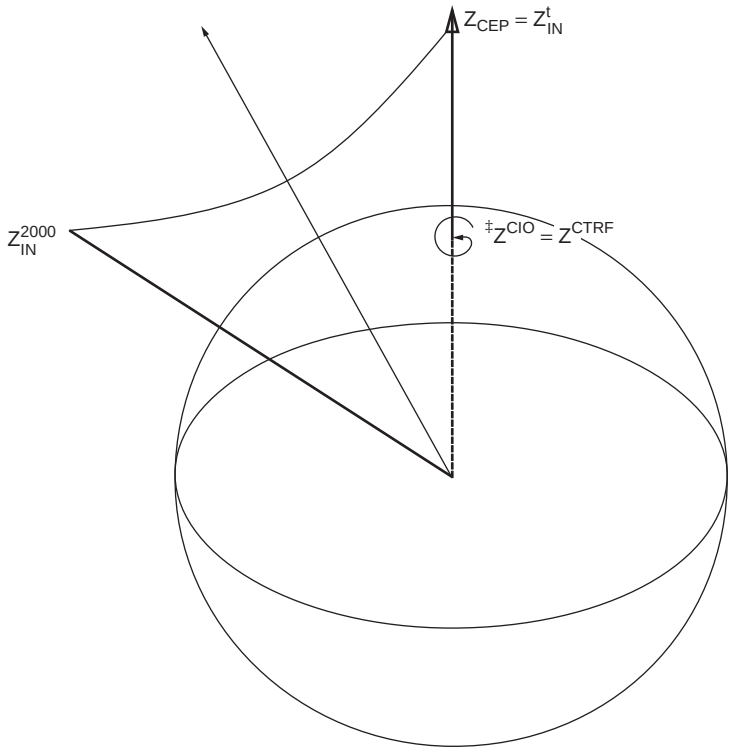

FIGURE 55.9 Relationship between the quasi-earth-fixed frame $\mathbf{X}_{CEP}$ and the inertial frame $\mathbf{X}_{in}$.

$$x_p(t) = x_p(t_0) + \dot{x}_p(t-t_0) + A_s^x \sin\left[\frac{2\pi}{T_1}(t-t_0)\right] + A_c^x \cos\left[\frac{2\pi}{T_1}(t-t_0)\right] + C_s^x \sin\left[\frac{2\pi}{T_2}(t-t_0)\right] + C_c^x \cos\left[\frac{2\pi}{T_2}(t-t_0)\right] \tag{55.79}$$

$$y_p(t) = y_p(t_0) + \dot{y}_p(t-t_0) + A_s^y \sin\left[\frac{2\pi}{T_1}(t-t_0)\right] + A_c^y \cos\left[\frac{2\pi}{T_1}(t-t_0)\right] + C_s^y \sin\left[\frac{2\pi}{T_2}(t-t_0)\right] + C_c^y \cos\left[\frac{2\pi}{T_2}(t-t_0)\right] \tag{55.80}$$

where T_1 = 365.25 days
T_2 = 435 days

Similarly, the ever-increasing angle GAST has to be corrected for seasonal variations in ω. These variations are in the order of ±1 msec. A prediction model for length-of-day variations is

$$\delta\text{UT1} = a \sin 2\pi t + b \cos 2\pi t + c \sin 4\pi t + d \cos 4\pi t \tag{55.81}$$

with a = +0.0220 sec
b = –0.0120 sec
c = –0.0060 sec
d = +0.0070 sec
t = 2000.000 + [(MJD – 51544.03)/365.2422].

With Eq. (55.72), we have

$$\text{GAST} = \text{GAST}_{(t)} + \delta\text{UT1} \tag{55.82}$$

Due to the flattening, f, $\mathbf{x}_{\text{in}}$ in Eq. (55.77) is not star-fixed but would be considered a proper (quasi-) inertial frame if we froze the frame at epoch t. So, Eq. (55.78) is more properly expressed as

$$\mathbf{x}_{\mathbf{CTRF}} = \mathbf{R}_S \mathbf{x}^t_{\mathbf{in}} \tag{55.83}$$

The motions of the CEP with respect to the stars are called *precession* and *nutation*.

Precession and Nutation

Precession and nutation represent the motion of the earth's spin axis with respect to an inertial frame.

To facilitate comparisons between observations of spatial objects (satellites, quasars, stars) that may be made at different epochs, a transformation is carried out between the inertial frame at epoch t (CEP at t) and the mean position of the inertial frame at an agreed-upon reference epoch t_0. The reference epoch is again 1.5 January 2000, for which JD_0 = 2,451,545.0; see the discussion on time and sidereal time earlier in this section. At this epoch we define the conventional inertial reference frame (CIRF). So we have

$$\mathbf{x}^t_{\mathbf{in}} = \mathbf{R}_{\text{NP}} \mathbf{x}^{\mathbf{2000}}_{\mathbf{in}} \tag{55.84}$$

All masses in the ecliptic plane (earth and sun) and close to it (planets) exert a torque on the tilted equatorial bulge of the earth. The result is that the CEP describes a cone with its half top angle equal to the obliquity ε: precession. The period is about 25,800 years. The individual orbits of the planets and moon cause deviations with respect to this cone: nutation. The largest effect is about 9 sec of arc, with a period of 18.6 years, caused by the inclined orbit of the moon.

The transformation $\mathbf{R}_{\text{NP}}$ is carried out in two steps. The mean position of the CEP is first updated for precession to a mean position at epoch t (now):

$$\mathbf{x}^{t,\mathbf{mean}}_{\mathbf{in}} = \mathbf{R}_P \mathbf{x}^{\mathbf{2000,mean}}_{\mathbf{in}} \tag{55.85}$$

Subsequently, the mean position of the CEP at epoch t is transformed to the true position of the CEP at epoch t due to nutation:

$$\mathbf{x}^{t,\mathbf{true}}_{\mathbf{in}} = \mathbf{R}_N \mathbf{x}^{t,\mathbf{mean}}_{\mathbf{in}} \tag{55.86}$$

Combining all transformations, we have

$$\mathbf{x}_{\mathbf{CTRF}} = \mathbf{R}_S \mathbf{R}_N \mathbf{R}_P \mathbf{x}_{\mathbf{CIRF}} \tag{55.87}$$

where $\mathbf{x}_{\text{CTFR}}$ is identical to $\mathbf{x}^{\text{CIO}}_{\text{earth-fixed}}$ and $\mathbf{x}_{\text{CIRF}}$ is identical to $\mathbf{x}^{2000}_{\text{star-fixed}}$

The rotation matrices $\mathbf{R}_P$ and $\mathbf{R}_N$ depend on the obliquity ε, longitude of sun, moon, etc. We have

$$\mathbf{R}_P = \mathbf{R}_3(-z)\mathbf{R}_2(\theta)\mathbf{R}_3(-\zeta) \tag{55.88}$$

with (see, e.g., IERS [1992])

$$\zeta = 2\,306''.218\,1T_u + 0''.301\,88T_u^2 + 0''.0.17\,998T_u^3$$
$$\theta = 2\,004''.310\,9T_u - 0''.426\,65T_u^2 - 0''.0.41\,833T_u^3$$
$$z = 2\,306''.218\,1T_u + 1''.094\,68T_u^2 + 0''.0.18\,203T_u^3$$

and

$$\mathbf{R}_N = \mathbf{R}_1(-\varepsilon - \Delta\varepsilon)\mathbf{R}_3(-\Delta\psi)\mathbf{R}_1(\varepsilon) \tag{55.89}$$

with $\varepsilon = 84381''.448 - 46''.8150T_u - 0''.018203T_u^2 + 0''.001813T_u^3$.

For the nutation in longitude, $\Delta\psi$, and the nutation in obliquity, $\Delta\varepsilon$, a trigonometric series expansion is available consisting of $106 \times 2 \times 2$ parameters and five arguments: mean anomaly of the moon, the mean anomaly of the sun, mean elongation of the moon from the sun, the mean longitude of the ascending node of the moon, and the difference between the mean longitude of the moon and the mean longitude of the ascending node of the moon. There are 2×2 constants in each term: a sine coefficient, a cosine coefficient, a time-invariant coefficient, and a time-variant coefficient.

For more detail on these transformations, refer to earth orientation literature, such as Mueller [1969], Moritz and Mueller [1988], and IERS [1992].

55.4 Mapping

The art of mapping is referred to a technique that maps information from an n-dimensional space $\mathbf{R}_n$ to an m-dimensional space $\mathbf{R}_m$. Often information belonging to a high-dimensional space is mapped to a low-dimensional space. In other words, one has

$$n > m \tag{55.90}$$

In geodesy and surveying one may want to map a three-dimensional world onto a two-dimensional world. In photogrammetry, an aerial photograph can be viewed as a mapping procedure as well: a two-dimensional photo of the three-dimensional terrain. In least-squares adjustment we map an n-dimensional observation space onto a u-dimensional parameter space. In this section we restrict our discussion to the mapping:

$$\mathbf{R}_n \rightarrow \mathbf{R}_m \tag{55.91}$$

with

$$n = 3 \tag{55.92}$$

$$m = 2 \tag{55.93}$$

A three-dimensional earth, approximated by a sphere or, better, by an ellipsoid of revolution, cannot be mapped onto a two-dimensional surface, which is flat at the start (plane) or can be made flat (the surface of a cylinder or a cone), without distorting the original relative positions in $\mathbf{R}_3$. Any figure or, better, the relative positions between an arbitrary number of points on a sphere or ellipsoid, will also be distorted when mapped onto a plane, cylinder, or cone. The distortions of the figure (or part thereof) will increase with the area. Likewise, the mapping will introduce distortions that will become larger as the extent of the area to be mapped increases.

If one approximates (maps) a sphere of the size of the earth, the radius R being

$$R \approx 6371.000 \text{ km} \tag{55.94}$$

onto a plane tangent in the center of one's engineering project of diameter D km, one finds increased errors in lengths, angles, and heights the further one gets away from the center of the project. Table 55.1 lists these errors in distance dS, angle $d\alpha$, and height dh, if one assumes the following case: one measures in the center of the project one angle of 60° and two equal distances of S km. In the plane assumption we would find in the two terminal points of both lines two equal angles of 60° and a distance between them of exactly S km. Basically, we have an equilateral triangle. In reality, on the curved, spherical earth we would measure angles larger than 60° and a distance between them shorter than S km. The error dh shows how the earth curves away from underneath the tangent plane in the center of the project.

TABLE 55.1 Errors in Length *dS* (km), Angle *dα* (arcseconds), and Height *dh* (km)[a]

Diameter, *D* (km)	Length, *S* (km)	*dS* (m)	*dS* (ppm)	*dα* (arcseconds)	*dα* (ppm)	*dh* (m)

[a] Depending on the diameter *D* (km) of a project or distance *S* (=*D* 12) from the center of the project for an equilateral triangle with sides of *S* km.

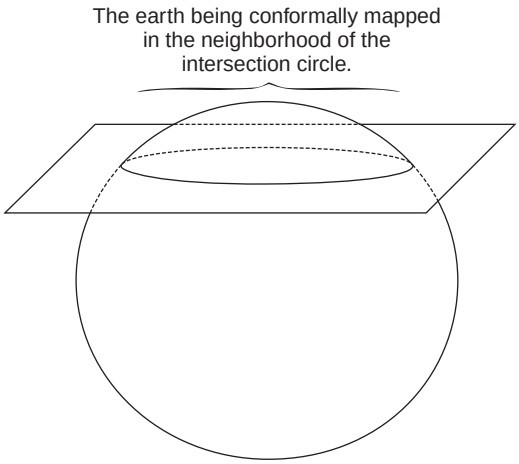

FIGURE 55.10 Mapping a sphere to a plane or lowered plane.

The table shows that errors in length and angle of larger than 1 ppm start to occur for project diameters larger than 20 km. Height differences obtained through leveling would be accurate enough, but vertical angles would start deviating from 90° by 1 arcsecond per 30 m. Within an area of 20 km fancy mapping procedures would not be needed to avoid errors of 1 ppm. The trouble starts if one wants to map an area of the size of the state of Indiana. A uniform strict mapping procedure has to be adhered to if one wants to work in one consistent system of mapping coordinates. In practice, a state of the size of Indiana is actually divided into two regions to keep the distortions within bounds. One may easily reduce the errors by a factor of 2 by making the plane not tangent to the sphere, but by lowering the plane from the center of the project by such an amount that the errors of *dS* in the center of the area are equal, but of opposite sign, to the errors *dS* at the border of the area (see Fig. 55.10). The U.S. State Plane Coordinate Systems are based on this practice.

As an alternative one may choose the mapping plane to be cylindrical or conical so that the mapping plane "follows" the earth's curvature at least in one direction (see Figs. 55.11 and 55.12). Also, with these alternatives distortions are reduced even further by having the cylindrical or conical surface not tangent to the sphere or ellipsoid, but intersecting the surface to be mapped just below the tangent point. After mapping, the cylinder or cone can be "cut" and made into a two-dimensional map. A cylinder and a cone are called *developable surfaces*.

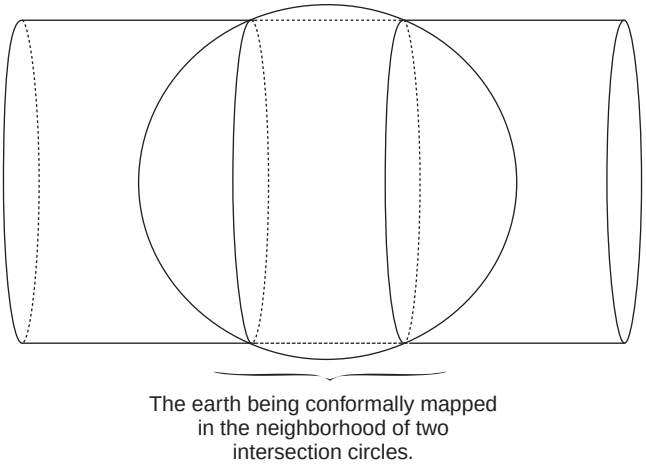

FIGURE 55.11 A cylinder trying to follow the earth's curvature.

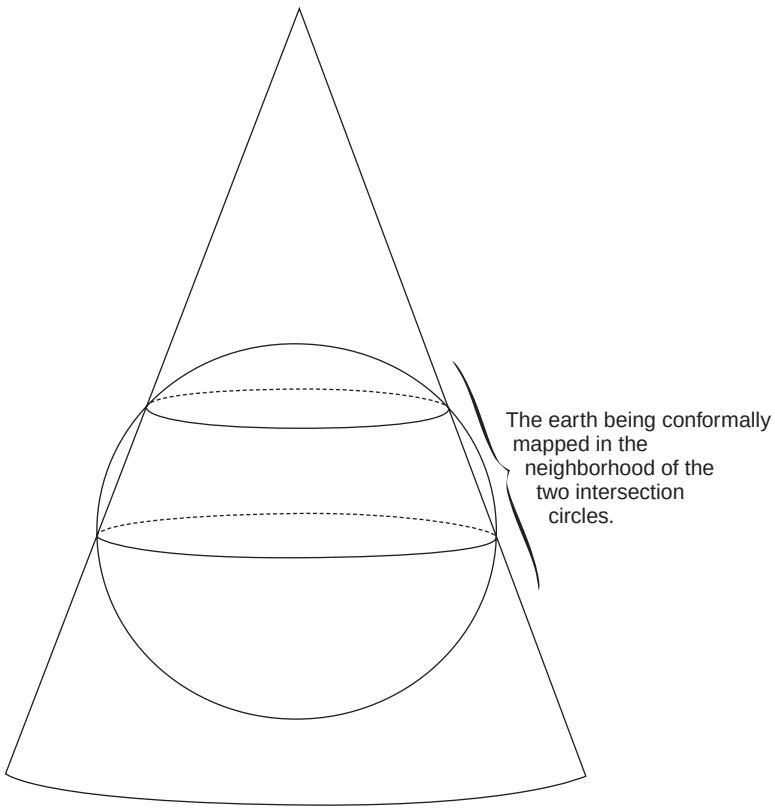

FIGURE 55.12 A cone trying to follow the earth's curvature.

The notion of distortion of a figure is applied to different elements of a figure. If a (spherical) triangle is mapped, one may investigate how the length of a side or the angle between two sides is distorted in the mapping plane.

Two Worlds

We live in R_3, which is to be mapped into R_2. In R_3 we need three quantities to position ourselves: $\{x, y, z\}$, $\{\lambda, \psi, h\}_R$, or $\{\lambda, \phi, h\}_{a,f}$; see Section 55.2. In R_2 we need only two quantities, such as two Cartesian mapping coordinates $\{X, Y\}$ or two polar mapping coordinates $\{r, \alpha\}$.

Real world → Mapped world

$$\left.\begin{array}{l}\{x,y,z\}\\ \text{or}\\ \{\lambda,\psi,h\}_R\\ \text{or}\\ \{\lambda,\phi,h\}_{a,f}\end{array}\right\} \rightarrow \left\{\begin{array}{l}\{X,Y\}\\ \text{or}\\ \{r,\alpha\}\end{array}\right.$$

The mapping M may be written symbolically as

$$\{r, \alpha\} = M\{x, y, z\}\} \tag{55.95}$$

or

$$\{X, Y\} = M'\{\lambda, \phi, h\}_{a,f} \tag{55.96}$$

M represents a mere mapping "prescription" of how the R_3 world is condensed into R_2 information. Note that the computer era made it possible to "store" the R_3 world digitally in R_3 (a file with three numbers per point). Only at the very end, if that information is to be presented on a map or computer screen, do we map to R_2.

The analysis of distortion is, in this view, the mere comparison of corresponding geometrical elements in the real world and in the mapped world. A distance $s\,(x, y, z)$ between points i and j in the real world is compared to a distance $S = S(X, Y)$ in the mapped world. A scale distortion may be defined as the ratio

$$\sigma = \frac{S\left(X_i, Y_i, X_j, Y_j\right)}{s\left(x_i, y_i, z_i, x_j, y_j, z_j\right)} \tag{55.97}$$

or, for infinitely small distances,

$$\sigma = \frac{dS\left(dX_{ij}, dY_{ij}\right)}{ds\left(dx_{ij}, dy_{ij}, dz_{ij}\right)} \tag{55.98}$$

where

$$x_{ij} = x_j - x_i \quad \text{and so forth} \tag{55.99}$$

Similarly, an angle θ_{jik} in point i to points j and k in the real world is being compared to an angle Θ_{jik} in the mapped world, the angular distortion $d\theta$:

$$d\theta = \Theta_{jik} - \theta_{jik} \tag{55.100}$$

Other features may be investigated to assess the distortion of a certain mapping; for example, one may want to compare the area in the real world to the area in the mapped world. Various mapping prescriptions (mapping equations) exist that minimize scale distortion, angular distortion, area distortion, or combinations of these. In surveying engineering, and for that matter in civil engineering, the most widely applied map projection is the one that minimizes angular distortion. Moreover, there exists a class of map projections that do not show any angular distortion throughout the map; in other words,

$$d\theta = 0 \tag{55.101}$$

This class of map projections is known as *conformal map projections*. One word of caution is needed: the angles are only preserved in an infinitely small area. In other words, the points *i*, *j*, *k* have to be infinitely close together.

The surveyor or civil engineer often works in a relatively small area (compared to the dimensions of the earth). Therefore, it is extremely handy for his or her angular measurements from theodolite or total station, made in the real world, to be preserved in the mapped world. As a matter of fact, any of a variety of conformal map projections are used throughout the world by national mapping agencies. The most widely used map projection, also used by the military, is a conformal map projection, the so-called *Universal Transverse Mercator* (UTM) projection. In the U.S. all states have adopted some sort of a state plane coordinate system. This system is basically a local reference frame based on a certain type of conformal mapping. See the following three subsections.

Without proof, the necessary and sufficient conditions for conformality are that the real-world coordinates *p* and *q* and the mapping coordinates *X* and *Y* fulfill the Cauchy–Riemann equations or conditions:

$$\begin{aligned} \frac{\partial X}{\partial p} &= +\frac{\partial Y}{\partial q} \\ \frac{\partial X}{\partial q} &= -\frac{\partial Y}{\partial p} \end{aligned} \tag{55.102}$$

Purposely, the real-world variables *p* and *q* have not been identified. First we want to enforce the natural restriction on *p*, *q*, *X*, *Y*: they have to be isometric coordinates. The mapping coordinates are often isometric by definition; however, the real-world coordinates, as the longitude λ and the spherical latitude ψ (or geodetic latitude ϕ), are not isometric.

For instance, one arcsecond in longitude expressed in meters is very latitude dependent and, moreover, is not equal to one arcsecond in latitude in the very same point; see Table 55.2.

Conformal Mapping Using Cartesian Differential Coordinates

In principle, we have four choices to map from R_3 to R_2:

A1: three-dimensional Cartesian → two-dimensional Cartesian
A2: three-dimensional Cartesian → two-dimensional curvilinear
B1: three-dimensional curvilinear → two-dimensional Cartesian
B2: three-dimensional curvilinear → two-dimensional curvilinear

Although all four modes have known applications, we treat an example in this section with the B1 mode of mapping, whereas the following subsection deals with an example from the B2 mode.

From Eqs. (55.29) and (55.30) we have

$$\begin{aligned} d\lambda_m &= (N+h)\cos\phi\, d\lambda_{\text{rad}} \\ d\phi_m &= (M+h)\, d\phi_{\text{rad}} \end{aligned} \tag{55.103}$$

TABLE 55.2 Radius of Curvature in the Meridian M, Radius of Curvature in the Prime Vertical N, and Metric Equivalence of 1 Arcsecond in Ellipsoidal or Spherical Longitude λ (m) and in Ellipsoidal or Spherical Latitude ϕ/ψ (m) as a Function of Geodetic Latitude ϕ and Spherical Latitude ψ

			Ellipsoid		Sphere	
ϕ/ψ	M	N	1 in. λ	1 in. ϕ	1 in. λ	1 in. ψ
00.0	6,335,439	6,378,137	30.922	30.715	30.887	30.887
10.0	6,337,358	6,378,781	30.455	30.724	30.418	30.887
20.0	6,342,888	6,380,636	29.069	30.751	29.025	30.887
30.0	6,351,377	6,383,481	26.802	30.792	26.749	30.887
40.0	6,361,816	6,386,976	23.721	30.843	23.661	30.887
50.0	6,372,956	6,390,702	19.915	30.897	19.854	30.887
60.0	6,383,454	6,394,209	15.500	30.948	15.444	30.887
70.0	6,392,033	6,397,072	10.607	30.989	10.564	30.887
80.0	6,397,643	6,398,943	05.387	31.017	05.364	30.887
90.0	6,399,594	6,399,594	00.000	31.026	00.000	30.887

Note: Ellipsoidal values for WGS84: a = 6,378,137 m, $1/f$ = 298.257 223 563. Spherical values: R = 6,371,000 m.

A line element (small distance) in the real world (on the ellipsoid, $h = 0$) is

$$ds^2 = d\lambda_m^2 + d\phi_m^2 \tag{55.104}$$

A line element (small distance) in the mapped world (on paper) is

$$dS^2 = dX^2 + dY^2 \tag{55.105}$$

Equation (55.104) leads to

$$ds^2 = N^2 \cos^2\phi d\lambda_{\text{rad}}^2 + M^2 d\phi_{\text{rad}}^2 \tag{55.106}$$

or

$$ds^2 = N^2 \cos^2\phi \left(d\lambda_{\text{rad}}^2 = \frac{M^2}{N^2 \cos^2\phi} d\phi_{\text{rad}}^2 \right) \tag{55.107}$$

Since we want to work with isometric coordinates in the real world (note that the mapping coordinates $\{X, Y\}$ are already isometric), we introduce the new variable dq. In other words, Eq. (55.107) becomes

$$ds^2 = N^2 \cos^2\phi \left(d\lambda^2 + dq^2 \right) \tag{55.108}$$

So, we have

$$dq = \frac{M}{N\cos\phi} d\phi_{\text{rad}} \tag{55.109}$$

Upon integration of Eq. (55.109) we obtain the isometric latitude q:

$$q = \ln\left[\tan\left(\frac{\pi}{4} + \frac{\phi}{2} \right) \left(\frac{1 - e\sin\phi}{1 + e\sin\phi} \right)^{e/2} \right] \tag{55.110}$$

The isometric latitude for a sphere ($e = 0$) becomes simply

$$q = \ln\tan\left(\frac{\pi}{4} + \frac{\psi}{2} \right) \tag{55.111}$$

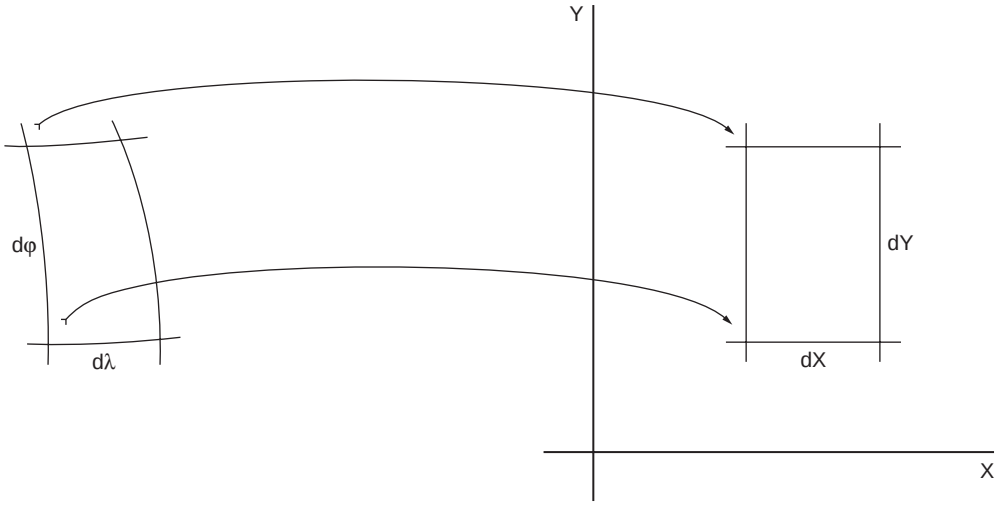

FIGURE 55.13 Spherical/ellipsoidal quadrangle mapped onto a planar Cartesian quadrangle.

Equating the variables from Eqs. (55.105) and (55.108) we have the mapping M between Cartesian mapping coordinates $\{X, Y\}$ and curvilinear coordinates $\{\lambda, q\}$ for both the sphere and the ellipsoid. Note that $\{\lambda, q\}$ play the role of the isometric coordinates $\{p, q\}$ in the Cauchy–Riemann equations.

So the mapping equations are simply

$$\begin{aligned} X &= \sigma\lambda \\ Y &= \sigma q \end{aligned} \tag{55.112}$$

or, for the sphere,

$$\begin{aligned} X &= \sigma\lambda \\ Y &= \sigma \ln \tan\left(\frac{\pi}{4} + \frac{\psi}{2}\right) \end{aligned} \tag{55.113}$$

Equation (55.113) represents the conformal mapping equations from the sphere to R_2. These are the formulas of the well-known Mercator projection (cylindrical type). Inspection of the linear scale σ reveals that this factor depends on the term $M/(N \cos \phi)$ for the ellipsoid or $1/\cos \phi$ for the sphere. This means that the linear distortion is only latitude dependent. In order to minimize this distortion, we simply apply this mapping to regions that are elongated in the longitudinal direction, where the linear distortion is constant. In case we want to map an arbitrarily oriented elongated region, we simply apply a coordinate transformation. In the subsection on coordinate transformations and conformal mapping we will perform such a coordinate transformation on these mapping equations.

So far, we have mapped a spherical quadrangle $d\lambda$, $d\psi$ or ellipsoidal "quadrangle" $d\lambda$, $d\phi$ to a planar quadrangle dX, dY; see Fig. 55.13.

Conformal Mapping Using Polar Differential Coordinates

The alternative is to map an ellipsoidal or spherical quadrangle onto a polar quadrangle. Figure 55.14 shows that one option is to look for a mapping between the polar mapping coordinates $\{r, \alpha\}$ and the real-world coordinates $\{\lambda, \phi\}$ or $\{\lambda, \psi\}$.

The similarity of roles played by the radius r and the latitude ϕ or ψ is more apparent if we view the *colatitude* θ, since this real-world coordinate radiates from one point as the radius r does:

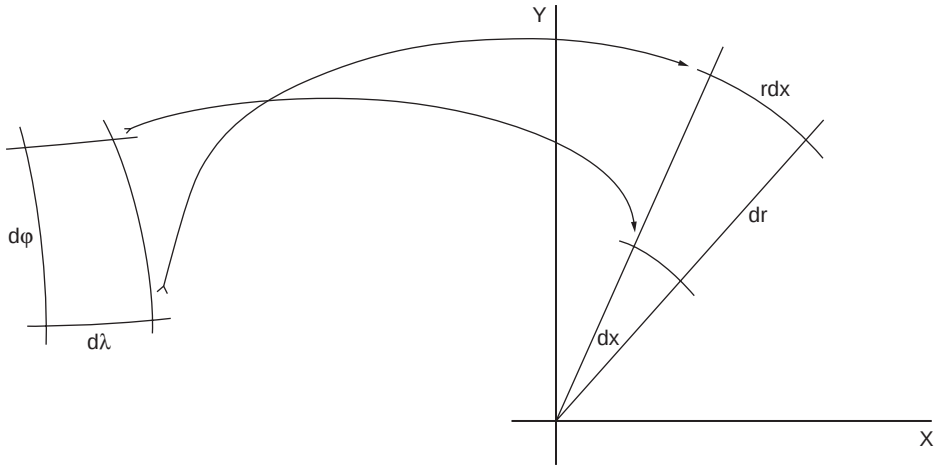

FIGURE 55.14 Spherical/ellipsoidal quadrangle mapped onto a planar polar quadrangle.

$$\theta = \frac{\pi}{2} - \psi \qquad (\text{or } \phi) \tag{55.114}$$

Considering now the line element *ds* on a sphere, we have

$$ds^2 = R^2 \sin^2\theta d\lambda_{\text{rad}}^2 + R^2 d\theta_{\text{rad}}^2 \tag{55.115}$$

or

$$ds^2 = R^2 \sin^2\theta \left(d\lambda_{\text{rad}}^2 + \frac{d\theta_{\text{rad}}^2}{\sin^2\theta} \right) \tag{55.116}$$

Introducing the new variable dq', we have

$$dq' = \frac{d\theta_{\text{rad}}}{\sin\theta} \tag{55.117}$$

Integration of Eq. (55.117) gives the isometric colatitude q':

$$q' = \int dq = \int \frac{d\theta}{\sin\theta} \tag{55.118}$$

or

$$q' = -\ln\left(\cot\frac{\theta}{2} \right) \tag{55.119}$$

A line element on the sphere in terms of isometric coordinates is

$$ds^2 = R^2 \sin^2\theta \left(d\lambda^2 + dq'^2 \right) \tag{55.120}$$

A line element *dS* (small distance) in the mapped world (on paper) is

$$dS^2 = r^2 d\alpha^2 + dr^2 \tag{55.121}$$

Now we want to derive isometric coordinates in the mapped world as well (we do not have a Cartesian, but a polar, representation). Among various options we choose

$$dS^2 = r^2\left(d\alpha^2 + \frac{dr^2}{r^2}\right) \tag{55.122}$$

Introducing the new variable $d\rho$,

$$d\rho = \frac{dr}{r} \tag{55.123}$$

Upon integration of Eq. (55.123), we obtain the isometric radius ρ:

$$\rho = \int d\rho = \int \frac{dr}{r} = \ln r + c_r \tag{55.124}$$

or

$$r = e^{\rho} \qquad r^2 = e^{2\rho} \tag{55.125}$$

The line element dS becomes with the new variable

$$dS^2 = e^{2\rho}\left(d\alpha^2 + d\rho^2\right) \tag{55.126}$$

The line element ds was

$$ds^2 = \mathbf{R}^2 \sin^2\theta\left(d\lambda^2 + dq'^2\right) \tag{55.127}$$

So the mapping equations are simply

$$\begin{aligned} \alpha &= \sigma\lambda \\ \rho &= \sigma q' \end{aligned} \tag{55.128}$$

or

$$\begin{aligned} \alpha &= \sigma\lambda \\ \ln r &= \sigma\left[-\ln\left(\cot\frac{\theta}{2}\right)\right] \end{aligned} \tag{55.129}$$

If one appropriately chooses the integration constant c_r, Eq. (55.126), to be

$$c_r = \ln 2 \tag{55.130}$$

the mapping Eq. (55.129) becomes

$$\begin{aligned} \alpha &= \sigma\lambda \\ \ln r &= \sigma\left[\ln 2 - \ln\left(\cot\frac{\theta}{2}\right)\right] = \ln\left(2\tan\frac{\theta}{2}\right) \end{aligned} \tag{55.131}$$

or

$$\begin{aligned} \alpha &= \sigma\lambda \\ r &= 2\sigma\tan\frac{\theta}{2} \end{aligned} \tag{55.132}$$

Equation (55.132) also represents conformal mapping equations from the sphere to R_2. They are the formulas of the well-known stereographic projection (planar type). Other choices of integration constants and integration interval would have led to the Lambert conformal projection (conical type).

The approaches laid out in this subsection and the preceding one are the theoretical basis of the U.S. State Plane Coordinate Systems. Refer to Stem [1991] for the formulas of the ellipsoidal equivalents.

Coordinate Transformations and Conformal Mapping

The two examples treated in the preceding two subsections can be treated for any arbitrary curvilinear coordinates. The widely used Transverse Mercator projection for the sphere is easily derived using a simple coordinate transformation. Rather than having the origin of the (co)latitude variable at the pole, we define a similar pole at the equator, and the new equator will be perpendicular to the old equator.

Having mapping poles at the equator leads to transverse types of conformal mapping. If the pole is neither at the North Pole nor at the equator, we obtain oblique variants of conformal mapping.

For the Transverse Mercator, the new equator may pass through a certain (old) longitude λ_0. For a UTM projection this λ_0 has specified values; for a state plane coordinate system the longitude λ may define the central meridian in a particular (part of the) state.

Two successive rotations will bring the old $\mathbf{x}$ frame to the new $\mathbf{x}'$ frame (see Section 55.2):

$$\mathbf{x}' = \mathbf{R}_1(\pi/2)\mathbf{R}_3(\lambda_0)\mathbf{x} \tag{55.133}$$

The original $\mathbf{x}$ frame expressed in curvilinear coordinates is

$$\mathbf{x} = R\begin{pmatrix} \cos\psi\cos\lambda \\ \cos\psi\sin\lambda \\ \sin\psi \end{pmatrix} \tag{55.134}$$

The new $\mathbf{x}'$-frame expressed in curvilinear coordinates is

$$\mathbf{x}' = R\begin{pmatrix} \cos\psi'\cos\lambda' \\ \cos\psi'\sin\lambda' \\ \sin\psi' \end{pmatrix} \tag{55.135}$$

Multiplying out the rotations in Eq. (55.135) we get

$$\mathbf{x}' = R\begin{pmatrix} \cos\psi'\cos\lambda' \\ \cos\psi'\sin\lambda' \\ \sin\psi' \end{pmatrix} = R\begin{pmatrix} x\cos\lambda_0 + y\sin\lambda_0 \\ z \\ x\sin\lambda_0 + y\cos\lambda_0 \end{pmatrix} \tag{55.136}$$

Substituting Eq. (55.134) into Eq. (55.136) and dividing by R we obtain

$$\begin{pmatrix} \cos\psi'\cos\lambda' \\ \cos\psi'\sin\lambda' \\ \sin\psi' \end{pmatrix} = \begin{pmatrix} \cos\psi\cos\lambda\cos\lambda_0 + \cos\psi\sin\lambda\sin\lambda_0 \\ \sin\psi \\ \cos\psi\cos\lambda\sin\lambda_0 - \cos\psi\sin\lambda\cos\lambda_0 \end{pmatrix} \tag{55.137}$$

which directly leads to

$$\tan\lambda' = \frac{\sin\psi}{\cos\psi\cos(\lambda-\lambda_0)} = \frac{\tan\psi}{\cos(\lambda-\lambda_0)}$$
$$\tan\psi' = \frac{\cos\psi\sin(\lambda-\lambda_0)}{\sqrt{\cos^2\psi\cos^2(\lambda-\lambda_0)+\sin^2\psi}} = \frac{\sin(\lambda-\lambda_0)}{\sqrt{\cos^2(\lambda-\lambda_0)+\tan^2\psi}} \tag{55.138}$$

The new longitudes λ' and latitudes ψ' are subjected to a (normal) Mercator projection according to

$$X' = \sigma\lambda'$$
$$Y' = \sigma q' = \sigma\ln\left[\tan\left(\frac{\pi}{4}+\frac{\psi'}{2}\right)\right] \tag{55.139}$$

The Transverse Mercator projection with respect to the central meridian λ_0 is obtained by a simple rotation, about –90°. The final mapping equations are

$$\begin{pmatrix} X \\ Y \\ 0 \end{pmatrix} = \mathbf{R}_3\left(-\frac{\pi}{2}\right)\begin{pmatrix} X' \\ Y' \\ 0 \end{pmatrix} = \begin{pmatrix} -Y' \\ X' \\ 0 \end{pmatrix} \tag{55.140}$$

When we start with ellipsoidal curvilinear coordinates, we cannot apply this procedure directly. However, when we follow a two-step procedure — mapping the ellipsoid conformal to the sphere, and then using the "rotated conformal" mapping procedure as just described — the treatise in this section will have a more general validity.

For more details on conformal projections using ellipsoidal coordinates, consult Bugayevskiy and Snyder [1998], Maling [1993], Stem [1991], and others.

55.5 Basic Concepts in Mechanics

Equations of Motion of a Point Mass in an Inertial Frame

To understand the motion of a satellite around the earth, we resort to two fundamental laws of physics: Isaac Newton's second law (the law of inertia) and Newton's law of gravitation.

Law of Inertia

The second law of Newton (the law of inertia) is as follows:

$$F = ma \tag{55.141}$$

The mass of a point mass m is the constant ratio that experimentally exists between the force **F**, acting on that point mass, and the acceleration that is the result of that force.

The acceleration **a**, the velocity **v**, and the distance **s** are related as follows:

$$a = \frac{dv}{dt} = \frac{d^2s}{dt^2} \tag{55.142}$$

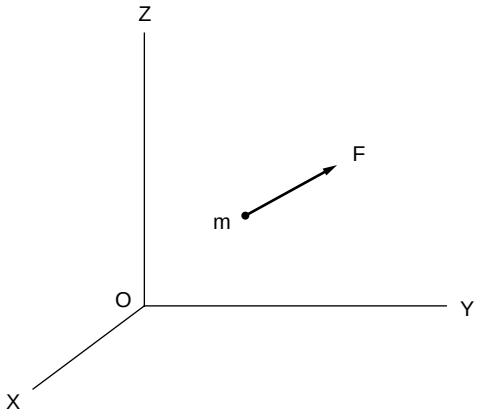

FIGURE 55.15 The acceleration of a point mass m.

Equation (55.141) can be written in vector form (see Fig. 55.15):

$$\mathbf{F} = m\mathbf{a} \quad \text{or} \quad \begin{pmatrix} F_x \\ F_y \\ F_z \end{pmatrix} = m \begin{pmatrix} \mathbf{a}_x \\ \mathbf{a}_y \\ \mathbf{a}_z \end{pmatrix} = m \begin{pmatrix} \ddot{X} \\ \ddot{Y} \\ \ddot{Z} \end{pmatrix} = m\ddot{\mathbf{X}} \tag{55.143}$$

with

$$\ddot{X} = \frac{d^2X}{dt^2} \text{ and similarly for } \ddot{Y} \text{ and } \ddot{Z} \tag{55.144}$$

Law of Gravitation

Until now we did not mention the cause of the force **F** acting on point mass m. If this force is caused by the presence of a second point mass, then Newton's law of gravitation says

$$F = G\frac{m_1 m_2}{|\mathbf{X}_{12}|^2} \tag{55.145}$$

Two point masses m_1 and m_2 attract each other with a force that is proportional to the masses of each point mass and inversely proportional to the square of the distance between them, $|\mathbf{X}_{12}|$.

$$G = 6.67259 \pm 0.00085 \times 10^{-11}\,\mathrm{m^3 kg^{-1} s^{-2}} \tag{55.146}$$

is the gravitation constant (e.g., Cohen and Taylor [1988]), and

$$|\mathbf{X}_{12}|^2 = (X_2 - X_1)^2 + (Y_2 - Y_1)^2 + (Z_2 - Z_1)^2 \tag{55.147}$$

The force **F** will be written in vector form (see Fig. 55.16):

$$\mathbf{F}_{12} = \begin{pmatrix} F_{12X} \\ F_{12Y} \\ F_{12Z} \end{pmatrix} = |\mathbf{F}_{12}| \begin{pmatrix} \sin\alpha \\ \sin\beta \\ \sin\gamma \end{pmatrix} = |\mathbf{F}_{12}| \begin{pmatrix} X_{12}/|\mathbf{X}_{12}| \\ Y_{12}/|\mathbf{X}_{12}| \\ Z_{12}/|\mathbf{X}_{12}| \end{pmatrix} \tag{55.148}$$

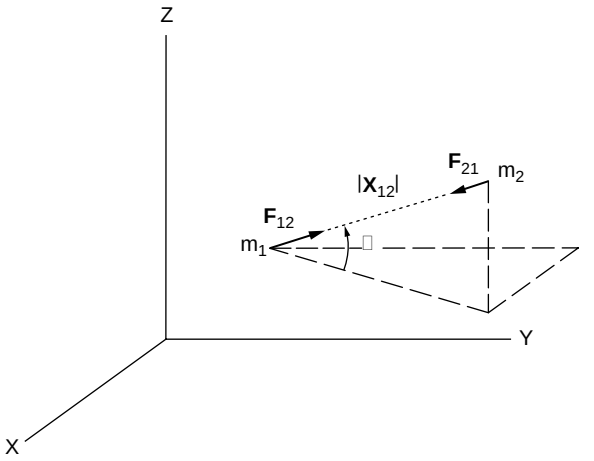

FIGURE 55.16 The attracting force $\mathbf{F}_{12}$ between two point masses m_1 and m_2.

with

$$X_{12} = X_2 - X_1 \qquad \text{and so forth} \tag{55.149}$$

Substituting Eq. (55.148) into Eq. (55.145),

$$\mathbf{F}_{12} = \frac{Gm_1m_2}{\left|\mathbf{X}_{12}\right|^2}\begin{pmatrix} X_{12}/\left|\mathbf{X}_{12}\right| \\ Y_{12}/\left|\mathbf{X}_{12}\right| \\ Z_{12}/\left|\mathbf{X}_{12}\right| \end{pmatrix} = \frac{Gm_1m_2}{\left|\mathbf{X}_{12}\right|^3}\begin{pmatrix} X_{12} \\ Y_{12} \\ Z_{12} \end{pmatrix} \tag{55.150}$$

or

$$\mathbf{F}_{12} = \frac{Gm_1m_2}{\left|\mathbf{X}_{12}\right|^3}\mathbf{X}_{12} \tag{55.151}$$

Equations (55.143) and (55.151) applied subsequently to two point masses m_1 and m_2 yield:

For m_1,

$$\mathbf{F}_1 = m_1\ddot{\mathbf{X}}_1 = \mathbf{F}_{12} = \frac{Gm_1m_2}{\left|\mathbf{X}_{12}\right|^3}\mathbf{X}_{12} \tag{55.152}$$

or

$$\ddot{\mathbf{X}}_1 = \frac{Gm_2}{\left|\mathbf{X}_{12}\right|^3}\mathbf{X}_{12} \tag{55.153}$$

For m_2,

$$\mathbf{F}_2 = m_2\ddot{\mathbf{X}}_2 = \mathbf{F}_{21} = -\mathbf{F}_{12} = \frac{-Gm_1m_2}{\left|\mathbf{X}_{12}\right|^3}\mathbf{X}_{12} \tag{55.154}$$

or

$$\ddot{\mathbf{X}}_2 = \frac{-Gm_1}{\left|\mathbf{X}_{12}\right|^3}\mathbf{X}_{12} \tag{55.155}$$

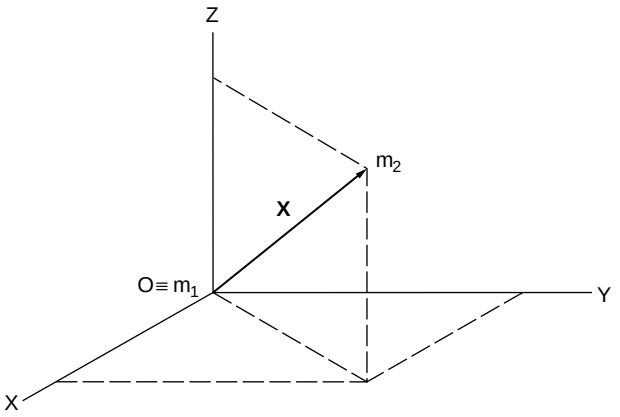

FIGURE 55.17 The inertial frame centered in m_1.

By subtracting Eq. (55.153) from Eq. (55.155) we get

$$\ddot{\mathbf{X}}_{12} = \ddot{\mathbf{X}}_2 - \ddot{\mathbf{X}}_1 = \frac{-G(m_1 + m_2)}{|\mathbf{X}_{12}|^3}\mathbf{X}_{12} \tag{55.156}$$

If m_1 resides in the origin of the inertial frame, then the subindices may be omitted:

$$\ddot{\mathbf{X}} = \frac{-G(m_1 + m_2)}{|\mathbf{X}|^3}\mathbf{X} \tag{55.157}$$

Equation (55.157) represents the equations of motion of m_2 in an inertial frame centered at m_1; see Fig. 55.17.

It will be clear that in m_1 the origin of an inertial frame can be defined if and only if $m_1 + m_2$. For the equations of motion of a satellite $m = m_2$ orbiting the earth $M = m_1$, Eq. (55.157) simplifies to

$$\ddot{\mathbf{X}} = \frac{-GM}{|\mathbf{X}|^3}\mathbf{X} \tag{55.158}$$

In Eq. (55.158) the product of the gravitational constant G and the mass of the earth M appears. For this product, the *geocentric gravitational constant*, a new equation is introduced:

$$\mu = GM \tag{55.159}$$

Potential

The equations of motion around a mass M,

$$\ddot{\mathbf{X}} = \frac{-\mu}{|\mathbf{X}|^3}\mathbf{X} \tag{55.160}$$

can be obtained through the definition of a scalar function V:

$$V = V(X, Y, Z) = \frac{\mu}{|\mathbf{X}|} = \frac{\mu}{\left(X^2 + Y^2 + Z^2\right)^{1/2}} \tag{55.161}$$

The partial derivatives of V with respect to $\mathbf{X}$ are

$$\frac{\partial V}{\partial X} = -\frac{\mu}{|\mathbf{X}|^2}\frac{\partial |\mathbf{X}|}{\partial X} = -\frac{\mu}{|\mathbf{X}|^3}X \tag{55.162}$$

$$\frac{\partial V}{\partial Y} = -\frac{\mu}{|\mathbf{X}|^2}\frac{\partial |\mathbf{X}|}{\partial Y} = -\frac{\mu}{|\mathbf{X}|^3}Y \tag{55.163}$$

$$\frac{\partial V}{\partial Z} = -\frac{\mu}{|\mathbf{X}|^2}\frac{\partial |\mathbf{X}|}{\partial Z} = -\frac{\mu}{|\mathbf{X}|^3}Z \tag{55.164}$$

Consequently, the equations of motion may be written as

$$\ddot{\mathbf{X}} = \begin{pmatrix} \dfrac{\partial V}{\partial X} \\ \dfrac{\partial V}{\partial Y} \\ \dfrac{\partial V}{\partial Z} \end{pmatrix} \equiv \operatorname{grad} V \equiv \nabla V \tag{55.165}$$

V has physical significance: it is the potential of a point mass of negligible mass in a gravity field of a point mass with sizable mass M at a distance $|\mathbf{X}|$.

55.6 Satellite Surveying

The Global Positioning System has become a tool used in a variety of fields within and outside engineering.
